Reduced Trx also deactivates the chloroplastic enzymes phosphofructokinase (PFK), the main flux-generating enzyme of glycolysis (Section 17-4Fb), and glucose-6-phosphate dehydrogenase, the first enzyme in the pentose phosphate pathway (Section 23-4A), whose products, ATP and NADPH, would otherwise be used by the Calvin cycle in a futile cycle. Thus in plants, *light stimulates the Calvin cycle while deactivating glycolysis and the pentose phosphate pathway, whereas darkness has the opposite effect (that is, the so-called dark reactions do not occur in the dark)*. Moreover, chloroplast ATP synthase is activated by reduced Trx, thus preventing it from uselessly hydrolyzing glycolytically produced ATP in the dark. Indeed, the redox state of Trx regulates a great variety of plant metabolic processes.

We have seen that ferredoxin reduces ferredoxin-NADP<sup>+</sup> reductase (Section 24-2Ch) and FTR, as well as supplying electrons to the cyclic pathway of chloroplast photosynthesis (Section 24-2Ch). In addition, ferredoxin is the reducing agent for three metabolically essential chloroplast enzymes: **sulfite reductase** (which reduces SO<sub>3</sub><sup>2-</sup> to S<sub>2</sub><sup>-</sup>), **nitrite reductase** (which reduces NO<sub>2</sub><sup>-</sup> to NH<sub>4</sub><sup>+</sup>), and **glutamate synthase** (which catalyzes the reaction of α-ketoglutarate and NH<sub>4</sub><sup>+</sup> to form glutamate; Section 26-5Aa). Thus Fd stands at the center of a complex web of enzymatic and regulatory processes.

### C. Photorespiration and the C<sub>4</sub> Cycle

It has been known since the 1960s that *illuminated plants consume O<sub>2</sub> and evolve CO<sub>2</sub> in a pathway distinct from oxidative phosphorylation*. In fact, at low CO<sub>2</sub> and high O<sub>2</sub> levels, this **photorespiration** process can outstrip photosynthetic CO<sub>2</sub> fixation. The basis of photorespiration was unexpected: O<sub>2</sub> competes with CO<sub>2</sub> as a substrate for RuBP carboxylase (RuBP carboxylase is therefore also called **RuBP carboxylase-oxygenase** or **RuBisCO**). In the oxygenase reaction, O<sub>2</sub> reacts with RuBisCO's second substrate, RuBP, to form 3PG and **2-phosphoglycolate** (Fig. 24-39). The 2-phosphoglycolate

**Figure 24-39** Probable mechanism of the oxygenase reaction catalyzed by RuBP carboxylase-oxygenase. Note the similarity of this mechanism to that of the carboxylase reaction catalyzed by the same enzyme (Fig. 24-34).

is hydrolyzed to **glycolate** by **glycolate phosphatase** and, as described below, is partially oxidized to yield  $\text{CO}_2$  by a series of enzymatic reactions that occur in the peroxisome and the mitochondrion. Thus photorespiration is a seemingly wasteful process that undoes some of the work of photosynthesis. In the following subsections we discuss the biochemical basis of photorespiration, its significance, and how certain plants manage to evade its deleterious effects.

### a. Photorespiration Dissipates ATP and NADPH

The photorespiration pathway is outlined in Fig. 24-40. Glycolate is exported from the chloroplast to the peroxisome (also called the glyoxisome, Sections 1-2Ad and 23-2), where it is oxidized by **glycolate oxidase** to **glyoxylate** and  $\text{H}_2\text{O}_2$ . The  $\text{H}_2\text{O}_2$ , a powerful and potentially harmful oxidizing agent, is disproportionated to  $\text{H}_2\text{O}$  and  $\text{O}_2$  in the peroxisome by the heme-containing enzyme **catalase**. Some of the glyoxylate is further oxidized by glycolate oxidase to oxalate. The remainder is converted to glycine in a **transamination reaction**, as discussed in Section 26-1A, and exported to the mitochondrion. There, two molecules of glycine are converted to one molecule of serine and one of  $\text{CO}_2$  by a reaction described in Section 26-3B. This is the origin of the  $\text{CO}_2$  generated by photorespiration. The serine is transported back to the peroxisome, where a transamination reaction converts it to **hydroxypyruvate**. This substance is reduced to **glycerate** in the cytosol by **hydroxypyruvate reductase**, which reenters the chloroplast, where it is reconverted to RuBP in the Calvin cycle. The net result of this complex photorespiration cycle is that some of the ATP and NADPH generated by the light reactions is uselessly dissipated.

Although photorespiration has no known metabolic function, the RuBisCOs from the great variety of photosynthetic organisms so far tested all exhibit oxygenase activity. Yet, over the eons, the forces of evolution must have optimized the function of this important enzyme. It is thought that photosynthesis evolved at a time when Earth's atmosphere contained large quantities of  $\text{CO}_2$  and very little  $\text{O}_2$ , so that photorespiration was of no consequence. It has therefore been suggested that the RuBisCO reaction has an obligate intermediate that is inherently autooxidizable. Another possibility is that photorespiration protects the photosynthetic apparatus from photooxidative damage when insufficient  $\text{CO}_2$  is available to otherwise dissipate its absorbed light energy. This hypothesis is supported by the observation that when chloroplasts or leaf cells are brightly illuminated in the absence of both  $\text{CO}_2$  and  $\text{O}_2$ , their photosynthetic capacity is rapidly and irreversibly lost.

### b. Photorespiration Limits the Growth Rates of Plants

The steady-state  $\text{CO}_2$  concentration attained when a photosynthetic organism is illuminated in a sealed system is named its  **$\text{CO}_2$  compensation point**. For healthy plants, this is the  $\text{CO}_2$  concentration at which the rates of photosynthesis and photorespiration are equal. For many species it is  $\sim 40$  to 70 ppm (parts per million)  $\text{CO}_2$  (the normal

**Figure 24-40 Photorespiration.** This pathway metabolizes the phosphoglycolate produced by the RuBP carboxylase-catalyzed oxidation of RuBP. The reactions occur, as indicated, in the chloroplast, the peroxisome, the mitochondrion, and the cytosol. Note that two glycines are required to form serine +  $\text{CO}_2$  (Section 26-3B).

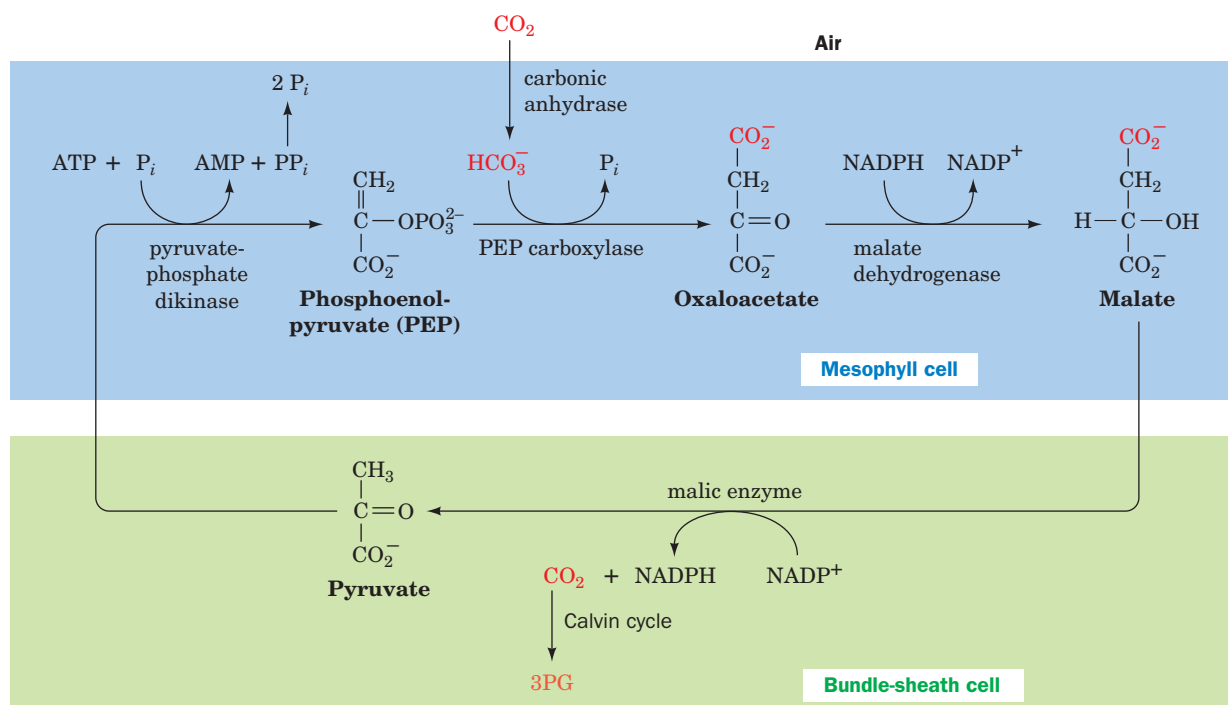

atmospheric concentration of  $\text{CO}_2$  is 330 ppm), so their photosynthetic  $\text{CO}_2$  fixation usually dominates their photorespiratory  $\text{CO}_2$  release. However, the  $\text{CO}_2$  compensation point increases with temperature because the oxygenase activity of RuBisCO increases more rapidly with temperature than does its carboxylase activity. Thus, *on a hot bright day, when photosynthesis has depleted the level of  $\text{CO}_2$  at the chloroplast and raised that of  $\text{O}_2$ , the rate of photorespiration may approach that of photosynthesis. This phenomenon is, in fact, a major limiting factor in the growth of many plants.* Indeed, plants possessing a RuBisCO with significantly less oxygenase activity would not only have increased photosynthetic efficiency but would need less water because they could spend less time with their **stomata** (the pores leading to their internal leaf spaces) open acquiring  $\text{CO}_2$  and would have a reduced need for fertilizer because they would require less RuBisCO. The control of photorespiration is therefore an important unsolved agricultural problem that is presently being attacked through genetic engineering studies (Section 5-5).

### c. $\text{C}_4$ Plants Concentrate $\text{CO}_2$

Certain species of plants, such as sugarcane, corn, and most important weeds, have a metabolic cycle that concentrates  $\text{CO}_2$  in their photosynthetic cells, thereby almost totally preventing photorespiration (their  $\text{CO}_2$  compensation points are in the range 2 to 5 ppm). The leaves of plants that have this so-called  **$\text{C}_4$  cycle** have a characteristic anatomy. Their fine veins are concentrically surrounded by a single layer of so-called **bundle-sheath cells**, which in turn are surrounded by **mesophyll cells**.

The  $\text{C}_4$  cycle (Fig. 24-41) was elucidated in the 1960s by Marshall Hatch and Roger Slack. It begins with the uptake of atmospheric  $\text{CO}_2$  by the mesophyll cells, which, lacking RuBisCO in their chloroplasts, do so by condensing it as  $\text{HCO}_3^-$  with phosphoenolpyruvate (PEP) to yield oxaloacetate. The oxaloacetate is reduced by NADPH to **malate**, which is exported to the bundle-sheath cells (the name  $\text{C}_4$  refers to these four-carbon acids). There the malate is oxidatively decarboxylated by  $\text{NADP}^+$  to form  $\text{CO}_2$ , pyruvate, and NADPH. The  $\text{CO}_2$ , which has been concentrated by this process, enters the Calvin cycle. The pyruvate is returned to the mesophyll cells, where it is phosphorylated to again form PEP. The enzyme that mediates this reaction, **pyruvate-phosphate dikinase**, has the unusual action of activating a phosphate group through the hydrolysis of ATP to  $\text{AMP} + \text{PP}_i$ . This  $\text{PP}_i$  is further hydrolyzed to two  $\text{P}_i$ , which is tantamount to the consumption of a second ATP.  $\text{CO}_2$  is thereby concentrated in the bundle-sheath cells at the expense of two ATPs per  $\text{CO}_2$ . The dark reactions of photosynthesis in  $\text{C}_4$  plants therefore consume a total of five ATPs per  $\text{CO}_2$  fixed versus the three ATPs required by the Calvin cycle alone. The additional ATP is presumably generated through the cyclic flow of electrons in the light reactions (Section 24-2Ch).

**$\text{C}_4$  plants**, which comprise ~5% of terrestrial plants, occur largely in unshaded areas of tropical regions because they grow faster under hot and sunny conditions than other, so-called  **$\text{C}_3$  plants** (so named because they initially fix  $\text{CO}_2$  in the form of three-carbon acids). In cooler climates, where photorespiration is less of a burden,  $\text{C}_3$  plants have the advantage because they require less energy to fix  $\text{CO}_2$ .

**Figure 24-41** The  $\text{C}_4$  pathway.  $\text{CO}_2$  is concentrated in the mesophyll cells and transported to the bundle-sheath cells for entry into the Calvin cycle.

#### d. CAM Plants Store CO<sub>2</sub> through a Variant of the C<sub>4</sub> Cycle

Desert-adapted plants known as succulents (e.g., cacti) employ a variant of the C<sub>4</sub> cycle that separates CO<sub>2</sub> acquisition and the Calvin cycle in time rather than in space. If, as most plants, they opened their stomata by day to acquire CO<sub>2</sub>, they would simultaneously transpire (lose by evaporation) what for them would be unacceptable amounts of water. To minimize this loss, these succulents only absorb CO<sub>2</sub> at night when the temperature is relatively cool. They store

this CO<sub>2</sub>, in a process known as **crassulacean acid metabolism (CAM)**; so named because it was first discovered in plants of the family Crassulaceae, by the synthesis of malate through the reactions of the C<sub>4</sub> pathway (Fig. 24-41). The large amount of PEP necessary to store a day's supply of CO<sub>2</sub> is obtained by the breakdown of starch via glycolysis. During the course of the day, this malate is broken down to CO<sub>2</sub>, which enters the Calvin cycle, and pyruvate, which is used to resynthesize starch. CAM plants are able, in this way, to carry out photosynthesis with minimal water loss.

## CHAPTER SUMMARY

**1 Chloroplasts** Photosynthesis is the light-driven fixation of CO<sub>2</sub> to form carbohydrates and other biological molecules. In plants, photosynthesis takes place in the chloroplast, which consists of an inner and an outer membrane surrounding the stroma, a concentrated enzyme solution in which the thylakoid membrane system is immersed. Photosynthesis occurs in two stages, the so-called light reactions in which light energy is harnessed to synthesize ATP and NADPH, and the dark reactions in which these products are used to drive the synthesis of carbohydrates from CO<sub>2</sub> and H<sub>2</sub>O. The thylakoid membrane is the site of the photosynthetic light reactions, whereas the dark reactions take place in the stroma. The counterpart of the thylakoid in photosynthetic bacteria is a specialized portion of the plasma membrane named the chromatophore.

**2 Light Reactions** Chlorophyll is the principal photoreceptor of photosynthesis. Light is absorbed initially by light-harvesting complexes (LHCs) that contain chlorophyll and accessory pigments such as carotenoids. The resulting excitation then migrates via exciton transfer until it reaches the reaction center chlorophyll, where it is trapped. LH2 from purple photosynthetic bacteria is a transmembrane protein that consists of eight or nine rotationally related subunits that each bind three BChl *a* molecules and one carotenoid. LH1, which is similarly arranged but 16-fold symmetric, contains a central hole that binds a photosynthetic reaction center (RC). Light energy absorbed by LH2 is transmitted to LH1, which, in turn, transmits it to the RC.

The purple photosynthetic bacterial RC (PbRC) is a protein that consists of three subunits and several redox-active small molecules that are arranged as two pseudosymmetrically related chains of electron carriers. The primary photon absorbing species of the *Rps. viridis* bacterial reaction center is a special pair of BChl *b* molecules known as P960. By rapid measurement techniques it has been determined that the electron ejected by P960\* passes by a third BChl *b* to a BPheo *b* molecule located in only one of the two chains (the other is apparently nonfunctional) and then sequentially to a menaquinone (Q<sub>A</sub>) and a ubiquinone (Q<sub>B</sub>). The resulting Q<sub>B</sub><sup>-</sup> is subsequently further reduced in a second one-electron transfer process and then takes up two protons from the cytosol to form Q<sub>B</sub>H<sub>2</sub>. The electrons taken up by this species are returned to P960 via a cytochrome *bc*<sub>1</sub> complex, cytochrome *c*<sub>2</sub>, and, in some purple photosynthetic bacteria, a four-heme *c*-type cytochrome associated with the photosynthetic reaction center. This cyclic electron-transport process functions to

translocate protons, via a Q cycle mediated by the cytochrome *bc*<sub>1</sub>, from the cytoplasm to the outside of the cell. The resulting proton gradient, in a process known as photophosphorylation, drives the synthesis of ATP. Since bacterial photosynthesis does not generate the reducing equivalents needed in many biosynthetic processes, photosynthetic bacteria require an outside source of reducing agents such as H<sub>2</sub>S.

In plants and cyanobacteria, the light reactions occur in two reaction centers, those of PSI and PSII, which are electrically “connected” in series. This enables the system to generate sufficient electromotive force to form NADPH by oxidizing H<sub>2</sub>O in a noncyclic pathway known as the Z-scheme. PSI and PSII both contain core antenna systems and their RCs are evolutionarily related to each other and to the PbRC. PSII contains an Mn<sub>2</sub>CaO<sub>4</sub> complex that oxidizes two H<sub>2</sub>O molecules to four H<sup>+</sup> and O<sub>2</sub> in four one-electron steps. The electrons are passed singly, through a Tyr side chain named Z, to photooxidized P680, the reaction center's photon-absorbing species, a special pair that consists of two Chl *a* molecules. The electron previously ejected from P680\* passes through a series of carriers resembling those of the PbRC to a pool of plastoquinone molecules. The electrons then enter the cytochrome *b*<sub>6</sub>*f* complex, which transports protons, via a Q cycle, from the stroma to the thylakoid space. These electrons are transferred individually, by a plastocyanin carrier, directly to PSI's photooxidized photon-absorbing pigment, P700, a pair of Chl *a*'s that resembles the PbRC's special pair. The electron that had been previously ejected from P700\* migrates through both sides of a bifurcated chain of Chl *a* molecules and then through a chain of three [4Fe-4S] clusters to a soluble ferredoxin (Fd) that contains a [2Fe-2S] cluster. The electron then reduces NADP<sup>+</sup> in a noncyclic process mediated by ferredoxin-NADP<sup>+</sup> reductase. Alternatively, it may be returned, presumably via ferredoxin-plastoquinone reductase, to the plastoquinone pool in a cyclic process that does not require electron input from PSII and only translocates protons across the thylakoid membrane. ATP is synthesized by the CF<sub>1</sub>CF<sub>0</sub>-ATP synthase, which closely resembles the analogous mitochondrial complex, in a reaction driven by the dissipation of the proton gradient across the thylakoid membrane.

**3 Dark Reactions** CO<sub>2</sub> is fixed in the photosynthetic dark reactions of plants and cyanobacteria by the reactions of the Calvin cycle. The first stage of the Calvin cycle, in sum, mediates the reaction 3RuBP + 3CO<sub>2</sub> → 6GAP with the consumption of 9 ATP and 6 NADPH generated by the light reactions. The second stage reshuffles the atoms of five GAPs to

reform the three RuBPs with which the cycle began, a process that requires no further input of free energy or reduction equivalents. The sixth GAP, the product of the Calvin cycle, is used to synthesize carbohydrates, amino acids, and fatty acids. The flux-controlling enzymes of the Calvin cycle are activated in the light through variations in the pH and the  $Mg^{2+}$  and NADPH concentrations, and by the redox level of thioredoxin. The central enzyme of the Calvin cycle, RuBP carboxylase, catalyzes both a carboxylase and an oxygenase reaction with RuBP. The latter reaction is the first step in the photorespiration cycle that liberates  $CO_2$ . The rate of photorespiration

increases with temperature and decreases with  $CO_2$  concentration, so photorespiration constitutes a significant energetic drain on most plants on hot bright days. Calvin cycle products are converted to sucrose, starch, and cellulose, as well as fatty acids and amino acids.  $C_4$  plants, which are most common in the tropics, have a system for concentrating  $CO_2$  in their photosynthetic cells so as to minimize the effects of photorespiration but at the cost of 2 ATP per  $CO_2$  fixed. Certain desert plants conserve water by absorbing  $CO_2$  at night and releasing it to the Calvin cycle by day. This crassulacean acid metabolism (CAM) occurs through a process similar to the  $C_4$  cycle.

## PROBLEMS

- Why is chlorophyll green in color when it absorbs in the red and the blue regions of the spectrum (Fig. 24-5)?
- The “red tide” is a massive proliferation of certain algal species that cause seawater to become visibly red. Describe the spectral characteristics of the dominant photosynthetic pigments in these algae.
- H<sub>2</sub><sup>18</sup>O is added to a suspension of chloroplasts capable of photosynthesis. Where does the label appear when the suspension is exposed to light?
- Indicate, where appropriate, the analogous components in the photosynthetic electron-transport chains of purple photosynthetic bacteria and chloroplasts.
- Antimycin inhibits photosynthesis in chloroplasts. Indicate its most likely site of action and explain your reasoning.
- Calculate the energy efficiency of cyclic and noncyclic photosynthesis in chloroplasts using 680-nm light. What would this efficiency be with 500-nm light? Assume that ATP formation requires 59 kJ · mol<sup>-1</sup> under physiological conditions.
- \*7. What is the minimum pH gradient required to synthesize ATP from ADP + P<sub>i</sub>? Assume  $[ATP]/([ADP][P_i]) = 10^3$ ,  $T = 25^\circ\text{C}$ , and that three protons must be translocated per ATP generated. (See Table 16-3 for useful thermodynamic information.)
- Indicate the average Calvin cycle labeling pattern in ribulose-5-phosphate after two rounds of exposure to <sup>14</sup>CO<sub>2</sub>.
- Chloroplasts are illuminated until the levels of their Calvin cycle intermediates reach a steady state. The light is then turned off. How do the levels of RuBP and 3PG vary after this time?
- What is the energy efficiency of the Calvin cycle combined with glycolysis and oxidative phosphorylation; that is, what percentage of the input energy can be metabolically recovered in synthesizing starch from CO<sub>2</sub> using photosynthetically produced NADPH and ATP rather than somehow directly storing these “high-energy” intermediates? Assume that each NADPH is energetically equivalent to three ATPs and that starch synthesis and breakdown are energetically equivalent to glycogen synthesis and breakdown.
- Predict the effect of an uncoupler such as dinitrophenol (Fig. 22-47) on production of (a) ATP and (b) NADPH in a chloroplast.
- Describe the effects of an increase in oxygen pressure on the dark reactions of photosynthesis.
- If a C<sub>3</sub> plant and a C<sub>4</sub> plant are placed together in a sealed illuminated box with sufficient moisture, the C<sub>4</sub> plant thrives while the C<sub>3</sub> plant sickens and eventually dies. Explain.
- The leaves of some species of desert plants taste sour in the early morning but, as the day wears on, they become tasteless and then bitter. Explain.

#### 8 Phospholipid and Glycolipid Metabolism

- Glycerophospholipids
- Sphingophospholipids
- Sphingoglycolipids

Lipids play indispensable roles in cell structure and metabolism. For example, triacylglycerols are the major storage form of metabolic energy in animals; cholesterol is a vital component of cell membranes and a precursor of the steroid hormones and bile salts; arachidonate, a  $C_{20}$  unsaturated fatty acid, is the precursor of the prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins, potent intercellular mediators that control a variety of complex processes; and complex glycolipids and phospholipids are major components of biological membranes. We dis-

cussed the structures of simple and complex lipids in Section 12-1. In the first half of this chapter, we consider the metabolism of fatty acids and triacylglycerols, including their digestion, oxidation, and biosynthesis. We then consider how cholesterol is synthesized and utilized, and how prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins are synthesized. We end by studying how complex glycolipids and phospholipids are synthesized from their simpler lipid and carbohydrate components.

### 1 LIPID DIGESTION, ABSORPTION, AND TRANSPORT

**Triacylglycerols** (also called **fats** or **triglycerides**) constitute ~90% of the dietary lipid and are the major form of metabolic energy storage in humans. Triacylglycerols consist of glycerol triesters of fatty acids such as palmitic and oleic acids

**1-Palmitoyl-2,3-dioleoyl-glycerol**

(the names and structural formulas of some biologically common fatty acids are listed in Table 12-1). Like glucose, they are metabolically oxidized to  $CO_2$  and  $H_2O$ . Yet, since most carbon atoms of triacylglycerols have lower oxidation states than those of glucose, *the oxidative metabolism of fats yields over twice the energy of an equal weight of dry carbohydrate or protein* (Table 25-1). Moreover, fats, being nonpolar, are stored in an anhydrous state, whereas glycogen, the storage form of glucose, is polar and is consequently stored in a hydrated form that contains about twice its dry weight of water. Fats therefore provide up to six times the metabolic energy of an equal weight of hydrated glycogen.

#### a. Lipid Digestion Occurs at Lipid–Water Interfaces

Since triacylglycerols are water insoluble, whereas digestive enzymes are water soluble, *triacylglycerol digestion takes place at lipid–water interfaces*. The rate of triacylglyc-

**Table 25-1** Energy Content of Food Constituents

erol digestion therefore depends on the surface area of the interface, a quantity that is greatly increased by the churning peristaltic movements of the intestine combined with the emulsifying action of **bile salts**. These are powerful digestive detergents that, as we shall see in Section 25-6C, are synthesized by the liver and secreted via the gallbladder into the small intestine where lipid digestion and absorption mainly take place.

### b. Pancreatic Lipase Requires Activation and Has a Catalytic Triad

Pancreatic **lipase (triacylglycerol lipase)** catalyzes the hydrolysis of triacylglycerols at their 1 and 3 positions to form sequentially **1,2-diacylglycerols** and **2-acylglycerols**, together with the Na<sup>+</sup> and K<sup>+</sup> salts of fatty acids (soaps). These soaps, being amphipathic, aid in the lipid emulsification process.

The enzymatic activity of pancreatic lipase greatly increases when it contacts the lipid–water interface, a phenomenon known as **interfacial activation**. Binding to the lipid–water interface requires the presence of mixed micelles of phosphatidylcholine (Fig. 12-4) and bile salts, as well as the pancreatically produced protein named **colipase**, which forms a 1:1 complex with lipase. This complex aids in the adsorption of the enzyme to emulsified oil droplets as well as stabilizes the enzyme in an active conformation. The X-ray structures, determined by Christian Cambillau, of pancreatic lipase–colipase complexes, alone and cocrystallized with mixed micelles of phosphatidylcholine and bile salts, have revealed the structural basis of lipase activation as well as how colipase and micelles aid lipase in binding to the lipid–water interface (Fig. 25-1).

The active site of the 449-residue pancreatic lipase, which is contained in the enzyme's N-terminal domain, has a catalytic triad that closely resembles that in the serine proteases (Section 15-3B; recall that ester hydrolysis is mechanistically similar to peptide hydrolysis). In aqueous solution (Fig. 25-1a), the lipase's active site is covered by a 26-residue helical lid. However, in the presence of the mixed micelles (Fig. 25-1b), the lid undergoes a complex structural reorganization that exposes the active site; causes a contacting 10-residue loop, the  $\beta 5$  loop, to change conformation in a way that forms the active enzyme's oxyanion hole; and generates a hydrophobic surface about the entrance to the active site. Indeed, the active site of the mixed micelle–containing complex contains a long rod of electron density that contacts the catalytic triad's Ser residue and appears to be a phosphatidylcholine molecule.

**Figure 25-1** X-ray structures of pancreatic lipase in complex with colipase. (a) In aqueous solution, and (b) cocrystallized with mixed micelles of phosphatidylcholine and bile salts. The lipase is drawn in ribbon form with its N-terminal domain (residues 1–336) cyan, its C-terminal domain (residues 337–449) green, the lid (residues 237–262) magenta, and the  $\beta 5$  loop (residues 76–85) orange. The colipase is yellow. A phosphatidylcholine molecule that is bound in the lipase active site in Part b is shown in stick form with C green, O red, and P orange. The micelles, which have irregular structures (e.g., Fig. 2-9), are not visible. [Based on X-ray structures by Christian Cambillau, LCCMB-CNRS, Marseille, France. PDBids 1N8S and 1LPB.]

Colipase binds to the C-terminal domain of lipase such that the hydrophobic tips of the three loops that comprise much of this 90-residue protein extend from the complex on the same face as lipase's active site. A continuous hydrophobic plateau is thereby created that extends over a distance of  $>50$  Å past the active site (bottom of Fig. 25-1b) and that, presumably, helps bind the complex to the lipid surface. In the presence of the mixed micelles, colipase changes conformation so as to form three hydrogen bonds to the opened lid, thereby stabilizing it in this conformation.

The mixed micelles are not visible in the X-ray structure. However, neutron diffraction studies, by Juan Fontecilla-Camps, of crystals of a lipase–colipase–micelle complex in which the lipase is in its active conformation reveal that the activating micelle interacts, not with the substrate site, but with the concave face of colipase and the adjacent tip of the lipase's C-terminal domain (left side of

**Figure 25-2** Catalytic action of phospholipase  $A_2$ . Phospholipase  $A_2$  hydrolytically excises the C2 fatty acid residue from a phospholipid to yield the corresponding lysophospholipid. The

bonds hydrolyzed by other types of phospholipases, which are named according to their specificities, are also indicated.

Fig. 25-1b). Apparently, micelle binding and substrate binding involve different regions of the lipase–colipase complex. Hence, strictly speaking, lipase activation appears not to be interfacial but, instead, occurs in the aqueous phase and requires the binding of colipase and a micelle.

### c. Pancreatic Phospholipase $A_2$ Has a Modified Catalytic Triad

Phospholipids are degraded by pancreatic **phospholipase  $A_2$** , which hydrolytically excises the fatty acid residue at C2 to yield the corresponding **lysophospholipids** (Fig. 25-2), which are also powerful detergents. Indeed, the phospholipid lecithin (phosphatidylcholine) is secreted in the bile, presumably to aid in lipid digestion.

Phospholipase  $A_2$ , as does triacylglycerol lipase, preferentially catalyzes reactions at interfaces. However, as Paul Sigler's determinations of the X-ray structures of the phospholipases  $A_2$  from cobra venom and bee venom revealed, its mechanism of interfacial activation differs from that of triacylglycerol lipase in that it does not change its conformation. Instead, phospholipase  $A_2$  contains a hy-

drophobic channel that provides the substrate with direct access from the phospholipid aggregate (micelle or membrane) surface to the bound enzyme's active site. Hence, on leaving its micelle to bind to the enzyme, the substrate need not become solvated and then desolvated (Fig. 25-3). In contrast, soluble and dispersed phospholipids must first surmount these significant kinetic barriers in order to bind to the enzyme.

The catalytic mechanism of phospholipase  $A_2$  also differs substantially from that of triacylglycerol lipase. Although the phospholipase  $A_2$  active site contains the His and Asp components of a catalytic triad, an enzyme-bound water molecule occupies the position expected for an active site Ser. Moreover, the active site contains a bound  $Ca^{2+}$  ion and does not form an acyl–enzyme intermediate. Sigler therefore proposed that phospholipase  $A_2$  catalyzes the direct hydrolysis of phospholipid with a His–Asp “catalytic dyad” activating an active site water molecule for nucleophilic attack on the ester, and with the  $Ca^{2+}$  ion stabilizing the oxyanion transition state. However, the subsequently determined X-ray structure, by Mahendra Jain and

**MJ33 [1-Hexadecyl-3-(trifluoroethyl)-*sn*-glycero-2-phosphomethanol]**

suggests that a second, previously unobserved water molecule, which is liganded by the Ca<sup>2+</sup> ion, is the attacking nucleophile (Fig. 25-4a). This has led to the formulation of a reaction mechanism (Fig. 25-4b) in which the Asp–His–water catalytic triad and the Ca<sup>2+</sup> ion both activate the second water molecule, with the Ca<sup>2+</sup> ion also stabilizing the resulting tetrahedral intermediate.

**Figure 25-4 Structure and mechanism of phospholipase A<sub>2</sub>.** (a) The X-ray structure of the 124-residue monomeric porcine phospholipase A<sub>2</sub> (lavender) in complex with the tetrahedral intermediate mimic MJ33. The enzyme's active site contains a catalytic triad similar to those of the serine proteases (Fig. 15-20) with a water molecule replacing the catalytic Ser. The His 48 and Asp 99 side chains of the catalytic triad together with MJ33 are drawn in stick form colored according to atom type (C gray, N blue, O red, F green, and P yellow). The water molecule of the catalytic triad and the catalytically important Ca<sup>2+</sup> ion are represented by red and cyan spheres. Catalytically important hydrogen bonds and Ca<sup>2+</sup> liganding interactions are represented by thin black lines. The tetrahedral phosphoryl group of MJ33 presumably occupies the site of the unobserved H<sub>2</sub>O. Residues 65 to 74 of the protein have been deleted for clarity. (1) The catalytic triad activates a second water molecule to attack the scissile carbonyl carbon with Ca<sup>2+</sup> coordinating the activated water molecule as well as electrostatically stabilizing the resulting tetrahedral intermediate (rather than doing so via nucleophilic catalysis as occurs in the serine proteases; Fig. 15-23). (2) The tetrahedral intermediate decomposes to yield products. [After Berg, O.G., Gelb, M.H., Tsai, M.-D., and Jain, M.K., *Chem. Rev.* **101**, 2638 (2001).]

#### d. Bile Salts and Fatty Acid-Binding Protein Facilitate the Intestinal Absorption of Lipids

The mixture of fatty acids and mono- and diacylglycerols produced by lipid digestion is absorbed by the cells lining the small intestine (the intestinal mucosa) in a process facilitated by bile salts. The micelles formed by the bile salts take up the nonpolar lipid degradation products so as to permit their transport across the unstirred aqueous boundary layer at the intestinal wall. The importance of this process is demonstrated in individuals with obstructed bile ducts: They absorb little of their dietary lipids but, rather, eliminate them in hydrolyzed form in their feces (**steatorrhea**). Evidently, *bile salts are not only an aid to lipid digestion but are essential for the absorption of lipid digestion products*. Bile salts are likewise required for the efficient intestinal absorption of the lipid-soluble vitamins A, D, E, and K.

Inside the intestinal cells, fatty acids form complexes with **intestinal fatty acid-binding protein (I-FABP)**, a cyto-

**Figure 25-5** X-ray structure of rat intestinal fatty acid-binding protein in complex with palmitate. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The palmitate is shown in space-filling form with C green and O red. [Based on an X-ray structure by James Sacchettini, Albert Einstein College of Medicine. PDBid 2IFB.]

plasmic protein, which serves to increase the effective solubility of these water-insoluble substances and also to protect the cell from their detergent-like effects (recall that soaps are fatty acid salts). The X-ray structures of rat I-FABP, both alone and in complex with a single molecule of palmitate, were determined by James Sacchettini. This monomeric, 131-residue protein consists largely of 10 antiparallel  $\beta$  strands organized into a stack of two approximately orthogonal  $\beta$  sheets (Fig. 25-5). The palmitate occupies a gap between two of the  $\beta$  strands such that it lies between the  $\beta$  sheets with an orientation that, over much of its length, is more or less parallel to the gapped  $\beta$  strands (this structure has therefore been described as forming a “ $\beta$ -clam”). The palmitate’s carboxyl group interacts with Arg 106, Gln 115, and two bound water molecules, whereas the methylene chain is encased by the side chains of several hydrophobic, mostly aromatic, residues.

#### e. Lipids Are Transported in Lipoprotein Complexes

The lipid digestion products absorbed by the intestinal mucosa are converted by these tissues to triacylglycerols (Section 25-4F) and then packaged into lipoprotein parti-

cles called **chylomicrons**. These, in turn, are released into the bloodstream via the lymph system for delivery to the tissues. Similarly, triacylglycerols synthesized by the liver are packaged into **very low density lipoproteins (VLDL)** and released directly into the blood. These lipoproteins, whose origins, structures, and functions are discussed in Section 12-5, maintain their otherwise insoluble lipid components in aqueous solution.

The triacylglycerol components of chylomicrons and VLDL are hydrolyzed to free fatty acids and glycerol in the capillaries of adipose tissue and skeletal muscle by **lipoprotein lipase** (Section 12-5Ba). The resulting free fatty acids are taken up by these tissues while the glycerol is transported to the liver or kidneys. There it is converted to the glycolytic intermediate dihydroxyacetone phosphate by the sequential actions of **glycerol kinase** and **glycerol-3-phosphate dehydrogenase** (Fig. 25-6).

Mobilization of triacylglycerols stored in adipose tissue involves their hydrolysis to glycerol and free fatty acids by **hormone-sensitive triacylglycerol lipase** (or just **hormone-sensitive lipase**). The free fatty acids are released into the bloodstream, where they bind to **serum albumin** (or just **albumin**), a soluble 585-residue monomeric protein that comprises about half of the blood serum protein. In the absence of albumin, the maximum solubility of free fatty acids is  $\sim 10^{-6}$  M. Above this concentration, free fatty acids form micelles that act as detergents to disrupt protein and membrane structure and would therefore be toxic. However, the effective solubility of fatty acids in fatty acid-albumin complexes is as much as 2 mM. Nevertheless, those rare individuals with **analbuminemia** (severely depressed levels of albumin) suffer no apparent adverse symptoms; evidently, their fatty acids are transported in complex with other serum proteins.

The X-ray structure of human serum albumin in its complexes with a variety of common fatty acids, determined by Stephen Curry, reveals that each albumin molecule can bind up to seven fatty acid molecules (Fig. 25-7). However, these binding sites have different fatty acid-binding affinities so that, under normal physiological conditions, albumin carries between 0.1 and 2 fatty acid molecules per protein molecule. Albumin also binds an extraordinarily broad range of drugs and is thereby a major and usually unpredictable influence on their pharmacokinetics (Section 15-4Ba). Indeed, the large amounts of fatty acids in the blood after meals can significantly affect the pharmacokinetics of a drug through competitive and/or cooperative interactions.

**Figure 25-6** Conversion of glycerol to the glycolytic intermediate dihydroxyacetone phosphate.

**Figure 25-7** X-ray structure of human serum albumin in complex with 7 molecules of palmitic acid. ## 2 FATTY ACID OXIDATION

The biochemical strategy of fatty acid oxidation was understood long before the advent of biochemical techniques involving enzyme purification or the use of radioactive tracers. In 1904, Franz Knoop, in the first use of chemical

labels to trace metabolic pathways, fed dogs fatty acids labeled at their  $\omega$  (last) carbon atom by a benzene ring and isolated the phenyl-containing metabolic products from their urine. Dogs fed labeled odd-chain fatty acids excreted **hippuric acid**, the glycine amide of **benzoic acid**, whereas those fed labeled even-chain fatty acids excreted **phenylacetic acid**, the glycine amide of **phenylacetic acid** (Fig. 25-8). Knoop therefore deduced that the oxidation of the carbon atom  $\beta$  to the carboxyl group is involved in fatty acid breakdown. Otherwise, the phenylacetic acid would be further oxidized to benzoic acid. Knoop proposed that this breakdown occurs by a mechanism known as  **$\beta$  oxidation** in which the fatty acid's  $C_\beta$  atom is oxidized. It was not until after 1950, following the discovery of coenzyme A, that the enzymes of fatty acid oxidation were isolated and their reaction mechanisms elucidated. This work confirmed Knoop's hypothesis.

### A. Fatty Acid Activation

Before fatty acids can be oxidized, they must be "primed" for reaction in an ATP-dependent acylation reaction to form fatty acyl-CoA. This activation process is catalyzed by a family of at least three **acyl-CoA synthetases** (also called **thiokinases**) that differ according to their chain-length specificities. These enzymes, which are associated with either the endoplasmic reticulum (ER) or the outer mitochondrial membrane, all catalyze the reaction

In the activation of  $^{18}\text{O}$ -labeled palmitate by a long-chain acyl-CoA synthetase, both the AMP and the acyl-CoA products become  $^{18}\text{O}$  labeled. This observation

**Figure 25-8** Franz Knoop's classic experiment indicating that fatty acids are metabolically oxidized at their  $\beta$ -carbon atom.  $\omega$ -Phenyl-labeled fatty acids containing an odd number of carbon atoms are oxidized to the phenyl-labeled  $C_1$  product, benzoic acid, whereas those with an even number of carbon atoms are oxidized to the phenyl-labeled  $C_2$  product, phenylacetic acid.

These products are excreted as their respective glycine amides, hippuric and phenylacetic acids. The vertical arrows indicate the deduced sites of carbon oxidation. The intermediate  $C_2$  products are oxidized to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  and were therefore not isolated.

**Figure 25-9** Mechanism of fatty acid activation catalyzed by acyl-CoA synthetase. Experiments utilizing  $^{18}\text{O}$ -labeled fatty acids (\*) demonstrate that the formation of acyl-CoA involves an intermediate acyladenylate mixed anhydride.

**Figure 25-10** Acylation of carnitine catalyzed by carnitine palmitoyltransferase.

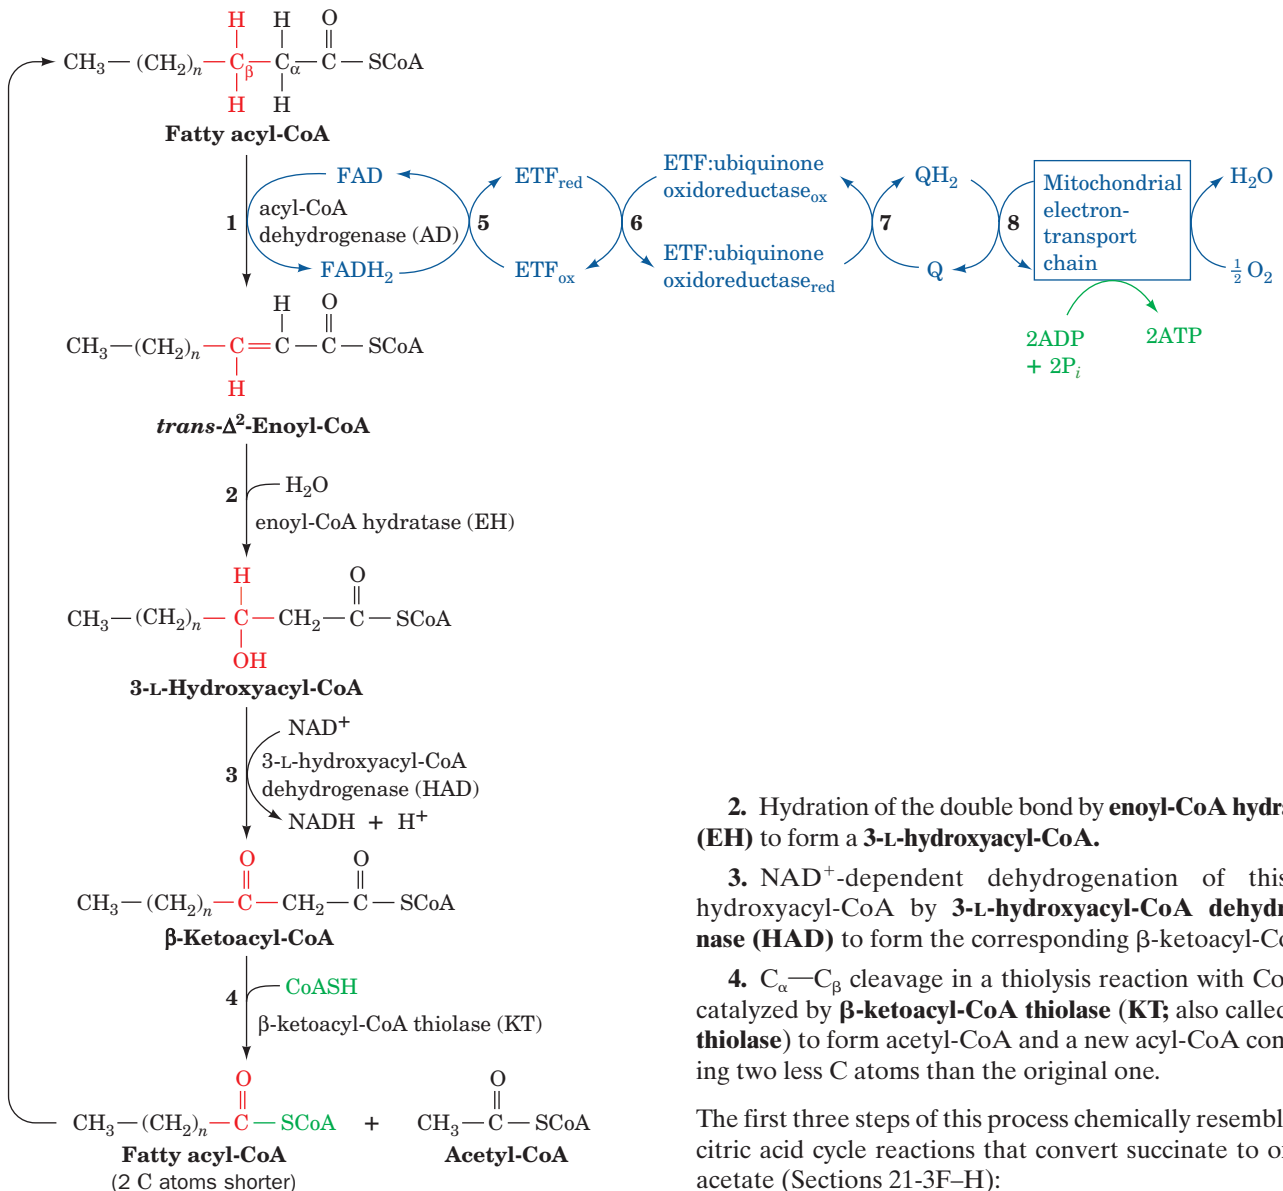

**Figure 25-11** Transport of fatty acids into the mitochondrion.

indicates that the reaction has an acyladenylate mixed anhydride intermediate that is attacked by the sulfhydryl group of CoA to form the thioester product (Fig. 25-9). The reaction involves both the cleavage and the synthesis of bonds with large negative free energies of hydrolysis so that the free energy change associated with the overall reaction is close to zero. The reaction is driven to completion in the cell by the highly exergonic hydrolysis of the product pyrophosphate ( $\text{PP}_i$ ) catalyzed by the ubiquitous **inorganic pyrophosphatase**. Thus, as commonly occurs in metabolic pathways, a reaction forming a “high-energy” bond through the hydrolysis of one of ATP’s phosphoanhydride bonds is driven to completion by the hydrolysis of its second such bond.

### B. Transport Across the Mitochondrial Membrane

Although fatty acids are activated for oxidation in the cytosol, they are oxidized in the mitochondrion as Eugene Kennedy and Albert Lehninger established in 1950. We must therefore consider how fatty acyl-CoA is transported across the inner mitochondrial membrane. A long-chain fatty acyl-CoA cannot directly cross the inner mitochondrial membrane. Rather, its acyl portion is first transferred to **carnitine** (Fig. 25-10), a compound that occurs in both plant and animal tissues. This transesterification reaction has an equilibrium constant close to 1, which indicates that the *O*-acyl bond of **acyl-carnitine** has a free energy of hydrolysis similar to that of the thioester. **Carnitine palmitoyltransferases I and II**, which can transfer a variety of acyl groups, are located, respectively, on the external and internal surfaces of the inner mitochondrial membrane. The translocation process itself is mediated by a specific carrier protein that transports acyl-carnitine into the mitochondrion while transporting free carnitine in the opposite direction. Acyl-CoA transport therefore occurs via four reactions (Fig. 25-11):

1. The acyl group of a cytosolic acyl-CoA is transferred to carnitine, thereby releasing the CoA to its cytosolic pool.
2. The resulting acyl-carnitine is transported into the mitochondrial matrix by the transport system.
3. The acyl group is transferred to a CoA molecule from the mitochondrial pool.
4. The product carnitine is returned to the cytosol.

**Figure 25-12** The  $\beta$ -oxidation pathway of fatty acyl-CoA.

See the Animated Figures

The cell thereby maintains separate cytosolic and mitochondrial pools of CoA. The mitochondrial pool functions in the oxidative degradation of pyruvate (Section 21-2A) and certain amino acids (Sections 26-3E–G) as well as fatty acids, whereas the cytosolic pool supplies fatty acid biosynthesis (Section 25-4). The cell similarly maintains separate cytosolic and mitochondrial pools of ATP and  $\text{NAD}^+$ .

### C. $\beta$ Oxidation

Fatty acids are dismembered through the  $\beta$  oxidation of fatty acyl-CoA, a process that occurs in four reactions (Fig. 25-12):

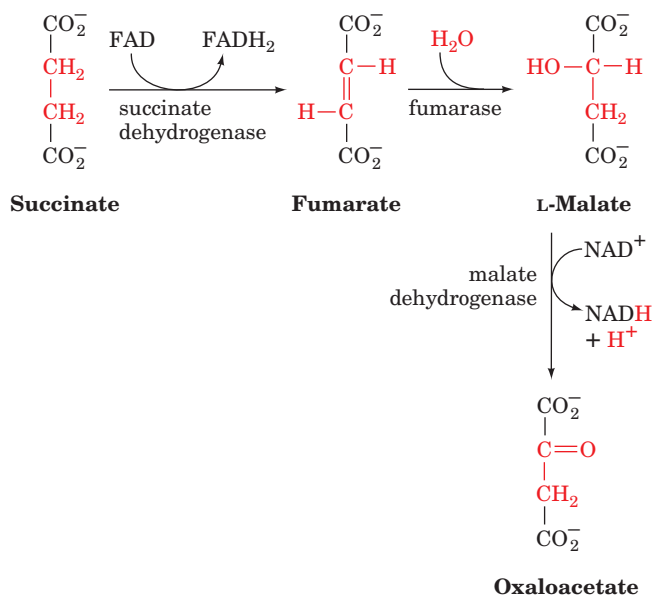

**1.** Formation of a trans- $\alpha, \beta$  double bond through dehydrogenation by the flavoenzyme **acyl-CoA dehydrogenase (AD)**.

**2.** Hydration of the double bond by **enoyl-CoA hydratase (EH)** to form a **3-L-hydroxyacyl-CoA**.

**3.**  $\text{NAD}^+$ -dependent dehydrogenation of this  $\beta$ -hydroxyacyl-CoA by **3-L-hydroxyacyl-CoA dehydrogenase (HAD)** to form the corresponding  $\beta$ -ketoacyl-CoA.

**4.**  $\text{C}_\alpha-\text{C}_\beta$  cleavage in a thiolysis reaction with CoA as catalyzed by  **$\beta$ -ketoacyl-CoA thiolase (KT)**; also called just **thiolase**) to form acetyl-CoA and a new acyl-CoA containing two less C atoms than the original one.

The first three steps of this process chemically resemble the citric acid cycle reactions that convert succinate to oxaloacetate (Sections 21-3F–H):

**Figure 25-13** Ribbon diagram of the active site region in a subunit of medium-chain acyl-CoA dehydrogenase from pig liver mitochondria in complex with octanoyl-CoA. The enzyme is a tetramer of identical 385-residue subunits, each of which binds an FAD prosthetic group (green) and its octanoyl-CoA substrate (whose octanoyl and CoA moieties are blue and white) in largely extended conformations. The octanoyl-CoA binds such that its  $C_{\alpha}$ — $C_{\beta}$  bond is sandwiched between the carboxylate group of Glu 376 (red) and the flavin ring (green), consistent with the proposal that Glu 376 is the general base that abstracts the  $\alpha$  proton in the  $\alpha,\beta$  dehydrogenation reaction catalyzed by the enzyme. [Based on an X-ray structure by Jung-Ja Kim, Medical College of Wisconsin. PDBid 3MDE.]  See Interactive

#### Exercise 23

Mitochondria contain four acyl-CoA dehydrogenases, with specificities for short- ( $C_4$  to  $C_6$ ), medium- ( $C_6$  to  $C_{10}$ ), long- (between medium and very long), and very long-chain ( $C_{12}$  to  $C_{18}$ ) fatty acyl-CoAs. The reaction catalyzed by these enzymes is thought to involve removal of a proton at  $C_{\alpha}$  and transfer of a hydride ion equivalent from  $C_{\beta}$  to FAD (Fig. 25-12, Reaction 1). The X-ray structure of the **medium-chain acyl-CoA dehydrogenase (MCAD)** in complex with **octanoyl-CoA**, determined by Jung-Ja Kim, clearly shows how the enzyme orients the enzyme's base (Glu 376), the substrate  $C_{\alpha}$ — $C_{\beta}$  bond, and the FAD prosthetic group for reaction (Fig. 25-13).

#### a. Acyl-CoA Dehydrogenase Is Reoxidized via the Electron-Transport Chain

The  $FADH_2$  resulting from the oxidation of the fatty acyl-CoA substrate is reoxidized by the mitochondrial electron-transport chain through the intermediacy of a series of electron-transfer reactions. **Electron-transfer flavo-protein (ETF)** transfers two electrons from  $FADH_2$  to the flavoiron-sulfur protein **ETF:ubiquinone oxidoreductase**, which in turn transfers two electrons to the mitochondrial electron-transport chain by reducing coenzyme Q (CoQ; Fig. 25-12, Reactions 5–8). Reduction of  $O_2$  to  $H_2O$  by the electron-transport chain beginning at the CoQ stage re-

sults in the synthesis of 1.5 ATPs per two electrons transferred (Section 22-2Bc).

#### b. Acyl-CoA Dehydrogenase Deficiency Has Fatal Consequences

The unexpected death of an apparently healthy infant, often overnight, has been, for lack of any real explanation, termed **sudden infant death syndrome (SIDS)**. MCAD has been shown to be deficient in up to 10% of these infants, making this genetic disease more prevalent than **phenylketonuria (PKU)** (Section 26-3Hd), a genetic defect in phenylalanine degradation for which babies born in the United States are routinely tested. Glucose is the principal energy metabolism substrate just after eating, but when the glucose level later decreases, the rate of fatty acid oxidation must correspondingly increase. The sudden death of infants lacking MCAD may be caused by the imbalance between glucose and fatty acid oxidation.

Lys 304, which becomes Glu in the most prevalent mutation among individuals with MCAD deficiency, is  $\sim 20$  Å distant from the enzyme's active site and hence cannot participate in binding substrate or FAD. However, since the side chains of Asp 300 and Asp 346 lie within 6 Å of Glu 304, near a subunit-subunit interface, it seems likely that the high concentration of negative charges resulting from the Lys 304  $\rightarrow$  Glu mutation structurally destabilizes the enzyme.

Deficiency of acyl-CoA dehydrogenase has also been implicated in **Jamaican vomiting sickness**, whose victims suffer violent vomiting followed by convulsions, coma, and death. Severe hypoglycemia is observed in most cases. This condition results from eating unripe **ackee fruit**, which contains **hypoglycin A**, an unusual amino acid, which is metabolized to **methylenecyclopropylacetyl-CoA (MCPA-CoA; Fig. 25-14)**. MCPA-CoA, a substrate for acyl-CoA dehydrogenase, is thought to undergo the first step of the reaction that this enzyme catalyzes, removal of a proton from  $C_{\alpha}$ , to form a reactive intermediate that covalently modifies the enzyme's FAD prosthetic group (Fig. 25-14). Since a normal step in the enzyme's reaction mechanism generates the reactive intermediate, MCPA-CoA is said to be a **mechanism-based inhibitor**.

#### c. Long-Chain Enoyl-CoAs Are Converted to Acetyl-CoA and a Shorter Acyl-CoA by Mitochondrial Trifunctional Protein

The products of acyl-CoA dehydrogenases are 2-enoyl-CoAs. Depending on their chain lengths their processing is continued by one of three systems (Fig. 25-12): the short-chain, medium-chain, or long-chain 2-enoyl-CoA hydratases (EHs), hydroxyacyl-CoA dehydrogenases (HADs), and  $\beta$ -ketoacyl-CoA thiolases (KTs). The long-chain (LC) versions of these enzymes are contained on one  $\alpha_4\beta_4$  octameric protein, **mitochondrial trifunctional protein**, located in the inner mitochondrial membrane. LCEH and LCHAD are contained on the  $\alpha$  subunits while LCKT is located on the  $\beta$  subunits. The protein is therefore a combination multi-functional protein (more than one enzyme activity on a sin-

**Figure 25-14** Metabolic conversions of hypoglycin A to yield a product that inactivates acyl-CoA dehydrogenase. Spectral

changes suggest that the enzyme's FAD prosthetic group has been modified.

gle polypeptide chain)—multienzyme complex (a complex of polypeptides catalyzing more than one reaction). The advantage of such a trifunctional enzyme is the ability to channel the intermediates toward the final product. Indeed, no long-chain hydroxyacyl-CoA or ketoacyl-CoA intermediates are released into solution by this system.

#### d. The Thiolase Reaction Occurs via Claisen Ester Cleavage

The final stage of the fatty acid  $\beta$ -oxidation process, the thiolase reaction, forms acetyl-CoA and a new acyl-CoA which is two carbon atoms shorter than the one that began the cycle. This occurs in five reaction steps (Fig. 25-15):

**1.** An active site thiol is added to the substrate  $\beta$ -keto group.

**2.** Carbon–carbon bond cleavage forms an acetyl-CoA carbanion intermediate that is stabilized by electron withdrawal into this thioester's carbonyl group. Such a reaction is known as a Claisen ester cleavage (the reverse of a Claisen condensation). The citric acid cycle enzyme citrate synthase also catalyzes a reaction that involves a stabilized acetyl-CoA carbanion intermediate (Section 21-3A).

**3.** The acetyl-CoA carbanion intermediate is protonated by an enzyme acid group, yielding acetyl-CoA.

**4 and 5.** Finally, CoA displaces the enzyme thiol group from the enzyme–thioester intermediate, yielding acyl-CoA.

The formation of an enzyme–thioester intermediate involving an active site thiol group is based on the observation that incubation of the enzyme with [ $^{14}C$ ]acetyl-CoA

**Figure 25-15** Mechanism of action of  $\beta$ -ketoacyl-CoA thiolase. An active site Cys residue participates in the formation of an enzyme–thioester intermediate.

**2,4-dienoyl-CoA reductase** reduces the  $\Delta^4$  double bond. The *E. coli* reductase produces *trans*-2-enoyl-CoA, a normal substrate of  $\beta$  oxidation. The mammalian reductase, however, yields *trans*-3-enoyl-CoA, which, to proceed along the  $\beta$ -oxidation pathway, must first be isomerized to *trans*-2-enoyl-CoA by **3,2-enoyl-CoA isomerase**.

**Problem 3: The Unanticipated Isomerization of 2,5-Enoyl-CoA by 3,2-Enoyl-CoA Isomerase**

Mammalian 3,2-enoyl-CoA isomerase catalyzes a reversible reaction that interconverts  $\Delta^2$  and  $\Delta^3$  double bonds. A carbonyl group is stabilized by being conjugated to a  $\Delta^2$  double bond. However, the presence of a  $\Delta^5$  double bond (originating from an unsaturated fatty acid with a double bond at an odd-numbered C atom such as the  $\Delta^9$  double bond of linoleic acid) is likewise stabilized by being conjugated with a  $\Delta^3$  double bond (right-hand pathway of Fig. 25-17). If a 2,5-enoyl-CoA is converted by 3,2-enoyl-CoA isomerase to 3,5-enoyl-CoA, which occurs up to 20% of the time, another enzyme is necessary to continue the oxidation: **3,5-2,4-Dienoyl-CoA isomerase** isomerizes the 3,5-diene to a 2,4-diene, which is then reduced by 2,4-dienoyl-CoA reductase and isomerized by 3,2-enoyl-CoA isomerase as in Problem 2 above. After two more rounds of  $\beta$  oxidation, the *cis*- $\Delta^4$  double bond originating from the *cis*- $\Delta^{12}$  double bond of linoleic acid is also dealt with as in Problem 2.

**E. Oxidation of Odd-Chain Fatty Acids**

Most fatty acids have even numbers of carbon atoms and are therefore completely converted to acetyl-CoA. Some plants and marine organisms, however, synthesize fatty acids with an odd number of carbon atoms. *The final round of  $\beta$  oxidation of these fatty acids forms propionyl-CoA, which, as we shall see, is converted to succinyl-CoA for entry into the citric acid cycle.* Propionate or propionyl-CoA is also produced by oxidation of the amino acids isoleucine, valine, and methionine (Section 26-3E). Furthermore, ruminant animals such as cattle derive most of their caloric intake from the acetate and propionate produced in their rumen (stomach) by bacterial fermentation of carbohydrates. These products are absorbed by the animal and metabolized after conversion to the corresponding acyl-CoA.

**a. Propionyl-CoA Carboxylase Has a Biotin Prosthetic Group**

The conversion of propionyl-CoA to succinyl-CoA involves three enzymes (Fig. 25-18). The first reaction is that of **propionyl-CoA carboxylase**, a biotin-dependent enzyme (Section 23-1Ab) with subunit composition  $\alpha_6\beta_6$ . The reaction, which resembles that catalyzed by the homologous biotin-containing enzyme pyruvate decarboxylase (Section 23-1Ac), occurs in two steps (Fig. 25-19):

**1.** Carboxylation of biotin at N1' by bicarbonate ion as in the pyruvate carboxylase reaction (Fig. 23-4). This step,

**Figure 25-18** Conversion of propionyl-CoA to succinyl-CoA.

which is driven by the concomitant hydrolysis of ATP to ADP and  $P_i$ , activates the resulting carboxyl group for transfer without further free energy input.

**2.** Stereospecific transfer of the activated carboxyl group from carboxybiotin to propionyl-CoA to form **(S)-methylmalonyl-CoA**. This step occurs via nucleophilic attack on carboxybiotin by a carbanion at C2 of propionyl-CoA (see below).

These two reaction steps occur at different catalytic sites on propionyl-CoA carboxylase. It therefore appears that the biotinyllysine linkage attaching the biotin ring to the enzyme forms a flexible tether that permits the efficient transfer of the biotin ring between these two active sites as occurs in pyruvate carboxylase (Section 23-1Ae).

Formation of the C2 carbanion in the second stage of the propionyl-CoA carboxylase reaction involves removal of a proton  $\alpha$  to a thioester. This proton is relatively acidic since, as we have seen in Section 25-2Cd, the negative charge on a carbanion  $\alpha$  to a thioester can be delocalized into the thioester's carbonyl group. This explains the relatively convoluted path taken in the conversion of propionyl-CoA to succinyl-CoA (Fig. 25-18). It would seem simpler, at least on paper, for this process to occur in one step, with carboxylation occurring on C3 of propionyl-CoA so as to form succinyl-CoA directly. Yet, the C3 carbanion required for

**Figure 25-19 The propionyl-CoA carboxylase reaction. (1)** The carboxylation of biotin with the concomitant hydrolysis of ATP is followed by **(2)** the carboxylation of a propionyl-CoA

carbanion by its attack on carboxybiotin. Each reaction step probably involves the intermediate formation of CO<sub>2</sub> as occurs in the pyruvate carboxylase reaction (Fig. 23-4).

such a carboxylation has a high free energy of formation. Nature has instead chosen a more facile, albeit less direct route, which carboxylates propionyl-CoA at a more reactive position and then rearranges the C<sub>4</sub> skeleton to form the desired product.

#### b. Methylmalonyl-CoA Mutase Contains a Coenzyme B<sub>12</sub> Prosthetic Group

**Methylmalonyl-CoA mutase**, which catalyzes the third reaction of the propionyl-CoA to succinyl-CoA conversion (Fig. 25-18), is specific for (*R*)-methylmalonyl-CoA even though propionyl-CoA carboxylase stereospecifically synthesizes (*S*)-methylmalonyl-CoA. This diversion is rectified by **methylmalonyl-CoA racemase**, which interconverts the (*R*) and (*S*) configurations of methylmalonyl-CoA, presumably by promoting the reversible dissociation of its acidic α-H via formation of a resonance-stabilized carbanion intermediate:

**Figure 25-20** The rearrangement catalyzed by methylmalonyl-CoA mutase.

Methylmalonyl-CoA mutase, which catalyzes an unusual carbon skeleton rearrangement (Fig. 25-20), utilizes a **5'-deoxyadenosylcobalamin (AdoCbl)** prosthetic group (also called **coenzyme B<sub>12</sub>**). Dorothy Hodgkin determined the structure of this complex molecule (Fig. 25-21) in 1956, a landmark achievement, through X-ray crystallographic analysis combined with chemical degradation studies. AdoCbl contains a hemelike **corrin** ring whose four pyrrole N atoms each ligand a 6-coordinate Co ion. The fifth Co ligand in the free coenzyme is an N atom of a **5,6-dimethylbenzimidazole (DMB)** nucleotide that is covalently linked to the corrin D ring. The sixth ligand is a 5'-deoxyadenosyl group in which the deoxyribose C5' atom forms a covalent C—Co bond, *one of only two known carbon–metal bonds in biology* (the other being a C—Ni bond in the bacterial enzyme **carbon monoxide dehydrogenase**). In some enzymes, the sixth ligand instead is a CH<sub>3</sub> group that likewise forms a C—Co bond.

**5'-Deoxyadenosylcobalamin (coenzyme B<sub>12</sub>)**

**Figure 25-21** Structure of 5'-deoxyadenosylcobalamin (coenzyme B<sub>12</sub>).

AdoCbl's reactive C—Co bond participates in two types of enzyme-catalyzed reactions:

1. Rearrangements in which a hydrogen atom is directly transferred between two adjacent carbon atoms with concomitant exchange of the second substituent, X:

where X may be a carbon atom with substituents, an oxygen atom of an alcohol, or an amine.

2. Methyl group transfers between two molecules.

There are about a dozen known cobalamin-dependent enzymes. However, only two occur in mammalian systems: (1) methylmalonyl-CoA mutase, which catalyzes a carbon skeleton rearrangement (the X group in the rearrangement is —COSC oA; Fig. 25-20) and is the only B<sub>12</sub>-containing enzyme that occurs in both eukaryotes and prokaryotes; and (2) **methionine synthase**, a methyl transfer enzyme that participates in methionine biosynthesis (Sections 26-3Ec and 26-5B). Defects in methylmalonyl-CoA mutase result in **methylmalonic aciduria**, a condition that is often fatal in infancy due to **acidosis** (low blood pH) without a diet de-

void of odd-chain fatty acids and low in the amino acid residues that are degraded to propionyl-CoA (Ile, Val, and Met; Section 26-3E).

### c. The Methylmalonyl-CoA Mutase Reaction Occurs via a Free Radical Mechanism

Methylmalonyl-CoA mutase from *Propionibacterium shermanii* is an αβ heterodimer whose catalytically active 728-residue α subunit is 24% identical to its catalytically inactive 638-residue β subunit. In contrast, the human enzyme is a homodimer whose subunits are 60% identical in sequence to *P. shermanii*'s α subunit. Hence *P. shermanii*'s β subunit is thought to be an evolutionary fossil.

The X-ray structure of methylmalonyl-CoA mutase from *P. shermanii* in complex with the substrate analog **2-carboxypropyl-CoA** (which lacks methylmalonyl-CoA's thioester oxygen atom) was determined by Philip Evans. Its AdoCbl cofactor is sandwiched between the α subunit's two domains: a 559-residue N-terminal α/β barrel (TIM barrel, the most common enzymatic motif; Section 8-3B) and a 169-residue C-terminal α/β domain that resembles a Rossmann fold (Section 8-3Bh). The structure of the α/β barrel contains several surprising features (Fig. 25-22):

1. The active sites of nearly all α/β barrel enzymes are located at the C-terminal ends of the barrel's β strands.

**Figure 25-22** X-ray structure of *P. shermanii* methylmalonyl-CoA mutase in complex with 2-carboxypropyl-CoA and AdoCbl.

(a) The catalytically active α subunit in which the N-terminal domain is cyan with the β strands of its α/β barrel orange, and the C-terminal domain is pink. The 2-carboxypropyl-CoA (magenta) and AdoCbl (green) are drawn in space-filling form. The 2-carboxypropyl-CoA passes through the center of the α/β barrel and is oriented such that the methylmalonyl group of methylmalonyl-CoA would contact the corrin ring of the AdoCbl, which is sandwiched between the enzyme's N- and C-terminal domains. (b) The arrangement of the AdoCbl and 2-carboxypropyl-CoA molecules which, together with the side

chain of His 610, are represented in stick form colored according to atom type (AdoCbl and His C green, 2-carboxypropyl-CoA C cyan, N blue, O red, P magenta, and S yellow). The corrin ring's Co atom is represented by a lavender sphere and the α/β barrel's β strands are represented by orange ribbons. The view is similar to that in Part a. Note that the DMB group (bottom) has swung away from the corrin ring (seen edgewise) to be replaced by the side chain of His 610 from the C-terminal domain and that the 5'-deoxyadenosyl group is unseen (due to disorder). [Based on an X-ray structure by Philip Evans, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 7REQ.]

 See Interactive Exercise 24

However, in methylmalonyl-CoA mutase, the AdoCbl is packed against the N-terminal ends of the barrel's  $\beta$  strands.

2. In free AdoCbl, the Co atom is axially ligated by an N atom of its DMB group and by the adenosyl residue's 5'-CH<sub>2</sub> group (Fig. 25-21). However, in the enzyme, the DMB has swung aside to bind in a separate pocket and has been replaced by the side chain of His 610 from the C-terminal domain. The adenosyl group is not visible in the structure due to disorder and hence has probably also swung aside.

3. In nearly all other  $\alpha/\beta$  barrel-containing enzymes, the center of the barrel is occluded by large, often branched, hydrophobic side chains. However, in methylmalonyl-CoA mutase, the 2-carboxypropyl-CoA's pantetheine group binds in a narrow tunnel through the center of the  $\alpha/\beta$  barrel so as to put the methylmalonyl group of an intact substrate in close proximity to the unligated face of the cobalamin ring. This tunnel provides the only direct access to the active site cavity, thereby protecting the reactive free radical intermediates that are produced in the catalytic reaction from side reactions (see below). The tunnel is lined by small hydrophilic residues (Ser and Thr).

Methylmalonyl-CoA mutase's substrate binding mode resembles those of several other AdoCbl-containing enzymes of known structure, which are collectively unique among  $\alpha/\beta$  barrel-containing proteins.

The proposed methylmalonyl-CoA mutase reaction mechanism (Fig. 25-23) begins with **homolytic cleavage** of the cobalamin C—Co(III) bond (the C and Co atoms each acquire one of the electrons that formed the cleaved electron pair bond). The Co ion therefore fluctuates between its Co(III) and Co(II) oxidation states [the two states are spectroscopically distinguishable: Co(III) is red and diamagnetic (no unpaired electrons), whereas Co(II) is yellow and paramagnetic (unpaired electrons)]. Note that a homolytic cleavage reaction is unusual in biology; most other biological bond cleavage reactions occur via **heterolytic cleavage** (in which the electron pair forming the cleaved bond is fully acquired by one of the separating atoms).

*The role of AdoCbl in the catalytic process is that of a reversible free radical generator.* The C—Co(III) bond is well suited to this function because it is inherently weak (dissociation energy = 109 kJ · mol<sup>-1</sup>) and appears to be further weakened through steric interactions with the enzyme. Indeed, as Fig. 25-22 indicates, the Co atom in methylmalonyl-CoA mutase has no sixth ligand and hence, as confirmed by spectroscopic measurements, is in its Co(II) state. The His N—Co bond is extremely long (2.5 Å vs 1.9–2.0 Å in various other B<sub>12</sub>-containing structures). It is proposed that this strained and hence weakened bond stabilizes the Co(II) state with respect to the Co(III) state, thus favoring the formation of the adenosyl radical and facilitating the homolytic cleavage through which the catalyzed reaction occurs (Fig. 23-23). The adenosyl radical presumably abstracts a hydrogen atom from the substrate, thereby facilitating the rearrangement reaction through the intermediate formation of a cyclopropyloxy radical.

#### d. Succinyl-CoA Cannot Be Directly Consumed by the Citric Acid Cycle

Methylmalonyl-CoA mutase catalyzes the conversion of a metabolite to a C<sub>4</sub> citric acid cycle intermediate, not acetyl-CoA. The route of succinyl-CoA oxidation is therefore not as simple as it may first appear. The citric acid cycle regenerates all of its C<sub>4</sub> intermediates so that these compounds are really catalysts, not substrates. Consequently, succinyl-CoA cannot undergo net degradation by citric acid cycle enzymes alone. Rather, *in order for a metabolite to undergo net oxidation by the citric acid cycle, it must first be converted either to pyruvate or directly to acetyl-CoA*. Net degradation of succinyl-CoA begins with its conversion, via the citric acid cycle, to malate. At high concentrations, malate is transported, by a specific transport protein, to the cytosol, where it may be oxidatively decarboxylated to pyruvate and CO<sub>2</sub> by **malic enzyme (malate dehydrogenase, decarboxylating)**:

(We previously encountered this enzyme in the C<sub>4</sub> cycle of photosynthesis; Fig. 24-41.) Pyruvate is then completely oxidized via pyruvate dehydrogenase and the citric acid cycle.

#### e. Pernicious Anemia Results from Vitamin B<sub>12</sub> Deficiency

The existence of **vitamin B<sub>12</sub>** came to light in 1926 when George Minot and William Murphy discovered that **pernicious anemia**, a rare but often fatal disease of the elderly characterized by decreased numbers of red blood cells, low hemoglobin levels (for reasons explained in Section 26-4D), and progressive neurological deterioration (caused by the accumulation of odd-chain fatty acid residues in neuronal membranes), can be treated by the daily consumption of large amounts of raw liver (a treatment that some patients considered worse than the disease). It was not until 1948, however, after a bacterial assay for antipernicious anemia factor had been developed, that vitamin B<sub>12</sub> was isolated.

Vitamin B<sub>12</sub> is synthesized by neither plants nor animals but only by a few species of bacteria. Herbivores obtain their vitamin B<sub>12</sub> from the bacteria that inhabit their gut (in fact, some animals, such as rabbits, must periodically eat some of their feces to obtain sufficient amounts of this essential substance). Humans, however, obtain almost all their vitamin B<sub>12</sub> directly from their diet, particularly from meat. The vitamin is specifically bound in the intestine by the glycoprotein **intrinsic factor** that is secreted by the stomach. This complex is absorbed by a specific receptor in the intestinal mucosa, where the complex is dissociated and the liberated vitamin B<sub>12</sub> transported to the bloodstream.

There it is bound by at least three different plasma globulins, called **transcobalamins**, which facilitate its uptake by the tissues.

Pernicious anemia is not usually a dietary deficiency disease but, rather, results from insufficient secretion of intrinsic factor, often due to an autoimmune attack against the

cells that produce it. The normal human requirement for cobalamin is very small,  $\sim 3 \mu\text{g} \cdot \text{day}^{-1}$ , and the liver stores a 3- to 5-year supply of this vitamin. This accounts for the insidious onset of pernicious anemia and the fact that true dietary deficiency of vitamin B<sub>12</sub>, even among strict vegetarians, is extremely rare.

**Figure 25-23** Proposed mechanism of methylmalonyl-CoA mutase. **(1)** The homolytic cleavage of the C—Co(III) bond yielding a 5'-deoxyadenosyl radical and cobalamin in its Co(II) oxidation state. **(2)** Abstraction of a hydrogen atom from the methylmalonyl-CoA by the 5'-deoxyadenosyl radical, thereby generating a methylmalonyl-CoA radical. **(3)** Carbon skeleton

rearrangement to form a succinyl-CoA radical via a proposed cyclopropyloxy radical intermediate. **(4)** Abstraction of a hydrogen atom from 5'-deoxyadenosine by the succinyl-CoA radical to form succinyl-CoA and regenerate the 5'-deoxyadenosyl radical. **(5)** Release of succinyl-CoA and reformation of the coenzyme.

## F. Peroxisomal $\beta$ Oxidation

In mammalian cells, the bulk of  $\beta$  oxidation occurs in the mitochondria, but peroxisomes (Fig. 25-24) also oxidize fatty acids, particularly those with very long chains or branched chains. *Peroxisomal  $\beta$  oxidation in animals functions to shorten very long chain fatty acids (>22 C atoms) so as to facilitate their degradation by the mitochondrial  $\beta$ -oxidation system. In yeast and plants, fatty acid oxidation occurs exclusively in the peroxisomes and glyoxysomes (specialized peroxisomes, Sections 23-2 and 1-2Ad).*

The peroxisomal pathway results in the same chemical changes to fatty acids as does the mitochondrial pathway, although the enzymes in these two organelles are different. The protein that transports very long-chain fatty acids into the peroxisome, **ALD protein** (see below), does not have a carnitine requirement. The very long-chain fatty acids that enter this compartment are activated by a peroxisomal very long-chain acyl-CoA synthetase to form their CoA esters, and are oxidized directly. The shorter chain acyl products of this  $\beta$ -oxidation process are then linked to carnitine for transport into mitochondria for further oxidation.

### a. Adrenoleukodystrophy Is Caused by a Defect in ALD Protein

**Adrenoleukodystrophy (ALD)** is a rare X-linked inherited disease that results in progressive brain damage and adrenal gland failure. It causes very long-chain saturated fatty acids to accumulate in the blood and destroy the insulating myelin sheath surrounding the axons of many neurons (Section 20-5Bc). Its varied neurological symptoms present (become evident) between the ages of 4 and 10 years and are usually fatal within 1 to 10 years (except after a successful bone marrow transplant). ALD is caused by a defective ALD protein, an ABC transporter (Section 20-3E). Thus in ALD patients, **lignoceric acid** (24:0; recall that the symbol  $n:m$  indicates a  $C_n$  fatty acid with  $m$  double bonds) is converted to lignoceroyl-CoA at only 13% of the normal rate, although once formed, it undergoes  $\beta$  oxidation at the normal rate.

### b. Peroxisomal $\beta$ Oxidation Differs in Detail from Mitochondrial $\beta$ Oxidation

The  $\beta$ -oxidation pathway in peroxisomes differs from that in mitochondria as follows:

1. The first enzyme in the peroxisomal pathway, **acyl-CoA oxidase**, catalyzes the reaction

This reaction involves participation of an FAD cofactor but differs from its mitochondrial counterpart in that the abstracted electrons are transferred directly to  $\text{O}_2$  rather than passing through the electron-transport chain with its concomitant oxidative phosphorylation (Fig. 25-12). Peroxisomal fatty acid oxidation is therefore less efficient than the mitochondrial process by two ATPs for each  $\text{C}_2$  cycle. The  $\text{H}_2\text{O}_2$  produced is disproportionated to  $\text{H}_2\text{O}$  and  $\text{O}_2$

**Figure 25-24 Peroxisomes.** These membrane-bounded organelles perform a variety of metabolic functions, including the oxidation of very long chain fatty acids. [© Donald Fawcett/Visuals Unlimited.]

through the action of peroxisomal catalase (Section 1-2Ad).

2. Peroxisomal enoyl-CoA hydratase and 3-L-hydroxyacyl-CoA dehydrogenase are activities that occur on a single polypeptide and therefore join the growing list of multifunctional enzymes. The reactions catalyzed are identical to those of the mitochondrial system (Fig. 25-12).

3. Peroxisomal thiolase has a different chain-length specificity than its mitochondrial counterpart. It is almost inactive with acyl-CoAs of length  $\text{C}_8$  or less so that fatty acids are incompletely oxidized by peroxisomes.

Although peroxisomal  $\beta$  oxidation is not dependent on the transport of acyl groups into the peroxisome as their carnitine esters, the peroxisome contains carnitine acyltransferases. Acyl-CoAs that have been chain-shortened by peroxisomal  $\beta$  oxidation are thereby converted to their carnitine esters. These substances, for the most part, passively diffuse out of the peroxisome to the mitochondrion, where they are oxidized further.

## G. Minor Pathways of Fatty Acid Oxidation

$\beta$  Oxidation is blocked by an alkyl group at the  $\text{C}_\beta$  of a fatty acid, and thus at any odd-numbered carbon atom. One such branched-chain fatty acid, a common dietary component, is **phytanic acid**. This metabolic breakdown product of chlorophyll's phytol side chain (Section 24-2A) is present in dairy products, ruminant fats, and fish although, surprisingly, chlorophyll itself is but a poor dietary source of phytanic acid for humans. The oxidation of branched-chain fatty acids such as phytanic acid is facilitated by  $\alpha$  **oxidation** (Fig. 25-25). In this process, the fatty acid is converted to its CoA thioester and its  $\text{C}_\alpha$  is hydroxylated by the  $\text{Fe}^{2+}$ -containing **phytanoyl-CoA hydroxylase**. The resulting

**Figure 25-25** Pathway of  $\alpha$  oxidation of fatty acids. Phytanic acid, a degradation product of the phytol side chain of chlorophyll, is metabolized through  $\alpha$  oxidation to **pristanic acid** followed by  $\beta$  oxidation.

CoA thioester is, in effect, oxidatively decarboxylated to yield a new fatty acid with an unsubstituted  $C_\beta$ . Further degradation of the molecule can then continue via six cycles of normal  $\beta$  oxidation to yield three propionyl-CoAs, three acetyl-CoAs, and one 2-methylpropionyl-CoA (which is converted to succinyl-CoA).

A rare genetic defect, **Refsum's disease** or **phytanic acid storage syndrome**, results from the accumulation of this metabolite throughout the body. The disease, which is characterized by progressive neurological difficulties such as tremors, unsteady gait, and poor night vision, results from a defective phytanoyl-CoA hydroxylase. Its symptoms can therefore be attenuated by a diet that restricts the intake of phytanic acid-containing foods.

Medium- and long-chain fatty acids are converted to dicarboxylic acids through  **$\omega$  oxidation** (oxidation of the last carbon atom). This process, which is catalyzed by enzymes of the ER, involves hydroxylation of a fatty acid's  $C_\omega$  atom by a **cytochrome P450**, a monooxygenase that utilizes NADPH and  $O_2$  (Section 15-4Bc). This  $CH_2-OH$  group is then oxidized to a carboxyl group, converted to a CoA derivative at either end, and oxidized via the  $\beta$ -oxidation pathway.  $\omega$  Oxidation is probably of only minor significance in fatty acid oxidation.

### 3 KETONE BODIES

Acetyl-CoA produced by oxidation of fatty acids in liver mitochondria can be further oxidized via the citric acid cycle as is discussed in Chapter 21. A significant fraction of this acetyl-CoA has another fate, however. By a process known as **ketogenesis**, which occurs primarily in liver mitochondria, acetyl-CoA is converted to **acetoacetate** or **D- $\beta$ -hydroxybutyrate**. These compounds, which together with **acetone** are somewhat inaccurately referred to as **ketone bodies**,

serve as important metabolic fuels for many peripheral tissues, particularly heart and skeletal muscle. The brain, under normal circumstances, uses only glucose as its energy source (fatty acids are unable to pass the blood-brain barrier), but during starvation, ketone bodies become the brain's major fuel source (Section 27-4A). *Ketone bodies are water-soluble equivalents of fatty acids.*

Acetoacetate formation occurs in three reactions (Fig. 25-26):

1. Two molecules of acetyl-CoA are condensed to **acetoacetyl-CoA** by thiolase (also called **acetyl-CoA acetyltransferase**) working in the reverse direction from the way it does in the final step of  $\beta$  oxidation (Section 25-2Cd).

2. Condensation of the acetoacetyl-CoA with a third acetyl-CoA by **HMG-CoA synthase** forms  **$\beta$ -hydroxy- $\beta$ -methylglutaryl-CoA (HMG-CoA)**. The mechanism of this reaction resembles the reverse of the thiolase reaction (Fig. 25-15) in that an active site thiol group forms an acyl-thioester intermediate.

3. Degradation of HMG-CoA to acetoacetate and acetyl-CoA in a mixed aldol-Claisen ester cleavage is catalyzed by **HMG-CoA lyase**. The mechanism of this reaction is analogous to the reverse of the citrate synthase reaction (Section 21-3A). (HMG-CoA is also a precursor in cholesterol biosynthesis and hence may be diverted to this purpose as is discussed in Section 25-6A.)

**Figure 25-26 Ketogenesis: the enzymatic reactions forming acetoacetate from acetyl-CoA.** (1) Two molecules of acetyl-CoA condense to form acetoacetyl-CoA in a thiolase-catalyzed reaction. (2) A Claisen ester condensation of the acetoacetyl-CoA with a third acetyl-CoA to form  $\beta$ -hydroxy- $\beta$ -methylglutaryl-CoA (HMG-CoA) as catalyzed by HMG-CoA synthase. (3) The degradation of HMG-CoA to acetoacetate and acetyl-CoA in a mixed aldol-Claisen ester cleavage catalyzed by HMG-CoA lyase.

The overall reaction catalyzed by HMG-CoA synthase and HMG-CoA lyase is

One may well ask why this apparently simple hydrolysis reaction occurs in such an indirect manner. The answer is unclear but may lie in the regulation of the process.

Acetoacetate may be reduced to D- $\beta$ -hydroxybutyrate by  **$\beta$ -hydroxybutyrate dehydrogenase**:

Note that this product is the stereoisomer of the L- $\beta$ -hydroxyacyl-CoA that occurs in the  $\beta$ -oxidation pathway. Acetoacetate, being a  $\beta$ -keto acid, also undergoes relatively facile nonenzymatic decarboxylation to acetone and

**Figure 25-27 The metabolic conversion of ketone bodies to acetyl-CoA.**

**Figure 25-28** Proposed mechanism of 3-ketoacyl-CoA transferase involving an enzyme-CoA thioester intermediate.

$\text{CO}_2$ . Indeed, the breath of individuals with **ketosis** (also called **ketoacidosis**), a potentially pathological condition in which acetoacetate is produced faster than it can be metabolized (a symptom of diabetes; Section 27-4B), has the characteristic sweet smell of acetone.

The liver releases acetoacetate and  $\beta$ -hydroxybutyrate, which are carried by the bloodstream to the peripheral tissues for use as alternative fuels. There, these products are converted to acetyl-CoA as is diagrammed in Fig. 25-27. The proposed reaction mechanism of **3-ketoacyl-CoA transferase** (Fig. 25-28), which catalyzes this pathway's second step, involves the participation of an active site carboxyl group both in an enzyme-CoA thioester intermediate and in an unstable anhydride. Succinyl-CoA, which acts as the CoA donor in this reaction, can also be converted to succinate with the coupled synthesis of GTP in the succinyl-CoA synthetase reaction of the citric acid cycle (Section 21-3Ea). The "activation" of acetoacetate bypasses this

step and therefore "costs" the free energy of GTP hydrolysis. The liver lacks 3-ketoacyl-CoA transferase, which permits it to supply ketone bodies to other tissues.

## 4 FATTY ACID BIOSYNTHESIS

*Fatty acid biosynthesis occurs through condensation of  $\text{C}_2$  units, the reverse of the  $\beta$ -oxidation process.* Through isotopic labeling techniques, David Rittenberg and Konrad Bloch demonstrated, in 1945, that these condensation units are derived from acetic acid. Acetyl-CoA was soon proven to be a precursor of the condensation reaction, but its mechanism remained obscure until the late 1950s when Salih Wakil discovered a requirement for bicarbonate in fatty acid biosynthesis and malonyl-CoA was shown to be an intermediate. In this section, we discuss the reactions of fatty acid biosynthesis.

### A. Pathway Overview

The pathway of fatty acid synthesis differs from that of fatty acid oxidation. This situation, as we saw in Section 18-1D, is typically the case of opposing biosynthetic and degradative pathways because it permits them both to be thermodynamically favorable and independently regulated under similar physiological conditions. Figure 25-29 outlines fatty acid oxidation and synthesis with emphasis on the differences between these pathways. Whereas fatty acid oxidation occurs in the mitochondrion and utilizes fatty acyl-CoA esters, fatty acid biosynthesis occurs in the cytosol with, as Roy Vagelos discovered, the growing fatty acids esterified to **acyl-carrier protein (ACP; Fig. 25-30)**. ACP, like CoA, contains a phosphopantetheine group that forms thioesters with acyl groups. The phosphopantetheine phosphoryl group is esterified to a Ser OH group of ACP, whereas in CoA it is esterified to AMP. In animals, ACP is part of a large multifunctional protein (Type I ACP; see below), whereas in *E. coli* it is a 125-residue polypeptide (Type II ACP). The phosphopantetheine group is transferred from CoA to apo-ACP to form the active holo-ACP by **phosphopantetheine transferase** (alternatively, **ACP synthase**).

The redox coenzymes of the animal fatty acid oxidative and biosynthetic pathways differ ( $\text{NAD}^+$  and FAD for oxidation; NADPH for biosynthesis) as does the stereochemistry of their intermediate steps, but their main difference is the manner in which  $\text{C}_2$  units are removed from or added to the fatty acyl thioester chain. In the oxidative pathway,  $\beta$ -ketothiolase catalyzes the cleavage of the  $\text{C}_\alpha-\text{C}_\beta$  bond of  $\beta$ -ketoacyl-CoA so as to produce acetyl-CoA and a new fatty acyl-CoA, which is shorter by a  $\text{C}_2$  unit. The  $\Delta G^{\circ\prime}$  of this reaction is very close to zero so it can also function in the reverse direction (ketone body formation). In the biosynthetic pathway, the condensation reaction is coupled to the hydrolysis of ATP, thereby driving the reaction to completion. This process involves two steps: (1) the ATP-dependent carboxylation of acetyl-CoA by **acetyl-CoA carboxylase (ACC)** to form **malonyl-CoA**, and (2) the

**Figure 25-29** Comparison of fatty acid  $\beta$  oxidation and fatty acid biosynthesis. Differences occur in (1) cellular location, (2) acyl group carrier, (3) electron acceptor/donor, (4) stereo-

chemistry of the hydration/dehydration reaction, and (5) the form in which  $C_2$  units are produced/donated. See the **Animated Figures**

exergonic decarboxylation of the malonyl group in the condensation reaction catalyzed by **fatty acid synthase**. These enzymes are discussed below.

**B. Acetyl-CoA Carboxylase**

ACC is a biotin-dependent enzyme that catalyzes the first committed step of fatty acid biosynthesis and one of its rate-controlling steps. It is a member of a family of biotin-dependent carboxylases that, in humans, has only three members besides ACC: propionyl-CoA carboxylase (Section 25-2Ea), pyruvate carboxylase (Fig. 23-4), and  **$\beta$ -methylcrotonyl-CoA carboxylase** (which participates in

the degradation of leucine; Section 26-3F). The ACC reaction, like those of the other biotin-dependent carboxylases, occurs in two steps, a  $CO_2$  activation and a carboxylation:

**Phosphopantetheine prosthetic group of ACP**

**Phosphopantetheine group of CoA**

**Figure 25-30** The phosphopantetheine group in acyl-carrier protein (ACP) and in CoA.

*E. coli* ACC is a multienzyme complex in which these steps are catalyzed by separate subunits: the homodimer biotin carboxylase (BC; 456 residues) and the  $\alpha_2\beta_2$  heterotetramer carboxyltransferase (CT; 319 and 304 residues). In addition, the biotin is linked as a biocytin residue (Fig. 23-3b) to the biotin carboxyl-carrier protein (BCCP; 156 residues), which forms homodimers. In contrast, mammalian and avian ACCs contain both enzymatic activities as well as the biotin carboxyl carrier on a single 2346-residue polypeptide chain in the order BC–BCCP–CT (which differs from the order in pyruvate carboxylase, which is BC–CT–BCCP; Section 23-1Ae). The structure of an intact ACC has not been determined, although the X-ray structure the *E. coli* BC subunit closely resembles the BC domain of pyruvate carboxylase (Fig. 23-5a). Interestingly, however, the CT domains of the various biotin-dependent carboxylases differ greatly in sequence and structure.

#### a. Acetyl-CoA Carboxylase Is Regulated by Hormonally Controlled Reversible Phosphorylation

ACC is subject to hormonal regulation. Glucagon as well as epinephrine and norepinephrine (adrenaline and noradrenaline; Section 18-3Ea) trigger the enzyme's cAMP-dependent increase in phosphorylation, which inactivates the enzyme. Insulin, on the other hand, stimulates enzyme dephosphorylation and thus its activation.

The mechanism by which cAMP causes an increase in the phosphorylation state of ACC is interesting. ACC is phosphorylated, *in vitro*, by two different kinases, the cAMP-dependent protein kinase A (PKA; Section 18-3Cb) at Ser 77 and **AMP-dependent protein kinase (AMPK; Sections 25-5a and 27-1)** (which is cAMP independent) at Ser 79, 1200, and 1215. Yet, when liver cells are incubated with cAMP-elevating hormones in the presence of  $^{32}\text{P}$ -ATP, Ser 77 is found not to be labeled. Evidently, an increase in [cAMP] results in a phosphorylation increase at sites modified by AMPK rather than by PKA. How can this be? It appears that, *in vivo*, the cAMP-dependent increase in phosphorylation occurs not through the phosphorylation of new sites but, rather, through the inhibition of dephosphorylation of previously phosphorylated positions. We have already seen such a mechanism in operation in the control of glycogen metabolism, where the cAMP-dependent phosphorylation of phosphoprotein phosphatase inhibitor-1 causes the inhibition of dephosphorylation (Section 18-3C). In the case of ACC, however, dephosphorylation is catalyzed by **phosphoprotein phosphatase-2A**, which is not affected by phosphoprotein phosphatase inhibitor-1. The mechanism by which PKA causes the increase in phosphorylation associated with AMPK activity is, as yet, unknown.

#### b. Avian and Mammalian Acetyl-CoA Carboxylases Undergo Enzyme Polymerization on Activation

Electron microscopy reveals that both avian and mammalian ACCs form long filaments of 20 to 40 protomers (Fig. 25-31). *This polymeric form of the enzyme is catalytically active but the protomer is not.* The rate of fatty acid

**Figure 25-31 Association of acetyl-CoA carboxylase protomers.** An electron micrograph with an accompanying interpretive drawing indicates that filaments of avian liver acetyl-CoA carboxylase consist of linear chains of flat rectangular protomers. [Courtesy of Malcolm Lane, The Johns Hopkins University School of Medicine.]

biosynthesis is therefore controlled by the position of the equilibrium between these forms:

Phosphorylation favors the inactive protomer while dephosphorylation favors the active polymer. Several metabolites also affect the activity of acetyl-CoA carboxylase. Citrate promotes the polymerization of ACC, whereas palmitoyl-CoA and other fatty acyl-CoA's promote its depolymerization. Thus, cytosolic citrate, whose concentration increases when the mitochondrial acetyl-CoA concentration builds up (Section 25-4D), activates fatty acid biosynthesis and hence is a feedforward activator, whereas palmitoyl-CoA, the pathway product, is a feedback inhibitor.

#### c. Mammalian Acetyl-CoA Carboxylase Has Two Major Isoforms

There are two major isoforms of mammalian ACC. **ACC1** occurs in adipose tissue and **ACC2** occurs in tissues that oxidize but do not synthesize fatty acids, such as heart muscle. Tissues that both synthesize and oxidize fatty acids, such as liver, contain both isoforms, which are homologous although the genes encoding them are located on different chromosomes. What is the function of ACC2? The product of the ACC-catalyzed reaction, malonyl-CoA, strongly inhibits

**Figure 25-32** Reaction cycle for the biosynthesis of fatty acids. The biosynthesis of palmitate requires seven cycles of C<sub>2</sub> elongation followed by a final hydrolysis step. See the Animated Figures

the mitochondrial import of fatty acyl-CoA for fatty acid oxidation, the major control point for this process. Thus it appears that ACC2 has a regulatory function (Section 25-5).

Prokaryotic acetyl-CoA carboxylases are not subject to any of these controls. This is because fatty acids in these organisms are not stored as fats but function largely as phospholipid precursors. The *E. coli* enzyme is instead regulated by guanine nucleotides so that fatty acids are synthesized in response to the cell's growth requirements.

### C. Fatty Acid Synthase

The synthesis of fatty acids from acetyl-CoA and malonyl-CoA involves seven enzymatic reactions that yield mainly palmitic acid (see below). These reactions were first studied in cell-free extracts of *E. coli*, in which they are catalyzed by independent enzymes together with ACP. These proteins are collectively known as **type II fatty acid synthase (FAS-II)**. FAS-II also occurs in chloroplasts, the only site of fatty acid synthesis in plants, and in vertebrate mitochondria, whose components are all nuclear encoded and closely resemble their bacterial counterparts. In fungi, however, fatty acids are synthesized by a 2600-kD  $\alpha_6\beta_6$  multifunctional enzyme, whereas in animals they are synthesized by a multifunctional enzyme consisting of two identical ~275-kD polypeptide chains, each containing all seven activities plus ACP and known as **type I fatty acid synthase (FAS-I)**. Most of the domains catalyzing these reactions in these so-called **megasynthases** are homologous to the corresponding proteins that constitute FAS-II, which indicates that they arose through the joining of what were previously independent proteins.

The reactions catalyzed by FAS-I to synthesize palmitate are diagrammed in Fig. 25-32. The long flexible phosphopantetheine chain of ACP (Fig. 25-30) functions to transport the substrate between the protein's various enzymatic domains:

**1a.** The transfer of the acetyl group from acetyl-CoA to ACP to yield acetyl-ACP as catalyzed by **malonyl/acetyl-CoA-ACP transacylase (MAT)**.

**Figure 25-33** The mechanism of carbon-carbon bond formation in fatty acid biosynthesis. The condensation of an acetyl group on the active site Cys of  $\beta$ -ketoacyl-ACP synthase (KS) with a malonyl group on the phosphopantetheine arm of ACP forms a  $\beta$ -ketoacyl-ACP. The reaction is driven by the exergonic elimination of  $\text{CO}_2$  from the malonyl group to generate a resonance-stabilized acetyl-ACP carbanion intermediate that functions as a good nucleophile.

**2a.** The loading of  **$\beta$ -ketoacyl-ACP synthase (KS)** (also known as **condensing enzyme**) by the transfer of the acetyl group from ACP to a KS Cys residue, thus maintaining the acetyl group's thioester linkage.

**1b.** The formation of malonyl-ACP in a reaction analogous to that of Reaction 1a, which in animals is catalyzed by the same enzyme, MAT.

**2b.** The coupling of the acetyl group to the  $\text{C}_\beta$  of the malonyl group on the ACP with the malonyl group's accompanying decarboxylation so as to form acetoacetyl-ACP and free the KS active site Cys-SH group (Fig. 25-33). Consequently, the  $\text{CO}_2$  taken up in the acetyl-CoA carboxylase reaction (Section 25-4B) does not appear in the product fatty acid. Rather, the decarboxylation functions to drive carbon-carbon bond formation in the condensation reaction, which through the acetyl-CoA carboxylase reaction, is coupled to ATP hydrolysis.

**3-5.** The reduction, dehydration, and further reduction of acetoacetyl-ACP so as to form **butyryl-ACP** as sequentially catalyzed by  **$\beta$ -ketoacyl-ACP reductase (KR)**,  **$\beta$ -hydroxyacyl-ACP dehydrase (DH)**, and **enoyl-ACP reductase (ER)**. The coenzyme in both reductive steps is NADPH, whereas in  $\beta$  oxidation, the analogs of Reactions 3 and 5, respectively, use  $\text{NAD}^+$  and FAD (Fig. 25-29). Moreover, Reaction 3 produces and Reaction 4 requires a D- $\beta$ -hydroxyacyl group, whereas the analogous reactions in  $\beta$  oxidation involve the corresponding L isomer.

**2a to 5 Repeat.** The butyryl group from the butyryl-ACP is transferred to the Cys-SH of KS. Thus the acetyl group with which the system was initially loaded has been elongated by a  $\text{C}_2$  unit. The ACP is "reloaded" with a malonyl group (Step 1b), and another cycle of  $\text{C}_2$  elongation occurs. This process occurs altogether seven times to yield **palmitoyl-ACP**.

**6.** The palmitoyl-ACP thioester bond is hydrolyzed by **palmitoyl thioesterase (TE)**, yielding palmitate, the normal product of the fatty acid synthase pathway, and regenerating the enzyme for a new round of synthesis.

The stoichiometry of palmitate synthesis therefore is

Since the 7 malonyl-CoA are derived from acetyl-CoA as follows:

the overall stoichiometry for palmitate biosynthesis is

#### a. Animal FAS-I Is a Flexible X-Shaped Dimer

Most but not all of the enzymatic activities of animal FAS-I remain functional when this dimeric enzyme is dissociated into monomers. Moreover, fragments resulting from the limited proteolysis of animal FAS-I exhibit many of the enzymatic activities of the intact protein. Apparently, *contiguous stretches of its polypeptide chain fold to form a series of autonomous domains, each with a specific but different catalytic activity*. Several other enzymes, for example, mammalian acetyl-CoA carboxylase (Section 25-4B), exhibit similar multifunctionality but none has as many separate catalytic activities as does animal FAS-I. The order of the domains along the animal FAS-I polypeptide chain is indicated in Fig. 25-34. Three of these domains besides ACP lack enzymatic activity: a linker domain

**Figure 25-34** Domain organization of porcine FAS-I at approximate sequence scale. [Modified from a drawing by Timm Maier and Nenad Ban, ETH Zurich, Switzerland.]

**Figure 25-35** X-ray structure of porcine FAS-I in complex with  $\text{NADP}^+$ . (a) The  $\sim 190$ -Å wide homodimer, as viewed perpendicular to its pseudo-2-fold axis (vertical black arrow), with its various domains colored as in Fig. 25-34 and its linkers gray. The bound  $\text{NADP}^+$  cofactors are drawn in space-filling form in blue. The attachment sites of the disordered ACP/TE

domains are indicated by black dots. The domain names of the second subunit have appended primes. (b) A corresponding schematic diagram indicating how the various domains are linked. [Courtesy of Timm Maier and Nenad Ban, ETH Zurich, Switzerland. PDBid 2VZ9.]

(LD) that bridges the KS and MAT domains; a pseudomethyltransferase ( $\Psi\text{ME}$ ) domain, so named because it is homologous to the methyltransferase family; and a pseudoketoreductase ( $\Psi\text{KR}$ ) domain, so named because it is a truncated form of the KR domain.

The X-ray structure of porcine FAS-I in complex with  $\text{NADP}^+$ , determined by Nenad Ban, reveals a pseudo-2-fold symmetric, X-shaped dimer (Fig. 25-35). Its two subunits associate via an extensive interface involving over 150 residues per chain from the KS, ER, and DH domains. However the upper and lower portions of the X are only loosely connected. The lower portion of the X contains the enzyme's two condensing activities, MAT and KS (which

catalyze reactions 1 and 2 in Fig. 25-32), whereas the upper portion of the X contains the enzyme's  $\beta$ -carbon modifying activities, DH, KR, and ER (which catalyze reactions 3–5 in Fig. 25-32). The C-terminal ACP and TE domains are flexibly tethered to the enzyme and are therefore unobserved. The KR–ACP linker consists of  $\sim 13$  residues and can therefore span a distance of up to  $\sim 40$  Å, whereas the ACP–TE linker has a length of  $\sim 25$  residues and can therefore extend  $\sim 80$  Å.

Each of the two reaction chambers of porcine FAS-I is lined by the full set of catalytic domains from one subunit, all of which must be visited by the phosphopantethiene arm of an ACP to carry out all the FAS reac-

**Figure 25-36** Domain organization of fungal FAS-I at approximate sequence scale. [Modified from a drawing by Simon Jenni and Nanad Ban, ETH Zurich, Switzerland.]

tions. The catalytic sites of these domains occur on both the front and back faces of the protein and their distribution has no discernable relationship to the order of the reactions in the catalytic cycle. In the structure shown in Fig. 25-35a, the length of the KR-ACP linker would allow the ACP to reach all the catalytic sites in the same reaction chamber but not those in the opposite reaction chamber (e.g., the distance between the ACP attachment site on one subunit and the MAT domain in the other is  $\sim 135$  Å). Nevertheless, mutational studies by Stuart Smith in which ACP on one subunit and MAT or KS on the other subunit were inactivated yielded functional enzymes albeit with reduced activities, thus indicating that an ACP domain can service both MAT domains and both KS domains. The most plausible explanation for these observations is that the upper portion of the X can rotate  $180^\circ$  with respect to the lower portion. This hypothesis is supported by the observation that the quite tenuous DH/KS contact that joins the top and bottom portions of the X lacks perfect 2-fold symmetry in Fig. 25-35a, thus indicating that this joint is flexible.

#### b. Fungal FAS-I Has a Barrel-Like Shape

The reactions catalyzed by  $\alpha_6\beta_6$  fungal FAS-I differ from those mediated by animal FAS-I in several respects:

1. The bifunctional MAT activity of animal FAS-I transfers both acetyl and malonyl groups from CoA to ACP (Reactions 1a and 1b of Fig. 25-32). However, fungal FAS-I employs a monofunctional **acetyl transferase (AT)** activity to transfer the incoming acetyl group from CoA to ACP and a **malonyl/palmitoyl transferase (MPT)** activity to do so for malonyl groups.

2. Animal FAS-I synthesizes an ACP-linked palmitoyl group, which its TE activity hydrolytically releases as palmitate (Reaction 6 of Fig. 25-32). In contrast, fungal FAS-I synthesizes ACP-linked palmitoyl ( $C_{16}$ ) and stearoyl ( $C_{18}$ ) groups in a ratio of roughly 2:3, which its bifunctional MPT activity then transfers to CoA to yield the pathway's final products, palmitoyl-CoA and stearoyl-CoA.

3. The ER activity in animal FAS-I uses NADPH to directly reduce the C=C double bond in Reaction 5 of Fig. 25-32. However, in fungal ER, NADPH reduces FMN to FMNH<sub>2</sub>, which in turn, reduces the double bond.

4. Fungal FAS-I has a **phosphopantetheine transferase (PPT)** activity that attaches the phosphopantetheine group to ACP. This activity is not part of animal FAS-I.

The distribution of the various enzymatic activities along the  $\alpha$  and  $\beta$  chains of fungal FAS-I (Fig. 25-36) bears no resemblance to that of animal FAS-I (Fig. 25-34). Note that the MPT activity is shared by both the  $\alpha$  and  $\beta$  chains.

The X-ray structure of FAS-I from the thermophilic fungus *Thermomyces lanuginosus* (Fig. 25-37), determined by Ban, reveals that it forms a hollow barrel-shaped protein with  $D_3$  symmetry (the rotational symmetry of a trigonal prism; Fig. 8-65b). The six  $\alpha$  chains form a  $D_3$ -symmetric wheel that is capped on each side by a 3-fold symmetric dome that is predominantly formed by the  $\beta$  chains. The central wheel splits the hollow interior of the barrel into two identical reaction chambers, each of which has several openings in its side walls through which small molecules can enter. The active sites of all the enzymatic activities face the interiors of the reaction chambers. Clearly, animal and fungal FAS-I's have divergently evolved from FAS-II.

**Figure 25-37** X-ray structure of *T. lanuginosus* FAS. The  $\sim 270$ -Å-high by  $\sim 250$ -Å-diameter  $\alpha_6\beta_6$  heterododecamer is viewed along a 2-fold axis (ellipsoid) and perpendicular to its 3-fold axis (triangle) with its various domains colored as in Fig. 25-36 and its linker domains gray. The attachment sites of the disordered ACP domains are indicated by black dots. [Courtesy of Simon Jenni and Nenad Ban, ETH Zurich, Switzerland. PDBids 2UV9 and 2UVA.]

The six ACP domains, which are N-terminally anchored to the chamber walls and C-terminally anchored to the middle of the central wheel, are disordered in the X-ray structure of *T. lanuginosus* FAS-I. However, they are visible in the otherwise closely similar X-ray structure of yeast FAS-I, which was independently determined by Ban and by Thomas Steitz. Structural considerations suggest that each doubly tethered ACP domain can swing to visit the required six catalytic centers, which in the case of the ACP tethered to subchamber 1 are KR from  $\alpha_1$ , KS from  $\alpha_2$ , MPT and DH from  $\beta_1$ , and AT and ER from  $\beta_2$ , where subchamber 2 is on the clockwise side of subchamber 1 as viewed from the top of the dome.

The PPT domains are located on the outside of the barrel where they cannot interact with the ACP domains. This suggests that they attach the phosphopantetheine groups to the ACPs before the barrel has fully assembled.

### c. Fatty Acid Synthase Inhibitors Are Drug Candidates

In well-nourished individuals, fatty acid synthesis proceeds at a low rate. However, certain tissues, particularly cancers, express high levels of FAS-I and produce fatty acids at a high rate. Consequently, inhibitors of animal FAS-I are being investigated as possible anticancer agents. Moreover, the differences between the enzymatic activities of the various types of FAS's, particularly their ER activities, makes FAS-II and fungal FAS-I targets for the development of novel antibiotics.

### d. Variations on a Theme: Polyketide Biosynthesis

**Polyketides** are a family of >10,000 diverse and structurally complex natural products, many of which have antibacterial, antifungal, antitumor, and immunosuppressive properties, that are synthesized by bacteria, fungi, plants, and certain marine animals. They are made by the modular condensation of acyl-CoA monomers such as acetyl-CoA and propionyl-CoA with malonyl-CoA and methylmalonyl-CoA extender units whose decarboxylation drives the condensation reaction. The name polyketide comes from the fact that the primary condensation products have  $\beta$ -keto functional groups. Palmitate is an example of a polyketide since it is formed by the condensation of one acetyl-CoA primer and seven malonyl-CoA extender units. Following each condensation reaction, the new  $\beta$ -keto group may be reduced, dehydrated, and reduced again as with fatty acids, or may undergo only partial modification.

Polyketides are synthesized by megasynthases. We have already seen that animal FAS-I contains seven enzymatic activities as well as ACP. Another example of a polyketide is **6-deoxyerythronolide B (6dEB)**, the parent **macrolactone** of the antibiotic **erythromycin A** (Section 32-3G), which is synthesized in the soil bacterium *Saccharopolyspora erythraea* from one propionyl-CoA primer and six (*S*)-methylmalonyl-CoA extenders by **deoxyerythronolide B synthase (DEBS; Fig. 25-38)**. DEBS is a 2000-kD,  $\alpha_2\beta_2\gamma_2$  complex of >3000-residue subunits

whose three homodimeric units each catalyze two elongation/modification cycles. Unlike FAS-I, which catalyzes several cycles of elongation/modification with the same active sites, DEBS catalyzes each elongation/modification cycle on a different module, which permits the differences in the modifications that occur at each cycle. Thus, DEBS, which has 28 different active sites, functions much like an assembly line. Module 4, as Fig. 25-38 indicates, is almost identical in function to FAS-I, containing KS, AT, ACP, KR, DH, and ER, and reducing its primary  $\beta$ -ketone condensation product to a methylene group. However, it does not contain TE because the elongation process is not complete after this phase. Module 3 contains only ACP, KS, and AT, the minimal set of activities for a module, and passes its  $\beta$ -ketone condensation product to module 4 without further modification. Modules 1, 2, 5, and 6 contain only ACP, AT, KS, and KR, the sites necessary for the condensation and ketone reduction steps, thereby generating hydroxy products. The overall organization of the modules therefore creates a polyhydroxy product containing one keto group and one methylene group in the chain. The DEBS final product, 6dEB, is a lactone produced by the reaction of the terminal hydroxyl group with the thioester anchoring the growing chain to the synthase. The various polyketide synthases have different organizations of modules, and consequently synthesize a multitude of different compounds.

### D. Transport of Mitochondrial Acetyl-CoA Into the Cytosol

Acetyl-CoA is generated in the mitochondrion by the oxidative decarboxylation of pyruvate as catalyzed by pyruvate dehydrogenase (Section 21-2A) as well as by the oxidation of fatty acids. When the need for ATP synthesis is low, so that the oxidation of acetyl-CoA via the citric acid cycle and oxidative phosphorylation is minimal, this mitochondrial acetyl-CoA may be stored for future use as fat. Fatty acid biosynthesis occurs in the cytosol but the mitochondrial membrane is essentially impermeable to acetyl-CoA. *Acetyl-CoA enters the cytosol in the form of citrate via the tricarboxylate transport system* (Fig. 25-39). Cytosolic **ATP-citrate lyase** then catalyzes the reaction

which resembles the reverse of the citrate synthase reaction (Section 21-3A) except that ATP hydrolysis is required to drive the intermediate synthesis of the “high-energy” citryl-CoA, whose hydrolysis drives the citrate synthase reaction to completion. ATP hydrolysis is therefore required in the ATP-citrate lyase reaction to power the resynthesis of this thioester bond. Oxaloacetate is reduced to malate by malate dehydrogenase. Malate may be oxidatively decarboxylated to pyruvate by malic enzyme (Section 25-2Ed) and be returned in this form to the mitochondrion. The malic enzyme reaction resembles that

**Figure 25-38** An example of polyketide biosynthesis: the synthesis of erythromycin A. [After Pfeifer, B.A., Admiraal, S.J., Gramajo, H., Cane, D.E., and Khosla, C., *Science* **291**, 1790 (2001).]

of isocitrate dehydrogenase in which a  $\beta$ -hydroxy acid is oxidized to a  $\beta$ -keto acid, whose decarboxylation is strongly favored (Section 21-3C). Malic enzyme's coenzyme is  $\text{NADP}^+$ , so when this route is used  $\text{NADPH}$  is produced for use in the reductive reactions of fatty acid biosynthesis.

Citrate transport out of the mitochondrion must be balanced by anion transport into the mitochondrion. Malate, pyruvate, and  $\text{P}_i$  can act in this capacity. Malate may therefore also be transported directly back to the mitochondrion without generating  $\text{NADPH}$ . As we have seen in Section 25-4C, synthesis of each palmitate ion requires 8 molecules of acetyl-CoA and 14 molecules of  $\text{NADPH}$ . As many as 8 of these  $\text{NADPH}$  molecules may be supplied with the 8 molecules of acetyl-CoA if all the malate produced in the cytosol is oxidatively decarboxylated. The re-

maining  $\text{NADPH}$  is provided through the pentose phosphate pathway (Section 23-4).

### E. Elongases and Desaturases

*Palmitate (16:0)*, the normal product of the animal fatty acid synthase pathway, is the precursor of longer chain saturated and unsaturated fatty acids through the actions of **elongases** and **desaturases**. Elongases are present in both the mitochondrion and the ER but the mechanisms of elongation at the two sites differ. Mitochondrial elongation (a process independent of the fatty acid synthase pathway) occurs by successive addition and reduction of acetyl units in a reversal of fatty acid oxidation; the only chemical difference between these two pathways occurs in the final reduction step in which  $\text{NADPH}$  takes the place of  $\text{FADH}_2$  as the terminal

**Figure 25-39** Transfer of acetyl-CoA from mitochondrion to cytosol via the tricarboxylate transport system.

redox coenzyme (Fig. 25-40). Elongation in the ER involves the successive condensations of malonyl-CoA with acyl-CoA. These reactions are each followed by NADPH-associated reductions similar to those catalyzed by FAS-I, the only difference being that the fatty acid is elongated as its CoA derivative rather than as its ACP derivative.

Unsaturated fatty acids are produced by **terminal desaturases**. Mammalian systems contain four terminal desaturases of broad chain-length specificities designated  $\Delta^9$ -,  $\Delta^6$ -,  $\Delta^5$ -, and  $\Delta^4$ -**fatty acyl-CoA desaturases**. These

**Figure 25-40** Mitochondrial fatty acid elongation. Elongation occurs by the reversal of fatty acid oxidation with the exception that the final reaction employs NADPH rather than  $\text{FADH}_2$  as its redox coenzyme.

membrane-bound, nonheme iron-containing enzymes catalyze the general reaction

where  $x$  is at least 5 and where  $(\text{CH}_2)_x$  can contain one or more double bonds. The  $(\text{CH}_2)_y$  portion of the substrate is always saturated. Double bonds are inserted between existing double bonds in the  $(\text{CH}_2)_x$  portion of the substrate and the CoA group such that the new double bond is three carbon atoms closer to the CoA group than the next double bond (not conjugated to an existing double bond) and, in animals, never at positions beyond C9. Mammalian terminal desaturases are components of mini-electron-transport systems that contain two other proteins: **cytochrome  $b_5$**  and **NADH-cytochrome  $b_5$  reductase**. The electron-transfer reactions mediated by these complexes occur at the inner surface of the ER membrane (Fig. 25-41) and are therefore not associated with oxidative phosphorylation.

#### a. Some Unsaturated Fatty Acids Must Be Obtained in the Diet

A variety of unsaturated fatty acids may be synthesized by combinations of elongation and desaturation reactions. However, since palmitic acid is the shortest available fatty acid in animals, the above rules preclude the formation of the  $\Delta^{12}$  double bond of linoleic acid [ $\Delta^{9,12}$ -octadecadienoic acid; 18:2 $n$ -6 (this nomenclature is explained in Table 12-1)], a required precursor of **prostaglandins**. *Linoleic acid must consequently be obtained in the diet (ultimately from plants that have  $\Delta^{12}$ - and  $\Delta^{15}$ -desaturases; it is abundant in most vegetable oils) and is therefore termed an essential fatty acid.* Indeed, animals maintained on a fat-free diet develop an ultimately fatal condition that is initially characterized by poor growth, poor wound healing, and dermatitis. Linoleic acid is also an important constituent of epidermal sphingolipids that function as the skin's water-permeability barrier.

Because of the inability of animal desaturases to add double bonds to positions beyond C9, another essential fatty acid is  **$\alpha$ -linolenic acid [ALA;  $\Delta^{9,12,15}$ -octadecatrienoic acid (18:3 $n$ -3, an  $\omega$ -3 fatty acid)]**. This fatty acid is a precursor to **EPA ( $\Delta^{5,8,11,14,17}$ -eicosapentaenoic acid; 20:5 $n$ -3)** and **DHA ( $\Delta^{4,7,10,13,16,19}$ -docosahexaenoic acid; 22:6 $n$ -3)**, polyunsaturated  $\omega$ -3 fatty acids recently found to be important dietary constituents (present in fish oils) that improve cognitive function and vision, and contribute to protection against inflammation and cardiovascular disease. DHA is, among other things, the predominant fatty acid in the phospholipids of retinal rod outer segments. Substitution of DHA with otherwise identical  $\omega$ -6 fatty acids in phospholipids results in impaired visual acuity. Deficiency of  $\omega$ -3 polyunsaturated fatty acids in brain phospholipids is associated with memory loss and diminished cognitive function.

#### F. Synthesis of Triacylglycerols

*Triacylglycerols are synthesized from fatty acyl-CoA esters and glycerol-3-phosphate or dihydroxyacetone phosphate (Fig. 25-42).* The initial step in this process is catalyzed either by **glycerol-3-phosphate acyltransferase** in mitochondria and the ER, or by **dihydroxyacetone phosphate acyltransferase** in the ER or peroxisomes. In the latter case, the product **acyl-dihydroxyacetone phosphate** is reduced to the corresponding **lysophosphatidic acid** by an NADPH-dependent reductase. The lysophosphatidic acid is converted to a triacylglycerol by the successive actions of **1-acylglycerol-3-phosphate acyltransferase**, **phosphatidic acid phosphatase**, and **diacylglycerol acyltransferase**. The intermediate phosphatidic acid and 1,2-diacylglycerol (DAG) can also be converted to phospholipids by the pathways described in Section 25-8. The acyltransferases are not completely specific for particular fatty acyl-CoAs, either in chain length or in degree of unsaturation, but in triacylglycerols of human adipose tissue, palmitate tends to be concentrated at position 1 and oleate at position 2.

#### a. Glyceroneogenesis Is Important for Triacylglycerol Biosynthesis

The dihydroxyacetone phosphate used to make glycerol-3-phosphate for triacylglycerol synthesis comes either from glucose via the glycolytic pathway (Fig. 17-3) or

**Figure 25-41** The electron-transfer reactions mediated by the  $\Delta^9$ -fatty acyl-CoA desaturase complex. Its three proteins, desaturase, cytochrome  $b_5$ , and NADH-cytochrome  $b_5$  reductase, are

situated in the endoplasmic reticulum membrane. [After Jeffcoat, R., *Essays Biochem.* **15**, 19 (1979).]

Figure 25-42 The reactions of triacylglycerol biosynthesis.

from oxaloacetate via an abbreviated version of gluconeogenesis (Fig. 23-8) termed **glyceroneogenesis**. Glyceroneogenesis is necessary in times of starvation, since approximately 30% of the fatty acids that enter the liver during a fast are reesterified to triacylglycerol and exported as VLDL (Section 25-1 and 25-6A). Adipocytes also carry out glyceroneogenesis in times of starvation. They do not carry out gluconeogenesis but contain the gluconeogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK), which is upregulated when glucose concentration is low, and participates in the glyceroneogenesis required for triacylglycerol biosynthesis.

## 5 REGULATION OF FATTY ACID METABOLISM

Discussions of metabolic control are usually concerned with the regulation of metabolite flow through a pathway in response to the differing energy needs and dietary states of an organism. For example, the difference in the energy requirement of muscle between rest and vigorous exertion may be as much as 100-fold. Such varying demands may be placed on the body when it is in either a fed or a fasted state. For instance, Eric Newsholme, an authority on the biochemistry of exercise, enjoys a 2-hour run before breakfast. Others might wish for no greater exertion than the motion of hand to mouth. In both individuals, glycogen and triacylglycerols serve as primary fuels for energy-requiring processes and are synthesized in times of quiet plenty for future use.

### a. Hormones Regulate Fatty Acid Metabolism

*Synthesis and breakdown of glycogen and triacylglycerols, as detailed in Chapter 18 and above, are processes that concern the whole organism, with its organs and tissues forming an interdependent network connected by the bloodstream.* The blood carries the metabolites responsible for energy production: triacylglycerols in the form of chylomicrons and VLDL (Section 12-5A), fatty acids as their albumin complexes (Section 25-1e), ketone bodies, amino acids, lactate, and glucose. The pancreatic  $\alpha$  and  $\beta$  cells sense the organism's dietary and energetic state mainly through the glucose concentration in the blood. The  $\alpha$  cells respond to the low blood glucose concentration of the fasting and energy-demanding states by secreting glucagon. The  $\beta$  cells respond to the high blood glucose concentration of the fed and resting states by secreting insulin. We have previously discussed (Sections 18-3E and 18-3F) how these hormones are involved in glycogen metabolism. *They also regulate the rates of the opposing pathways of lipid metabolism and therefore control whether fatty acids will be oxidized or synthesized.* Their targets are the regulatory (flux-generating) enzymes of fatty acid synthesis and breakdown in specific tissues (Fig. 25-43).

We are already familiar with most of the mechanisms by which the catalytic activities of regulatory enzymes may be

controlled: substrate availability, allosteric interactions, and covalent modification (phosphorylation). These are examples of **short-term regulation**, regulation that occurs with a response time of minutes or less. *Fatty acid synthesis is controlled, in part, by short-term regulation.* Acetyl-CoA carboxylase, which catalyzes the first committed step of this pathway, is inhibited by palmitoyl-CoA and by the glucagon-stimulated cAMP-dependent increase in phosphorylation, and is activated by citrate and by insulin-stimulated dephosphorylation (Section 25-4B).

Another mechanism exists for controlling a pathway's regulatory enzymes: alteration of the amount of enzyme present by changes in the rates of protein synthesis and/or breakdown. This process requires hours or days and is therefore called **long-term regulation** (the control of protein synthesis and breakdown is discussed in Chapters 31 and 32). *Lipid biosynthesis is also controlled by long-term regulation*, with insulin stimulating and starvation inhibiting the synthesis of acetyl-CoA carboxylase and fatty acid synthase. The presence in the diet of polyunsaturated fatty acids also decreases the concentrations of these enzymes. The amount of adipose tissue lipoprotein lipase, the enzyme that initiates the entry of lipoprotein-packaged fatty acids into adipose tissue for storage (Section 12-5Ba), is also increased by insulin and decreased by starvation. In contrast, the concentration of heart lipoprotein lipase, which controls the entry of fatty acids from lipoproteins into heart tissue for oxidation rather than storage, is decreased by insulin and increased by starvation. *Starvation and/or regular exercise, by decreasing the glucose concentration in the blood, change the body's hormone balance. This situation results in long-term changes in gene expression that increase the levels of fatty acid oxidation enzymes and decrease those of lipid biosynthesis.*

*Fatty acid oxidation is regulated largely by the concentration of fatty acids in the blood, which is, in turn, controlled by the hydrolysis rate of triacylglycerols in adipose tissue by hormone-sensitive triacylglycerol lipase.* This enzyme is so named because it is susceptible to regulation by phosphorylation and dephosphorylation in response to hormonally controlled cAMP levels. Epinephrine and norepinephrine, as does glucagon, act to increase adipose tissue cAMP concentrations. cAMP allosterically activates protein kinase A (PKA) which, in turn, increases the phosphorylation levels of susceptible enzymes. Phosphorylation activates hormone-sensitive triacylglycerol lipase, thereby stimulating lipolysis in adipose tissue, raising blood fatty acid levels, and ultimately activating the  $\beta$ -oxidation pathway in other tissues such as liver and muscle. In liver, this process leads to the production of ketone bodies that are secreted into the bloodstream for use by peripheral tissues as an alternative fuel to glucose. PKA, acting in concert with AMP-dependent protein kinase (AMPK), also causes the inactivation of acetyl-CoA carboxylase (Section 25-4B), one of the rate-determining enzymes of fatty acid synthesis, so that *cAMP-dependent phosphorylation simultaneously stimulates fatty acid oxidation and inhibits fatty acid synthesis.*

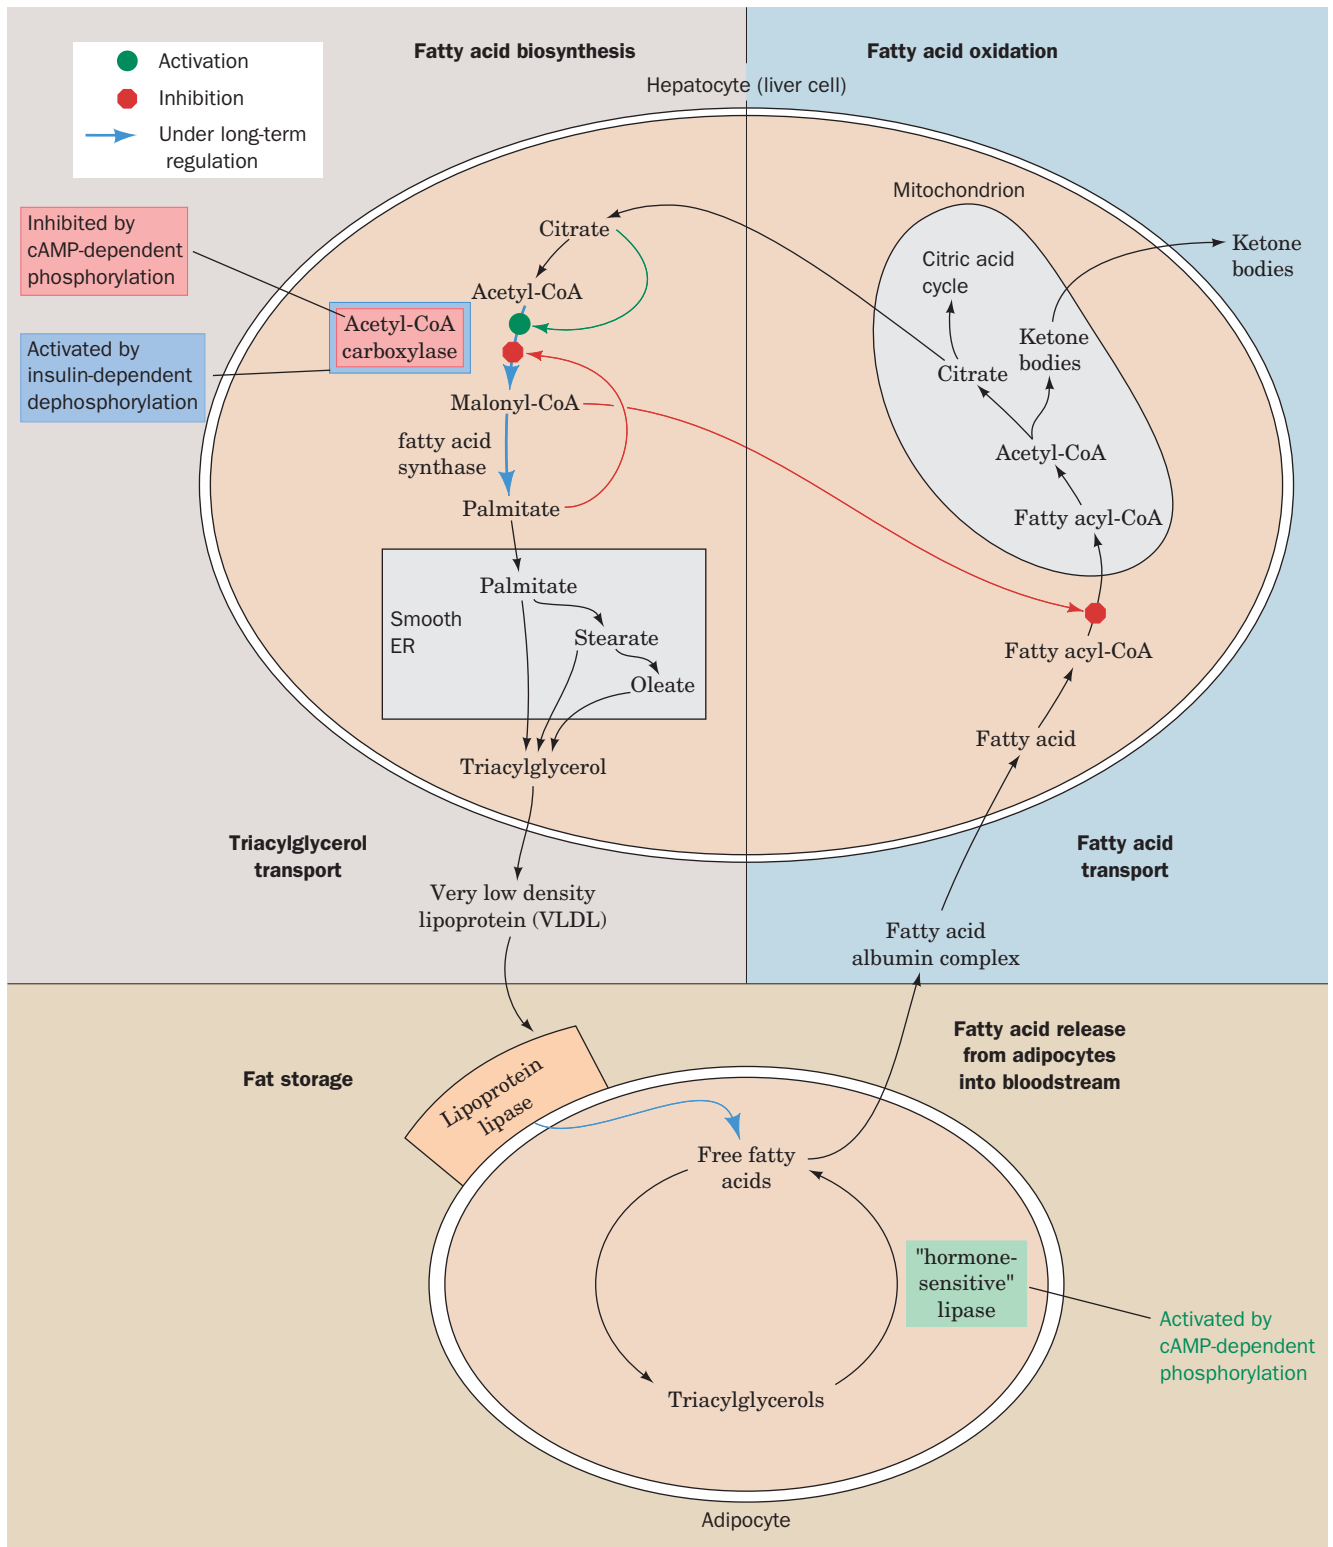

Figure 25-43 Sites of regulation of fatty acid metabolism.

Insulin has the opposite effect of glucagon and epinephrine: It stimulates the formation of glycogen and triacylglycerols. This protein hormone, which is secreted in response to high blood glucose concentrations, triggers a highly complex signal transduction network (Section 19-4F)

that induces the long-term regulation of numerous enzymes as well as decreasing cAMP levels. This latter situation leads to the dephosphorylation and thus the inactivation of hormone-sensitive triacylglycerol lipase, thereby reducing the amount of fatty acid available for oxidation. Insulin

also stimulates the dephosphorylation of acetyl-CoA carboxylase, thereby activating this enzyme (Section 25-4Ba). The glucagon–insulin ratio is therefore of prime importance in determining the rate and direction of fatty acid metabolism.

Another control point that inhibits fatty acid oxidation when fatty acid synthesis is stimulated is the inhibition of carnitine palmitoyltransferase I by malonyl-CoA. This inhibition keeps the newly synthesized fatty acids out of the mitochondrion (Section 25-2B) and thus away from the  $\beta$ -oxidation system. As we have seen (Section 25-4Bc), heart muscle, an oxidative tissue that does not carry out fatty acid biosynthesis, contains an isoform of acetyl-CoA carboxylase, ACC2, whose sole function appears to be the synthesis of malonyl-CoA to regulate fatty acid oxidation.

AMPK may itself be an important regulator of fatty acid metabolism. This phosphorylating enzyme is activated by AMP and inhibited by ATP and thus has been proposed to serve as a fuel gauge for the cell. When ATP levels are high, signaling the fed and rested state, this kinase is inhibited, allowing ACC to become dephosphorylated (activated) so as to stimulate malonyl-CoA production for fatty acid synthesis in adipose tissue and for inhibition of fatty acid oxidation in muscle cells. When activity levels increase causing ATP levels to decrease with a concomitant increase in AMP levels, AMPK is activated to phosphorylate (inac-

tivate) ACC. The resulting decrease in malonyl-CoA levels causes fatty acid biosynthesis to decrease in adipose tissue while fatty acid oxidation increases in muscle to provide the ATP for continued activity.

## 6 CHOLESTEROL METABOLISM

Cholesterol is a vital constituent of cell membranes and the precursor of steroid hormones and bile salts. It is clearly essential to life, yet its deposition in arteries has been associated with cardiovascular disease and stroke, two leading causes of death in humans. In a healthy organism, an intricate balance is maintained between the biosynthesis, utilization, and transport of cholesterol, keeping its harmful deposition to a minimum. In this section, we study the pathways of cholesterol biosynthesis and transport and how they are controlled. We also examine how cholesterol is utilized in the biosynthesis of steroid hormones and bile salts.

### A. Cholesterol Biosynthesis

All of the carbon atoms of cholesterol are derived from acetate (Fig. 25-44). Observation of their pattern of incorporation into cholesterol led Konrad Bloch to propose that acetate was first converted to **isoprene units**,  $C_5$  units that have the carbon skeleton of **isoprene**:

**Figure 25-44** All of cholesterol's carbon atoms are derived from acetate.

**Isoprene**  
(2-Methyl-1,3-butadiene)

**An isoprene unit**

Isoprene units are condensed to form a linear precursor to cholesterol, and then cyclized.

**Squalene**, a polyisoprenoid hydrocarbon (Fig. 25-45a), was demonstrated to be the linear intermediate in cholesterol biosynthesis by the observation that feeding isotopically labeled squalene to animals yields labeled cholesterol. Squalene may be folded in several ways that would enable it to cyclize to the four-ring sterol nucleus (Section 12-1E). The folding pattern proposed by Bloch and Robert B. Woodward (Fig. 25-45b) proved to be correct.

**Figure 25-45** Squalene. (a) Extended conformation. Each box contains one isoprene unit. (b) Folded in preparation for cyclization as predicted by Bloch and Woodward.

**Figure 25-46** The branched pathway of isoprenoid metabolism in mammalian cells. The pathway produces ubiquinone, dolichol, farnesylated and geranylgeranylated

proteins, and isopentenyl adenosine, a modified tRNA base, in addition to cholesterol.

Bloch's outline for the major stages of cholesterol biosynthesis was

This pathway has been experimentally verified and its details elaborated. It is now known to be part of a branched pathway (Fig. 25-46) that produces several other essential isoprenoids in addition to cholesterol, namely, ubiquinone (CoQ; Fig. 22-17*b*), dolichol (Fig. 23-15), farnesylated and geranylgeranylated proteins (Fig. 12-29), and **isopentenyl-adenosine** (a modified base of tRNA; Fig. 32-10). We shall examine in detail the portion of this pathway that synthesizes cholesterol. Note, however, that >25,000 isoprenoids (also known as **terpenoids**), mostly of plant, fungal, and bacterial origin, have been characterized. These serve as membrane constituents (e.g., cholesterol), hormones

(steroids), pheromones, defensive agents, photoprotective agents (e.g.,  $\beta$ -carotene; Section 24-2Ad), and visual pigments (e.g., retinal; Section 12-3Ab), to name only a few of their many biological functions.

#### a. HMG-CoA Is a Key Cholesterol Precursor

Acetyl-CoA is converted to isoprene units by a series of reactions that begins with formation of hydroxymethylglutaryl-CoA (HMG-CoA; Fig. 25-26), a compound we previously encountered as an intermediate in ketone body biosynthesis (Section 25-3). HMG-CoA synthesis requires the participation of two enzymes: thiolase and HMG-CoA synthase. The enzymes forming the HMG-CoA leading to ketone bodies occur in the mitochondria, whereas those responsible for the synthesis of the HMG-CoA that is destined for cholesterol biosynthesis are located in the cytosol. Their catalytic mechanisms, however, are identical.

HMG-CoA is the precursor of two isoprenoid intermediates, **isopentenyl pyrophosphate** and **dimethylallyl pyrophosphate**:

**Isopentenyl pyrophosphate**

**Dimethylallyl pyrophosphate**

The formation of isopentenyl pyrophosphate involves four reactions (Fig. 25-47):

1. The CoA thioester group of HMG-CoA is reduced to an alcohol in an NADPH-dependent four-electron reduction catalyzed by **HMG-CoA reductase**, yielding **mevalonate**.
2. The new OH group is phosphorylated by **mevalonate-5-phosphotransferase**.
3. The phosphate group is converted to a pyrophosphate by **phosphomevalonate kinase**.
4. The molecule is decarboxylated and the resulting alcohol dehydrated by **pyrophosphomevalonate decarboxylase**.

*HMG-CoA reductase mediates the rate-determining step of cholesterol biosynthesis and is the most elaborately regulated enzyme of this pathway.* This 888-residue ER membrane-bound enzyme is regulated, as we shall see in Section 25-6Bb, by competitive and allosteric mechanisms, phosphorylation/dephosphorylation, and long-term regulation. Cholesterol itself is an important feedback regulator of the enzyme.

#### b. Pyrophosphomevalonate Decarboxylase Catalyzes an Apparently Concerted Reaction

**5-Pyrophosphomevalonate** is converted to isopentenyl pyrophosphate by an ATP-dependent dehydration–decarboxylation reaction catalyzed by **pyrophosphomevalonate decarboxylase** (Fig. 25-48). When  $[3\text{-}^{18}\text{O}]5\text{-pyrophosphomevalonate}$  ( $^*\text{O}$  in Fig. 25-48) is used as a substrate, the labeled oxygen appears in  $\text{P}_i$ . This observation suggests that 3-phospho-5-pyrophosphomevalonate is a reaction intermediate. Since all attempts to isolate this intermediate have failed, however, it has been proposed that phosphorylation, the  $\alpha,\beta$  elimination of  $\text{CO}_2$ , and the elimination of  $\text{P}_i$  occur in a concerted reaction.

**HMG-CoA**

**Mevalonate**

**Phosphomevalonate**

**5-Pyrophosphomevalonate**

**Isopentenyl pyrophosphate**

**Figure 25-47** Formation of isopentenyl pyrophosphate from HMG-CoA.

**Figure 25-48** Action of pyrophosphomevalonate decarboxylase. The enzyme catalyzes an ATP-dependent concerted dehydration–decarboxylation of pyrophosphomevalonate, yielding isopentenyl pyrophosphate.

The equilibration between isopentenyl pyrophosphate and dimethylallyl pyrophosphate is catalyzed by **isopentenyl pyrophosphate isomerase**. The reaction appears to occur via a protonation/deprotonation reaction involving the intermediacy of a tertiary carbocation intermediate. Cys and Glu residues have been implicated as the general acid and base catalysts, respectively (Fig. 25-49), as supported by site-directed mutagenesis and the X-ray structure of the enzyme. The carbocation is thought to be stabilized through interactions with the aromatic  $\pi$  cloud of an adjacent Trp residue. Aromatic residues provide electron-rich interactions with positively charged groups without forming covalent bonds that would destroy the intermediate.

### c. Squalene Is Formed by the Condensation of Six Isoprene Units

Four isopentenyl pyrophosphates and two dimethylallyl pyrophosphates condense to form the  $C_{30}$  cholesterol precursor squalene in three reactions catalyzed by two enzymes (Fig. 25-50):

**1. Prenyltransferase (farnesyl pyrophosphate synthase)** catalyzes the head-to-tail (1'–4) condensation of dimethylallyl pyrophosphate and isopentenyl pyrophosphate to yield **geranyl pyrophosphate**.

**2. Prenyltransferase** catalyzes a second head-to-tail condensation of geranyl pyrophosphate and isopentenyl pyrophosphate to yield **farnesyl pyrophosphate (FPP)**.

**3. Squalene synthase (SQS)** then catalyzes the head-to-head (1–1') condensation of two farnesyl pyrophosphate molecules to form squalene. Farnesyl pyrophosphate is also a precursor to dolichol, farnesylated and geranylgeranylated proteins, and ubiquinone (Fig. 25-46).

Prenyltransferase catalyzes the condensation of isopentenyl pyrophosphate with an allylic (conjugated to a  $C=C$  double bond) pyrophosphate. It is specific for isopentenyl pyrophosphate but can use either the 5-carbon dimethylallyl pyrophosphate or the 10-carbon **geranyl pyrophosphate** as its allylic substrate. The prenyltransferase-catalyzed condensation mechanism is particularly interesting since it is one of the few known enzyme-catalyzed reactions that pro-

**Figure 25-49** Mechanism of isopentenyl pyrophosphate isomerase. The enzyme interconverts isopentenyl pyrophosphate and dimethylallyl pyrophosphate by a protonation/deprotonation reaction involving a carbocation intermediate in which a Cys and a Glu residue act as a proton donor and acceptor. The carbocation intermediate appears to be stabilized by  $\pi$  interactions with a nearby Trp side chain.

**Figure 25-50** Formation of squalene from isopentenyl pyrophosphate and dimethylallyl pyrophosphate. The pathway involves two head-to-tail condensations catalyzed by prenyltransferase and a head-to-head condensation catalyzed by squalene synthase.

ceed via a carbocation intermediate. Two possible condensation mechanisms can be envisioned (Fig. 25-51):

**Scheme I** An S<sub>N</sub>1 mechanism in which an allylic carbocation forms by the elimination of PP<sub>i</sub>. Isopentenyl pyrophosphate then condenses with this carbocation, forming a new carbocation that eliminates a proton to form product.

**Scheme II** An S<sub>N</sub>2 reaction in which the allylic PP<sub>i</sub> is displaced in a concerted manner. In this case, an enzyme nucleophile, X, assists in the reaction. This group is eliminated in the second step with the loss of a proton to form product.

Dale Poulter and Hans Rilling used chemical logic to differentiate between these two mechanisms. Capitalizing

on the observation that S<sub>N</sub>1 reactions are much more sensitive to electron-withdrawing groups than S<sub>N</sub>2 reactions, they synthesized a geranyl pyrophosphate derivative in which the H at C2 is replaced by the electron-withdrawing group F. This allylic substrate for the second (1'-4) condensation catalyzed by prenyltransferase, not surprisingly, has the same K<sub>M</sub> as the natural substrate (F and H have similar atomic radii):

It is, however, the V<sub>max</sub> of this reaction that tells the story. If the reaction is an S<sub>N</sub>2 displacement, the fluoro derivative

**Figure 25-51** Two possible mechanisms for the prenyltransferase reaction. Scheme I involves the formation of a carbocation intermediate, whereas Scheme II involves the participation of an enzyme nucleophile, X.

should react at a rate similar to that of the natural substrate. If, instead, the reaction has an  $S_N1$  mechanism, the fluoro derivative should react orders of magnitude more slowly than the natural substrate. In fact, 3-fluorogeranyl pyrophosphate forms product at <1% of the rate of the natural substrate, strongly supporting an  $S_N1$  mechanism with a carbocation intermediate.

Carbocations are now known to participate in several reactions of isoprenoid biosynthesis. The enzymes are classified according to how they generate these carbocations. Class I enzymes do so via the release of pyrophosphate, as we have seen for prenyltransferase. Class II enzymes do so by protonating a double bond, as does isopentenyl pyrophosphate isomerase (Fig. 25-49), or an epoxide, as we shall see below for oxidosqualene cyclase.

Squalene, the immediate sterol precursor, is formed by the head-to-head condensation of two FPP molecules by SQS. Although the enzyme is a Class I enzyme that is structurally related to prenyltransferase and generates carbocations by the release of pyrophosphate, the reaction is not a simple head-to-tail condensation, as might be expected, but, rather, proceeds via a complex two-step mechanism with each step catalyzed by a different active site on the enzyme (Fig. 25-52):

**Step I** The reaction of two FPP molecules to yield the stable intermediate **presqualene pyrophosphate**. This reac-

**Figure 25-52** Action of squalene synthase. The enzyme catalyzes the head-to-head condensation of two farnesyl pyrophosphate molecules to form squalene.

tion is initiated by the elimination of  $PP_i$  from one farnesyl pyrophosphate molecule to form an allylic carbocation at C1 that is stabilized by a  $\pi$  interaction with an essential Tyr

**Figure 25-53** Proposed mechanism for the formation of presqualene pyrophosphate from two farnesyl pyrophosphate molecules by squalene synthase (Fig. 25-52, Step I). (1) The pyrophosphate group on one farnesyl pyrophosphate leaves, yielding an allylic carbocation. This reaction step is facilitated by proton donation from the side chain of an essential Tyr residue, which then stabilizes the allylic cation via  $\pi$ -cation interactions. (2) The  $C2=C3$  double bond of the second farnesyl pyrophosphate nucleophilically attacks the allylic carbocation to form a tertiary carbocation at C3. (3) The abstraction of the pro-*S* proton at  $C1'$  by the phenolate group of the essential Tyr residue results in the formation of a  $C1'-C3$  bond yielding presqualene pyrophosphate.

residue (Fig. 25-53). The highly reactive electron-deficient carbocation inserts into the electron-rich  $C2=C3$  double bond of the second molecule, yielding presqualene pyrophosphate, a cyclopropylcarbinyl pyrophosphate.

**Step II** The rearrangement and reduction of presqualene pyrophosphate by NADPH to form squalene. This reaction involves the formation and rearrangement of a cyclopropylcarbinyl cation in a complex reaction sequence called a **1'-2-3 process** (Fig. 25-54).

SQS, a monomeric protein, is anchored to the ER membrane via a short C-terminal transmembrane domain, with its active site facing the cytosol. This allows it to accept its water-soluble substrates, farnesyl pyrophosphate and NADPH, from the cytosol and release its hydrophobic product, squalene, in the ER membrane.

**Figure 25-54** Mechanism of rearrangement and reduction of presqualene pyrophosphate to squalene as catalyzed by squalene synthase (Fig. 25-52, Step II). (1) Presqualene's pyrophosphate group leaves, yielding a primary carbocation at  $C1$ . (2) The electrons forming the  $C1'-C3$  bond migrate to  $C1$ , forming squalene's  $C1-C1'$  bond and a tertiary carbocation at  $C3$ . (3) The process is completed by the addition of an NADPH-supplied hydride ion to  $C1'$  and the formation of the  $C2=C3$  double bond.

The X-ray structure of the 417-residue human SQS, in complex with the inhibitor **CP-320473**,

determined by Jayvardhan Pandit, reveals that the protein folds as a single domain with a large channel across one face into which CP-320473 binds (Fig. 25-55). The channel is lined with Asp and Arg residues that mutagenesis studies indicate are involved in FPP binding. Of these, the conserved Asp 80 and Asp 84 are implicated in binding  $Mg^{2+}$  ions that ligand an FPP pyrophosphate group. These Asp residues are adjacent to Tyr 171, which forms the base of the channel and which mutagenesis studies have identified as the essential Tyr that is implicated in stabilizing the allylic carbocation intermediate in Step I of the SQS reaction. Step II of the SQS reaction requires that its highly reactive carbocation intermediates be shielded from contact with the aqueous solvent to prevent it from quenching the reaction. This suggests that for Step II, the presqualene pyrophosphate product of Step I moves deeper into the channel into a pocket that is lined with hydrophobic groups, including Phe 288, whose mutation inactivates the enzyme. This further suggests that Phe 288 functions to stabilize one of the cationic intermediates in Step II (Fig. 25-54) through  $\pi$ -cation interactions.

#### d. Lanosterol Is Produced by Squalene Cyclization

Squalene, an open-chain  $C_{30}$  hydrocarbon, is cyclized to form the tetracyclic steroid skeleton in two steps. **Squalene**

**epoxidase** catalyzes the oxidation of squalene to form **2,3-oxidosqualene** (Fig. 25-56). **Oxidosqualene cyclase** (alternatively, **lanosterol synthase**) converts this epoxide to **lanosterol**, the sterol precursor of cholesterol. The highly exergonic reaction is a complex process involving cyclization of 2,3-oxidosqualene to a **protosterol** cation, via a Class II mechanism involving protonation of the epoxide, and rearrangement of this cation to lanosterol by a series of 1,2 hydride and methyl shifts (Fig. 25-57). Note that this reaction generates six of lanosterol's seven chiral centers.

The X-ray structure of human oxidosqualene cyclase in complex with lanosterol, determined by Armin Ruf, reveals that this 732-residue monomeric and monotopic [integral but not transmembrane] protein contains two structurally similar domains named  $\alpha/\alpha$  barrels (Fig. 25-58a). An  $\alpha/\alpha$  barrel consists of two concentric barrels of 6 helices each, with the helices of the inner barrel largely parallel to each other and antiparallel to those of the outer barrel (much like an  $\alpha/\beta$  barrel with the  $\beta$  strands of the inner barrel replaced by helices but with only 6  $\alpha/\alpha$  units rather than 8  $\alpha/\beta$  units). The enzyme's active site is located inside an elongated central cavity (Fig. 25-58b) to which the lanosterol is bound and which is accessible from the membrane via a nonpolar channel through the enzyme's membrane-immersed part.

The interactions of 2,3-oxidosqualene with oxidosqualene cyclase cause it to fold and react such that it only forms lanosterol. The active site cavity is lined with several conserved aromatic side chains that are suitably positioned to stabilize the catalyzed reaction's intermediate carbocations, while shielding the cationic intermediates from premature quenching by either enzyme nucleophiles or water. The cationic cascade (Fig. 25-57) is initiated by proton donation by Asp 455 to the epoxide ring of the prefolded 2,3-oxidosqualene, and is quenched by His 232 acting as a general base.

The importance of the proper placement of residues for the formation of the correct product was demonstrated by site-directed mutagenesis: The conversion of Thr 384 in

**Figure 25-55** X-ray structure of human squalene synthase (SQS) in complex with the inhibitor CP-320473. This inhibitor together with the side chains of D80, D84, Y171, and F288 are drawn in ball-and-stick form colored according to atom type (inhibitor C green, protein C cyan, N blue, O red, and Cl magenta). The protein is viewed looking into its central channel with the putative active sites for Steps I and II of the catalyzed reaction at the bottom and top of the cleft, respectively. The protein's C-terminal transmembrane segment (residues 371–417) together with its N-terminal 30 residues were excised to facilitate its crystallization, which did not affect its *in vitro* catalytic activity. [Based on an X-ray structure by Jayvardhan Pandit, Pfizer Central Research, Groton, Connecticut. PDBid 1EZF.]

**Figure 25-58** X-ray structure of human oxidosqualene cyclase in complex with its product lanosterol. The monomeric protein is shown in ribbon form (a) viewed along the axis of its  $\alpha/\alpha$  barrels, and (b) rotated  $90^\circ$  about the horizontal axis with respect to Part a. The inner helices of its two  $\alpha/\alpha$  barrels are cyan, its outer helices are purple, its nonpolar membrane-immersed portion is orange, and the remainder of the protein is pink. The lanosterol, which occupies the enzyme's centrally located active site cavity, is shown in Part a in space-filling form and in Part b in stick form embedded in its semitransparent space-filling form, both with C

green and O red. The catalytically important side chains of His 232 and Asp 455, together with molecules of the detergent  $\beta$ -octylglucoside and fragments of lipids that coat the enzyme's membrane-immersed portion, are drawn in stick form with side chain C magenta, lipid and detergent C yellow, and O red. The arrow in Part b points to the membrane-immersed opening of the enzyme's active site cavity. [Based on an X-ray structure by Armin Ruf, F. Hoffmann-La Roche AG, Basel, Switzerland. PDBid 1W6K.]

#### e. Cholesterol Is Synthesized from Lanosterol

Conversion of lanosterol to cholesterol (Fig. 25-59) is a 19-step process that we shall not explore in detail. It involves an oxidation and loss of three methyl groups. The first methyl group is removed as formate and the other two are eliminated as  $\text{CO}_2$  in reactions that all require NADPH and  $\text{O}_2$ . The enzymes involved in this process are embedded in the ER membrane.

#### f. Cholesterol Is Transported in the Blood and Taken Up by Cells in Lipoprotein Complexes

Transport and cellular uptake of cholesterol are described in Section 12-5. To recapitulate, cholesterol synthesized by the liver is either converted to bile salts for use in the digestive process (Section 25-1) or esterified by acyl-

CoA:cholesterol acyltransferase (ACAT) to form cholesteryl esters

which are secreted into the bloodstream as part of the lipoprotein complexes called **very low density lipoproteins (VLDL)**. As the VLDL circulate, their component triacyl-

**Figure 25-59** The 19-reaction conversion of lanosterol to cholesterol. [After Rilling, H.C. and Chayet, L.T., in Danielsson, H. and Sjövall, J. (Eds.), *Sterols and Bile Acids*, p. 33, Elsevier

(1985), as modified by Bae, S.-H. and Paik, Y.-K., *Biochem. J.* **326**, 609–616 (1997).]

glycerols and most types of their **apolipoproteins** (Table 12-6) are removed in the capillaries of muscle and adipose tissues, sequentially converting the VLDL to **intermediate-density lipoproteins (IDL)** and then to **low-density lipoproteins (LDL)**. Peripheral tissues normally obtain most of their exogenous cholesterol from LDL by receptor-mediated endocytosis (Fig. 25-60; Section 12-5Bc). Inside the cell, cholesteryl esters are hydrolyzed by a lysosomal lipase to free cholesterol, which is either incorporated into cell membranes or reesterified by ACAT for storage as cholesteryl ester droplets.

Dietary cholesterol, cholesteryl esters, and triacylglycerols are transported in the blood by intestinally synthesized lipoprotein complexes called **chylomicrons**. After removal of their triacylglycerols at the peripheral tissues, the resulting **chylomicron remnants** bind to specific liver cell remnant receptors and are taken up by receptor-mediated endocytosis in a manner similar to that of LDL. In the liver, dietary cholesterol is either used in bile salt biosynthesis (Section 25-6C) or packaged into VLDL for export. *Liver and peripheral tissues therefore have two ways of obtaining cholesterol: They may either synthesize it from acetyl-CoA*

**Figure 25-60** LDL receptor-mediated endocytosis in mammalian cells. LDL receptor is synthesized on the endoplasmic reticulum, processed in the Golgi complex, and inserted into the plasma membrane as a component of coated pits. LDL is specifically bound by the LDL receptor on the coated pit and brought into the cell in endosomes that deliver LDL to lysosomes while recycling LDL receptor to the plasma

membrane (Section 12-5Bc). Lysosomal degradation of LDL releases cholesterol, whose presence decreases the rate of synthesis of HMG-CoA reductase and LDL receptors (*down arrows*) while increasing that of acyl-CoA:cholesterol acyltransferase (ACAT; *up arrow*). [After Brown, M.S. and Goldstein, J.L., *Curr. Top. Cell. Reg.* **26**, 7 (1985).]  See the Animated Figures

by the *de novo* pathway we have just discussed, or they may obtain it from the bloodstream by receptor-mediated endocytosis. A small amount of cholesterol also enters cells by a non-receptor-mediated pathway. Note however, that the brain, which comprises ~2% of the human body mass but contains ~30% of its cholesterol, must synthesize all of its cholesterol because cholesterol cannot pass the blood-brain barrier.

Cholesterol actually circulates back and forth between the liver and peripheral tissues. While LDL transports cholesterol from the liver, cholesterol is transported back to the liver by **high-density lipoproteins (HDL)**. Surplus cholesterol is disposed of by the liver as bile salts, thereby protecting the body from an overaccumulation of this water-insoluble substance.

### B. Control of Cholesterol Biosynthesis and Transport

Cholesterol biosynthesis and transport must be tightly regulated. There are three ways in which the cellular cholesterol supply is maintained:

1. By regulating the activity of HMG-CoA reductase, the enzyme catalyzing the rate-limiting step in the *de novo* cholesterol biosynthesis pathway. This is accomplished in two ways:
  - (i) Short-term regulation of the enzyme's catalytic activity by (a) competitive inhibition, (b) allosteric effects, and (c) covalent modification involving reversible phosphorylation.
  - (ii) Long-term regulation of the enzyme's concentration by modulating its rates of synthesis and degradation.
2. By regulating the rate of LDL receptor synthesis, and therefore the rate of cholesterol uptake. High intracellular concentrations of cholesterol suppress LDL receptor synthesis, whereas low cholesterol concentrations stimulate it.
3. By regulating the rate of esterification and hence the removal of free cholesterol. ACAT, the enzyme that catalyzes intracellular cholesterol esterification, is regulated by reversible phosphorylation and by long-term control.

#### a. HMG-CoA Reductase Is the Primary Control Site for Cholesterol Biosynthesis

HMG-CoA reductase is the rate-limiting enzyme in cholesterol biosynthesis and, as therefore might be expected, constitutes the pathway's main regulatory site. The pathway branches after this reaction, however (Fig. 25-46); ubiquinone, dolichol, farnesylated and geranylgeranylated proteins, and isopentenyl adenosine are also essential, albeit minor, products. HMG-CoA is therefore subject to "multivalent" control, both long-term and short-term, in order to coordinate the synthesis of all of these products.

#### b. Long-Term Feedback Regulation of HMG-CoA Reductase Is Its Primary Means of Control

The main way in which HMG-CoA reductase is controlled is by long-term feedback control of the amount of enzyme present in the cell. When either LDL-cholesterol or

mevalonate levels fall, the amount of HMG-CoA reductase present in the cell can rise as much as 200-fold, due to an increase in enzyme synthesis combined with a decrease in its degradation. When LDL-cholesterol or **mevalonolactone** (an internal ester of mevalonate that is hydrolyzed to mevalonate and metabolized in the cell)

are added back to a cell, these effects are reversed.

The mechanism by which cholesterol serves to control the expression of the >20 genes involved in its biosynthesis and uptake, such as those encoding HMG-CoA reductase and the LDL receptor, has been elucidated by Michael Brown and Joseph Goldstein. These genes all contain a DNA sequence upstream from the transcription initiation site called the **sterol regulatory element (SRE)**. In order for these genes to be transcribed, a specific transcription factor, the **sterol regulatory element binding protein (SREBP)**, must bind to the SRE (eukaryotic gene expression is discussed in Section 34-3). SREBP is synthesized as an integral membrane protein that, when the cholesterol concentration is sufficiently high (Fig. 25-61a), resides in the ER membrane in complex with **SREBP cleavage-activating protein (SCAP)** and a protein named **Insig**. SREBP (~1160 residues) consists of three domains (Fig. 25-61a): (1) an ~480-residue cytosolic N-terminal domain that is a member of the **basic helix-loop-helix/leucine zipper (bHLH/Z)** family of transcription factors (Section 34-3Br), which specifically binds to SREs; (2) an ~90-residue transmembrane (TM) domain consisting of two TM helices connected by an ~30-residue hydrophilic luminal loop; and (3) an ~590-residue cytosolic C-terminal regulatory domain. SCAP (1276 residues) consists of two domains: (1) a 730-residue N-terminal domain that contains eight TM helices; and (2) a 546-residue cytosolic C-terminal domain that contains five copies of the protein-protein interaction motif known as a **WD repeat** (also called a WD40 sequence motif because it is ~40 residues long; Section 19-2Cc) and which presumably forms a 5-bladed  $\beta$  propeller similar to the 7-bladed  $\beta$  propeller of the  $G_{\beta}$  subunit (Fig. 19-19b). Insig (named to denote *insulin-induced gene*, although the insulin effect was later found to be indirect) consists mainly of six TM helices. SCAP and SREBP associate through the interaction of the SCAP's regulatory domain with SREBP's WD domain (Fig. 25-61a).

SCAP functions as a sterol sensor. An ~170-residue segment of its TM domain, the **sterol-sensing domain**, interacts with sterols although how it does so is unknown. When the cholesterol in the ER membrane is depleted (Fig. 25-61b), SCAP changes conformation and then

**Figure 25-61 The cholesterol-mediated proteolytic activation of SREBP.** (a) When cholesterol levels in the cell are high, the Insig–SCAP–SREBP complex resides in the ER membrane. (b) When cholesterol levels are low, SCAP releases Insig and binds COPII protein. The SCAP–SREBP complex is then transported, via COPII-coated vesicles, to the Golgi apparatus, where SREBP

undergoes sequential proteolytic cleavage by the membrane-bound proteases S1P and S2P. This releases SREBP’s bHLH/Z-containing N-terminal domain, which enters the nucleus where it binds to the SREs of its target genes, thereby inducing their transcription. [After Goldstein, J., Rawson, R.B., and Brown, M., *Arch. Biochem. Biophys.* **397**, 139 (2002).]

releases Insig, which allows SCAP to bind to the Sec24 cargo-binding subunit of the COPII coated vesicle protein (Section 12-4Ca). The COPII vesicle then escorts its bound SREBP–SCAP complex to the Golgi apparatus.

In the Golgi apparatus, SREBP is sequentially cleaved by two membrane-bound proteases (Fig. 25-61b). **Site-1 protease (S1P)**, a serine protease of the subtilisin family, cleaves SREBP in the luminal loop that connects its two transmembrane helices but only when it is associated with SCAP. This cleavage exposes a peptide bond located 3 residues from the beginning of SREBP’s N-terminal

TM helix to cleavage by **site-2 protease (S2P)**, a zinc metalloprotease. This releases the bHLH/Z domain to migrate to the nucleus where it activates the transcription of its target genes. The cholesterol level in the cell thereby rises until SCAP no longer induces the translocation of SREBP to the Golgi, a classic case of feedback inhibition.

This complex regulatory pathway was elucidated, in part, through the generation of several lines of transgenic mice that overexpress one or another of the foregoing proteins, and knockout mice that lack one or another of these

proteins. For example, knockout mice lacking either SCAP or S1P in their livers have decreased expression of both HMG-CoA reductase and LDL receptor, even when fed a cholesterol-deficient diet. In contrast, transgenic mice that overexpress SREBP or SCAP have greatly increased expression of the foregoing proteins. In fact, animals overproducing only the bHLH/Z domain of SREBP have massively enlarged livers (up to 4-fold larger than normal) due to engorgement with triacylglycerols and cholesteryl esters and yet they continue to transcribe SREBP's target genes such that their mRNA levels are up to 75-fold greater than normal. Many individuals suffering from obesity or diabetes caused by insulin resistance (type 2 diabetes; Section 27-4B) have fatty livers, which in some cases leads to liver failure. Fatty livers due to insulin resistance appear to be caused by elevated levels of SREBP in response to elevated insulin levels.

The level of HMG-CoA reductase also responds to the level of the cholesterol precursor lanosterol (Section 25-6Ad). HMG-CoA reductase's ER membrane-bound N-terminal domain contains eight TM helices, whereas its C-terminal domain, which contains its active site and is linked to the N-terminal domain via a flexible Pro-rich sequence, projects into the cytosol. Insig binds to an enzymatic complex that marks proteins for degradation by covalently linking them to the protein **ubiquitin** (Section 32-6B). When lanosterol accumulates in the ER membrane, the N-terminal domain of HMG-CoA reductase also binds to Insig, and is thus marked for destruction. Consequently, the >12-hour half-life of HMG-CoA reductase in sterol-deprived cells decreases to <1 hour when sterols are plentiful.

### c. Regulation of HMG-CoA Reductase by Covalent Modification Is a Means of Cellular Energy Conservation

*HMG-CoA reductase exists in interconvertible more active and less active forms, as do glycogen phosphorylase (Section 18-3Ca), glycogen synthase (Section 18-3D), pyruvate dehydrogenase (Section 21-2Cb), and acetyl-CoA carboxylase (Section 25-4Ba), among others.* The unmodified form of HMG-CoA reductase is more active and the phosphorylated form is less active. HMG-CoA reductase is phosphorylated (inactivated) at its Ser 871 in a bicyclic cascade system by the covalently modifiable enzyme AMP-dependent protein kinase (AMPK), which, as we saw in Section 25-4Ba, also acts on acetyl-CoA carboxylase [in this context, this enzyme was originally named **HMG-CoA reductase kinase (RK)**, until it was found to be identical to AMPK]. It appears that this control is exerted to conserve energy when ATP levels fall and AMP levels rise, by inhibiting biosynthetic pathways. This hypothesis was tested by Brown and Goldstein, who used genetic engineering techniques to produce hamster cells containing a mutant HMG-CoA reductase with Ala replacing Ser 871 and therefore incapable of phosphorylation control. These cells respond normally to feedback regulation of cholesterol biosynthesis by LDL-cholesterol and mevalonate but, un-

like normal cells, do not decrease their synthesis of cholesterol on ATP depletion, supporting the idea that control of HMG-CoA reductase by phosphorylation is involved in energy conservation.

### d. LDL Receptor Activity Controls Cholesterol Homeostasis

LDL receptors clearly play an important role in the maintenance of plasma LDL-cholesterol levels. In normal individuals, about half of the IDL formed from the VLDL reenters the liver through LDL receptor-mediated endocytosis (IDL and LDL both contain apolipoproteins that specifically bind to the LDL receptor; Section 12-5Bc). The remaining IDL are converted to LDL (Fig. 25-62a). *The serum concentration of LDL therefore depends on the rate at which liver removes IDL from the circulation, which, in turn, depends on the number of functioning LDL receptors on the liver cell surface.*

High blood cholesterol (**hypercholesterolemia**), which results from the overproduction and/or underutilization of LDL, is known to be caused by either of two metabolic irregularities: (1) the genetic disease **familial hypercholesterolemia (FH)** or (2) the consumption of a high-cholesterol diet. FH is a dominant genetic defect that results in a deficiency of functional LDL receptors (Section 12-5Ca). Homozygotes for this disorder lack functional LDL receptors, so their cells can absorb neither IDL nor LDL by receptor-mediated endocytosis. The increased concentration of IDL in the bloodstream leads to a corresponding increase in LDL, which is, of course, underutilized since it cannot be taken up by the cells (Fig. 25-62b). FH homozygotes therefore have plasma LDL-cholesterol levels three to five times higher than average. FH heterozygotes, which are far more common, have about half of the normal number of functional LDL receptors and plasma LDL-cholesterol levels about twice the average.

*The long-term ingestion of a high-cholesterol diet has an effect similar, although not as extreme, as FH (Fig. 25-62c).* Excessive dietary cholesterol enters the liver cells in chylomicron remnants and represses the synthesis of LDL receptor protein. The resulting insufficiency of LDL receptors on the liver cell surface has consequences similar to those of FH.

LDL receptor deficiency, whether of genetic or dietary origin, raises the LDL level by two mechanisms: (1) increased LDL production resulting from decreased IDL uptake and (2) decreased LDL uptake. Two strategies for reversing these conditions (besides maintaining a low-cholesterol diet) are being used in humans:

1. *Ingestion of anion exchange resins (Section 6-3A) that bind bile salts, thereby preventing their intestinal absorption (resins are insoluble in water).* Bile salts, which are derived from cholesterol, are normally efficiently recycled by the liver (Section 25-6C). Elimination of resin-bound bile salts in the feces forces the liver to convert more cholesterol to bile salts than otherwise. The consequent decrease in the serum cholesterol concentration induces synthesis of LDL receptors (of course, not in FH homozygotes). Unfortunately, the

**Figure 25-62 Control of plasma LDL production and uptake by liver LDL receptors.** (a) In normal human subjects, VLDL is secreted by the liver and converted to IDL in the capillaries of the peripheral tissues. About half of the plasma IDL particles bind to the LDL receptor and are taken up by the liver. The remainder are converted to LDL at the peripheral tissues. (b) In individuals with familial hypercholesterolemia (FH), liver LDL receptors are diminished or eliminated because of a genetic

defect. (c) In normal individuals who have a long-term high-cholesterol diet, the liver is filled with cholesterol, which represses the rate of LDL receptor production. Receptor deficiency, whether of genetic or dietary cause, raises the plasma LDL level by increasing the rate of LDL production and decreasing the rate of LDL uptake. [After Goldstein, J.L. and Brown, M.S., *J. Lipid Res.* **25**, 1457 (1984).]

decreased serum cholesterol level also induces the synthesis of HMG-CoA reductase, which increases the rate of cholesterol biosynthesis. Ingestion of bile salt-binding resins such as **cholestyramine** (sold as **Questran**) therefore provides only a 15 to 20% drop in serum cholesterol levels.

**2. Treatment with competitive inhibitors of HMG-CoA reductase.** These include (Fig. 25-63) the fungal derivatives **lovastatin** (also called **mevinolin** and sold as **Mevacor**), **pravastatin** (**Pravachol**), and **simvastatin** (**Zocor**) as well as the synthetic inhibitor **atorvastatin** (**Lipitor**), compounds

**Figure 25-63** Some competitive inhibitors of HMG-CoA reductase used for the treatment of hypercholesterolemia. The molecular formulas of lovastatin (Mevacor), pravastatin (Pravachol), simvastatin (Zocor), and atorvastatin (Lipitor), all of which are potent competitive inhibitors of HMG-CoA

reductase, are given. The structures of HMG-CoA and mevalonate are shown for comparison. Note that lovastatin, pravastatin, and simvastatin are lactones, whereas atorvastatin and mevalonate are hydroxy acids. The lactones are hydrolyzed enzymatically *in vivo* to their active hydroxy-acid forms.

that are collectively known as **statins**. Indeed, Lipitor is presently one of the most widely prescribed drugs in the United States. The initial decreased cholesterol supply in the cell caused by the presence of statins is again met by induction of LDL receptors and HMG-CoA reductase so that, at the new steady state, the HMG-CoA reductase level is almost that of the predrug state. However, the increased number of LDL receptors causes increased removal of both LDL and IDL (the apoB-containing precursor to LDL), decreasing serum LDL levels appreciably. Lipitor-treated FH heterozygotes routinely show a serum cholesterol decrease of 40–50%.

*The combined use of these agents, moreover, results in a clinically dramatic 50 to 60% decrease in serum cholesterol levels.*

#### e. Overexpression of LDL Receptor Prevents Diet-Induced Hypercholesterolemia

Experiments are well underway toward the treatment of hypercholesterolemic individuals by **gene therapy**

(Section 5-5Hb). A line of transgenic mice has been developed that overproduce the human LDL receptor. When fed a diet high in cholesterol, fat, and bile salts, these transgenic animals did not develop a detectable increase in plasma LDL. In contrast, normal mice fed the same diet exhibited large increases in plasma LDL levels. Evidently, the unregulated overexpression of LDL receptors can prevent diet-induced hypercholesterolemia, at least in mice.

#### C. Cholesterol Utilization

*Cholesterol is the precursor of steroid hormones and bile salts.* Steroid hormones, which are grouped into five categories, **progestins**, **glucocorticoids**, **mineralocorticoids**, **androgens**, and **estrogens**, mediate a wide variety of vital physiological functions (Section 19-1G). All contain the four-ring structure of the sterol nucleus and are remarkably similar in structure, considering the enormous differences in their physiological effects. A simplified

**Figure 25-64** Simplified scheme of steroid biosynthesis. The enzymes involved are (1) the cholesterol side chain cleavage enzyme, (2) steroid C17 hydroxylase, (3) steroid C17, C20 lyase,

(4) steroid C21 hydroxylase, (5) steroid 11 $\beta$ -hydroxylase, (6) steroid C18 hydroxylase, (7) 18-hydroxysteroid oxidase, and (8) aromatase.

biosynthetic scheme (Fig. 25-64) indicates their structural similarities and differences. We shall not discuss the details of these pathways.

The quantitatively most important pathway for the excretion of cholesterol in mammals is the formation of **bile acids**. The major bile acids, **cholate** and **chenodeoxycholate**,

**Figure 25-66 Prostaglandin structures.** (a) The carbon skeleton of prostanic acid, the prostaglandin parent compound. (b) Structures of prostaglandins A through I. (c) Structures of prostaglandins E $_1$ , E $_2$ , and F $_{2\alpha}$  (the first prostaglandins to be identified).

form a cyclopentane ring (Fig. 25-66a). Prostaglandins A through I differ in the substituents on the cyclopentane ring (Fig. 25-66b): **PGAs** are  $\alpha,\beta$ -unsaturated ketones, **PGEs** are  $\beta$ -hydroxy ketones, **PGFs** are 1,3-diols, etc. In **PGF $_{\alpha}$** , the C9 OH group is on the same side of the ring as R $_1$ ; it is on the opposite side in **PGF $_{\beta}$** . The numerical subscript in the name refers to the number of double bonds contained on the side chains of the cyclopentane ring (Fig. 25-66c).

In humans, the most prevalent prostaglandin precursor is **arachidonic acid (5,8,11,14-eicosatetraenoic acid)**, a C $_{20}$  polyunsaturated fatty acid that has four nonconjugated double bonds. The double bond at C14 is six carbon atoms from the terminal carbon atom (the  $\omega$  carbon atom), making arachidonic acid an  $\omega$ -6 fatty acid. As Sune Bergström and Bengt Samuelsson demonstrated, arachidonic acid is syn-

thesized from the essential fatty acid linoleic acid (also an  $\omega$ -6 fatty acid). This occurs via its desaturation with a  $\Delta^6$ -desaturase to yield  **$\gamma$ -linolenic acid (GLA)**, followed by elongation and a second desaturation, this time with a  $\Delta^5$ -desaturase (Fig. 25-67; Section 25-4E). Prostaglandins with the subscript 1 (the “series-1” prostaglandins) are synthesized from **dihomo- $\gamma$ -linolenic acid (DGLA; 8,11,14-eicosatrienoic acid)**, whereas “series-2” prostaglandins are synthesized from arachidonic acid.  $\alpha$ -Linolenic acid (ALA), another essential fatty acid since the  $\Delta^{15}$ -desaturase required for its synthesis occurs only in plants, is a precursor of 5,8,11,14,17-eicosapentaenoic acid (EPA) and the “series-3” prostaglandins. Since arachidonate is the primary prostaglandin precursor in humans, we shall mostly refer to the series-2 prostaglandins in our examples. Note, however, that when dietary linoleic acid and  $\alpha$ -linolenic acid are equally available, the relative activities of the  $\Delta^5$ - and  $\Delta^6$ -desaturases are important in determining the relative amounts of these prostaglandin precursors.

### a. Arachidonate Is Generated by Phospholipid Hydrolysis

Arachidonate is stored in cell membranes esterified at glycerol C2 of phosphatidylinositol and other phospholipids. The production of arachidonate metabolites is controlled by the rate of arachidonate release from these phospholipids through three alternative pathways (Fig. 25-68):

**1. Phospholipase A $_2$**  hydrolyzes acyl groups at C2 of phospholipids (Fig. 25-68b, left).

**2. Phospholipase C** (Section 19-4B) specifically hydrolyzes the phosphatidylinositol head group to yield a **1,2-diacylglycerol (DAG)** and **phosphoinositol**. DAG is phosphorylated by **diacylglycerol kinase** to phosphatidic acid, a phospholipase A $_2$  substrate (Fig. 25-68b, center). (Recall that DAG and the various phosphorylated forms of phosphoinositol are also important signaling molecules in that they mediate the phosphoinositide cascade; Section 19-4.)

**3.** The DAG also may be hydrolyzed directly by **diacylglycerol lipase** (Fig. 25-68b, right). Corticosteroids are used as anti-inflammatory agents because they inhibit phospholipase A $_2$ , reducing the rate of arachidonate production.

### b. Aspirin Inhibits Prostaglandin Synthesis

The use of **aspirin** as an analgesic (pain-relieving), antipyretic (fever-reducing), and anti-inflammatory agent has been widespread since the nineteenth century. Yet, it was not until 1971 that John Vane discovered its mechanism of action. *Aspirin, as do other nonsteroidal anti-inflammatory drugs (NSAIDs), inhibits the synthesis of prostaglandins from eicosanoid precursors* (Section 25-7Ba). These inhibitors have therefore proved to be valuable tools in the elucidation of prostaglandin biosynthesis pathways and have provided a starting point for the rational synthesis of new anti-inflammatory drugs.

**Figure 25-67** Synthesis of prostaglandin precursors. The linoleic acid derivatives dihomoGLA (DGLA), arachidonic acid,

and 5,8,11,14,17-eicosapentaenoic acid (EPA) are the respective precursors of the series-1, series-2, and series-3 prostaglandins.

### c. Arachidonic Acid Is a Precursor of Leukotrienes, Thromboxanes, and Prostacyclins

Arachidonic acid also serves as a precursor to compounds whose synthesis is not inhibited by aspirin. In fact,

there are two main pathways of eicosanoid metabolism. The so-called cyclic pathway, which is inhibited by NSAIDs, forms prostaglandin's characteristic cyclopentane ring, whereas the so-called linear pathway, which is

**Figure 25-68** Release of arachidonic acid by phospholipid hydrolysis. (a) The sites of hydrolytic cleavage mediated by phospholipases A<sub>2</sub> and C. The polar head group, X, is often

inositol and its various phosphorylated forms (Section 19-4D). (b) Pathways of arachidonic acid liberation from phospholipids.

Figure 25-69 The cyclic and linear pathways of arachidonic acid metabolism.

Figure 25-70 The cyclic pathway of arachidonic acid metabolism. This pathway's branches lead to prostaglandins, prostacyclins, and thromboxanes.

not inhibited by these agents, leads to the formation of the **leukotrienes** and **HPETEs** (Fig. 25-69; Section 25-7C).

Studies using NSAIDs helped demonstrate that two structurally related and highly short-lived classes of compounds, the prostacyclins and the thromboxanes (Fig. 25-70), are also products of the cyclic pathway of eicosanoid metabolism. The specific products produced by this branched pathway depend on the tissue involved. For example, blood platelets (thrombocytes) produce thromboxanes almost exclusively; vascular endothelial cells, which make up the walls of veins and arteries, predominantly synthesize the prostacyclins; and heart muscle makes PGI<sub>2</sub>, PGE<sub>2</sub>, and PGF<sub>2α</sub> in more or less equal quantities. In the remainder of this section, we study the cyclic and the linear pathways of eicosanoid metabolism.

### B. The Cyclic Pathway of Eicosanoid Metabolism: Prostaglandins, Prostacyclins, and Thromboxanes

The first step in the cyclic pathway of eicosanoid metabolism is catalyzed by **PGH synthase (PGHS)**; also called **prostaglandin H synthase** and **prostaglandin endoperoxide synthase**; Fig. 25-71). This heme-containing enzyme contains two catalytic activities: a cyclooxygenase activity and a peroxidase activity. The former catalyzes the tyrosyl radical-mediated addition of two molecules of O<sub>2</sub> to arachidonic acid, forming **PGG<sub>2</sub>**. The latter converts the hydroperoxy function of PGG<sub>2</sub> to an OH group, yielding **PGH<sub>2</sub>**. *PGH<sub>2</sub> is the immediate precursor of all series-2 prostaglandins, prostacyclins, and thromboxanes* (Fig. 25-70). The cyclooxygenase activity of the enzyme gives it its common name, **COX** [not to be confused with cytochrome c oxidase, which is also called COX (Section 22-2C5)].

PGHS, a homodimeric glycoprotein of 576-residue subunits, is a monotopic membrane protein that extends into the lumen of the endoplasmic reticulum. Its X-ray structure, determined by Michael Garavito, reveals that each of its subunits folds into three domains (Fig. 25-72a): an N-terminal module that structurally resembles **epidermal growth factor (EGF)**; a central membrane-binding motif; and a C-terminal enzymatic domain. The 44-residue membrane-binding motif has a hydrophobic surface that faces away from the body of the protein [as is also true of oxidosqualene cyclase (Fig. 25-58b) and fatty acid amide hydrolase (Fig. 12-28)].

The peroxidase active site of PGHS occurs at the interface between the large and small lobes of the catalytic domain, in a shallow cleft that contains the enzyme's Fe(III)-heme prosthetic group. The cleft exposes a large portion of the heme to solvent and is therefore thought to comprise the substrate binding site.

The cyclooxygenase active site lies on the opposite side of the heme at the end of a long narrow hydrophobic channel (~8 × 25 Å) extending from the outer surface of the membrane-binding motif to the center of each subunit (Fig. 25-72b). This channel allows access of the membrane-associated substrate to the active site. Tyr 385, which lies near the top of the channel, just beneath the heme, has

**Figure 25-71** Reactions catalyzed by PGH synthase (PGHS).

The enzyme contains two activities: a cyclooxygenase, which catalyzes Steps 1 to 3 and is inhibited by aspirin; and a peroxidase, which catalyzes Step 4. (1) A radical at Tyr 385 that is generated by the enzyme's heme cofactor stereospecifically abstracts a hydrogen atom from C13 of arachidonic acid, which then rearranges so that the radical is on C11. (2) The radical reacts with O<sub>2</sub> to yield a hydroperoxide radical. (3) The radical cyclizes and reacts with a second O<sub>2</sub> molecule at C15 to yield a peroxide in a process that regenerates the Tyr radical. (4) The enzyme's peroxidase activity converts the peroxide at C15 to a hydroxyl group.

been shown to form a transient radical during the cyclooxygenase reaction as does, for example, Tyr 244 of cytochrome c oxidase (Section 22-2C5c). Indeed, the mutagenic replacement of PGHS's Tyr 385 by Phe abolishes its cyclooxygenase activity. The Tyr 385 radical is generated via an intramolecular oxidation by the heme cofactor.

(a)

a PGHS subunit (green), the left subunit in Part a as viewed from  $30^{\circ}$  to the left. The peroxidase active site is located above the heme (pink). The hydrophobic channel, which penetrates the subunit from the membrane-binding motif at the bottom of the figure to the cyclooxygenase active site below the heme, is represented by its van der Waals surface (blue dots). The three residues in the channel that are shown in stick form in orange are, from top to bottom: Tyr 385, Ser 530, which is acetylated by aspirin, and Arg 120. [Courtesy of Michael Garavito, Michigan State University. PDBid 1CQE.]

The fate of  $\text{PGH}_2$  depends on the relative activities of the enzymes catalyzing the specific interconversions (Fig. 25-70). Platelets contain **thromboxane synthase**, which mediates the formation of **thromboxane  $A_2$  ( $\text{Tx}A_2$ )**, a vasoconstrictor and stimulator of platelet aggregation (an initial step in blood clotting; Section 35-1). Vascular endothelial cells contain **prostacyclin synthase**, which catalyzes the synthesis of **prostacyclin  $I_2$  ( $\text{PGI}_2$ )**, a vasodilator and inhibitor of platelet aggregation. These two substances act in opposition, maintaining a balance in the cardiovascular system.

#### a. NSAIDs Inhibit PGH Synthase

Nonsteroidal anti-inflammatory drugs (NSAIDs; Fig. 25-73) inhibit the synthesis of the prostaglandins, prostacyclins, and thromboxanes by inhibiting or inactivating the cyclooxygenase activity of PGHS. Aspirin (**acetylsalicylic acid**), for example, acetylates this enzyme: If [ $^{14}\text{C}$ -acetyl] acetylsalicylic acid is incubated with the enzyme, radioactivity becomes irreversibly associated with the inactive enzyme as Ser 530 becomes acetylated (Fig. 25-74). The X-ray structure of PGHS reveals that Ser 530, which is not implicated in catalysis, extends into the cyclooxygenase channel just below Tyr 385 such that its acetylation would block arachidonic acid's access to the active site (Fig. 25-72b). The structure of PGHS, which was crystallized with the NSAID **flurbiprofen** (Fig. 25-73), indicates that this drug binds in the

cyclooxygenase channel, with its carboxyl group forming an ion pair with Arg 120 (Fig. 25-72a). Evidently, flurbiprofen, and by implication other NSAIDs, inhibits the cyclooxygenase activity of PGHS by blocking its active site channel.

Low doses of aspirin,  $\sim 80$  mg (baby aspirin) every day, significantly reduce the long-term incidence of heart attacks and strokes. Such low doses selectively inhibit platelet aggregation and thus blood clot formation because these enucleated cells, which have a lifetime in the circulation of  $\sim 10$  days, cannot resynthesize their inactivated enzymes. Vascular endothelial cells are not so drastically affected since, for the most part, they are far from the site where aspirin is absorbed, are exposed to lesser concentrations of aspirin and, in any case, can synthesize additional PGHS.

#### b. COX-2 Inhibitors Lack the Side Effects of Other NSAIDs

PGHS has two isoforms, **COX-1** and **COX-2**, that share a high degree (60%) of sequence identity and structural homology. COX-1 is constitutively (without regulation) expressed in most, if not all, mammalian tissues, thereby supporting levels of prostaglandin synthesis necessary to maintain organ and tissue homeostasis such as that of the gastrointestinal mucosa. In contrast, COX-2 is only expressed in certain tissues in response to inflammatory stim-

**Figure 25-73** Some nonsteroidal anti-inflammatory drugs (NSAIDs).

uli such as cytokines, protein growth factors, and endotoxins, and hence is responsible for the elevated prostaglandin levels that cause inflammation. The NSAIDs in Fig. 25-73 are relatively nonspecific and therefore can have adverse side effects, most notably gastrointestinal ulceration, when used to treat inflammation or fever. A structure-based drug design program (Section 15-4Ad) was therefore instituted to create inhibitors that would target COX-2 but not COX-1. The three-dimensional structures of COX-1 and COX-2 are almost identical. However, their amino acid differences, specifically I523V, I434V, and H513R (COX-1 amino acid on the left and COX-2 amino acid on the right), make COX-2's active site channel ~20% larger in volume

than that of COX-1. In addition, the fourth helix of the membrane-binding domain is oriented slightly differently so as to provide a larger opening to the channel. Medicinal chemists therefore synthesized inhibitors, collectively known as **coxibs**, that could enter the COX-2 channel but are excluded from that of COX-1. Two of these inhibitors, **rofecoxib (Vioxx)** and **celecoxib (Celebrex; Fig. 25-75)**, became major drugs for the treatment of inflammatory diseases such as arthritis because they lack the major side

**Figure 25-74** Inactivation of PGH synthase by aspirin. Aspirin acetylates Ser 530 of PGH synthase, thereby blocking the enzyme's cyclooxygenase activity.

**Figure 25-75** COX-2 inhibitors. Rofecoxib and celecoxib are specific inhibitors of COX-2 (PGH synthase-2).

effects of the nonspecific NSAIDs. However, in 2004, Vioxx was withdrawn from the pharmaceutical market because of unanticipated cardiac side effects arising from its attenuation of PGI<sub>2</sub> formation.

### c. COX-3 May Be the Target of Acetaminophen

Acetaminophen, which is among the most widely used analgesic/antipyretic drugs (but possesses little anti-inflammatory activity, so that it is not really an NSAID), does not significantly bind to either COX-1 or COX-2. Thus its mechanism of action remained a mystery until the discovery by Daniel Simmons of a third COX isozyme, **COX-3**, a splice variant of COX-1, that is selectively inhibited by acetaminophen as well as by certain NSAIDs. This suggests that COX-3 is the primary target of drugs that decrease pain and fever.

### C. The Linear Pathway of Eicosanoid Metabolism: Leukotrienes and Lipoxins

Arachidonic acid can be converted by a linear pathway to several different **hydroperoxyeicosatetraenoic acids (HPETEs)** by the **5-, 12-, and 15-lipoxygenases (5-, 12-, and 15-LOs; Fig. 25-69)**. **Hepoxilins** are hydroxy epoxy derivatives of **12-HPETE** whose functions are not as yet well understood. **Lipoxins**, the products of a second lipoxygenase acting on **15-HPETE**, are anti-inflammatory substances. Leukotrienes, derived from the 5-LO reaction, are synthesized by a variety of white blood cells, mast cells (connective tissue cells derived from the blood-forming tissues that secrete substances which mediate inflammatory and allergic reactions), as well as lung, spleen, brain, and heart. **Peptidoleukotrienes (LTC<sub>4</sub>, LTD<sub>4</sub>, and LTE<sub>4</sub>)** are now recognized to be the components of the **slow reacting substances of anaphylaxis (SRS-A; anaphylaxis is a violent and potentially fatal allergic reaction)** released from sensitized lung after immunological challenge. These substances act at very low concentrations (as little as 10<sup>-10</sup> M) to contract vascular, respiratory, and intestinal smooth muscle. Peptidoleukotrienes, for example, are ~10,000-fold more potent than histamine, a well-known stimulant of allergic reactions. In the respiratory system, they constrict bronchi, especially the smaller airways; increase mucus secretion; and are thought to be the mediators in asthma. They are also implicated in immediate hypersensitivity (allergic) reactions, inflammatory reactions, and heart attacks.

#### a. Leukotriene Synthesis

The first two reactions in the conversion of arachidonic acid to leukotrienes are both catalyzed by 5-LO, which contains a nonheme, non-[Fe-S] cluster iron atom that must be in its Fe(III) state to be active. These reactions occur as follows (Fig. 25-76):

**1.** The oxidation of arachidonic acid to form 5-HPETE, a substance that, in itself, is not a physiological mediator. This reaction occurs in three steps:

**(a)** The active site iron atom, in its active Fe(III) state,

**Figure 25-76** The 5-LO-catalyzed oxidation of arachidonic acid to LTA<sub>4</sub> via the intermediate 5-HPETE.

abstracts an electron from the central methylene group of the 5,8-pentadiene moiety of arachidonate and the resulting free radical loses a proton to an enzymatic base.

**(b)** The free radical rearranges and adds O<sub>2</sub> to form a hydroperoxide radical.

**(c)** The hydroperoxide radical reacts with the active site iron, now in its Fe(II) form, to yield the hydroperoxide in its anionic form, which the enzyme then protonates to yield the hydroperoxide product, regenerating the active Fe(III) enzyme.

**2.** The base-catalyzed elimination of water to form the unstable epoxide **leukotriene A<sub>4</sub> (LTA<sub>4</sub>)**; the subscript indicates the number of carbon-carbon double bonds in the molecule, which is also its series number).

The X-ray structure of the rabbit reticulocyte 15-LO, a homolog of 5-LO, in complex with the competitive inhibitor **RS75091**

was determined by Michelle Browner. This 663-residue monomeric protein consists of an N-terminal 8-stranded  $\beta$  barrel domain and a C-terminal catalytic domain (Fig. 25-77). Its active site Fe atom is coordinated by four invariant His residues and by a C-terminal carboxylate oxygen in a liganding arrangement that is best described as a distorted octahedron with one of its six vertices unoccupied. The Fe, which is well below the protein surface, faces an internal cavity occupied by RS75091. This identifies the substrate binding cavity, which is lined with mostly hydrophobic residues and follows an irregular pathway past the Fe atom to the protein surface. Intriguingly, 15-LO (as does soybean **lipoxygenase-1**) contains two rarely observed  $\pi$  helices (Fig. 8-14c), each of which contains two of the Fe-liganding His residues. Each of these  $\pi$  helices is embedded in a longer helix rather than being at the end of an  $\alpha$  helix as is the case for all previously observed  $\pi$  helices.

The sizes of the substrate-binding cavities of the 5- and 12-LOs have been predicted through their homology modeling (Section 9-3B) with 15-LO. 5-LO and 12-LO have smaller amino acids substituted for those in 15-LO, such that, for example, 5-LO is predicted to have a cavity with  $\sim 20\%$  greater volume than that of 15-LO. The mutagenesis of 5-LO by Harmut Kuhn so as to decrease the size of its cavity yielded an enzyme with the specificity of 15-LO, thus supporting the proposal that it is the size of the cavity that determines lipoxygenase specificity.

### b. Peptidoleukotrienes

$LTA_4$  is converted to peptidoleukotrienes by reaction with **LTC<sub>4</sub> synthase**, a **glutathione-S-transferase** that catalyzes the addition of the glutathione sulfhydryl group to the  $LTA_4$  epoxide, forming the first of the peptidoleukotrienes, **leukotriene C<sub>4</sub> (LTC<sub>4</sub>)**, (Fig. 25-78).  **$\gamma$ -Glutamyltransferase** removes glutamic acid, converting LTC<sub>4</sub> to **leukotriene D<sub>4</sub> (LTD<sub>4</sub>)**. LTD<sub>4</sub> is converted to **leukotriene E<sub>4</sub> (LTE<sub>4</sub>)** by a dipeptidase that removes glycine.  $LTA_4$  can also be hydrolyzed to **leukotriene B<sub>4</sub> (LTB<sub>4</sub>)**, a potent chemotactic agent (a substance that attracts motile cells) involved in attracting certain types of white blood cells to fight infection.

Various inflammatory and hypersensitivity disorders (such as asthma) are associated with elevated levels of leukotrienes. The development of drugs that inhibit leukotriene synthesis has therefore been an active field of

**Figure 25-77** X-ray structure of rabbit reticulocyte 15-lipoxygenase (15-LO) in complex with its competitive inhibitor **RS75091**. The N-terminal  $\beta$  barrel domain is gold and the C-terminal catalytic domain is light blue with its two Fe-liganding  $\pi$  helical segments magenta. The Fe is represented by an orange sphere and the RS75091 is drawn in space-filling form with C green and O red. [Based on an X-ray structure by Michelle Browner, Roche Bioscience, Palo Alto, California. PDBid 1LOX.]

research. 5-LO activity requires the presence of **5-lipoxygenase-activating protein (FLAP)**, a homotrimeric integral membrane protein of 161-residue subunits that is located in both the nuclear and ER membranes. FLAP, which has no enzymatic activity, binds the arachidonic acid substrate of 5-LO and facilitates enzyme–substrate binding as well as 5-LO's interaction with the membrane. Several inhibitors of leukotriene synthesis, such as **MK-591**,

bind to FLAP so as to inhibit both of its functions.

**Figure 25-78** Formation of the leukotrienes from LTA<sub>4</sub>.

The X-ray structure of human FLAP in complex with MK-591 (Fig. 25-79), determined by Joseph Becker, reveals that each subunit forms an up–down–up–down four-helix bundle whose N- and C-termini are on the luminal side of the membrane, and that its three identical subunits have extensive intersubunit contacts, thereby forming a 12-helix bundle. MK-591 binds in lipid-exposed grooves between pairs of subunits. Moreover, the trimer forms an elongated pocket along its 3-fold axis that is open to the lumen. This, together with biochemical data, suggests that one 5-LO molecule binds to the cytosolic surface of a FLAP trimer where, through conformational changes in FLAP, it accepts arachidonic acid molecules that FLAP has extracted from the membrane. Inhibitors such as MK-591 presumably block this extraction process.

**Figure 25-79** X-ray structure of human 5-lipoxygenase-activating protein (FLAP) in complex with MK-591. The protein is drawn in ribbon form and viewed from within the membrane with its approximate molecular 3-fold axis vertical. The subunit closest to the viewer of this homotrimeric protein is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The other subunits are pale blue and pale orange. The bound MK-591 is drawn in stick form with C magenta, N blue, O red, S yellow, and C green. The inferred position of the membrane is indicated by the horizontal black lines. ### c. Diets Rich in Marine Lipids May Decrease Cholesterol, Prostaglandin, and Leukotriene Levels

Greenland Eskimos have a very low incidence of coronary heart disease and thrombosis despite their high dietary intake of cholesterol and fat. Their consumption of marine animals provides them with a higher proportion of unsaturated fats than the typical American diet. A major unsaturated component of marine lipids is 5,8,11,14,17-

eicosapentaenoic acid (EPA; Fig. 25-67), an  $\omega$ -3 fatty acid, rather than the arachidonic acid precursor linoleic acid, an  $\omega$ -6 fatty acid. EPA inhibits formation of  $\text{TxA}_2$  (Fig. 25-70) and is a precursor of the **series-5 leukotrienes**, compounds with substantially lower physiological activities than their arachidonate-derived (series-4) counterparts. This suggests that a diet containing marine lipids should decrease the extent of prostaglandin- and leukotriene-mediated inflammatory responses. Indeed, dietary enrichment with EPA inhibits the *in vitro* chemotactic and aggregating activities of neutrophils (a type of white blood cell). Moreover, an EPA-rich diet decreases the cholesterol and triacylglycerol levels in the plasma of hypertriacylglycerolemic patients.

#### d. Lipoxins and Aspirin-Induced *epi*-Lipoxins Have Anti-Inflammatory Properties

Eicosanoids are usually associated with the inflammatory response. However, some eicosanoids have anti-inflammatory

properties. The **lipoxins (LXs)**, products of the 12- and 15-LO pathways (sometimes also involving 5-LO), are so named because they are synthesized through *lipoxygenase interactions*. Their activities appear to inhibit those of leukotrienes and hence they are anti-inflammatory. There are many ways for LXs to be synthesized by combinations of the actions of 5-, 12-, and 15-LOs. Here we discuss only one such route (Fig. 25-80, *left*). **Lipoxin A<sub>4</sub> (LXA<sub>4</sub>)** synthesis from arachidonic acid begins in endothelial and epithelial cells by the 15-LO-catalyzed synthesis of **(15S)-hydroperoxyeicosatetraenoic acid [(15S)-HPETE]**, which is reduced by **glutathione peroxidase** to **(15S)-hydroxyeicosatetraenoic acid [(15S)-HETE]**. The (15S)-HETE then makes its way to leukocytes where it is converted to LXA<sub>4</sub> by 5-LO and a hydrolase.

Charles Serhan discovered an additional pathway for the anti-inflammatory action of aspirin that also involves lipoxin production. As we have previously seen (Fig. 25-74), aspirin covalently inhibits the cyclooxygenase activity of

**Figure 25-80 Lipoxin biosynthesis.** The biosynthesis of the lipoxin LXA<sub>4</sub> (*left*) and the aspirin-triggered *epi*-lipoxin (ATL) 15-*epi*-LXA<sub>4</sub> (*right*). In endothelial and epithelial cells, arachidonic acid is converted by 15-LO and glutathione

peroxidase to (15S)-HETE or by aspirin-acetylated COX-2 to (15R)-HETE. After transfer to leukocytes, 5-LO and a hydrolase convert these intermediate products to LXA<sub>4</sub> and 15-*epi*-LXA<sub>4</sub>.

PGHS (COX). However, aspirin-acetylated COX-2 retains a residual 15-LO activity (Steps 3 and 4 in Fig. 25-71) through which it initiates a pathway that converts arachidonic acid to the anti-inflammatory agents called **aspirin-triggered epi-lipoxins (ATLs)**; Fig. 25-80, right). This pathway begins in endothelial and epithelial cells with the aspirin-acetylated COX-2-catalyzed conversion of arachidonic acid to **(15R)-hydroxyeicosatetraenoic acid [(15R)-HETE]**, the epimer of (15S)-HETE. In leukocytes, 5-LO and a hydrolase then convert (15R)-HETE to the anti-inflammatory agent **15-epi-lipoxin A<sub>4</sub> (15-epi-LXA<sub>4</sub>)**.

These are indeed exciting times in the study of eicosanoid metabolism and its physiological manifestations. As the mechanisms of action of the prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins are becoming better understood, they are providing the insights required for the development of new and improved therapeutic agents.

## 8 PHOSPHOLIPID AND GLYCOLIPID METABOLISM

The “complex lipids” are dual-tailed amphipathic molecules composed of either 1,2-diacyl-*sn*-glycerol or *N*-acylsphingosine (ceramide) linked to a polar head group that is either a carbohydrate or a phosphate ester (Fig. 25-81; Sections 12-1C and 12-1D; *sn* stands for stereospecific numbering, which assigns the 1 position to the group occupying the *pro-S* position of a prochiral center). Hence, there are two categories of phospholipids, **glycerophospholipids** and **sphingophospholipids**, and two categories of glycolipids, **glyceroglycolipids** and **sphingoglycolipids** (also called **glycosphingolipids**; **GSLs**). In this section we describe the biosynthesis of the complex lipids from their simpler components. We shall see that the great variety of these substances is matched by the numerous enzymes required for their specific syntheses. Note also that these substances are synthesized in membranes, mostly on the cytosolic face of the endoplasmic reticulum, and from there are transported to their final cellular destinations as indicated in Sections 12-4B–D.

### A. Glycerophospholipids

Glycerophospholipids have significant asymmetry in their C1- and C2-linked fatty acyl groups: C1 substituents are

mostly saturated fatty acids, whereas those at C2 are by and large unsaturated fatty acids. We shall examine the major pathways of biosynthesis and metabolism of the glycerophospholipids with an eye toward understanding the origin of this asymmetry.

#### a. Biosynthesis of Diacylglycerophospholipids

The triacylglycerol precursors 1,2-diacyl-*sn*-glycerol and phosphatidic acid are also the precursors of certain glycerophospholipids (Figs. 25-42 and 25-81). Activated phosphate esters of the polar head groups (Table 12-2) react with the C3 OH group of 1,2-diacyl-*sn*-glycerol to form the phospholipid’s phosphodiester bond. In some cases the phosphoryl group of phosphatidic acid is activated and reacts with the unactivated polar head group.

The mechanism of activated phosphate ester formation is the same for both the polar head groups **ethanolamine** and **choline** (Fig. 25-82):

1. ATP first phosphorylates the OH group of choline or ethanolamine.

2. The phosphoryl group of the resulting **phosphoethanolamine** or **phosphocholine** then attacks CTP, displacing PP<sub>i</sub>, to form the corresponding CDP derivatives, which are activated phosphate esters of the polar head group.

3. The C3 OH group of 1,2-diacyl-*sn*-glycerol attacks the phosphoryl group of the activated CDP–ethanolamine or CDP–choline, displacing CMP to yield the corresponding glycerophospholipid.

The liver also converts phosphatidylethanolamine to phosphatidylcholine by trimethylating its amino group, using **S-adenosylmethionine** (Section 26-3Ea) as the methyl donor.

**Phosphatidylserine** is synthesized from phosphatidylethanolamine by a head group exchange reaction catalyzed by **phosphatidylethanolamine:serine transferase** in which serine’s OH group attacks the donor’s phosphoryl group (Fig. 25-83). The original head group is then eliminated, forming phosphatidylserine.

In the synthesis of **phosphatidylinositol** and **phosphatidylglycerol**, the hydrophobic tail is activated rather than the polar head group. Phosphatidic acid, the precursor of 1,2-diacyl-*sn*-glycerol (Fig. 25-42), attacks the α-phosphoryl group of CTP to form the activated **CDP-**

**Figure 25-81** The glycerolipids and sphingolipids. The structures of the common head groups, X, are presented in Table 12-2.

**Figure 25-82** The biosynthesis of phosphatidylethanolamine and phosphatidylcholine. In mammals, CDP-ethanolamine and CDP-choline are the precursors of the head groups.

**diacylglycerol** and  $\text{PP}_i$  (Fig. 25-84). Phosphatidylinositol results from the attack of inositol on CDP-diacylglycerol. Phosphatidylglycerol is formed in two reactions: (1) attack of the C1 —OH group of *sn*-glycerol-3-phosphate on CDP-diacylglycerol, yielding **phosphatidylglycerol phosphate**; and (2) hydrolysis of the phosphoryl group to form phosphatidylglycerol.

**Cardiolipin**, an important phospholipid first isolated from heart tissue, is synthesized from two molecules of phosphatidylglycerol (Fig. 25-85). The reaction occurs by the attack of the C1 OH group of one of the phosphatidylglycerol molecules on the phosphoryl group of the other, displacing a molecule of glycerol.

Enzymes that synthesize phosphatidic acid have a general preference for saturated fatty acids at C1 and for unsaturated fatty acids at C2. Yet, this general preference cannot account, for example, for the observations that ~80%

**Figure 25-83** Phosphatidylserine synthesis. Serine replaces ethanolamine in phosphatidylethanolamine by a head group exchange reaction.

of brain phosphatidylinositol has a stearoyl group (18:0) at C1 and an arachidonoyl group (20:4) at C2, and that ~40% of lung phosphatidylcholine has palmitoyl groups (16:0) at both positions (this latter substance is the major component of the surfactant that prevents the lung from collapsing when air is expelled; its deficiency is responsible for **respiratory distress syndrome** in premature infants). William Lands showed that such side chain specificity results from “remodeling” reactions in which specific acyl groups of individual glycerophospholipids are exchanged by specific phospholipases and acyltransferases.

#### b. Biosynthesis of Plasmalogens and Alkylacylglycerophospholipids

Eukaryotic membranes contain significant amounts of two other types of glycerophospholipids:

**1. Plasmalogens**, which contain a hydrocarbon chain linked to glycerol C1 via a vinyl ether linkage:

**A plasmalogen**

**Figure 25-84** The biosynthesis of phosphatidylinositol and phosphatidylglycerol. In mammals, this process involves a CDP-diacylglycerol intermediate.

**Figure 25-85** The formation of cardiolipin.

**Figure 25-86** The biosynthesis of ethanolamine plasmalogen via a pathway in which 1-alkyl-2-acyl-*sn*-glycerophosphoethanolamine is an intermediate. The participating enzymes are (1) alkyl-DHAP synthase, (2) 1-alkyl-*sn*-glycerol-3-phosphate dehydrogenase, (3) acyl-CoA:1-alkyl-*sn*-glycerol-3-phosphate acyltransferase, (4) 1-alkyl-2-acyl-*sn*-glycerol-3-phosphate phosphatase, (5) CDP-ethanolamine:1-alkyl-2-acyl-*sn*-glycerophosphoethanolamine transferase, and (6) 1-alkyl-2-acyl-*sn*-glycerophosphoethanolamine desaturase.

**2. Alkylacylglycerophospholipids**, in which the alkyl substituent at glycerol C1 is attached via an ether linkage:

**An alkylacyl-glycerophospholipid**

About 20% of mammalian glycerophospholipids are plasmalogens. The exact percentage varies both from species to species and from tissue to tissue within a given organism. While plasmalogens comprise only 0.8% of the phospholipids in human liver, they account for 23% of those in human nervous tissue. The alkylacylglycerophospholipids are less abundant than the plasmalogens; for instance, 59% of the ethanolamine glycerophospholipids of human heart are plasmalogens, whereas only 3.6% are alkylacylglycerophospholipids. However, in bovine erythrocytes, 75% of the ethanolamine glycerophospholipids are of the alkylacyl type.

The pathway forming ethanolamine plasmalogens and alkylacylglycerophospholipids involves several reactions (Fig. 25-86):

1. Exchange of the acyl group of **1-acyldihydroxyacetone phosphate** for an alcohol.
2. Reduction of the ketone to **1-alkyl-*sn*-glycerol-3-phosphate**.
3. Acylation of the resulting C2 OH group by acyl-CoA.
4. Hydrolysis of the phosphoryl group to yield an alkylacylglycerol.
5. Attack by the new OH group of alkylacylglycerol on CDP-ethanolamine to yield **1-alkyl-2-acyl-*sn*-glycerophosphoethanolamine**.
6. Introduction of a double bond into the alkyl group to form the plasmalogen by a desaturase having the same cofactor requirements as the fatty acid desaturases (Section 25-4E).

Recall that the precursor-product relationship between the alkylacylglycerophospholipid and the plasmalogen was

established through studies using [ $^{14}\text{C}$ ]ethanolamine (Section 16-3Be).

The alkylacylglycerophospholipid with an acetyl group at  $\text{R}_2$  and a choline polar head group (X), **1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine**, is known as **platelet-activating factor (PAF)**. This molecule has diverse functions and acts at very low concentrations ( $10^{-10}\text{ M}$ ) to lower blood pressure and to cause blood platelets to aggregate.

## B. Sphingophospholipids

Only one major phospholipid contains ceramide (*N*-acylsphingosine) as its hydrophobic tail: **sphingomyelin (*N*-acylsphingosine phosphocholine;** Section 12-1D), an important structural lipid of nerve cell membranes. The molecule was once thought to be synthesized from *N*-acylsphingosine and CDP-choline. However, it is now known that the main route of sphingomyelin synthesis occurs through donation of the phosphocholine group of phosphatidylcholine to *N*-acylsphingosine (Fig. 25-87). These pathways were differentiated by establishing the precursor-product relationships between CDP-choline, phosphatidylcholine, and sphingomyelin (Section 16-3Be). Mouse liver microsomes were isolated and incubated for a short time with [ $^3\text{H}$ ]choline. Radioactivity appeared in sphingomyelin only after first appearing in both CDP-choline and phosphatidylcholine, ruling out the direct transfer of phosphocholine from CDP-choline to *N*-acylsphingosine.

The most prevalent acyl groups of sphingomyelin are palmitoyl (16:0) and stearoyl (18:0) groups. Longer chain fatty acids such as nervonic acid (24:1) and behenic acid (22:0) occur with lesser frequency in sphingomyelins.

## C. Sphingoglycolipids

Most sphingolipids are sphingoglycolipids, that is, their polar head groups consist of carbohydrate units (Section 12-1D). The principal classes of sphingoglycolipids, as indicated in Fig. 25-88, are **cerbrosides** (ceramide monosaccharides), **sulfatides** (ceramide monosaccharide sulfates), **globosides** (neutral ceramide oligosaccharides), and **gangliosides** (acidic, sialic acid-containing ceramide oligosaccharides). The carbohydrate unit is glycosidically attached to the *N*-acylsphingosine at its C1 OH group (Fig. 25-81).

The lipids providing the carbohydrate that covers the external surfaces of eukaryotic cells are sphingoglycolipids. Along with glycoproteins (Section 23-3), they are biosynthesized on the luminal surfaces of the endoplasmic reticulum and the Golgi apparatus and reach the plasma membrane through vesicle flow (Sections 12-4C and 12-4D), where membrane fusion results in their facing the external surface of the lipid bilayer (Fig. 12-60). Degradation of sphingoglycolipids occurs in the lysosomes after endocytosis from the plasma membrane.

In the following subsections, we discuss the biosynthesis and breakdown of *N*-acylsphingosine and sphingoglycolipids and consider the diseases caused by deficiencies in their degradative enzymes.

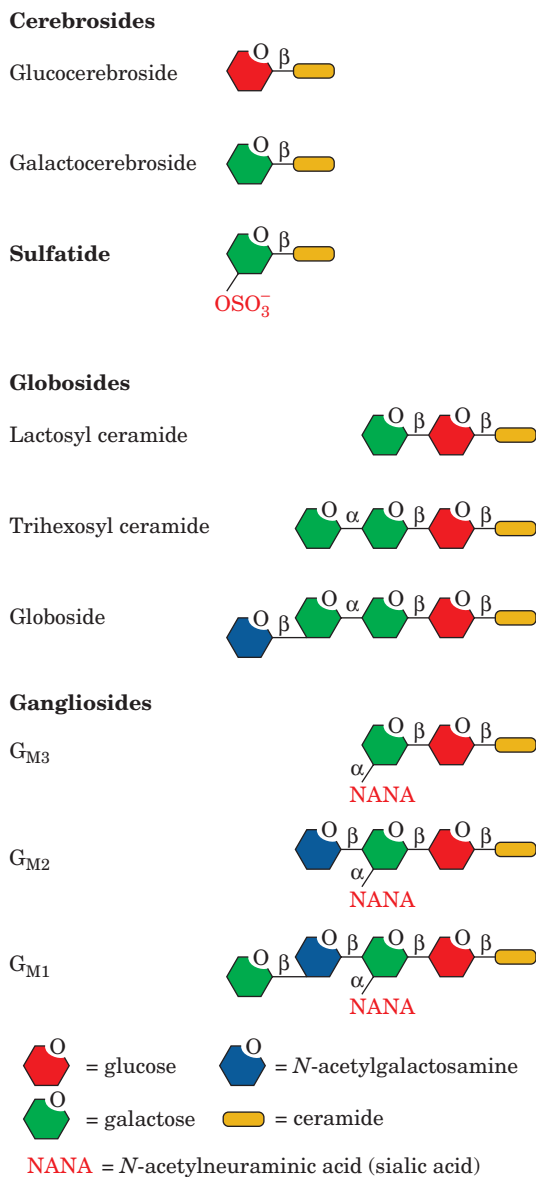

### a. Biosynthesis of Ceramide (*N*-Acylsphingosine)

Biosynthesis of *N*-acylsphingosine occurs in four reactions from the precursors palmitoyl-CoA and serine (Fig. 25-89):

**1. 3-Ketosphinganine synthase (serine palmitoyltransferase)**, a pyridoxal phosphate-dependent enzyme, catalyzes the condensation of palmitoyl-CoA with serine yielding **3-ketosphinganine** (pyridoxal phosphate-dependent reactions are discussed in Section 26-1A).

**Figure 25-87** The synthesis of sphingomyelin from *N*-acylsphingosine and phosphatidylcholine.

**Figure 25-88** Diagrammatic representation of the principal classes of sphingoglycolipids. The G<sub>M</sub> ganglioside structures are presented in greater detail in Fig. 12-7.

**2. 3-Ketosphinganine reductase** catalyzes the NADPH-dependent reduction of 3-ketosphinganine's keto group to form **sphinganine (dihydrosphinganine)**.

**3. Dihydroceramide** is formed by transfer of an acyl group from an acyl-CoA to the sphinganine's 2-amino group, forming an amide bond.

**4. Dihydroceramide dehydrogenase** converts dihydroceramide to ceramide by an FAD-dependent oxidation reaction.

**b. Biosynthesis of Cerebrosides (Glycosylceramides)**

**Galactocerebroside (1-β-galactosylceramide)** and **glucocerebroside (1-β-glucosylceramide)** are the two most common cerebrosides. In fact, the term cerebroside is often

**Figure 25-89** The biosynthesis of ceramide (*N*-acylsphingosine).

used synonymously with galactocerebroside. Both are synthesized from ceramide by addition of a glycosyl unit from the corresponding UDP–hexose (Fig. 25-90). Galactocerebroside is a common component of brain lipids. Glucocerebroside, although relatively uncommon, is the precursor of globosides and gangliosides.

**Figure 25-90** The biosynthesis of cerebrosides.

**Figure 25-91** The biosynthesis of sulfatides.

### c. Biosynthesis of Sulfatides

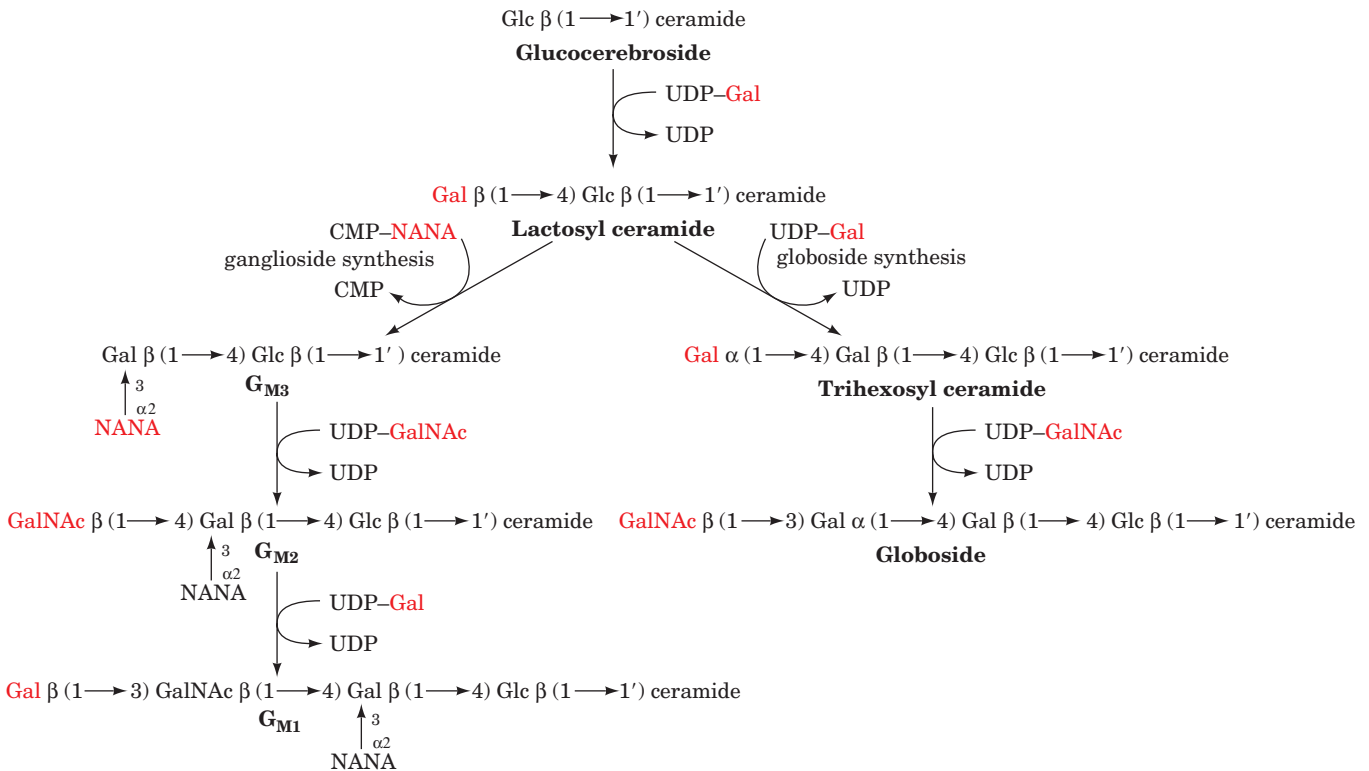

Sulfatides (galactocerebroside-3-sulfate) account for 15% of the lipids of white matter in the brain. They are formed by transfer of an “activated” sulfate group from **3'-phosphoadenosine-5'-phosphosulfate (PAPS)** to the C3 OH group of galactose in galactocerebroside (Fig. 25-91).

### d. Biosynthesis of Globosides and Gangliosides

Biosynthesis of both globosides (neutral ceramide oligosaccharides) and gangliosides (acidic, sialic acid-containing ceramide oligosaccharides) is catalyzed by a series of **glycosyltransferases**. While the reactions are chemically similar, each is catalyzed by a specific enzyme. The pathways begin with transfer of a galactosyl unit from UDP–Gal to glucocerebroside to form a β(1 → 4) linkage (Fig. 25-92). Since this bond is the same as that linking glucose and galactose in lactose, this glycolipid is often referred to as **lactosyl ceramide**. Lactosyl ceramide is the precursor of both globosides and gangliosides. To form a globoside, one galactosyl and one *N*-acetylgalactosaminyl unit are sequentially added to lactosyl ceramide from UDP–Gal and UDP–GalNAc, respectively. The  $G_M$  gangliosides are formed by addition of ***N*-acetylneuraminic acid (NANA, sialic acid)**

from CMP–NANA to lactosyl ceramide in α(2 → 3) linkage yielding  $G_{M3}$ . The sequential additions to  $G_{M3}$  of the *N*-acetylgalactosamine and galactose units from UDP–GalNAc and UDP–Gal yield gangliosides  $G_{M2}$  and  $G_{M1}$ . Other gangliosides are formed by adding a second

**Figure 25-92** The biosynthesis of globosides and  $G_M$  gangliosides.

NANA group to  $G_{M3}$ , forming  $G_{D3}$ , or by adding an *N*-acetylglucosamine unit to lactosyl ceramide before NANA addition, forming  $G_{A2}$ . Hundreds of different gangliosides are known.

### e. Sphingoglycolipid Degradation and Lipid Storage Diseases

Sphingoglycolipids are lysosomally degraded by a series of enzymatically mediated hydrolytic reactions (Fig. 25-93). These reactions are catalyzed at the lipid–water interface by soluble enzymes, often with the aid of **sphingolipid activator proteins (SAPs; including saposins,  $G_{M2}$ -activator protein, and SAP-A through SAP-D)**. These nonenzymatic ancillary proteins are thought to increase the accessibility of the carbohydrate moiety of the sphingolipid to the degradation enzyme. For example,  $G_{M2}$ -activator binds  $G_{M2}$  and helps expose it to the surface of the membrane. The  $G_{M2}$ -activator– $G_{M2}$  complex can then bind **hexosaminidase A**, an  $\alpha\beta$  dimer that hydrolyzes *N*-acetylgalactosamine from  $G_{M2}$  at the lipid–water interface (Fig. 25-94).

The hereditary absence of one of the sphingolipid hydrolases or a SAP results in a **sphingolipid storage disease** (Table 25-2). One of the most common such conditions is **Tay–Sachs disease**, an autosomal recessive deficiency in hexosaminidase A. The absence of hexosaminidase A activity results in the neuronal accumulation of  $G_{M2}$  as shell-like inclusions (Fig. 25-95).

Although infants born with Tay–Sachs disease at first appear normal, by  $\sim 1$  year of age, when sufficient  $G_{M2}$  has accumulated to interfere with neuronal function, they be-

come progressively weaker, retarded, and blinded until they die, usually by the age of 3 years. It is possible, however, to screen potential carriers of this disease by a simple serum assay. It is also possible to detect the disease *in utero* by assay of amniotic fluid or amniotic cells obtained by amniocentesis. The assay involves use of an artificial hexosaminidase substrate, **4-methylumbelliferyl- $\beta$ -D-*N*-acetylglucosamine**, which yields a fluorescent product on hydrolysis:

**Figure 25-93** The breakdown of sphingolipids by lysosomal enzymes. The genetic diseases caused by the corresponding enzyme deficiencies are noted in red.

**Figure 25-94** Model for  $G_{M2}$ -activator protein-stimulated hydrolysis of ganglioside  $G_{M2}$  by hexosaminidase A.  $G_{M2}$ -activator protein binds and lifts  $G_{M2}$  out of the membrane so that it can be recognized and cleaved by the  $\alpha\beta$  dimer of hexosaminidase A. [After Kolter, T. and Sandhoff, K., *Angew. Chem. Int. Ed.* **38**, 1532 (1999).]

**Table 25-2** Sphingolipid Storage Diseases

Disease	Enzyme Deficiency	Principal Storage Substance	Major Symptoms
G <sub>M1</sub> Gangliosidosis	G <sub>M1</sub> $\beta$ -galactosidase	Ganglioside G <sub>M1</sub>	Mental retardation, liver enlargement, skeletal involvement, death by age 2
Tay–Sachs disease	Hexosaminidase A	Ganglioside G <sub>M2</sub>	Mental retardation, blindness, death by age 3
Fabry’s disease	$\alpha$ -Galactosidase A	Trihexosylceramide	Skin rash, kidney failure, pain in lower extremities
Sandhoff’s disease	Hexosaminidases A and B	Ganglioside G <sub>M2</sub> and globoside	Similar to Tay–Sachs disease but progressing more rapidly
Gaucher’s disease	Glucocerebrosidase	Glucocerebroside	Liver and spleen enlargement, erosion of long bones, mental retardation in infantile form only
Niemann–Pick disease	Sphingomyelinase	Sphingomyelin	Liver and spleen enlargement, mental retardation
Farber’s lipogranulomatosis	Ceramidase	Ceramide	Painful and progressively deformed joints, skin nodules, death within a few years
Krabbe’s disease	Galactocerebrosidase	Deacylated galactocerebroside	Loss of myelin, mental retardation, death by age 2
Metachromatic leukodystrophy (Sulfatide lipidosis)	Arylsulfatase A	Sulfatide	Mental retardation, death in first decade

**Figure 25-95** Cytoplasmic membranous body in a neuron affected by Tay–Sachs disease. [Courtesy of John S. O’Brien, University of California at San Diego Medical School.]

Since this substrate is also recognized by **hexosaminidase B**, which is unaffected in Tay–Sachs disease, the hexosaminidase B is first heat inactivated since it is more heat labile than hexosaminidase A. As a result of mass screening efforts, the tragic consequences of this genetic enzyme deficiency are being averted. The other sphingolipid storage diseases, although less common, have similar consequences (Table 25-2). In recent years, DNA sequencing techniques that screen potential carriers for the most common mutations have become economically feasible.

## CHAPTER SUMMARY

**1 Lipid Digestion, Absorption, and Transport** Triacylglycerols, the storage form of metabolic energy in animals, provide up to six times the metabolic energy of an equal weight of hydrated glycogen. Dietary lipids are digested by pancreatic digestive enzymes such as lipase and phospholipase A<sub>2</sub> that are active at the lipid–water interface of bile salt–

stabilized emulsions. Bile salts are also essential for the intestinal absorption of dietary lipids, as is fatty acid–binding protein. Dietary triacylglycerols and those synthesized by the liver are transported in the blood as chylomicrons and VLDL, respectively. Triacylglycerols present in these lipoproteins are hydrolyzed by lipoprotein lipase outside the cells and enter

them as free fatty acids. Fatty acids resulting from hydrolysis of adipose tissue triacylglycerols by hormone-sensitive triacylglycerol lipase are transported in the bloodstream as fatty acid–albumin complexes.

**2 Fatty Acid Oxidation** Before fatty acids are oxidized, they are converted to their acyl-CoA derivatives by acyl-CoA synthase in an ATP-requiring process, transported into mitochondria as carnitine esters, and reconverted inside the mitochondrial matrix to acyl-CoA.  $\beta$  Oxidation of fatty acyl-CoA occurs in 2-carbon increments so as to convert even-chain fatty acyl-CoAs completely to acetyl-CoA. The pathway involves FAD-dependent dehydrogenation of an alkyl group, hydration of the resulting double bond,  $\text{NAD}^+$ -dependent oxidation of this alcohol to a ketone, and C—C bond cleavage to form acetyl-CoA and a new fatty acyl-CoA with two fewer carbon atoms. The process then repeats itself. Complete oxidation of the acetyl-CoA, NADH, and  $\text{FADH}_2$  is achieved by the citric acid cycle and oxidative phosphorylation. Oxidation of unsaturated fatty acids and odd-chain fatty acids also occurs by  $\beta$  oxidation but requires the participation of additional enzymes. Odd-chain fatty acid oxidation generates propionyl-CoA, whose further metabolism requires the participation of (1) propionyl-CoA carboxylase, which has a biotin prosthetic group, (2) methylmalonyl-CoA racemase, and (3) methylmalonyl-CoA mutase, which contains AdoCbl (coenzyme  $\text{B}_{12}$ ). Methylmalonyl-CoA mutase catalyzes a carbon skeleton rearrangement reaction via a free radical mechanism in which the free radical is generated by the homolytic cleavage of AdoCbl's C—Co(III) bond.

$\beta$  Oxidation of fatty acids takes place in the peroxisomes in addition to the mitochondrion. The peroxisomal pathway differs from the mitochondrial pathway in that the  $\text{FADH}_2$  produced in the first step, rather than generating ATP by oxidative phosphorylation, is directly oxidized by  $\text{O}_2$  to produce  $\text{H}_2\text{O}_2$ . Peroxisomal enzymes are specific for long-chain fatty acids and function in a chain-shortening process via  $\beta$  oxidation. The resultant intermediate chain-length products are transferred to the mitochondrion for complete oxidation.

**3 Ketone Bodies** A significant fraction of the acetyl-CoA produced by fatty acid oxidation in the liver is converted to acetoacetate and D- $\beta$ -hydroxybutyrate, which, together with acetone, are referred to as ketone bodies. The first two compounds serve as important fuels for the peripheral tissues.

**4 Fatty Acid Biosynthesis** Fatty acid biosynthesis differs from fatty acid oxidation in several respects. Whereas fatty acid oxidation occurs in the mitochondrion utilizing fatty acyl-CoA esters, fatty acid biosynthesis occurs in the cytosol with the growing fatty acids esterified to acyl-carrier protein (ACP). The redox coenzymes differ (FAD and  $\text{NAD}^+$  for oxidation; NADPH for biosynthesis), as does the stereochemistry of the pathway's intermediate steps. Oxidation produces acetyl-CoA, whereas malonyl-CoA is the immediate precursor in biosynthesis. Malonyl-CoA is produced by the ATP-driven reaction of  $\text{HCO}_3^-$  with acetyl-CoA as catalyzed by the biotin-containing enzyme acetyl-CoA carboxylase, although this  $\text{HCO}_3^-$  is not incorporated into the final fatty acid product. In bacteria, fatty acids synthesis is carried out by a series of independent enzymes that are collectively known as FAS-I. In animals, fatty acid synthesis yielding palmitate occurs on a single X-shaped homodimeric protein known as FAS-II, each of whose subunits contain all six activities required to do so on

separate domains that are serviced by ACP. In fungi, FAS-II is an  $\alpha_6\beta_6$  heterododecamer that forms a barrel-shaped protein that contains two equivalent reaction chambers. Similar but more extensive systems are used in the synthesis of the various polyketides. Acetyl-CoA is transferred from the mitochondrion to the cytosol as citrate via the tricarboxylate transport system and released by citrate cleavage to yield acetyl-CoA and oxaloacetate. Oxaloacetate is converted to malate and then to pyruvate for transport back to the mitochondrion, a process that also generates some of the NADPH required for biosynthesis. Palmitate is the primary product of fatty acid biosynthesis in animals. Longer chain fatty acids and unsaturated fatty acids are synthesized from palmitate by elongation and desaturation reactions. Certain essential unsaturated fatty acids cannot be synthesized by animals and hence must be obtained from the diet. Triacylglycerols are synthesized from fatty acyl-CoA esters and glycerol-3-phosphate.

**5 Regulation of Fatty Acid Metabolism** Fatty acid metabolism is regulated through the allosteric control of hormone-sensitive triacylglycerol lipase and acetyl-CoA carboxylase, phosphorylation/dephosphorylation, and/or changes in the rates of protein synthesis and breakdown. This regulation is mediated by the hormones glucagon, epinephrine, and norepinephrine, which activate degradation, and by insulin, which activates biosynthesis. These hormones interact to control the cAMP concentration, which in turn controls phosphorylation/dephosphorylation ratios via PKA. AMPK, which senses the level of ATP, is also an important regulator of fatty acid metabolism.

**6 Cholesterol Metabolism** Cholesterol is a vital constituent of cell membranes and is the precursor of the steroid hormones and bile salts. Its biosynthesis, transport, and utilization are rigidly controlled. Cholesterol is synthesized in the liver from acetate in a pathway that involves formation of HMG-CoA from three molecules of acetate followed by reduction, phosphorylation, decarboxylation, and dehydration to the isoprene units isopentenyl pyrophosphate and dimethylallyl pyrophosphate. Four of these isoprene units are then condensed via cationic mechanisms to form squalene, which, in turn, undergoes a cyclization reaction, via a cationic cascade, to form lanosterol, the sterol precursor to cholesterol.

The pathway's major control point is at HMG-CoA reductase. This enzyme is regulated by competitive and allosteric mechanisms, by phosphorylation/dephosphorylation, and, most importantly, by long-term control of the rates of enzyme synthesis and degradation. Long-term control is mediated by the integral membrane protein SREBP, which when the cholesterol level is low, is escorted by SCAP to the Golgi apparatus via COPII-coated vesicles. There it is sequentially cleaved by the proteases S1P and S2P, thereby releasing its soluble bHLH/Z domain to travel to the nucleus where it induces the transcription of SRE-containing genes such as those encoding HMG-CoA reductase and the LDL receptor. In addition, when sterol levels are high, the rate at which HMG-CoA reductase is proteolytically degraded is greatly increased.

The liver secretes cholesterol into the bloodstream in esterified form as part of the VLDL. This complex is sequentially converted to IDL and then to LDL. LDL, which is brought into the cells by receptor-mediated endocytosis, carries the major portion of cholesterol to peripheral tissues for utilization. Excess cholesterol is returned to the liver from peripheral tissues

by HDL. The cellular supply of cholesterol is controlled by three mechanisms: (1) long- and short-term regulation of HMG-CoA reductase; (2) control of LDL receptor synthesis by cholesterol concentration; and (3) long- and short-term regulation of acyl-CoA:cholesterol acyltransferase (ACAT), which mediates cholesterol esterification. Cholesterol is the precursor to the steroid hormones, which are classified as progestins, glucocorticoids, mineralocorticoids, androgens, and estrogens. The only pathway for the excretion of cholesterol in mammals is through the formation and elimination of bile salts.

**7 Eicosanoid Metabolism: Prostaglandins, Prostacyclins, Thromboxanes, Leukotrienes, and Lipoxins** Prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins are eicosanoid products produced largely by the metabolism of arachidonate. These highly unstable compounds have profound physiological effects at extremely low concentrations. They are involved in the inflammatory response, the production of pain and fever, the regulation of blood pressure, and many other important physiological processes. Arachidonate is synthesized from linoleic acid, an essential fatty acid, and stored as phosphatidylinositol and other phospholipids. Prostaglandins, prostacyclins, and thromboxanes are synthesized via the cyclic pathway, whereas leukotrienes and lipoxins are synthesized via the linear pathway. Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) inhibit the cyclic pathway but not the linear pathway. COX-2 inhibitors are NSAIDs that bind to COX-2 but not COX-1, thereby eliminating the side effects of other NSAIDs. Peptidoleukotrienes have been identified as the slow reacting substances of anaphylaxis (SRS-A) released from sensitized lung after immuno-

logical challenge. Lipoxins and aspirin-induced *epi*-lipoxins have anti-inflammatory properties.

**8 Phospholipid and Glycolipid Metabolism** Complex lipids have either a phosphate ester or a carbohydrate as their polar head group and either 1,2-diacyl-*sn*-glycerol or ceramide (*N*-acylsphingosine) as their hydrophobic tail. Phospholipids are either glycerophospholipids or sphingophospholipids, whereas glycolipids are either glyceroglycolipids or sphingoglycolipids. The polar head groups of glycerophospholipids, which are phosphate esters of either ethanolamine, serine, choline, inositol, or glycerol, are attached to 1,2-diacyl-*sn*-glycerol's C3 OH group by means of CTP-linked transferase reactions. The specific long-chain fatty acids found at the C1 and C2 positions are incorporated by "remodeling reactions" after the addition of the polar head group. Plasmalogens and alkylacylglycerophospholipids, respectively, contain a long-chain alkyl group in a vinyl ether linkage or in an ether linkage to glycerol's C1 OH group. Platelet-activating factor (PAF) is an important alkylacylglycerophospholipid. The only major sphingophospholipid is sphingomyelin (*N*-acylsphingosine phosphocholine), an important structural lipid of nerve cell membranes. Most sphingolipids contain polar head groups composed of carbohydrate units and are therefore referred to as sphingoglycolipids. The principal classes of sphingoglycolipids are cerebroside, sulfatide, globoside, and ganglioside. Their carbohydrate units, which are attached to *N*-acylsphingosine's C1 OH group by glycosidic linkages, are formed by stepwise addition of activated monosaccharide units. Several lysosomal sphingolipid storage diseases, including Tay-Sachs disease, result from deficiencies in the enzymes that degrade sphingoglycolipids.

## PROBLEMS

1. The venoms of many poisonous snakes, including rattlesnakes, contain a phospholipase A<sub>2</sub> that causes tissue damage that is seemingly far out of proportion to the small amount of enzyme injected. Explain.
2. Explain why individuals with a hereditary deficiency of carnitine palmitoyltransferase II have muscle weakness. Why are these symptoms more severe during fasting?
3. Why are the livers of Jamaican vomiting sickness victims usually depleted of glycogen?
4. Compare the metabolic efficiencies, in moles of ATP pro-

duced per gram, of completely oxidized fat (tripalmitoyl glycerol) versus glucose derived from glycogen. Assume that the fat is anhydrous and the glycogen is stored with twice its weight of water.

5. Methylmalonyl-CoA mutase is incubated with deuterated methylmalonyl-CoA. The coenzyme B<sub>12</sub> extracted from this mutase is found to contain deuterium at its 5'-methylene group. Account for the transfer of label from substrate to coenzyme.
6. What is the energetic price, in ATP units, of converting acetoacetyl-CoA to acetoacetate and then resynthesizing acetoacetyl-CoA?

**7.** A fasting animal is fed palmitic acid that has a  $^{14}\text{C}$ -labeled carboxyl group. (a) After allowing sufficient time for fatty acid breakdown and resynthesis, what would be the  $^{14}\text{C}$ -labeling pattern in the animal's palmitic acid residues? (b) The animal's liver glycogen becomes  $^{14}\text{C}$  labeled although there is no net increase in the amount of this substance present. Indicate the sequence of reactions whereby the glycogen becomes labeled. Why is there no net glycogen synthesis?

**8.** What is the ATP yield from the complete oxidation of a molecule of (a)  $\alpha$ -linolenic acid (9,12,15-octadecatrienoic acid, 18:3 $n$ -3) and (b) **margaric acid** (heptadecanoic acid, 17:0)? Which has the greater amount of available biological energy on a per carbon basis?

**\*9.** The role of coenzyme  $\text{B}_{12}$  in mediating hydrogen transfer was established using the coenzyme  $\text{B}_{12}$ -dependent bacterial enzyme **dioldehydrase**, which catalyzes the reaction:

The enzyme converts  $[1\text{-}^3\text{H}_2]1,2\text{-propanediol}$  to  $[1,2\text{-}^3\text{H}]$ propionaldehyde with the incorporation of tritium into both  $\text{C}5'$  positions of  $5'$ -deoxyadenosylcobalamin's  $5'$ -deoxyadenosyl residue. Suggest the mechanism of this reaction. What would be the products of the dioldehydrase reaction if the enzyme was supplied with  $[5'\text{-}^3\text{H}]$ deoxyadenosylcobalamin and unlabeled 1,2-propanediol?

**10.** Why is it important that liver cells lack 3-ketoacyl-CoA transferase (Fig. 25-27)?

**11.** What is the energetic price, in ATP equivalents, of breaking down palmitic acid to acetyl-CoA and then resynthesizing it?

**12.** Is the fatty acid shown below likely to be synthesized in animals? Explain.

**13.** What is the energetic price, in ATP equivalents, of synthesizing cholesterol from acetyl-CoA?

**14.** What would be the  $^{14}\text{C}$ -labeling pattern in cholesterol if it were synthesized from HMG-CoA that was  $^{14}\text{C}$  labeled (a) at  $\text{C}5$ , its carboxyl carbon atom, or (b)  $\text{C}1$ , its thioester carbon atom?

**15.** Hypercholesterolemic individuals taking statins are sometimes advised to take supplements of coenzyme Q. Explain.

**\*16.** A child suffering from severe abdominal pain is admitted to the hospital several hours after eating a meal consisting of hamburgers, fried potatoes, and ice cream. Her blood has the appearance of "creamed tomato soup" and on analysis is found to contain massive quantities of chylomicrons. As the attending physician, what is your diagnosis of the patient's difficulty (the cause of the abdominal pain is unclear)? What treatment would you prescribe to alleviate the symptoms of this inherited disease?

**17.** Although linoleic acid is an essential fatty acid in animals, it is not required by animal cells in tissue culture. Explain.

**18.** The inactivation of the peroxidase function of prostaglandin H synthase (PGHS) also inactivates its cyclooxygenase function but not vice versa. Explain.

# Amino Acid Metabolism

## CHAPTER 26

### 1 Amino Acid Deamination

- A. Transamination
- B. Oxidative Deamination: Glutamate Dehydrogenase
- C. Other Deamination Mechanisms

### 2 The Urea Cycle

- A. Carbamoyl Phosphate Synthetase: Acquisition of the First Urea Nitrogen Atom
- B. Ornithine Transcarbamoylase
- C. Argininosuccinate Synthetase: Acquisition of the Second Urea Nitrogen Atom
- D. Argininosuccinase
- E. Arginase
- F. Regulation of the Urea Cycle

### 3 Metabolic Breakdown of Individual Amino Acids

- A. Amino Acids Can Be Glucogenic, Ketogenic, or Both
- B. Alanine, Cysteine, Glycine, Serine, and Threonine Are Degraded to Pyruvate
- C. Asparagine and Aspartate Are Degraded to Oxaloacetate
- D. Arginine, Glutamate, Glutamine, Histidine, and Proline Are Degraded to  $\alpha$ -Ketoglutarate
- E. Isoleucine, Methionine, and Valine Are Degraded to Succinyl-CoA
- F. Leucine and Lysine Are Degraded to Acetoacetate and/or Acetyl-CoA
- G. Tryptophan Is Degraded to Alanine and Acetoacetate
- H. Phenylalanine and Tyrosine Are Degraded to Fumarate and Acetoacetate

### 4 Amino Acids as Biosynthetic Precursors

- A. Heme Biosynthesis and Degradation
- B. Biosynthesis of Physiologically Active Amines
- C. Glutathione
- D. Tetrahydrofolate Cofactors: The Metabolism of  $C_1$  Units

### 5 Amino Acid Biosynthesis

- A. Biosynthesis of the Nonessential Amino Acids
- B. Biosynthesis of the Essential Amino Acids

### 6 Nitrogen Fixation

$\alpha$ -Amino acids, in addition to their role as protein monomeric units, are energy metabolites and precursors of many biologically important nitrogen-containing compounds, notably heme, physiologically active amines, glutathione, nucleotides, and nucleotide coenzymes. Amino acids are classified into two groups: **essential** and **nonessential**. Mammals synthesize the nonessential amino acids from

metabolic precursors but must obtain the essential amino acids from their diet. Excess dietary amino acids are neither stored for future use nor excreted. Rather, they are converted to common metabolic intermediates such as pyruvate, oxaloacetate, acetyl-CoA, and  $\alpha$ -keto-glutarate. Consequently, *amino acids are also precursors of glucose, fatty acids, and ketone bodies and are therefore metabolic fuels.*

In this chapter, we consider the pathways of amino acid breakdown, synthesis, and utilization. We begin by examining the three common stages of amino acid breakdown:

**1. Deamination** (amino group removal), whereby amino groups are converted either to ammonia or to the amino group of aspartate.

**2.** Incorporation of ammonia and aspartate nitrogen atoms into urea for excretion.

**3.** Conversion of amino acid carbon skeletons (the  $\alpha$ -keto acids produced by deamination) to common metabolic intermediates.

Many of these reactions are similar to those we have considered in other pathways. Others employ enzyme cofactors we have not previously encountered. One of our goals in studying amino acid metabolism is to understand the mechanisms of action of these cofactors.

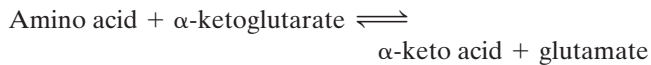

After our discussion of amino acid breakdown, we examine the pathways by which amino acids are utilized in the biosynthesis of heme, physiologically active amines, and glutathione (the synthesis of nucleotides and nucleotide coenzymes is the subject of Chapter 28). Next, we study amino acid biosynthesis pathways. The chapter ends with a discussion of nitrogen fixation, a process that converts atmospheric  $N_2$  to ammonia and is therefore the ultimate biological source of metabolically useful nitrogen.

### 1 AMINO ACID DEAMINATION

*The first reaction in the breakdown of an amino acid is almost always removal of its  $\alpha$ -amino group with the object of excreting excess nitrogen and degrading the remaining carbon skeleton or converting it to glucose.* Urea, the predominant nitrogen excretion product in terrestrial mammals, is synthesized from ammonia and aspartate. Both of these latter substances are derived mainly from glutamate, a product of most deamination reactions. In this section we

examine the routes by which  $\alpha$ -amino groups are incorporated into glutamate and then into aspartate and ammonia. In Section 26-2, we discuss urea biosynthesis from these precursors.

Most amino acids are deaminated by **transamination**, the transfer of their amino group to an  $\alpha$ -keto acid to yield the  $\alpha$ -keto acid of the original amino acid and a new amino acid, in reactions catalyzed by **aminotransferases** (alternatively, **transaminases**). The predominant amino group acceptor is  $\alpha$ -ketoglutarate, producing glutamate as the new amino acid:

Glutamate's amino group, in turn, is transferred to oxaloacetate in a second transamination reaction, yielding aspartate:

Transamination, of course, does not result in any net deamination. Deamination occurs largely through the oxidative deamination of glutamate by **glutamate dehydrogenase (GDH)**, yielding ammonia. The reaction requires  $\text{NAD}^+$  or  $\text{NADP}^+$  as an oxidizing agent and regenerates  $\alpha$ -ketoglutarate for use in additional transamination reactions:

The mechanisms of transamination and oxidative deamination are the subjects of this section. We also consider other means of amino group removal from specific amino acids.

## A. Transamination

### a. Aminotransferase Reactions Occur in Two Stages

**1.** The amino group of an amino acid is transferred to the enzyme, producing the corresponding keto acid and the aminated enzyme.

**2.** The amino group is transferred to the keto acid acceptor (e.g.,  $\alpha$ -ketoglutarate), forming the amino acid product (e.g., glutamate) and regenerating the enzyme.

To carry the amino group, aminotransferases require participation of an aldehyde-containing coenzyme, **pyridoxal-5'-phosphate (PLP)**, a derivative of **pyridoxine (vitamin B<sub>6</sub>)** (Fig. 26-1a,b). The amino group is accommodated by conversion of this coenzyme to **pyridoxamine-5'-phosphate (PMP)** (Fig. 26-1c). PLP is covalently attached to the enzyme via a Schiff base (imine) linkage formed by the

**Figure 26-1** Forms of pyridoxal-5'-phosphate. (a) Pyridoxine (vitamin B<sub>6</sub>). (b) Pyridoxal-5'-phosphate (PLP).

(c) Pyridoxamine-5'-phosphate (PMP). (d) The Schiff base that forms between PLP and an enzyme  $\epsilon$ -amino group.

condensation of its aldehyde group with the  $\epsilon$ -amino group of an enzymatic Lys residue (Fig. 26-1*d*). This Schiff base, which is conjugated to the coenzyme's pyridinium ring, is the focus of the coenzyme's activity.

Esmond Snell, Alexander Braunstein, and David Metzler demonstrated that the aminotransferase reaction occurs via a Ping Pong Bi Bi mechanism whose two stages consist of three steps each (Fig. 26-2):

### Steps 1 & 1': Transimination:

### Steps 2 & 2': Tautomerization:

### Steps 3 & 3': Hydrolysis:

**Figure 26-2** The mechanism of PLP-dependent enzyme-catalyzed transamination. The first stage of the reaction, in which the  $\alpha$ -amino group of an amino acid is transferred to PLP yielding an  $\alpha$ -keto acid and PMP, consists of three steps: (1) transimination; (2) tautomerization, in which the Lys released during the transimination reaction acts as a general acid-base

catalyst; and (3) hydrolysis. The second stage of the reaction, in which the amino group of PMP is transferred to a different  $\alpha$ -amino acid and PLP, is essentially the reverse of the first stage: Steps 3', 2', and 1' are, respectively, the reverse of Steps 3, 2, and 1.  See the Animated Figures

### b. Stage I: Conversion of an Amino Acid to an $\alpha$ -Keto Acid

**Step 1.** The amino acid's nucleophilic amino group attacks the enzyme–PLP Schiff base carbon atom in a **transimination (trans-Schiffization)** reaction to form an amino acid–PLP Schiff base (aldimine), with concomitant release of the enzyme's Lys amino group. This Lys is then free to act as a general base at the active site.

**Step 2.** The amino acid–PLP Schiff base tautomerizes to an  $\alpha$ -keto acid–PMP Schiff base by the active site Lys–catalyzed removal of the amino acid  $\alpha$  hydrogen and protonation of PLP atom C4' via a resonance-stabilized carbanion intermediate. This resonance stabilization facilitates the cleavage of the C $_{\alpha}$ –H bond.

**Step 3.** The  $\alpha$ -keto acid–PMP Schiff base is hydrolyzed to PMP and an  $\alpha$ -keto acid.

### c. Stage II: Conversion of an $\alpha$ -Keto Acid to an Amino Acid

To complete the aminotransferase's catalytic cycle, the coenzyme must be converted from PMP back to the enzyme–PLP Schiff base. This involves the same three steps as above, but in reverse order:

**Step 3'.** PMP reacts with an  $\alpha$ -keto acid to form a Schiff base.

**Step 2'.** The  $\alpha$ -keto acid–PMP Schiff base tautomerizes to form an amino acid–PLP Schiff base.

**Step 1'.** The  $\epsilon$ -amino group of the active site Lys residue attacks the amino acid–PLP Schiff base in a transimination reaction to regenerate the active enzyme–PLP Schiff base, with release of the newly formed amino acid.

The reaction's overall stoichiometry therefore is

Examination of the amino acid–PLP Schiff base's structure (Fig. 26-2, Step 1) reveals why this system is called “an electron-pusher's delight.” *Cleavage of any of the amino acid C $_{\alpha}$  atom's three bonds (labeled a, b, and c) produces a resonance-stabilized C $_{\alpha}$  carbanion whose electrons are*

*delocalized all the way to the coenzyme's protonated pyridinium nitrogen atom; that is, PLP functions as an electron sink.* For transamination reactions, this electron-withdrawing capacity facilitates removal of the  $\alpha$  proton (*a* bond cleavage) in the tautomerization of the Schiff base. PLP-dependent reactions involving *b* bond cleavage (amino acid decarboxylation) and *c* bond labilization are discussed in Section 26-4B and in Sections 26-3Bb and 26-3G, respectively.

Aminotransferases differ in their specificity for amino acid substrates in the first stage of the transamination reaction, thereby producing the correspondingly different  $\alpha$ -keto acid products. Most aminotransferases, however, accept only  $\alpha$ -ketoglutarate or (to a lesser extent) oxaloacetate as the  $\alpha$ -keto acid substrate in the second stage of the reaction, thereby yielding glutamate or aspartate as their only amino acid products. *The amino groups of most amino acids are consequently funneled into the formation of glutamate or aspartate, which are themselves interconverted by glutamate–aspartate aminotransferase:*

Oxidative deamination of glutamate (Section 26-1B) yields ammonia and regenerates  $\alpha$ -ketoglutarate for another round of transamination reactions. Ammonia and aspartate are the two amino group donors in the synthesis of urea.

### d. The Glucose–Alanine Cycle Transports Nitrogen to the Liver

An important exception to the foregoing is a group of muscle aminotransferases that accept pyruvate as their  $\alpha$ -keto acid substrate. The product amino acid, alanine, is released into the bloodstream and transported to the liver, where it undergoes transamination to yield pyruvate for use in gluconeogenesis (Section 23-1A). The resulting glucose is returned to the muscles, where it is glycolytically degraded to pyruvate. This is the **glucose–alanine cycle** (Fig. 26-3). The amino group ends up in either ammonium ion or aspartate for urea biosynthesis. Evidently, the glucose–alanine cycle functions to transport nitrogen from muscle to liver.

During starvation the glucose formed in the liver by this route is also used by the other peripheral tissues, breaking the

Figure 26-3 The glucose–alanine cycle. See the Animated Figures

cycle. Under these conditions both the amino group and the pyruvate originate from muscle protein degradation, providing a pathway yielding glucose for other tissue use (recall that muscle is not a gluconeogenic tissue; Section 23-1).

Nitrogen is also transported to the liver in the form of glutamine, synthesized from glutamate and ammonia in a reaction catalyzed by **glutamine synthetase** (Section 26-5Ab). The ammonia is released for urea synthesis in liver mitochondria or for excretion in the kidney through the action of **glutaminase** (Section 26-3D).

## B. Oxidative Deamination: Glutamate Dehydrogenase

Glutamate is oxidatively deaminated in the mitochondrial matrix by glutamate dehydrogenase (GDH), the only known enzyme that, in at least some organisms, can accept either  $\text{NAD}^+$  or  $\text{NADP}^+$  as its redox coenzyme. Oxidation is thought to occur with transfer of a hydride ion from glutamate's  $\text{C}_\alpha$  to  $\text{NAD(P)}^+$ , thereby forming  $\alpha$ -iminoglutarate, which is hydrolyzed to  $\alpha$ -ketoglutarate and ammonia (Fig. 26-4). GDH is allosterically inhibited by GTP, NADH, and nonpolar compounds such as palmitoyl-CoA and steroid hormones. It is activated by ADP,  $\text{NAD}^+$ , and leucine (the most abundant amino acid in proteins; Table 4-1).

### a. The X-Ray Structures of GDH Reveal its Allosteric Mechanism

The X-ray structures of homohexameric GDH from bovine and human liver mitochondria, determined by Thomas Smith, reveal that each monomer has three domains, a substrate domain, a coenzyme domain, and an antenna domain. The protein, which has  $D_3$  symmetry, can be considered to be a dimer of trimers, with the antenna domains of each trimer wrapping around each other about the 3-fold axis (Fig. 26-5a). Structural comparison of a 501-residue

monomer of the bovine GDH–glutamate–NADH–GTP complex (Fig. 26-5b) with that of the 96% identical human **apoenzyme** (no active site or regulatory ligands bound; Fig. 26-5c) reveals that, on binding ligands, the coenzyme binding domain rotates about the so-called pivot helix so as to close the cleft between the coenzyme and substrate domains. Simultaneously, the antenna domain twists in a way that unwinds one turn of the antenna helix that is connected to the pivot helix. Although the closed form is required for catalysis, the open form favors the association and dissociation of substrates and products. In the open state, Arg 463 (human numbering) in the center of the pivot helix interacts with the activator ADP (whose binding site in the bovine complex is occupied by the ADP moiety of an NADH; Fig. 26-5b), whereas in the closed state, the side chain of His 454 hydrogen-bonds to the  $\gamma$ -phosphate of the inhibitor GTP. The GTP binding site is distorted and blocked in the open state so that GTP binding favors the closed form of the enzyme. This results in tight binding of substrates and products and hence inhibition of the enzyme. ADP binding favors the open form, allowing product dissociation, and therefore activates the enzyme. Allosteric interactions appear to be communicated between subunits through the interactions of the antenna domains. In fact, bacterial GDHs, which lack allosteric regulation, differ from mammalian GDHs mainly by the absence of antenna domains.

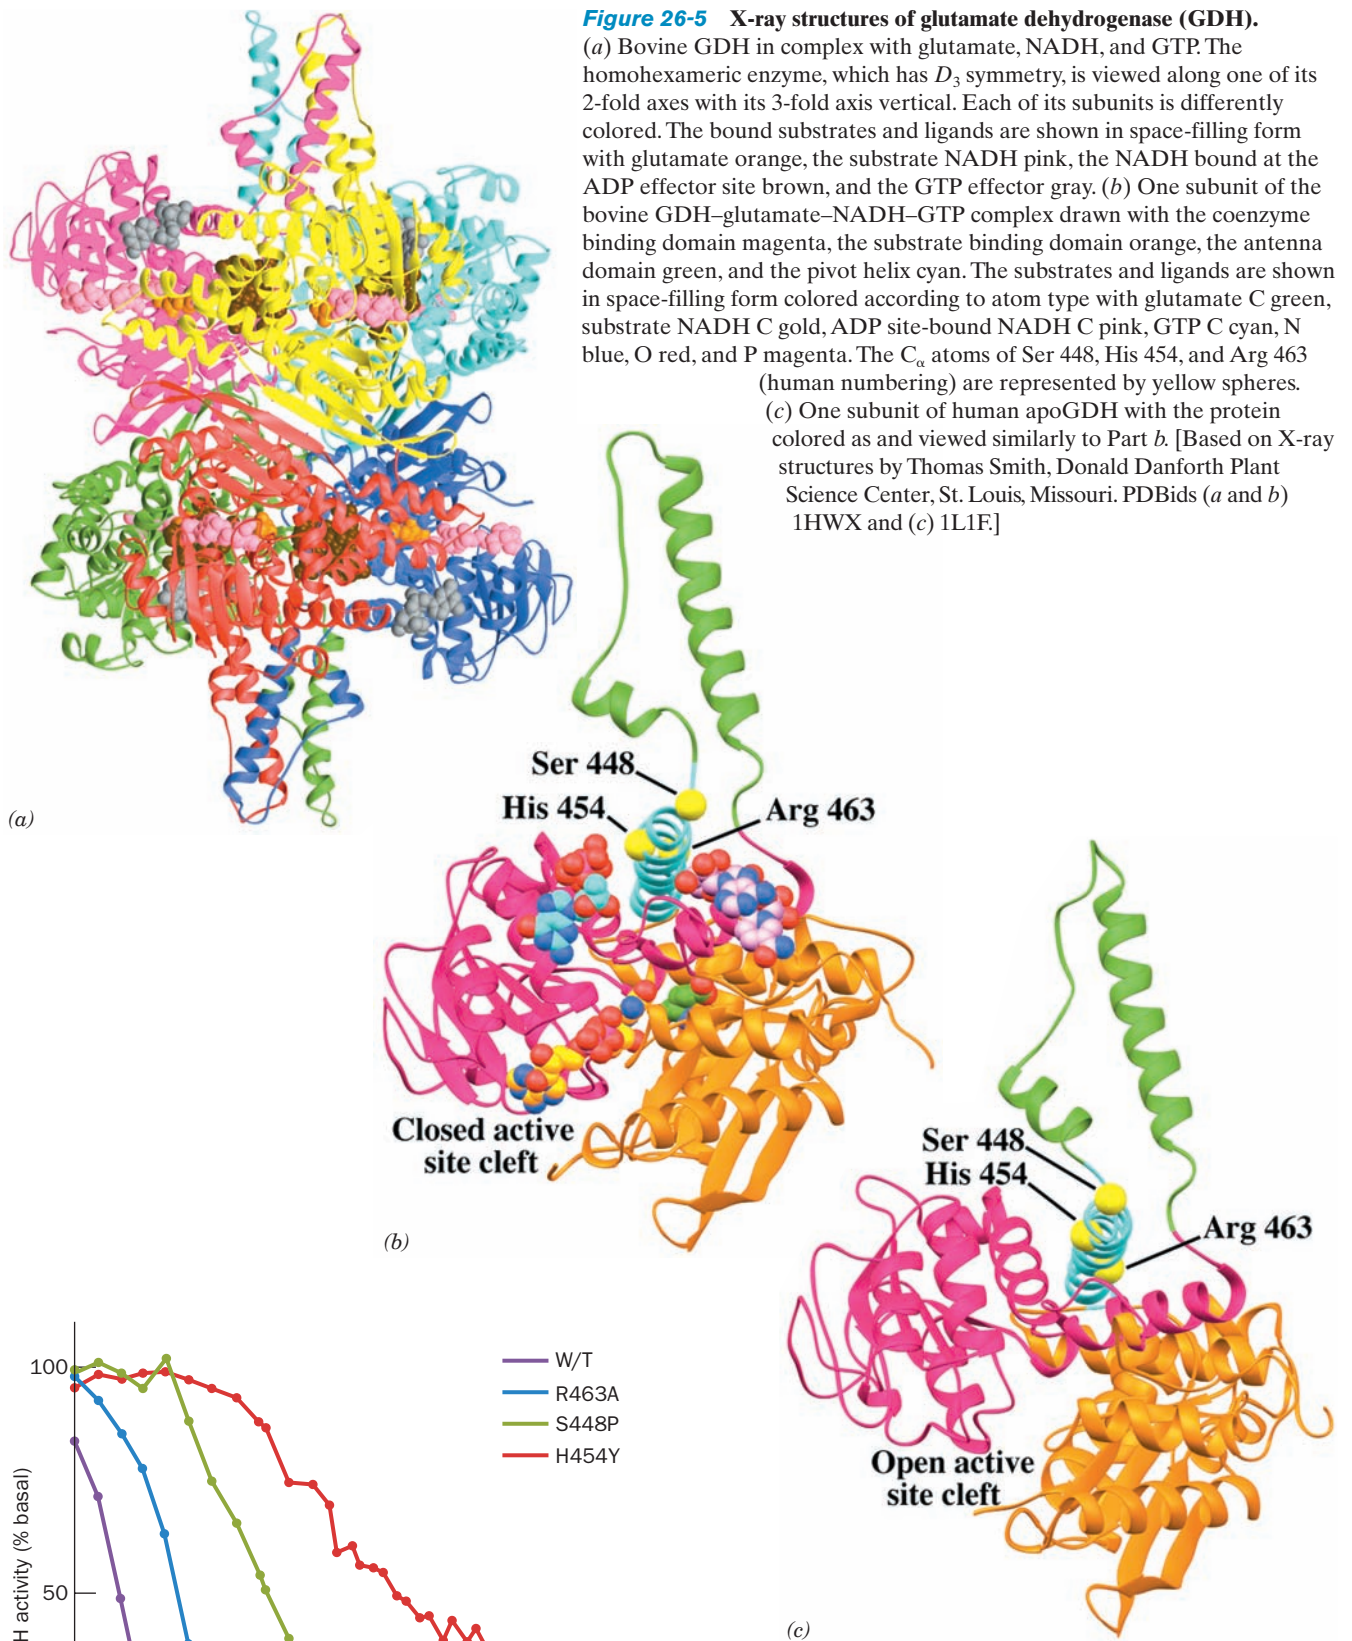

### b. Hyperinsulinism/Hyperammonemia (HI/HA) Is Caused by Uncontrolled GDH Activity

Charles Stanley has reported a new form of congenital hyperinsulinism that is characterized by hypoglycemia and **hyperammonemia (HI/HA)**; hyperammonemia is elevated levels of ammonia in the blood) and has shown that it is caused by mutations in GDH at the N-terminal end of its pivot helix in the GTP binding site or in the antenna domain near its joint with the pivot helix. The mutant enzymes have reduced sensitivity to GTP inhibition but retain their ability to be activated by ADP. The GDH mutants S448P, H454Y, and R463A, which were respectively designed to affect the antenna region, the GTP binding site, and the ADP binding site (Fig. 26-5b), all have decreased sensitivity to GTP inhibition (Fig. 26-6), with H454Y and S448P, which were previously known to be associated with HI/HA, conferring the most resistance to GTP inhibition. The hypoglycemia and hyperammonemia in HI/HA patients arises from the increased activity of the GDH mutants in the breakdown direction, producing increased amounts of  $\alpha$ -ketoglutarate and  $\text{NH}_3$ . The increased levels of  $\alpha$ -ketoglutarate stimulate the citric acid cycle and oxidative phosphorylation, which has been shown to lead to increased insulin secretion and hypoglycemia, thereby producing the symptoms of the disease. The  $\text{NH}_4^+$  produced is usually converted to urea (Section 26-2) but can also be exported to the bloodstream.

If this scenario for the cause of HI/HA is correct, it requires a reassessment of the role of GDH in ammonia homeostasis. The equilibrium position of the GDH reaction greatly favors the synthesis of Glu ( $\Delta G^{o'} \approx 30 \text{ kJ} \cdot \text{mol}^{-1}$  for the reaction as written in Fig. 26-4), but studies of cellular

**Figure 26-4** The oxidative deamination of glutamate by glutamate dehydrogenase. This reaction involves the intermediate formation of  $\alpha$ -iminoglutarate.

**Figure 26-6 Inhibition of human glutamate dehydrogenase (GDH) by GTP.** Human wild-type and mutant GDHs were expressed in *E. coli* and assayed for sensitivity to GTP inhibition. The midpoint of each curve corresponds to the concentration of GTP causing 50% inhibition. [After Fang, J., Hsu, B.Y.L., MacMullen, C.M., Poncz, M., Smith, T.J., and Stanley, C.A., *Biochem. J.* **363**, 81 (2002)].

substrate and product concentrations suggested that the enzyme functions close to equilibrium ( $\Delta G \approx 0$ ) *in vivo*. It was therefore widely accepted that increases in  $[\text{NH}_3]$ , high levels of which are toxic, would cause GDH to act in reverse, removing  $\text{NH}_3$  and hence preventing its buildup to toxic levels. However, since HI/HA patients have increased GDH activity yet have higher levels of  $\text{NH}_3$  than normal, this accepted role of GDH cannot be correct. Indeed, if GDH functioned close to equilibrium, changes in its activity resulting from allosteric interactions would not result in significant flux changes.

### C. Other Deamination Mechanisms

Two nonspecific amino acid oxidases, **L-amino acid oxidase** and **D-amino acid oxidase**, catalyze the oxidation of L- and D-amino acids, utilizing FAD as their redox coenzyme [rather than  $\text{NAD(P)}^+$ ]. The resulting  $\text{FADH}_2$  is reoxidized by  $\text{O}_2$ .

D-Amino acid oxidase occurs mainly in kidney. Its function is an enigma since D-amino acids are associated mostly with bacterial cell walls (Section 11-3Ba). A few amino acids, such as serine and histidine, are deaminated nonoxidatively (Sections 26-3B and 26-3D).

## 2 THE UREA CYCLE

Living organisms excrete the excess nitrogen resulting from the metabolic breakdown of amino acids in one of three ways. Many aquatic animals simply excrete ammonia. Where water is less plentiful, however, processes have evolved that convert ammonia to less toxic waste products that therefore require less water for excretion. One such product is urea, which is excreted by most terrestrial vertebrates; another is **uric acid**, which is excreted by birds and terrestrial reptiles:

Accordingly, living organisms are classified as being either **ammonotelic** (ammonia excreting), **ureotelic** (urea excreting), or **uricotelic** (uric acid excreting). Some animals can shift from ammonotelism to ureotelism or uricotelism if their water supply becomes restricted. Here we focus our attention on urea formation. Uric acid biosynthesis is discussed in Section 28-4A.

*Urea is synthesized in the liver by the enzymes of the urea cycle.* It is then secreted into the bloodstream and

sequestered by the kidneys for excretion in the urine. The urea cycle was elucidated in outline in 1932 by Hans Krebs and Kurt Henseleit (the first known metabolic cycle; Krebs did not elucidate the citric acid cycle until 1937). Its individual reactions were later described in detail by Sarah Ratner and Philip Cohen. The overall urea cycle reaction is

Thus, the two urea nitrogen atoms are contributed by  $\text{NH}_3$  and aspartate, whereas the carbon atom comes from  $\text{HCO}_3^-$ . Five enzymatic reactions are involved in the urea cycle, two of which are mitochondrial and three cytosolic (Fig. 26-7). In this section, we examine the mechanisms of these reactions and their regulation.

### A. Carbamoyl Phosphate Synthetase: Acquisition of the First Urea Nitrogen Atom

**Carbamoyl phosphate synthetase (CPS)** is technically not a urea cycle enzyme. It catalyzes the condensation and activation of  $\text{NH}_3$  and  $\text{HCO}_3^-$  to form **carbamoyl phosphate**, the first of the cycle's two nitrogen-containing substrates, with the concomitant hydrolysis of two ATPs. Eukaryotes have two forms of CPS:

1. Mitochondrial **CPS I** uses  $\text{NH}_3$  as its nitrogen donor and participates in urea biosynthesis.
2. Cytosolic **CPS II** uses glutamine as its nitrogen donor and is involved in pyrimidine biosynthesis (Section 28-2A). The reaction catalyzed by CPS I involves three steps (Fig. 26-8):

1. Activation of  $\text{HCO}_3^-$  by ATP to form **carboxyphosphate** and ADP.
2. Nucleophilic attack of  $\text{NH}_3$  on carboxyphosphate, displacing the phosphate to form **carbamate** and  $\text{P}_i$ .
3. Phosphorylation of carbamate by the second ATP to form carbamoyl phosphate and ADP.

The reaction is essentially irreversible and is the rate-limiting step of the urea cycle. CPS I is subject to allosteric activation by **N-acetylglutamate** as is discussed in Section 26-2F.

*E. coli* contains only one type of CPS, which is homologous to both CPS I and CPS II. The enzyme is a heterodimer but when allosterically activated by ornithine (a urea cycle intermediate), it forms a tetramer of heterodimers,  $(\alpha\beta)_4$ . Its small subunit (382 residues) functions to hydrolyze glutamine and deliver the resulting  $\text{NH}_3$  to its large subunit (1073 residues). However, if the enzyme's **glutaminase (glutamine**

**Figure 26-7 (Opposite) The urea cycle.** Its five enzymes are (1) carbamoyl phosphate synthetase, (2) ornithine transcarbamoylase, (3) argininosuccinate synthetase, (4) argininosuccinase, and (5) arginase. The reactions occur in part in the mitochondrion and in part in the cytosol with ornithine and citrulline being transported across the mitochondrial membrane by specific transport systems (yellow circles). One of the urea amino groups (green) originates as the  $\text{NH}_3$  product of the glutamate dehydrogenase reaction (top). The other amino group (red) is obtained from aspartate through the transfer of an amino acid to oxaloacetate via transamination (right). The fumarate product of the argininosuccinase reaction is converted to oxaloacetate for entry into gluconeogenesis via the same reactions that occur in the citric acid cycle but take place in the cytosol (bottom). The ATP utilized in Reactions 1 and 3 of the cycle can be regenerated by oxidative phosphorylation from the NAD(P)H produced in the glutamate dehydrogenase (top) and malate dehydrogenase (bottom) reactions.  See the Animated Figures

amidotransferase) activity is eliminated (e.g., by site-directed mutagenesis), the large subunit can still produce carbamoyl phosphate if  $\text{NH}_3$  is supplied in high enough concentration. The large subunit is composed of two nearly

**Figure 26-8 The mechanism of action of CPS I.** (1) Activation of  $\text{HCO}_3^-$  by phosphorylation forms the intermediate, carboxyphosphate; (2) nucleophilic attack on carboxyphosphate by  $\text{NH}_3$  forms the reaction's second intermediate, carbamate; and (3) phosphorylation of carbamate by ATP yields the reaction product carbamoyl phosphate.

superimposable halves that have 40% sequence identity. The N-terminal half contains the carboxyphosphate synthetic component and an oligomerization domain while the C-terminal half contains the carbamoyl phosphate synthetic component and an allosteric binding domain.

#### a. *E. coli* CPS Contains an Extraordinarily Long Tunnel

The X-ray structure of *E. coli* CPS in complex with  $\text{Mn}^{2+}$ , ADP,  $\text{P}_i$ , and ornithine, determined by Hazel Holden and Ivan Rayment, reveals that the active site for synthesis of the carboxyphosphate intermediate is  $\sim 45 \text{ \AA}$  away from the ammonia synthesis site and also  $\sim 35 \text{ \AA}$  away from the carbamoyl phosphate synthesis active site. Astonishingly, the three sites are connected by a narrow  $96\text{-\AA}$ -long molecular tunnel that runs nearly the length of the elongated protein molecule (Fig. 26-9). It therefore appears that CPS guides its intermediate products from the active site in which they are formed to that in which they are utilized. This phenomenon, in which the intermediate of two reactions is directly transferred from one enzyme active site to

**Figure 26-9 X-ray structure of *E. coli* carbamoyl phosphate synthetase (CPS).** The protein is represented by its  $\text{C}_\alpha$  backbone. The small subunit (magenta) contains the glutamine binding site where  $\text{NH}_3$  is produced or bound. The large subunit consists of the carboxyphosphate domain (green), the oligomerization domain (yellow), the carbamoyl phosphate domain (blue), and the allosteric binding domain (orange). The  $96\text{-\AA}$ -long tunnel connecting the three active sites is outlined in red. [Courtesy of Hazel Holden and Ivan Rayment, University of Wisconsin. PDBid 1JDB.]

another, is called **channeling** (the term “tunneling” is reserved for certain quantum mechanical phenomena).

Channeling increases the rate of a metabolic pathway by preventing the loss of its intermediate products as well as protecting the intermediate from degradation.  $\text{NH}_3$  must travel  $\sim 45 \text{ \AA}$  down the CPS tunnel to react with carboxyphosphate to form the next intermediate, carbamate. The carbamate, in turn, must travel an additional  $\sim 35 \text{ \AA}$  to the site where it is phosphorylated by ATP to form the final product carbamoyl phosphate. The  $\text{NH}_3$  transfer tunnel is lined with polar groups capable of forming hydrogen bonds with  $\text{NH}_3$ , whereas the tunnel through which carbamate travels is lined with backbone atoms and lacks charged groups that might induce its hydrolysis as it diffuses between active sites. Shielding and channeling are necessary because the intermediates carboxyphosphate and carbamate are extremely reactive, having half-lives of 28 and 70 ms, respectively, at neutral pH. Also, channeling allows the local concentration of  $\text{NH}_3$  to reach a higher value than is present in the cellular medium. We shall encounter several other examples of channeling in our studies of metabolic enzymes, but the CPS tunnel is far longer than that in any other known enzyme.

### B. Ornithine Transcarbamoylase

**Ornithine transcarbamoylase** transfers the carbamoyl group of carbamoyl phosphate to **ornithine**, yielding **citrulline** (Fig. 26-7, Reaction 2; note that both of these compounds are “nonstandard”  $\alpha$ -amino acids in that they do not occur in proteins). The reaction occurs in the mitochondrion so that ornithine, which is produced in the cytosol, must enter the mitochondrion via a specific transport system. Likewise, since the remaining urea cycle reactions occur in the cytosol, citrulline must be exported from the mitochondrion.

### C. Argininosuccinate Synthetase: Acquisition of the Second Urea Nitrogen Atom

Urea’s second nitrogen atom is introduced in the urea cycle’s third reaction by the condensation of citrulline’s ureido group with an aspartate amino group by **argininosuccinate synthetase** (Fig. 26-10). The ureido oxygen atom is activated as a leaving group through formation of a

citrullyl–AMP intermediate, which is subsequently displaced by the aspartate amino group. Support for the existence of the citrullyl–AMP intermediate comes from experiments using  $^{18}\text{O}$ -labeled citrulline (\* in Fig. 26-10). The label was isolated in the AMP produced by the reaction, demonstrating that at some stage of the reaction, AMP and citrulline are linked covalently through the ureido oxygen atom.

### D. Argininosuccinase

With formation of argininosuccinate, all of the urea molecule components have been assembled. However, the amino group donated by aspartate is still attached to the aspartate carbon skeleton. This situation is remedied by the **argininosuccinase**-catalyzed elimination of arginine from the aspartate carbon skeleton forming fumarate (Fig. 26-7, Reaction 4). Arginine is urea’s immediate precursor. The fumarate produced in the argininosuccinase reaction reacts via the fumarase and malate dehydrogenase reactions to form oxaloacetate (Fig. 26-7, *bottom*), which is then used in gluconeogenesis (Section 23-1).

### E. Arginase

The urea cycle’s fifth and final reaction is the **arginase**-catalyzed hydrolysis of arginine to yield urea and regenerate ornithine (Fig. 26-7, Reaction 5). Ornithine is then returned to the mitochondrion for another round of the cycle. The urea cycle thereby converts two amino groups, one from  $\text{NH}_3$  and one from aspartate, and a carbon atom from  $\text{HCO}_3^-$  to the relatively nontoxic excretion product urea at the cost of four “high-energy” phosphate bonds (three ATP hydrolyzed to two ADP, two  $\text{P}_i$ , AMP, and  $\text{PP}_i$ , followed by rapid  $\text{PP}_i$  hydrolysis). This energetic cost, together with that of gluconeogenesis, is supplied by the oxidation of the acetyl-CoA formed by the breakdown of amino acid carbon skeletons (e.g., threonine, Fig. 26-12). Indeed, half the oxygen that the liver consumes is used to provide this energy.

### F. Regulation of the Urea Cycle

Carbamoyl phosphate synthetase I, the mitochondrial enzyme that catalyzes the first committed reaction of the urea

**Figure 26-10** The mechanism of action of **argininosuccinate synthetase**. The steps involved are (1) activation of the ureido oxygen of citrulline through the formation of citrullyl–AMP and

(2) displacement of AMP by the  $\alpha$ -amino group of aspartate. The asterisk (\*) traces the fate of  $^{18}\text{O}$  originating in citrulline’s ureido group.

cycle, is allosterically activated by ***N*-acetylglutamate**:

***N*-Acetylglutamate**

This metabolite is synthesized from glutamate and acetyl-CoA by ***N*-acetylglutamate synthase** and hydrolyzed by a specific hydrolase. The rate of urea production by the liver is, in fact, correlated with the *N*-acetylglutamate concentration. Increased urea synthesis is required when amino acid breakdown rates increase, generating excess nitrogen that must be excreted. Increases in these breakdown rates are signaled by an increase in glutamate concentration through transamination reactions (Section 26-1). This situation, in turn, causes an increase in *N*-acetylglutamate synthesis, stimulating carbamoyl phosphate synthetase and thus the entire urea cycle.

The remaining enzymes of the urea cycle are controlled by the concentrations of their substrates. Thus, inherited deficiencies in urea cycle enzymes other than arginase do not result in significant decreases in urea production (the total lack of any urea cycle enzyme results in death shortly after birth). Rather, the deficient enzyme's substrate builds up, increasing the rate of the deficient reaction to normal. The anomalous substrate buildup is not without cost, however. The substrate concentrations become elevated all the way back up the cycle to  $\text{NH}_3$ , resulting in hyperammonemia. Although the root cause of  $\text{NH}_3$  toxicity is not completely understood, high  $[\text{NH}_3]$  puts an enormous strain on the  $\text{NH}_3$ -clearing system, especially in the brain (symptoms of urea cycle enzyme deficiencies include mental retardation and lethargy). This clearing system has been proposed to involve glutamate dehydrogenase (working in reverse) and **glutamine synthetase**, which decrease the  $\alpha$ -ketoglutarate and glutamate pools (Sections 26-1 and 26-5Ab). The brain is most sensitive to the depletion of these pools. Depletion of  $\alpha$ -ketoglutarate decreases the rate of the energy-generating citric acid cycle, whereas decreasing the glutamate concentration disturbs neuronal function, since it is both a neurotransmitter and a precursor to  $\gamma$ -aminobutyrate (GABA), another neurotransmitter (Section 20-5Cf). Glutamate depletion would also decrease the functioning of the urea cycle, since it is also the precursor to *N*-acetylglutamate, the major regulator of the cycle. The involvement of GDH in  $\text{NH}_3$  clearance is a subject of debate in light of the observation that HI/HA involves deinhibition of GDH (Section 26-1Bb), suggesting that increased GDH activity increases the  $\text{NH}_3$  concentration rather than decreasing it.

### 3 METABOLIC BREAKDOWN OF INDIVIDUAL AMINO ACIDS

The degradation of amino acids converts them to citric acid cycle intermediates or their precursors so that they can be metabolized to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  or used in gluconeogenesis.

Indeed, oxidative breakdown of amino acids typically accounts for 10 to 15% of the metabolic energy generated by animals. In this section we consider how amino acid carbon skeletons are catabolized. The 20 "standard" amino acids (the amino acids of proteins) have widely differing carbon skeletons, so their conversions to citric acid cycle intermediates follow correspondingly diverse pathways. We shall not describe all of the many reactions involved in detail. Rather, we shall consider how these pathways are organized and focus on a few reactions of chemical and/or medical interest.

#### A. Amino Acids Can Be Glucogenic, Ketogenic, or Both

"Standard" amino acids are degraded to one of seven metabolic intermediates: pyruvate,  $\alpha$ -ketoglutarate, succinyl-CoA, fumarate, oxaloacetate, acetyl-CoA, or acetoacetate (Fig. 26-11). The amino acids may therefore be divided into two groups based on their catabolic pathways (Fig. 26-11):

1. **Glucogenic amino acids**, whose carbon skeletons are degraded to pyruvate,  $\alpha$ -ketoglutarate, succinyl-CoA, fumarate, or oxaloacetate and are therefore glucose precursors (Section 23-1A).

**Figure 26-11** Degradation of amino acids to one of seven common metabolic intermediates. Glucogenic and ketogenic degradations are indicated in green and red, respectively.

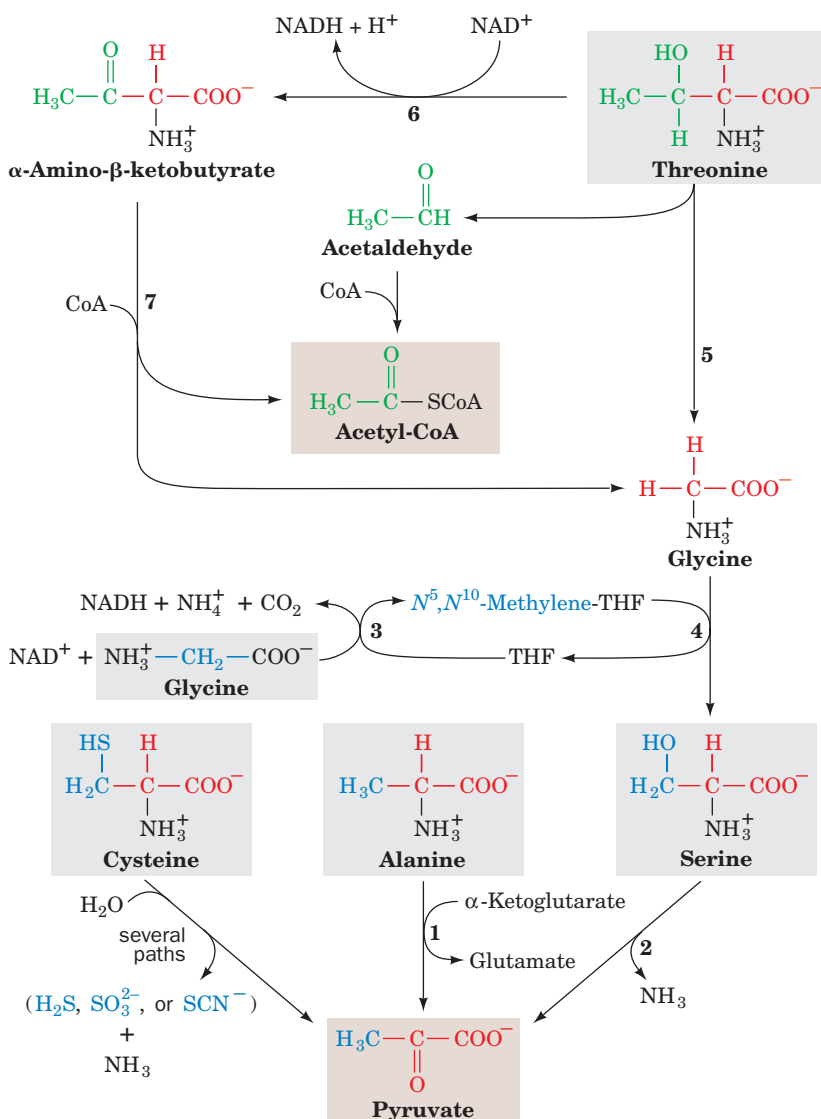

**2. Ketogenic amino acids**, whose carbon skeletons are broken down to acetyl-CoA or acetoacetate and can thus be converted to ketone bodies or fatty acids (Sections 25-3 and 25-4).

For example, alanine is glucogenic because its transamination product, pyruvate (Section 26-1A), can be converted to glucose via gluconeogenesis (Section 23-1A). Leucine, on the other hand, is ketogenic; its carbon skeleton is converted to acetyl-CoA and acetoacetate (Section 26-3F). Since animals lack any metabolic pathway for the net conversion of acetyl-CoA or acetoacetate to gluconeogenic precursors, no net synthesis of carbohydrates is possible from leucine, or from lysine, the only other purely ketogenic amino acid. Isoleucine, phenylalanine, threonine, tryptophan, and tyrosine, however, are both glucogenic and ketogenic; isoleucine, for example, is broken down to succinyl-CoA and acetyl-CoA and hence is a precursor of both carbohydrates and ketone bodies (Section 26-3Ed). The remaining 13 amino acids are purely glucogenic.

In studying the specific pathways of amino acid breakdown, we shall organize the amino acids into groups that are degraded into each of the seven metabolic intermediates mentioned above: pyruvate, oxaloacetate,  $\alpha$ -ketoglutarate, succinyl-CoA, fumarate, acetyl-CoA, and acetoacetate. When acetoacetyl-CoA is a product in amino acid degradation, it can, of course, be directly converted to acetyl-CoA (Section 25-3). We also discuss the pathway by which, in liver, it is converted instead to acetoacetate for use as an alternative fuel source in peripheral tissues (Section 25-3).

### B. Alanine, Cysteine, Glycine, Serine, and Threonine Are Degraded to Pyruvate

Five amino acids, alanine, cysteine, glycine, serine, and threonine, are broken down to yield pyruvate (Fig. 26-12). Tryptophan should also be included in this group since one of its breakdown products is alanine (Section 26-3G), which, as we have seen (Section 26-1Ad), is transaminated to pyruvate.

**Figure 26-12** The pathways converting alanine, cysteine, glycine, serine, and threonine to pyruvate. The enzymes involved are (1) alanine aminotransferase, (2) serine dehydratase, (3) glycine cleavage system, (4) and (5) serine hydroxymethyltransferase, (6) threonine dehydrogenase, and (7)  $\alpha$ -amino- $\beta$ -ketobutyrate lyase.

Serine is converted to pyruvate through dehydration by **serine dehydratase**. This PLP–enzyme, like the aminotransferases (Section 26-1), functions by forming a PLP–amino acid Schiff base, which facilitates the removal of the amino acid’s  $\alpha$ -hydrogen atom. In the serine dehydratase reaction, however, the  $\text{C}_\alpha$  carbanion breaks down with the elimination of the amino acid’s  $\text{C}_\beta$  OH, rather than with tautomerization (Fig. 26-2, Step 2), so that the substrate undergoes  $\alpha,\beta$  elimination of  $\text{H}_2\text{O}$  rather than deamination (Fig. 26-13). The product of the dehydration, the enamine **aminoacrylate**, tautomerizes nonenzymatically to the corresponding imine, which spontaneously hydrolyzes to pyruvate and ammonia.

Cysteine may be converted to pyruvate via several routes in which the sulfhydryl group is released as  $\text{H}_2\text{S}$ ,  $\text{SO}_3^{2-}$  or  $\text{SCN}^-$ .

Glycine is converted to serine by the enzyme **serine hydroxymethyltransferase**, another PLP-containing enzyme (Fig. 26-12, Reaction 4). This enzyme utilizes  $N^5,N^{10}$ -methylene-tetrahydrofolate ( $N^5,N^{10}$ -methylene-THF) as a cofactor to provide the  $\text{C}_1$  unit necessary for this conversion. We shall defer a detailed discussion of THF cofactors until Section 26-4D.

#### a. The Glycine Cleavage System Is a Multienzyme Complex

The methylene group of the  $N^5,N^{10}$ -methylene-THF utilized in the conversion of glycine to serine is obtained from the methylene group of a second glycine via a reaction in which this glycine’s remaining atoms are released as  $\text{CO}_2$  and  $\text{NH}_4^+$  (Fig. 26-12, Reaction 3). This reaction is catalyzed by the **glycine cleavage system** (also called the **glycine decarboxylase multienzyme system** in plants and **glycine synthase** when acting in the reverse direction; Section 26-5Ae), a complex resembling the pyruvate dehydrogenase complex (Section 21-2A) that consists of four proteins (Fig. 26-14):

1. A PLP-dependent glycine decarboxylase (**P-protein**).
2. A lipoamide-containing aminomethyl carrier (**H-protein**), which carries the aminomethyl group remaining after glycine decarboxylation.

3. An  $N^5,N^{10}$ -methylene-THF synthesizing enzyme [**T-protein**; alternatively **aminomethyltransferase (AMT)**], which accepts a methylene group from the aminomethyl carrier (H-protein; the amino group is released as ammonia).

4. An  $NAD^+$ -dependent, FAD-requiring dihydrolipoyl dehydrogenase (**L-protein**), a protein shared by and known as E3 in the pyruvate dehydrogenase complex (Section 21-2A).

Unlike the pyruvate dehydrogenase complex, the glycine cleavage system components are only loosely associated and hence are isolated as individual proteins. Nevertheless, H-protein has the central role in this multienzyme system: Its oxidized lipoyllysyl arm (Section 21-2Ad) is reduced as it accepts an aminomethyl group from P-protein (Fig. 26-14, Step 2), it donates the methylene group to THF in complex with T-protein as ammonia is released (Fig. 26-14, Step 3), and is then reoxidized by L-protein (Fig. 26-14, Step 4). The X-ray structure of pea leaf H-protein (Fig. 26-15), determined by Roland Douce, reveals that it is largely composed of a sandwich of 3-stranded and 6-stranded antiparallel  $\beta$  sheets that structurally resembles the lipoyl domain of E2 in the pyruvate dehydrogenase complex (Fig. 21-10a).

The aminomethylthio group is unstable and ordinarily is rapidly hydrolyzed to formaldehyde and  $NH_4^+$ . However, on its aminomethylation, the previously exposed lipoyl group (Fig. 26-15a) inserts into a hydrophobic cleft

in the H-protein where its amino group hydrogen-bonds to Glu 14 (Fig. 26-15b), thereby shielding the aminomethyl group from hydrolysis. Indeed, the replacement of Glu 14 by Ala results in the rapid hydrolysis of the aminomethyl group. It therefore appears that the T-protein in the  $THF \cdot T \cdot H$  complex functions to release the lipoyl group from the H-protein cleft and to orient the THF for approach to the methylene C of the aminomethyl group for reaction.

Two observations indicate that the above pathway is the major route of glycine degradation in mammalian tissues:

1. The serine isolated from an animal that has been fed  $[2-^{14}C]$ glycine is  $^{14}C$  labeled at both C2 and C3. This observation indicates that the methylene group of the  $N^5,N^{10}$ -methylene-THF utilized by serine hydroxymethyltransferase is obtained from glycine C2.

2. The inherited human disease **nonketotic hyperglycinemia**, which is characterized by mental retardation and accumulation of large amounts of glycine in body fluids, results from the absence of one of the components of the glycine cleavage system.

The glycine cleavage system and serine hydroxymethyltransferase occupy a vital role in green leaves, catalyzing the rapid destruction of the huge amounts of glycine produced by photorespiration (Section 24-3Ca). In fact, these

**Figure 26-15** X-ray structure of H-protein from the pea leaf glycine cleavage system. (a) The oxidized lipoamide-containing form in which the side chain of Glu 14 together with that of Lys 63 with its covalently linked lipoyl group are represented in ball-and-stick form colored according to atom type (Glu 14 C gold, Lys 63 C cyan, lipoyl C green, N blue, O red, and S yellow). (b) The reduced aminomethyl-dihydrolipoamide form of H-protein viewed and colored as in Part a. The dot surface represents the protein's solvent-accessible surface. Note how the

aminomethyl-dihydrolipoamide has changed conformation relative to the lipoamide in Part a so as to bind in a hydrophobic cleft in the protein where its amino group is hydrogen bonded to Glu 14 (*dashed black bond*). This protects the aminomethyl group from hydrolysis. [Based on X-ray structures by Roland Douce, Centre National de la Recherche Scientifique et Commissariat à l'Énergie Atomique, Grenoble, France. PDBids (a) 1HPC and (b) 1HTP.]

enzymes comprise about half the proteins present in the mitochondria from pea and spinach leaves.

Threonine is both glucogenic and ketogenic, since one of its degradation routes produces both pyruvate and acetyl-CoA (Fig. 26-12, Reactions 6 and 7). Its major route of breakdown is through **threonine dehydrogenase**, producing  **$\alpha$ -amino- $\beta$ -ketobutyrate**, which is converted to acetyl-CoA and glycine by  **$\alpha$ -amino- $\beta$ -ketobutyrate lyase**. The glycine may be converted, through serine, to pyruvate.

### b. Serine Hydroxymethyltransferase Catalyzes PLP-Dependent $C_\alpha$ — $C_\beta$ Bond Cleavage

Threonine may also be converted directly to glycine and acetaldehyde (the latter being subsequently oxidized to

acetyl-CoA), at least *in vitro*, via Reaction 5 of Fig. 26-12. Surprisingly, this reaction is catalyzed by serine hydroxymethyltransferase. We have heretofore considered PLP-catalyzed reactions that begin with the cleavage of an amino acid's  $C_\alpha$ —H bond (Fig. 26-2). Degradation of threonine to glycine and acetaldehyde by serine hydroxymethyltransferase demonstrates that PLP also facilitates cleavage of an amino acid's  $C_\alpha$ — $C_\beta$  bond by delocalizing the electrons of the resulting carbanion into the conjugated PLP ring:

### c. PLP Facilitates the Cleavage of Different Bonds in Different Enzymes

How can the same amino acid-PLP Schiff base be involved in the cleavage of the different bonds to an amino acid  $C_\alpha$  in different enzymes? The answer to this conundrum was suggested by Harmon Dunathan. For electrons to be withdrawn into the conjugated ring system of PLP, the  $\pi$ -orbital system of PLP must overlap with the bonding orbital containing the electron pair being delocalized. This is possible only if the bond being broken lies in the plane perpendicular to the plane of the PLP  $\pi$ -orbital system (Fig. 26-16a). Different bonds to  $C_\alpha$  can be placed in this plane by rotation about the  $C_\alpha$ —N bond. Indeed, the X-ray structure of aspartate aminotransferase reveals that the  $C_\alpha$ —H of its aspartate substrate assumes just this

**Figure 26-16** Bond orientation in a PLP-amino acid Schiff base. (a) The  $\pi$ -orbital framework of a PLP-amino acid Schiff base. The bond to  $C_\alpha$  in the plane perpendicular to the PLP  $\pi$ -orbital system (from X in the illustration) is labile as a consequence of its overlap with the  $\pi$  system, which permits the broken bond's electron pair to be delocalized over the conjugated molecule. (b) The Schiff base complex of the inhibitor  **$\alpha$ -methylaspartate** with PLP in the X-ray structure of porcine aspartate aminotransferase as viewed normal to the pyridoxal ring. This inhibitor is drawn in ball-and-stick form with C green, N blue, O red, and P gold, with the exception that the methyl C atom and the bond linking it to the aspartate residue are magenta. Here the methyl C occupies the position of the H atom that the enzyme normally excises from aspartate. Note that the bond linking the methyl C to aspartate is in the plane perpendicular to the pyridoxal ring and is thus ideally oriented for bond cleavage. [Part b based on an X-ray structure by David Metzler and Arthur Arnone, University of Iowa. PDBid 1AJS.]

conformation (Fig. 26-16b). Evidently, each enzyme specifically cleaves its corresponding bond because the enzyme binds the amino acid–PLP Schiff base adduct with this bond in the plane perpendicular to that of the PLP ring. This is an example of stereoelectronic assistance (Section 15-1Eb): The enzyme binds substrate in a conformation that minimizes the electronic energy of the transition state.

### C. Asparagine and Aspartate Are Degraded to Oxaloacetate

Transamination of aspartate leads directly to oxaloacetate:

Asparagine is also converted to oxaloacetate in this manner after its hydrolysis to aspartate by **L-asparaginase**:

Interestingly, L-asparaginase is an effective chemotherapeutic agent in the treatment of cancers that must obtain asparagine from the blood, particularly **acute lymphoblastic leukemia**. The cancerous cells express particularly low levels of the enzyme asparagine synthetase (Section 26-5Ab) and hence die without an external source of asparagine. However, L-asparaginase treatment may select for cells with increased levels of asparagine synthetase expression, and hence, in these cases, the surviving cancer cells are resistant to this treatment.

### D. Arginine, Glutamate, Glutamine, Histidine, and Proline Are Degraded to $\alpha$ -Ketoglutarate

Arginine, glutamine, histidine, and proline are all degraded by conversion to glutamate (Fig. 26-17), which in turn is oxidized to  $\alpha$ -ketoglutarate by glutamate dehydrogenase (Section 26-1). Conversion of glutamine to glutamate involves only one reaction: hydrolysis by **glutaminase**. Histidine's conversion to glutamate is more complicated: It is nonoxidatively deaminated, then it is hydrated, and its imidazole ring is cleaved to form **N-formiminoglutamate**. The formimino group is then transferred to tetrahydrofolate forming glutamate and **N<sup>5</sup>-formimino-tetrahydrofolate** (Section 26-4D). Both arginine and proline are converted to glutamate through the intermediate formation of **glutamate-5-semialdehyde**.

### E. Isoleucine, Methionine, and Valine Are Degraded to Succinyl-CoA

Isoleucine, methionine, and valine have complex degradative pathways that all yield propionyl-CoA. Propionyl-CoA, which is also a product of odd-chain fatty acid degradation, is converted, as we have seen, to succinyl-CoA by a series of reactions involving the participation of biotin and coenzyme B<sub>12</sub> (Section 25-2E).

#### a. Methionine Breakdown Involves Synthesis of S-Adenosylmethionine and Cysteine

Methionine degradation (Fig. 26-18) begins with its reaction with ATP to form **S-adenosylmethionine (SAM; alternatively AdoMet)**. This sulfonium ion's highly reactive methyl group makes it an important biological methylating agent. For instance, we have already seen that SAM is the methyl donor in the synthesis of phosphatidylcholine from phosphatidylethanolamine (Section 25-8Aa). It is also the methyl donor in the conversion of norepinephrine to epinephrine (Section 26-4B).

Methylation reactions involving SAM yield **S-adenosylhomocysteine** in addition to the methylated acceptor. The former product is hydrolyzed to adenosine and **homocysteine** in the next reaction of the methionine degradation pathway. The homocysteine may be methylated to form methionine via a B<sub>12</sub>-requiring reaction in which **N<sup>5</sup>-methyl-THF** is the methyl donor. Alternatively, the homocysteine may combine with serine to yield **cystathionine** in a PLP-requiring reaction, which subsequently forms cysteine (cysteine biosynthesis) and  **$\alpha$ -ketobutyrate**. The  $\alpha$ -ketobutyrate continues along the degradative pathway to propionyl-CoA and then succinyl-CoA.

#### b. Hyperhomocysteinemia Is Associated with Disease

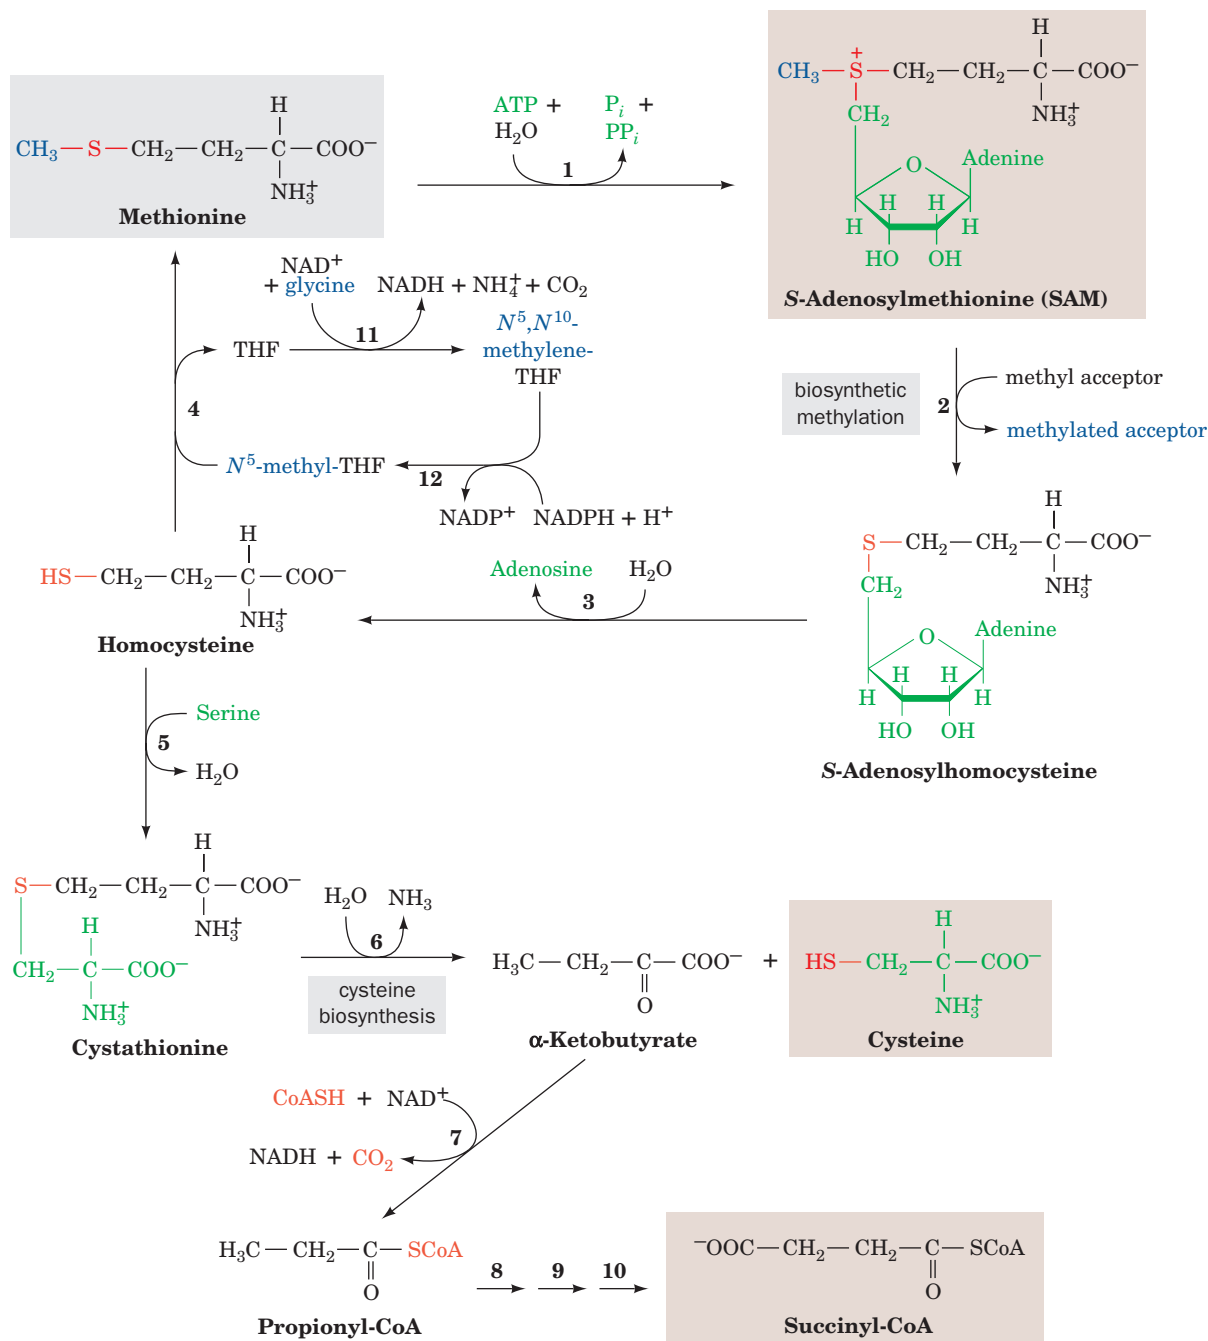

Imbalance between the rate of production of homocysteine through methylation reactions utilizing SAM (Fig. 26-18, Reactions 2 and 3) and its rate of breakdown by either remethylation to form methionine (Fig. 26-18, Reaction 4) or reaction with serine to form cystathionine in the

**Figure 26-17** Degradation pathways of arginine, glutamate, glutamine, histidine, and proline to  $\alpha$ -ketoglutarate. The enzymes catalyzing the reactions are (1) glutamate dehydrogenase, (2) glutaminase, (3) arginase, (4) ornithine- $\delta$ -aminotransferase, (5) glutamate-5-semialdehyde dehydrogenase, (6) proline oxidase, (7) spontaneous, (8) histidine ammonia lyase, (9) urocanate hydratase, (10) imidazolone propionase, and (11) glutamate formiminotransferase.

cysteine biosynthesis pathway (Fig. 26-18, Reaction 5) can result in an increase in the release of homocysteine to the extracellular medium and ultimately the plasma and urine. Moderately elevated concentrations of homocysteine in the plasma, **hyperhomocysteinemia**, for reasons that are poorly understood, are closely associated with cardiovascular disease, cognitive impairment, and **neural tube defects** [the cause of a variety of severe birth defects including **spina bifida** (defects in the spinal column that often result in paralysis) and **anencephaly** (the invariably fatal failure of the brain to develop, which is the leading cause of infant death due to congenital anomalies)]. Hyperhomo-

cysteinemia is readily controlled by ingesting the vitamin precursors of the coenzymes that participate in homocysteine breakdown, namely,  $\text{B}_6$  (pyridoxine, the PLP precursor; Fig. 26-1),  $\text{B}_{12}$  (Fig. 25-21), and folate (Section 26-4D). Folate, especially, appears to alleviate hyperhomocysteinemia; its administration to pregnant women dramatically reduces the incidence of neural tube defects in newborns. This has led to the discovery that 10% of the population is homozygous for the A222V mutation in  $\text{N}^5, \text{N}^{10}$ -methylene-tetrahydrofolate reductase (**MTHFR**; Fig. 26-18, Reaction 12; Section 26-4D), the enzyme that generates  $\text{N}^5$ -methyl-THF for the methionine synthase reaction (Fig. 26-18,

**Figure 26-18** The pathway of methionine degradation, yielding cysteine and succinyl-CoA as products. The enzymes involved are (1) methionine adenosyltransferase in a reaction that yields the biological methylating agent *S*-adenosylmethionine (SAM), (2) methyltransferase, (3) adenosylhomocysteinase, (4) methionine synthase (a coenzyme B<sub>12</sub>-dependent enzyme), (5) cystathionine β-synthase (a PLP-dependent enzyme), (6) cystathionine γ-lyase (a PLP-dependent enzyme), (7) α-keto

acid dehydrogenase, (8) propionyl-CoA carboxylase, (9) methylmalonyl-CoA racemase, (10) methylmalonyl-CoA mutase (a coenzyme B<sub>12</sub>-dependent enzyme; Reactions 8–10 are discussed in Section 25-2E), (11) glycine cleavage system (Figs. 26-12 and 26-14) or serine hydroxymethyltransferase (Fig. 26-12), (12) N<sup>5</sup>,N<sup>10</sup>-methylene-tetrahydrofolate reductase (a coenzyme B<sub>12</sub>- and FAD-dependent enzyme; Figs. 26-19 and 26-49).

Reaction 4). This mutation does not affect this homotetrameric enzyme's reaction kinetics but instead increases the rate at which it dissociates into dimers that readily lose their essential flavin cofactor. Folate derivatives that bind to the enzyme decrease its rate of dissociation and

flavin loss, thus increasing the mutant enzyme's overall activity and decreasing the homocysteine concentration.

The X-ray structure of *E. coli* MTHFR (which is 30% identical with the catalytic domain of human MTHFR), determined by Rowena Matthews and Martha Ludwig,

**Figure 26-19** X-ray structure of *E. coli*  $N^5,N^{10}$ -methylene-tetrahydrofolate reductase (MTHFR). The structure is viewed along the axis of its  $\alpha/\beta$  barrel looking toward the C-terminal ends of its  $\beta$  strands. The protein is colored according to its secondary structure with  $\beta$  strands yellow and  $\alpha$  helices cyan except for helix  $\alpha 5$ , which is red. The enzyme's bound FAD is drawn in ball-and-stick form with C yellow, N blue, O red, and P green. Note that the AMP moiety of the FAD is in contact with helix  $\alpha 5$ . [Courtesy of Rowena Matthews and Martha Ludwig, University of Michigan. PDBid 1B5T.]

reveals that this 296-residue enzyme forms an  $\alpha/\beta$  barrel. The FAD cofactor binds at the C-terminal ends of barrel strands  $\beta 3$ ,  $\beta 4$ , and  $\beta 5$  and along helix  $\alpha 5$  (Fig. 26-19). Ala 177, which corresponds to Ala 222 in the mammalian enzyme, does not interact directly with the active site FAD. Instead it occupies a position flush against helix  $\alpha 5$  (which ends with residue 176). It is postulated that the replacement of Ala 177 by a bulkier Val residue would force helix  $\alpha 5$  to reorient. Since this helix appears to be involved in the subunit interface as well as in FAD binding, its reorientation is likely to decrease the strength of subunit and FAD interactions.

Why should this mutation be so prevalent in the human population? What selective advantage, if any, might it confer? We have seen that the gene for sickle-cell anemia provides a selective advantage against malaria (Section 7-3Ab). However, the selective advantage of the A222V mutation in human MTHFR is as yet a matter of speculation.

### c. Methionine Synthase Is a Coenzyme $B_{12}$ -Dependent Enzyme

**Methionine synthase** (alternatively **homocysteine methyltransferase**), the enzyme that catalyzes Reaction 4 in Fig. 26-18, is the only coenzyme  $B_{12}$ -associated enzyme in mammals besides methylmalonyl-CoA mutase (Section 25-2Eb). However, in methionine synthase, the cobalamin Co ion is axially liganded by a methyl group forming **methylcobalamin** rather than by a 5'-deoxyadenosyl group as occurs in methylmalonyl-CoA mutase (Fig. 25-21). This

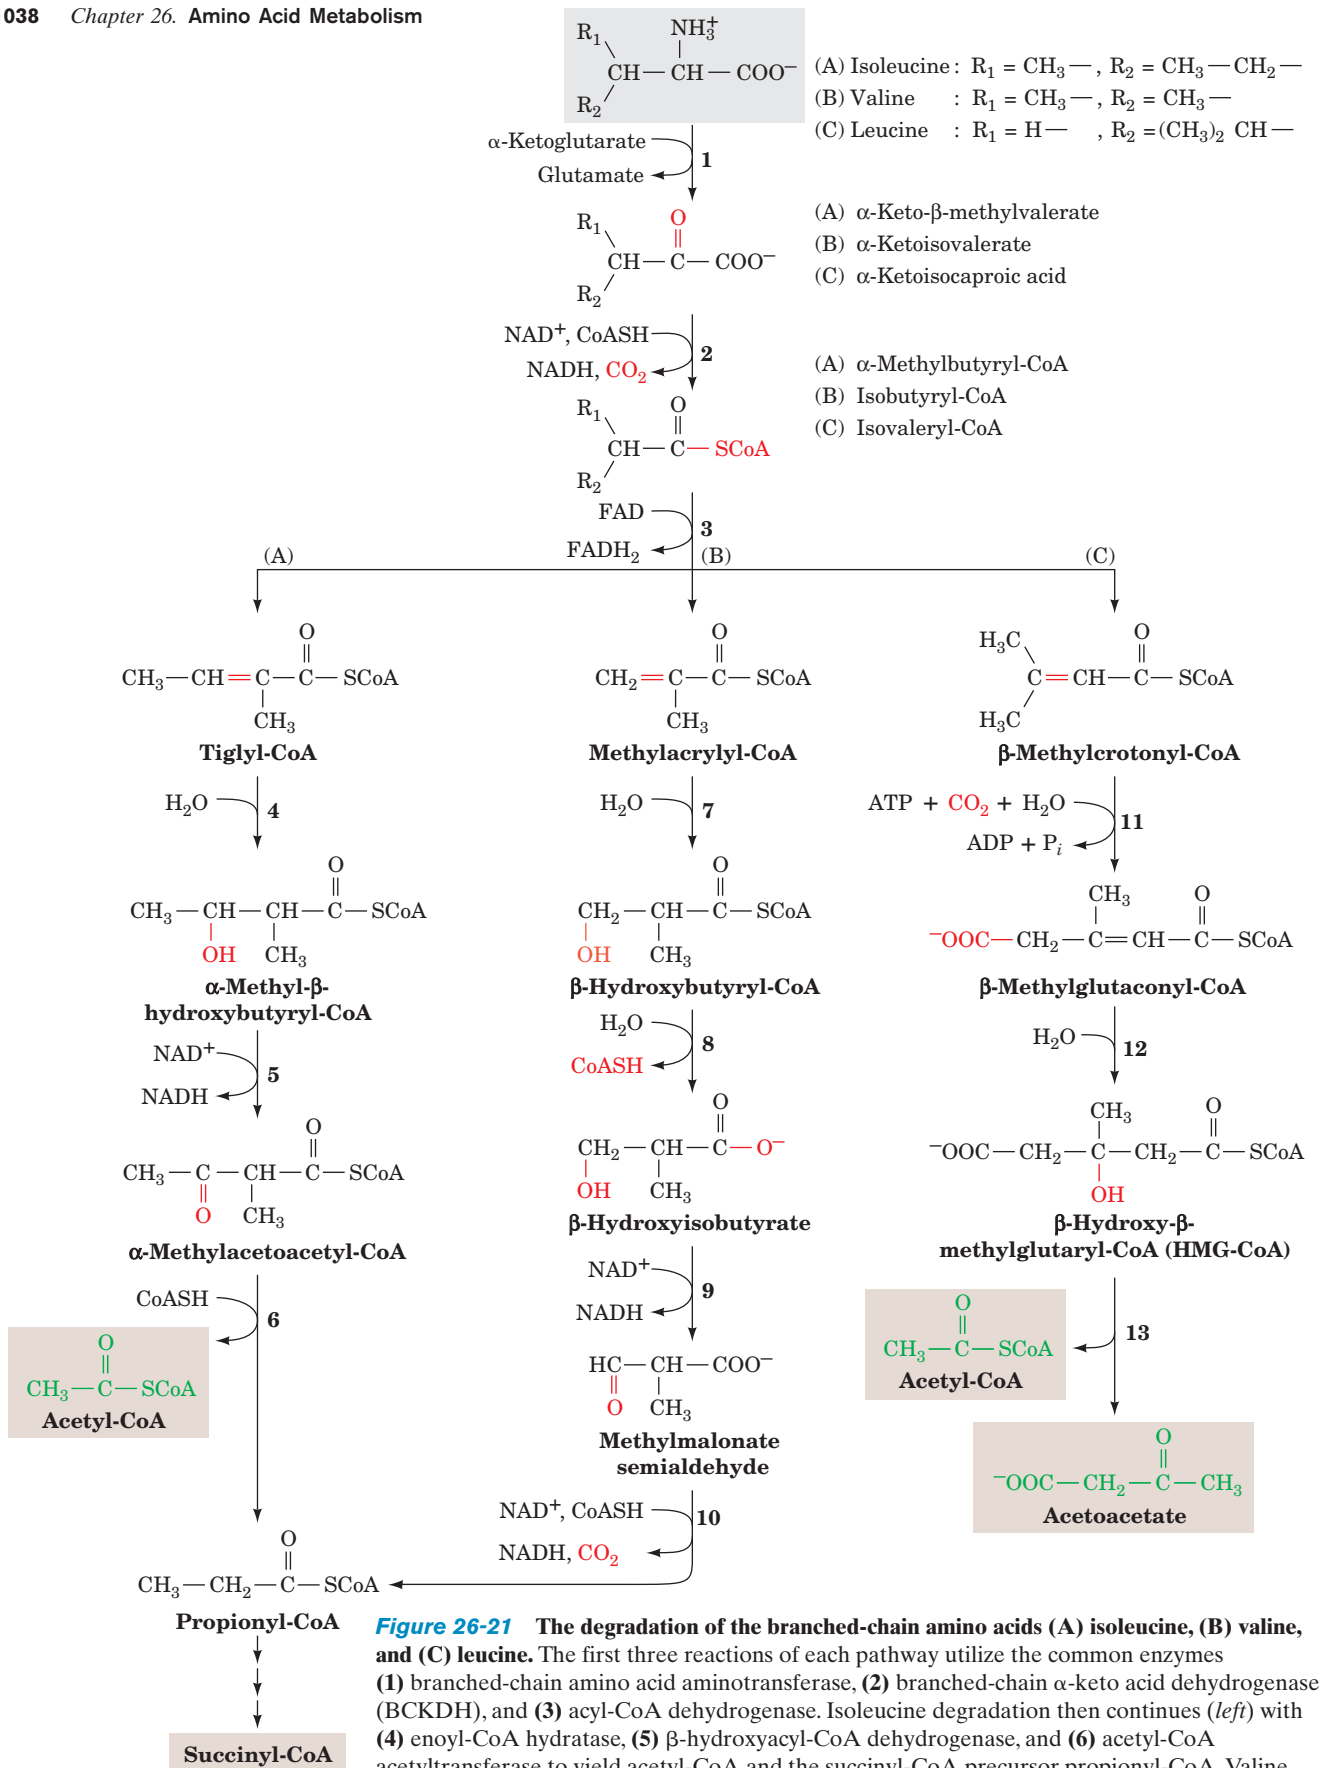

is because the cobalamin functions to accept the methyl group from  $N^5$ -methyl-THF to yield methylcobalamin (and THF), which, in turn, donates the methyl group to homocysteine to yield methionine.

The X-ray structure of the 246-residue methylcobalamin-binding portion of the 1227-residue monomeric *E. coli* methionine synthase, also determined by Matthews and Ludwig, reveals that it consists of two domains, an N-terminal helical domain and a C-terminal Rossmann fold-like  $\alpha/\beta$  domain, with the corrin ring sandwiched between them (Fig. 26-20). The  $\alpha/\beta$  domain resembles the corrin-binding  $\alpha/\beta$  domain in methylmalonyl-CoA mutase (Fig. 25-22) and, in fact, sequence homologies suggest that this domain is a common binding motif in  $B_{12}$ -associated enzymes. The Co ion's second axial ligand is a His side chain as is also the case in methylmalonyl-CoA mutase; the coenzyme's 5,6-dimethylbenzimidazole (DMB) moiety, which ligands the Co ion in free methylcobalamin, has swung aside to become anchored to the protein at some distance from the corrin ring.

**Figure 26-20** X-ray structure of the  $B_{12}$ -binding domains of *E. coli* methionine synthase. Its N-terminal helical domain (residues 651–743) is cyan and its C-terminal  $\alpha/\beta$  domain (residues 744–896) is pink. The methylcobalamin cofactor and its axially liganded His 759 side chain are drawn in stick form with cobalamin C green, His C gold, N blue, O red, and the Co ion and its axially liganded methyl group represented by light blue and orange spheres, respectively. [Based on an X-ray structure by Rowena Matthews and Martha Ludwig, University of Michigan. PDBid 1BMT.]

**d. Branched-Chain Amino Acid Degradation Pathways Contain Themes Common to All Acyl-CoA Oxidations**

Degradation of the branched-chain amino acids isoleucine, leucine, and valine begins with three reactions that employ common enzymes (Fig. 26-21, *top*): (1) transamination to the corresponding  $\alpha$ -keto acid, (2) oxidative decarboxylation to the corresponding acyl-CoA, and (3) dehydrogenation by FAD to form a double bond.

The remainder of the isoleucine degradation pathway (Fig. 26-21, *left*) is identical to that of fatty acid oxidation (Section 25-2C): (4) double-bond hydration, (5) dehydrogenation by  $\text{NAD}^+$ , and (6) thiolitic cleavage yielding acetyl-CoA and propionyl-CoA, which is subsequently converted to succinyl-CoA. Valine degradation is a variation on this theme (Fig. 26-21, *center*): Following (7) double-bond hydration, (8) the CoA thioester bond is hydrolyzed before (9) the second dehydrogenation reaction. The thioester bond is then regenerated as propionyl-CoA in the sequence's last reaction (10), an oxidative decarboxylation rather than a thiolitic cleavage.

**e. Maple Syrup Urine Disease Results from a Defect in Branched-Chain Amino Acid Degradation**

**Branched-chain  $\alpha$ -keto acid dehydrogenase (BCKDH;** also known as  **$\alpha$ -ketoisovalerate dehydrogenase**), which catalyzes Reaction 2 of branched-chain amino acid degradation (Fig. 26-21), is a multienzyme complex containing three enzymatic components, E1, E2, and E3, together with **BCKDH kinase** (phosphorylation inactivates) and **BCKDH phosphatase** (dephosphorylation activates), which impart control by covalent modification. This complex closely resembles the pyruvate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase multienzyme complexes (Sections 21-2A and 21-3D). Indeed, all three of these multienzyme complexes share a common protein component, E3 (dihydrolipoyl dehydrogenase), and employ the coenzymes thiamine pyrophosphate (TPP), lipoamide, and FAD in addition to their terminal oxidizing agent,  $\text{NAD}^+$ .

A genetic deficiency in BCKDH causes **maple syrup urine disease (MSUD)**, so named because the consequent buildup of branched-chain  $\alpha$ -keto acids imparts the urine with the characteristic odor of maple syrup. Unless promptly treated by a diet low in branched-chain amino acids (but not too low because they are essential amino acids; Section 26-5), MSUD is rapidly fatal.

MSUD is an autosomal recessive disorder that is caused by defects in any of four of the complex's six subunits, E1 $\alpha$ , E1 $\beta$ , E2, or E3 (E1 is an  $\alpha_2\beta_2$  heterotetramer). The determination of the X-ray structure of human BCKDH E1 by Wim Hol (Fig. 26-22) has enabled the interpretation of several of the mutations causing MSUD. The most common mutation is Y393N- $\alpha$ , the so-called Mennonite mutation, which occurs once in every 176 live births in the Old Order Mennonite population (versus 1 in 185,000 worldwide). This mutation is so common among Old Order Mennonites that it has been attributed to a founder effect, that is, a mutation that originated in one of the handful of founders of this isolated community. The E1 tetramer can be considered to be a dimer of  $\alpha\beta$  heterodimers with a TPP cofactor at the interface between an  $\alpha$  subunit and a  $\beta$  subunit and with each  $\alpha$  subunit

contacting both the  $\beta$  and  $\beta'$  subunits (Fig. 26-22*a*). The amino acid change in the Mennonite mutation occurs at the  $\alpha$ - $\beta'$  interface: Tyr 393 $\alpha$  is hydrogen bonded to both His 385 $\alpha$  and Asp 328 $\beta'$  (Fig. 26-22*b*). Its mutation to Asn disrupts these interactions and thereby impedes tetramerization.

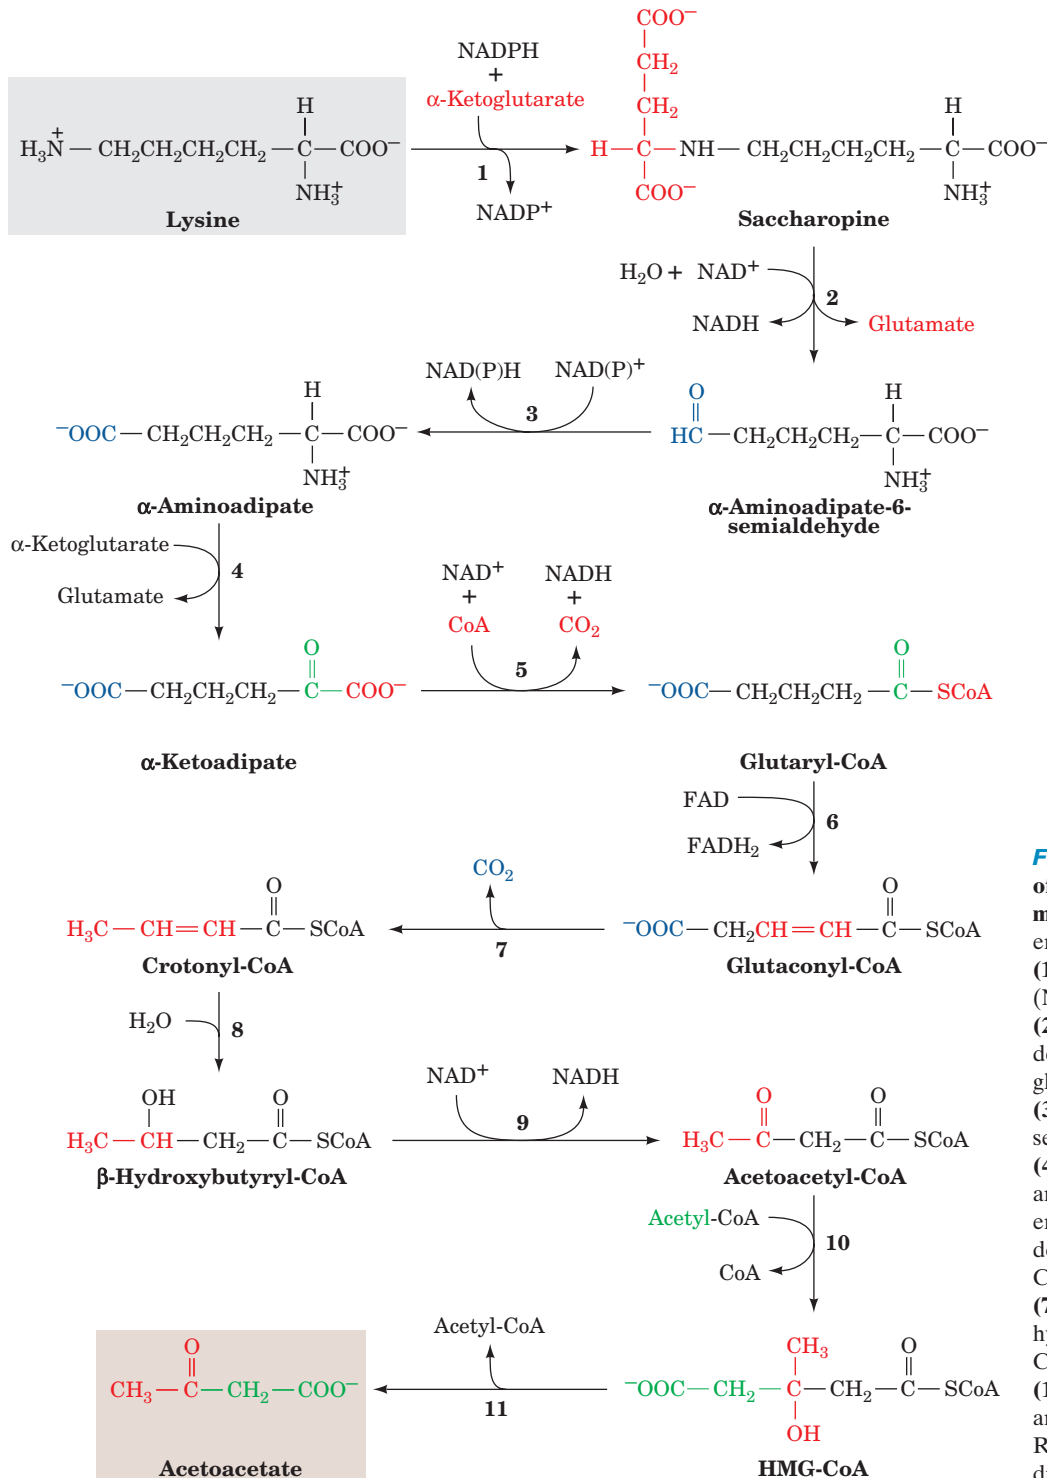

**Figure 26-22** X-ray structure of the E1 component of the human branched-chain  $\alpha$ -keto acid dehydrogenase multienzyme complex. (a) The  $\alpha_2\beta_2$  heterotetramer. The  $\alpha$  subunits are colored cyan and orange, and the  $\beta$  subunits are blue and pink. The thiamine pyrophosphate (TPP) cofactor and Tyr 393 $\alpha$  (which is mutated to Asn in the Mennonite mutation, causing maple syrup urine disease) are shown in space-filling form with TPP C green, Tyr 393 $\alpha$  C gold, N blue, O red, S yellow, and P magenta. Note the similarity of this structure to that of the E1 component of the pyruvate dehydrogenase multienzyme complex (Fig. 21-12a). (b) The  $\alpha$ - $\beta'$  interface colored as in Part a and showing the interactions of Tyr 393 $\alpha$  with His 385 $\alpha$  and Asp 328 $\beta'$ . The side chains of these residues are drawn in ball-and-stick form with C green, N blue, and O red and with the hydrogen bonds between them represented by dashed lines. [Based on an X-ray structure by Wim Hol, University of Washington. PDBid 1DTW.]

### F. Leucine and Lysine Are Degraded to Acetoacetate and/or Acetyl-CoA

Leucine is oxidized by a combination of reactions used in  $\beta$  oxidation and ketone body synthesis (Fig. 26-21, right). The first dehydrogenation and the hydration reactions are interspersed by (11) a carboxylation reaction catalyzed by the biotin-containing enzyme  **$\beta$ -methylcrotonyl-CoA carboxylase**. The hydration reaction (12) then produces  **$\beta$ -hydroxy- $\beta$ -methylglutaryl-CoA (HMG-CoA)**, which is cleaved by HMG-CoA lyase to form acetyl-CoA and the

ketone body acetoacetate (13) (which, in turn, may be converted to 2 acetyl-CoA; Section 25-3).

Although there are several pathways for lysine degradation, the one that proceeds via formation of the  $\alpha$ -ketoglutarate-lysine adduct **saccharopine** predominates in mammalian liver (Fig. 26-23). This pathway is of interest because we have encountered 7 of its 11 reactions in other pathways. Reaction 4 is a PLP-dependent transamination. Reaction 5 is the oxidative decarboxylation of an  $\alpha$ -keto acid by a multienzyme complex similar to pyruvate dehydrogenase

**Figure 26-23** The pathway of lysine degradation in mammalian liver. The enzymes involved are (1) saccharopine dehydrogenase (NADP<sup>+</sup>, lysine forming), (2) saccharopine dehydrogenase (NAD<sup>+</sup>, glutamate forming), (3) aminoadipate semialdehyde dehydrogenase, (4) aminoadipate aminotransferase (a PLP enzyme), (5)  $\alpha$ -keto acid dehydrogenase, (6) glutaryl-CoA dehydrogenase, (7) decarboxylase, (8) enoyl-CoA hydratase, (9)  $\beta$ -hydroxyacyl-CoA dehydrogenase, (10) HMG-CoA synthase, and (11) HMG-CoA lyase. Reactions 10 and 11 are discussed in Section 25-3.

and  $\alpha$ -ketoglutarate dehydrogenase (Sections 21-2A and 21-3D). Reactions 6, 8, and 9 are standard reactions of fatty acyl-CoA oxidation: dehydrogenation by FAD, hydration, and dehydrogenation by  $\text{NAD}^+$ . Reactions 10 and 11 are standard reactions in ketone body formation. Two molecules of  $\text{CO}_2$  are produced at Reactions 5 and 7 of the pathway.

The sacharopine pathway is thought to predominate in mammals because a genetic defect in the enzyme that catalyzes Reaction 1 in the sequence results in **hyperlysinemia** and **hyperlysinuria** (elevated levels of lysine in the blood and urine, respectively) along with mental and physical retardation. This is yet another example of how the study of rare inherited disorders has helped to trace metabolic pathways.

Leucine's carbon skeleton, as we have seen, is converted to one molecule each of acetoacetate and acetyl-CoA, whereas that of lysine is converted to one molecule of acetoacetate and two of  $\text{CO}_2$ . Since neither acetoacetate nor acetyl-CoA can be converted to glucose in animals, leucine and lysine are purely ketogenic amino acids.

### G. Tryptophan Is Degraded to Alanine and Acetoacetate

The complexity of the major tryptophan degradation pathway (Fig. 26-24) precludes detailed discussion of all of its reactions. However, one reaction in the pathway is of particular interest. Reaction 4, cleavage of **3-hydroxykynurenine**

**Figure 26-24** The pathway of tryptophan degradation. The enzymes involved are (1) tryptophan-2,3-dioxygenase, (2) formamidase, (3) kynurenine-3-monooxygenase, (4) kynureninase (PLP dependent), (5) 3-hydroxyanthranilate-3,4-dioxygenase, (6) amino carboxymuconate semialdehyde decarboxylase, (7) aminomuconate semialdehyde dehydrogenase,

(8) hydratase, (9) dehydrogenase, and (10–16) enzymes of Reactions 5 through 11 in lysine degradation (Fig. 26-23). 2-Amino-3-carboxymuconate-6-semialdehyde, in addition to undergoing Reaction 6, spontaneously forms **quinolinate**, an  $\text{NAD}^+$  and  $\text{NADP}^+$  precursor (Section 28-5A).

**Figure 26-25** Proposed mechanism for the PLP-dependent kynureninase-catalyzed C<sub>β</sub>-C<sub>γ</sub> bond cleavage of 3-hydroxykynurenine. The reaction occurs in eight steps: (1) transimination; (2) tautomerization; (3) attack of an enzyme

nucleophile, X; (4) C<sub>β</sub>-C<sub>γ</sub> bond cleavage with formation of an acyl-enzyme intermediate; (5) acyl-enzyme hydrolysis; (6) and (7) tautomerization; and (8) transimination.

to alanine and 3-hydroxyanthranilate, is catalyzed by **kynureninase**, a PLP-dependent enzyme. The reaction further demonstrates the enormous versatility of PLP. We have seen how PLP can labilize an α-amino acid's C<sub>α</sub>-H and C<sub>α</sub>-C<sub>β</sub> bonds (Fig. 26-16). Here we see the facilitation of C<sub>β</sub>-C<sub>γ</sub> bond cleavage. The reaction follows the same steps as transamination reactions but does not hydrolyze the tautomerized Schiff base (Fig. 26-25). The proposed reaction mechanism involves an attack of an enzyme nucleophile on the carbonyl carbon (C<sub>γ</sub>) of the tautomerized

3-hydroxykynurenine-PLP Schiff base (Fig. 26-25, Step 3). This is followed by C<sub>β</sub>-C<sub>γ</sub> bond cleavage to generate an acyl-enzyme intermediate together with a tautomerized alanine-PLP adduct (Fig. 26-25, Step 4). Hydrolysis of the acyl-enzyme then yields 3-hydroxyanthranilate, whose further degradation yields **α-ketoadipate** (Fig. 26-24, Reactions 5-9). α-Ketoadipate is also an intermediate in lysine breakdown (Fig. 26-23, Reaction 4) so that the last seven reactions in the degradation of both these amino acids are identical, forming acetoacetate and two molecules of CO<sub>2</sub>.

**Figure 26-26** The pathway of phenylalanine degradation. The enzymes involved are (1) phenylalanine hydroxylase, (2) aminotransferase, (3) *p*-hydroxyphenylpyruvate dioxygenase, (4) homogentisate dioxygenase, (5) maleylacetoacetate isomerase, and (6) fumarylacetoacetase. The symbols labeling the various carbon atoms serve to indicate the group migration that occurs in Reaction 3 of the pathway (see Fig. 26-31).

## H. Phenylalanine and Tyrosine Are Degraded to Fumarate and Acetoacetate

Since the first reaction in phenylalanine degradation is its hydroxylation to tyrosine, a single pathway (Fig. 26-26) is responsible for the breakdown of both of these amino acids. The final products of the six-reaction degradation are fumarate, a citric acid cycle intermediate, and acetoacetate, a ketone body.

### a. Pterins Are Redox Cofactors

The hydroxylation of phenylalanine by the nonheme iron-containing homotetrameric enzyme **phenylalanine hydroxylase (PAH)** requires O<sub>2</sub> and that the iron be in the Fe(II) state. The enzyme also requires the participation of **biopterin**, a **pterin** derivative. Pterins are compounds that contain the **pteridine** ring (Fig. 26-27). Note the resemblance between the pteridine ring and the isoalloxazine ring of the flavin coenzymes; the positions of the nitrogen atoms in pteridine are identical with those of the B and C rings of isoalloxazine. Folate derivatives also contain the pterin ring (Section 26-4D). Pterins, like flavins, participate in biological oxidations. The active form of biopterin is the fully reduced form, **5,6,7,8-tetrahydrobiopterin (BH<sub>4</sub>)**. It is produced from **7,8-dihydrobiopterin** and NADPH, in what

**Figure 26-27** The pteridine ring, the nucleus of biopterin and folate. Note the similar structures of pteridine and the isoalloxazine ring of flavin coenzymes.

may be considered a priming reaction, by **dihydrofolate reductase** (Fig. 26-28).

Each 452-residue subunit of the PAH homotetramer contains three domains, an N-terminal regulatory domain, a catalytic domain, and a C-terminal tetramerization domain. However, the 325-residue catalytic domain alone forms catalytically competent dimers. The X-ray structure of the catalytic domain of PAH in its Fe(II) state in complex with  $\text{BH}_4$ , determined by Edward Hough, reveals that the Fe(II) is octahedrally coordinated by His 285, His 290, Glu 330, and three water molecules, and that atom O4 of  $\text{BH}_4$  is hydrogen bonded to two of these waters (Fig. 26-29).

In the phenylalanine hydroxylase reaction, 5,6,7,8-tetrahydrobiopterin is hydroxylated to **pterin-4a-carbinolamine** (Fig. 26-28), which is converted to **7,8-dihydrobiopterin (quinoid form)** by **pterin-4a-carbinolamine dehydratase**. The quinoid is subsequently reduced by the NAD(P)H-requiring enzyme **dihydropteridine reductase** to regenerate the active cofactor. Note that although dihydrofolate reductase and dihydropteridine reductase produce the same product, they utilize different tautomers of the substrate. Although this suggests that these enzymes may be evolutionarily related, the comparison of their X-ray structures indicates that this is not the case: Dihydropteridine reductase resembles nicotinamide

**Figure 26-28** The formation, utilization, and regeneration of 5,6,7,8-tetrahydrobiopterin ( $\text{BH}_4$ ) in the phenylalanine hydroxylase reaction.

**Figure 26-29** The active site of the Fe(II) form of phenylalanine hydroxylase (PAH) in complex with 5,6,7,8-tetrahydrobiopterin (BH<sub>4</sub>). The Fe(II) (orange sphere) is octahedrally coordinated (gray lines) by His 285, His 290, and Glu 330 (C green, N blue, and O red) and three water molecules (red spheres). BH<sub>4</sub> atom O4 is hydrogen bonded (black dashed lines) to two of these water molecules. [Based on an X-ray structure by Edward Hough, University of Tromsø, Norway. PDBid 1J8U.]

coenzyme-requiring flavin-dependent enzymes such as glutathione reductase and dihydrolipoyl dehydrogenase (Section 21-2B).

#### b. Phenylalanine Hydroxylase Is Controlled by Phosphorylation and by Allosteric Interactions

PAH initiates the detoxification of high concentrations of phenylalanine as well as the synthesis of the catecholamine hormones and neurotransmitters (Section 26-4B). It is allosterically activated by its substrate, phenylalanine, and by phosphorylation at its Ser 16 by the cAMP-dependent protein kinase A (PKA; Section 18-3Cb). Its second substrate, BH<sub>4</sub>, allosterically inhibits the enzyme.

#### c. The NIH Shift

An unexpected aspect of the PAH reaction is that a <sup>3</sup>H atom, which begins on C4 of phenylalanine's phenyl ring, ends up on C3 of this ring in tyrosine (Fig. 26-28, right) rather than being lost to the solvent by replacement with the OH group. The mechanism postulated to account for this **NIH shift** (so called because it was first characterized by chemists at the National Institutes of Health) involves the activation of oxygen by the pterin and Fe cofactors to form the pterin-4a-carbinolamine and a reactive oxyferryl group [Fe(IV)=O<sup>2-</sup>; Fig. 26-30, Steps 1 and 2] that reacts with the substrate to form an epoxide across the phenyl ring's 3,4 bond (Fig. 26-30, Step 3). This is followed by epoxide opening to form a carbocation at C3 (Fig. 26-30, Step 4). Migration of a hydride from C4 to C3 forms a more stable carbocation (an oxonium ion; Fig. 26-30, Step 5). This migration is followed by ring aromatization to form tyrosine

(Fig. 26-30, Step 6). **Tyrosine hydroxylase** and **tryptophan hydroxylase** (Section 26-4B) are both homologous to phenylalanine hydroxylase and utilize this same NIH shift reaction mechanism, although there may not be an epoxide intermediate in these cases.

Reaction 3 in the phenylalanine degradation pathway (Fig. 26-26) provides another example of an NIH shift. This reaction, which is catalyzed by the Fe(II)-containing ***p*-hydroxyphenylpyruvate dioxygenase**, involves the oxidative decarboxylation of an  $\alpha$ -keto acid as well as ring hydroxylation. In this case, the NIH shift involves migration of an alkyl group rather than of a hydride ion to form a more stable carbocation (Fig. 26-31). This shift, which has been demonstrated through isotope-labeling studies (represented by the different symbols in Figs. 26-26 and 26-31), accounts for the observation that C3 is bonded to C4 in ***p*-hydroxyphenylpyruvate** but to C5 in **homogentisate**.

#### d. Alkaptonuria and Phenylketonuria Result from Defects in Phenylalanine Degradation

Archibald Garrod realized in the early 1900s that human genetic diseases result from specific enzyme deficiencies. We have repeatedly seen how this realization has contributed to the elucidation of metabolic pathways. The first such disease to be recognized was **alkaptonuria**, which, Garrod observed, resulted in the excretion of large quantities of homogentisic acid. This condition results from deficiency of **homogentisate dioxygenase** (Fig. 26-26, Reaction 4). Alkaptonurics suffer no ill effects other than arthritis later in life (although their urine darkens alarmingly because of the rapid air oxidation of the homogentisate they excrete).

Individuals suffering from **phenylketonuria (PKU)** are not so fortunate. Severe mental retardation occurs within a few months of birth if the disease is not detected and treated immediately (see below). Indeed, ~1% of the patients in mental institutions were, at one time (before routine screening), phenylketonurics. PKU is caused by the inability to hydroxylate phenylalanine (Fig. 26-26, Reaction 1) and therefore results in increased blood levels of phenylalanine (**hyperphenylalaninemia**). The excess phenylalanine is transaminated to **phenylpyruvate**

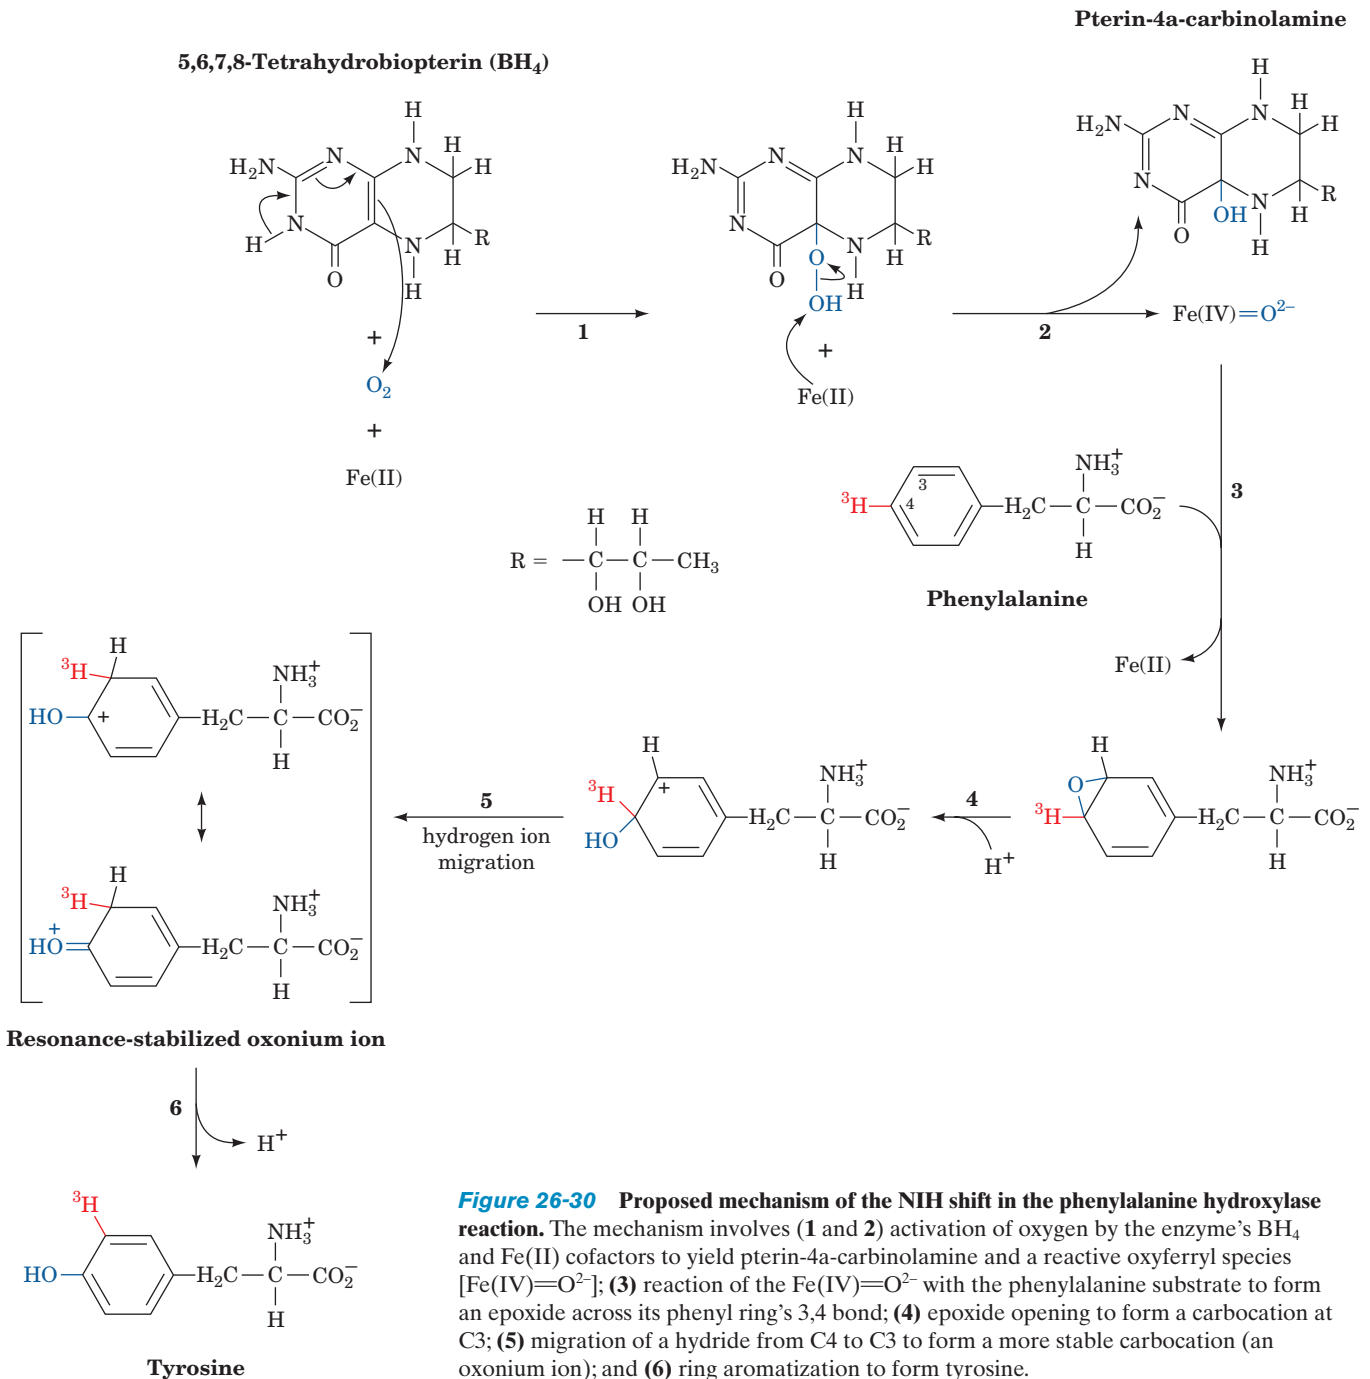

**Phenylpyruvate**

by an otherwise minor pathway. The "spillover" of phenylpyruvate (a phenylketone) into the urine was the first observation connected with the disease and gave the disease its name, although it has since been demonstrated that it is the high concentration of phenylalanine itself that gives rise to brain dysfunction. All babies born in the United States are now screened for PKU immediately after birth by testing for elevated levels of phenylalanine in the blood.

Classic PKU results from a deficiency in phenylalanine hydroxylase (PAH). When this was established in 1947, it was the first human inborn error of metabolism whose basic biochemical defect had been identified. Since then, over

400 mutations have been identified in PAH. Because all of the tyrosine breakdown enzymes are normal, treatment consists in providing the patient with a low-phenylalanine diet and monitoring the blood level of phenylalanine to ensure that it remains within normal limits for the first 5 to 10 years of life (the adverse effects of hyperphenylalaninemia seem to disappear after that age). PAH deficiency also accounts for another common symptom of PKU: Its victims have lighter hair and skin color than their siblings. This is because tyrosine hydroxylation, the first reaction in the formation of the black skin pigment **melanin** (Section 26-4B), is inhibited by elevated phenylalanine levels.

Other causes of hyperphenylalaninemia have been discovered since the introduction of infant screening techniques. These result from deficiencies in the enzymes catalyzing the formation or regeneration of 5,6,7,8-tetrahydrobiopterin (BH<sub>4</sub>), the PAH cofactor (Fig. 26-28). In such cases, patients must also be supplied with **L-3,4-dihydroxyphenylalanine (L-DOPA)** and **5-hydroxytryptophan**, metabolic precursors of the neurotransmitters **norepinephrine** and **serotonin**, respectively, since tyrosine hydroxylase and tryptophan hydroxylase, the PAH homologs that produce these physiologically active amines, also require 5,6,7,8-tetrahydrobiopterin (Section 26-4B). Unfortunately, simply adding BH<sub>4</sub> to the diet of

**Figure 26-31** The NIH shift in the *p*-hydroxyphenylpyruvate dioxygenase reaction. Carbon atoms are labeled as an aid to following the group migration constituting the shift.

an affected individual is not an effective treatment because  $BH_4$  is unstable and cannot cross the blood–brain barrier.

## 4 AMINO ACIDS AS BIOSYNTHETIC PRECURSORS

Certain amino acids, in addition to their major function as protein building blocks, are essential precursors of a variety of important biomolecules, including nucleotides and nucleotide coenzymes, heme, various hormones and neurotransmitters, and glutathione. In this section, we consider the pathways producing some of these substances. We begin by discussing the biosynthesis of heme from glycine and succinyl-CoA. We then examine the pathways by which tyrosine, tryptophan, glutamate, and histidine are converted to various neurotransmitters and study certain aspects of glutathione biosynthesis and the involvement of this tripeptide in amino acid transport and other processes. Finally, we consider the role of folate derivatives in the biosynthetic transfer of  $C_1$  units. The biosynthesis of nucleotides and nucleotide coenzymes is the subject of Chapter 28.

### A. Heme Biosynthesis and Degradation

Heme (Fig. 26-32), as we have seen, is an Fe-containing prosthetic group that is an essential component of many proteins, notably hemoglobin, myoglobin, and the cytochromes. The initial reactions of heme biosynthesis are common to the formation of other tetrapyrroles including

**Figure 26-32** Structure of heme. Heme's C and N atoms are derived from those of glycine and acetate.

chlorophyll in plants and bacteria (Section 24-2A) and coenzyme B<sub>12</sub> in bacteria (Section 25-2Eb).

### a. Porphyrins Are Derived from Succinyl-CoA and Glycine

Elucidation of the heme biosynthesis pathway involved some interesting detective work. David Shemin and David Rittenberg, who were among the first to use isotopic tracers in the elucidation of metabolic pathways, demonstrated, in 1945, that *all of heme's C and N atoms can be derived from acetate and glycine*. Only glycine, out of a variety of <sup>15</sup>N-labeled metabolites they tested (including ammonia, glutamate, leucine, and proline), yielded <sup>15</sup>N-labeled heme in the hemoglobin of experimental subjects to whom these metabolites were administered. Similar experiments, using acetate labeled with <sup>14</sup>C in its methyl or carboxyl groups, or [<sup>14</sup>C<sub>α</sub>]glycine, demonstrated that 24 of heme's 34 carbon atoms are derived from acetate's methyl carbon, 2 from acetate's carboxyl carbon, and 8 from glycine's C<sub>α</sub> atom (Fig. 26-32). None of the heme atoms is derived from glycine's carboxyl carbon atom.

Figure 26-32 indicates that heme C atoms derived from acetate methyl groups occur in groups of three linked atoms. Evidently, acetate is first converted to some other metabolite that has this labeling pattern. Shemin and Rittenberg postulated that this metabolite is succinyl-CoA based on the following reasoning (Fig. 26-33):

1. Acetate is metabolized via the citric acid cycle (Section 21-1B).

2. Labeling studies indicate that atom C3 of the citric acid cycle intermediate succinyl-CoA is derived from acetate's methyl C atom, whereas atom C4 comes from acetate's carboxyl C atom.

3. After many turns of the citric acid cycle, C1 and C2 of succinyl-CoA likewise become fully derived from acetate's methyl C atom.

We shall see that this labeling pattern indeed leads to that of heme.

In the mitochondria of yeast and animals as well as in some bacteria, the first phase of heme biosynthesis is a condensation of succinyl-CoA with glycine followed by decarboxylation to form **δ-aminolevulinic acid (ALA)** as catalyzed by the PLP-dependent enzyme **δ-aminolevulinic acid synthase (ALA synthase or ALAS; Fig. 26-34)**. The carboxyl group lost in the decarboxylation (Fig. 26-34, Reaction 5) originates in glycine, which is why heme contains no label from this group.

### b. The Pyrrole Ring Is the Product of Two ALA Molecules

The pyrrole ring is formed in the next phase of the pathway through linkage of two molecules of ALA to yield **porphobilinogen (PBG)**. The reaction is catalyzed by **porphobilinogen synthase [PBGs; alternatively, δ-aminolevulinic acid dehydratase (ALAD)]**, which in yeast and mammals, is Zn<sup>2+</sup>-dependent and involves Schiff base formation of one of the substrate molecules with an enzyme amine

**Figure 26-33** The origin of the C atoms of succinyl-CoA as derived from acetate via the citric acid cycle. C atoms labeled with triangles and squares are derived, respectively, from acetate's methyl and carboxyl C atoms. Filled symbols label atoms derived from acetate in the present round of the citric acid cycle, whereas open symbols label atoms derived from acetate in previous rounds of the citric acid cycle. Note that the C1 and C4 atoms of succinyl-CoA are scrambled on forming the 2-fold symmetric succinate.

group (in some bacteria and all plants, Mg<sup>2+</sup> substitutes for Zn<sup>2+</sup>). One possible mechanism of this condensation–elimination reaction involves formation of a second Schiff base between the ALA–enzyme Schiff base and the second ALA molecule (Fig. 26-35). At this point, if we continue tracing the acetate and glycine labels through the PBG synthase reaction (Fig. 26-35), we can begin to see how heme's labeling pattern arises.

The X-ray structure of human PBGS in covalent complex with its product PBG, determined by Jonathan Cooper, indicates that this enzyme is a homooctamer with D<sub>4</sub> symmetry. Each of its 330-residue subunits consists of an α/β barrel and a 39-residue N-terminal tail that wraps around a neighboring monomer (related to it by 2-fold symmetry) so that the protein is better described as a relatively loosely organized tetramer of compact dimers. As is the case with nearly all α/β barrel enzymes, PBGS's active site (Fig. 26-36a) lies at the mouth of the barrel at the

**Figure 26-34** The mechanism of action of the PLP-dependent enzyme  $\delta$ -aminolevulinic acid synthase (ALAS). The reaction steps are (1) transamination, (2) PLP-stabilized carbanion formation,

(3) C—C bond formation, (4) CoA elimination, (5) decarboxylation facilitated by the PLP-Schiff base, and (6) transimination yielding ALA and regenerating the PLP-enzyme.

C-terminal ends of its  $\beta$  strands. The active site is covered by a loop that comparison with other PBGS structures indicates forms a flexible lid over the substrate, an arrangement that is reminiscent of the glycolytic enzyme triose phosphate isomerase (TIM; Fig. 17-11). PBG is covalently bound to Lys 252 and its free amino group is coordinated to the active site Zn<sup>2+</sup> ion. Lys 199 appears to be properly positioned to act as a general acid–base catalyst.

Inhibition of PBG synthase by Pb<sup>2+</sup> (a competitor of its active site Zn<sup>2+</sup> ion) is one of the major manifestations of lead poisoning, which is among the most common acquired environmental diseases. Indeed, it has been suggested that the accumulation, in the blood, of ALA, which resembles the neurotransmitter  $\gamma$ -aminobutyric acid (Section 26-4B), is responsible for the psychosis that often accompanies lead poisoning.

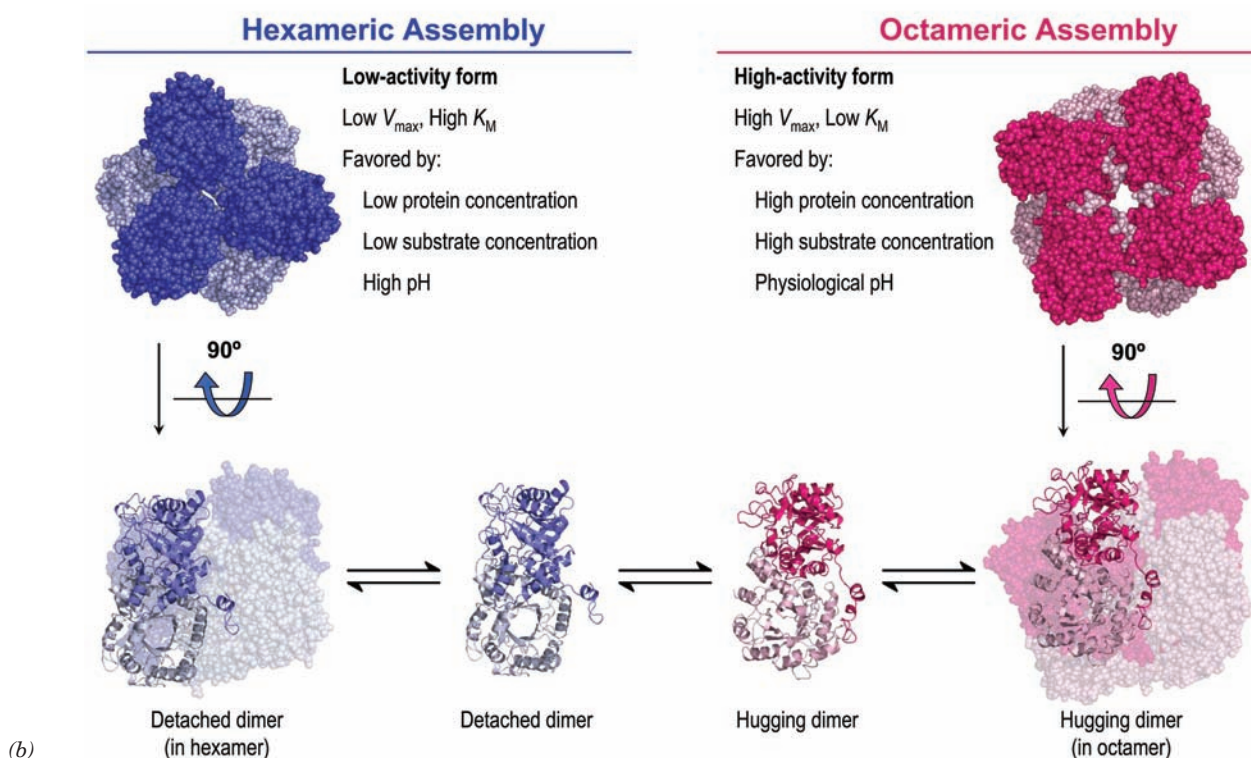

### c. PBGS Has Two Quaternary States with Different Enzymatic Activities

Although the X-ray structure of wild-type human PBGS indicates that it is a  $D_4$ -symmetric homooctamer, the X-ray structure of its rare F12L mutant form, determined by Eileen Jaffe, is a  $D_3$ -symmetric homohexamer (Fig. 26-36b). Moreover, the F12L mutant has far less activity than does wild-type PBGS, even though residue 12 is far from the enzyme's active site in both proteins. This is apparently due to a conformational change in PBGS's N-terminal arm: In the octamer, the N-terminal arms of two adjacent monomers wrap around each other's barrel to form a so-called hugging dimer, whereas in the hexamer, the N-terminal arms extend away from the core of the protein to form a so-called detached dimer (Fig. 26-36b). Nevertheless, the  $\alpha/\beta$  barrels of these two oligomeric forms are closely superimposable. The difference in the activities of these two quaternary forms is caused by the binding of an allosteric  $\text{Mg}^{2+}$  ion in the octamer's "hugging" interface that is absent in the detached dimer.

The alternate oligomeric forms have been observed in solutions of wild-type PBGS and the equilibrium between these forms can be varied by changing the pH, the enzyme concentration, and the substrate concentration, as well as through mutation. Jaffe has therefore proposed that this quaternary structural change is an allosteric mechanism for controlling the activity of the enzyme. In contrast, in the symmetry and sequential models of allosterism (Sections 10-4B and 10-4C), the quaternary state of the enzyme does not change during an allosteric transition.

Jaffe has termed enzymes that control their activities by changing their oligomeric states **morpheins** [pronounced morph-ee'-in; derived from the verb "to morph" and the classic pronunciation of the word protein (pro-tee'-in)]. Although PBGS is the first known morphein, several others have since been identified (e.g., ribonucleotide reductase; Section 28-3Ad). In fact, it may be that morpheins are relatively common because when an enzyme is purified, inactive fractions are usually assumed to be denatured and are therefore discarded rather than being characterized.

**Figure 26-36** X-ray structure of human porphobilinogen synthase (PBGS). (a) PBGS in covalent complex with its porphobiligen (PBG) product. A monomer of this homooctameric protein is viewed perpendicular to the axis of its  $\alpha/\beta$  barrel and is drawn in gray with its  $\beta$  strands cyan and the loop forming its flexible lid (residues 201–222) magenta. The PBG, product, Lys 252 to which it is covalently linked, and the three Cys side chains that ligand the active site  $Zn^{2+}$  ion (blue sphere) are shown in stick form with PBG C pink, side chain C green, N blue, O red, S yellow, and the N–C bond linking Lys 252 to PBG gold. The active site  $Zn^{2+}$  ion is liganded (black lines) by the S atoms of Cys 122, Cys 124, Cys 132, and the PBG amino group. Lys 199, which lies directly behind Lys 252 in this view, appears to be properly positioned to act as an acid–base catalyst. [Based on an X-ray structure by Jonathan Cooper,

University of Southampton, U.K. PDBid 1E51.] (b) Quaternary structural changes between the low activity hexameric state of the F12L mutant of human PBGS (blue) and the high activity octameric state of the wild-type enzyme (red). In the upper panel, the proteins are viewed along their 3-fold and 4-fold axes with the subunits closest to the viewer more darkly colored. In the lower panel, the outer drawings are viewed along their 2-fold axes with one dimer drawn in ribbon form and the others in space-filling form. The inner drawings show only the dimers into which the oligomers are assumed to dissociate before reassembling to an alternate quaternary state. [Courtesy of Sarah Lawrence and Eileen Jaffe, The Fox Chase Cancer Center, Philadelphia, Pennsylvania. The X-ray structure of the F12L mutant was determined by Eileen Jaffe. PDBid 1PV8.]

#### d. The Porphyrin Ring Is Formed from Four PBG Molecules

The next phase of heme biosynthesis is the condensation of four PBG molecules to form **uroporphyrinogen III**, the porphyrin nucleus, in a series of reactions catalyzed by **porphobilinogen deaminase** (alternatively, **hydroxymethylbilane synthase** or **uroporphyrinogen synthase**) and **uroporphyrinogen III synthase**. The reaction (Fig. 26-37) begins with the enzyme's displacement of the amino group in PBG to form a covalent adduct. A second, third, and fourth PBG then sequentially add through the displacement of the primary amino group on one PBG by a carbon atom on the pyrrole ring of the succeeding PBG to yield a linear tetrapyrrole that is hydrolyzed and released from the enzyme as **hydroxymethylbilane** (also called **preuroporphyrinogen**).

#### e. Porphobilinogen Deaminase Has a Dipyrrromethane Cofactor

Peter Shoolingin-Jordan and Alan Battersby independently showed that porphobilinogen deaminase contains a unique **dipyrrromethane** cofactor (two pyrroles linked by a methylene bridge; rings C<sub>1</sub> and C<sub>2</sub> in Fig. 26-37), which is covalently linked to the enzyme via a C—S bond to an enzyme Cys residue. Thus, the methylbilane–enzyme complex really contains a linear hexapyrrole. The subsequent reaction step, also catalyzed by porphobilinogen deaminase (Step 5 in Fig. 26-37), is the hydrolysis of the bond linking the second and third pyrrole units of the hexapyrrole to yield hydroxymethylbilane and the dipyrrromethane cofactor. This cofactor is still linked to the enzyme, which is therefore ready to catalyze a new round of hydroxymethylbilane synthesis.

How is the dipyrrromethane cofactor assembled? Shoolingin-Jordan has shown that porphobilinogen deaminase synthesizes its own cofactor from two PBG units using, it appears, the same catalytic machinery with which it synthesizes methylbilane. However, the enzyme Cys reacts much more rapidly with presynthesized hydroxymethylbilane to form a reaction intermediate (the product of Step 2 in Fig. 26-37) that continues to add two more PBG units. When hydroxymethylbilane is released, the enzyme retains its dipyrrromethane cofactor.

The X-ray structure of human porphobilinogen deaminase (whose sequence is >45% identical to those of the *E. coli* enzyme), in covalent complex with its dipyrrromethane cofactor, indicates that this monomeric, 364-residue protein folds into three nearly equal sized domains (Fig. 26-38). The dipyrrromethane cofactor lies deep in a cleft between domains 1 and 2 such that there is still considerable unoccupied space in the cleft. Although the enzyme sequentially appends four PBG residues to the cofactor, it has only one catalytic site.

If the enzyme has only one catalytic site, how does it reposition the polypyrrole chain after each catalytic cycle so that it can further extend this chain? One possibility is that the polypyrrole chain fills the cavity next to the cofactor. This model provides a simple steric rationale for why the length of the polypyrrole chain is limited to six residues (the final four of which are hydrolytically cleaved away by the enzyme to yield the hydroxymethylbilane product and regenerate the dipyrrromethane cofactor).

**Figure 26-38** X-ray structure of human porphobilinogen deaminase in covalent complex with its dipyrrromethane cofactor. The protein is shown in ribbon form with domain 1 (residues 1–116 and 216–239) magenta, domain 2 (residues 117–215) cyan, and domain 3 (residues 240–364) orange. The dipyrrromethane cofactor and the Cys side chain to which it is covalently linked are drawn in stick form with C green, N blue, O red, and S yellow. [Based on an X-ray structure by Zhi-Jie Liu, Institute of Biophysics, Beijing, China. PDBid 3ECR.]

#### f. Protoporphyrin IX Biosynthesis Requires Four More Reactions

Cyclization of the hydroxymethylbilane product requires **uroporphyrinogen III synthase** (Fig. 26-37). In the absence of this enzyme, hydroxymethylbilane is released from the synthase and rapidly cyclizes nonenzymatically to the symmetric **uroporphyrinogen I**. Heme, however, is an asymmetric molecule; the methyl substituent of pyrrole ring D has an inverted placement compared to those of rings A, B, and C (Fig. 26-32). This ring reversal to yield uroporphyrinogen III has been shown by Battersby to proceed through attachment of the methylenes from rings A and C to the same carbon of ring D so as to form a spiro compound (a bicyclic compound with a carbon atom common to both rings; Fig. 26-37).

Heme biosynthesis takes place partly in the mitochondrion and partly in the cytosol (Fig. 26-39). ALA is mitochondrially synthesized and is transported to the cytosol for conversion to PBG and then to uroporphyrinogen III. **Protoporphyrin IX**, to which Fe is added to form heme, is produced from uroporphyrinogen III in a series of reactions catalyzed by (1) **uroporphyrinogen decarboxylase**, which decarboxylates all four acetate side chains (A) to form methyl groups (M); (2) **coproporphyrinogen oxidase**, which oxidatively decarboxylates two of the propionate side chains (P) to vinyl groups (V); and (3) **protoporphyrinogen**

**Figure 26-39** The overall pathway of heme biosynthesis.  $\delta$ -Aminolevulinic acid (ALA) is synthesized in the mitochondrion by ALA synthase. ALA (left) leaves the mitochondrion and is converted to PBG, four molecules of which condense to form a porphyrin ring. The next two reactions involve oxidation of the pyrrole ring substituents yielding protoporphyrinogen IX whose

formation is accompanied by its transport back into the mitochondrion. After oxidation of the methylene groups linking the pyrroles to yield protoporphyrin IX, ferrochelatase catalyzes the insertion of  $\text{Fe}^{2+}$  to yield heme. A, P, M, and V, respectively, represent acetyl, propionyl, methyl, and vinyl ( $-\text{CH}_2=\text{CH}_2$ ) groups. C atoms originating as the carboxyl group of acetate are red.

**oxidase**, which oxidizes the methylene groups linking the pyrrole rings to methenyl groups. Altogether, six carboxyl groups originally from carboxyl-labeled acetate are lost as  $\text{CO}_2$ . The only remaining C atoms from carboxyl-labeled acetate are the carboxyl groups of heme's two propionate side chains (P). During the coproporphyrinogen oxidase reaction, the macrocycle is transported back into the mitochondrion for the pathway's final reactions.

#### g. Ferrochelatase Catalyzes the Insertion of Fe(II) Into Protoporphyrin IX to Form Heme

Protoporphyrin IX is converted to heme by the insertion of Fe(II) into the tetrapyrrole nucleus by **ferrochelatase**, a protein that is associated with the inner mitochondrial membrane on the matrix side. The X-ray structure of human ferrochelatase in complex with its heme product (Fig. 26-40), determined by Harry Dailey and William Lanzilotta, reveals that the 369-residue subunits of this homodimeric protein consist of two structurally similar domains and a C-terminal extension that occurs only in animal ferrochelatases (Fig. 26-40). This C-terminal extension participates in hydrogen bonding between the monomers; bacterial ferrochelatases, which lack

this extension, are monomeric although they are otherwise structurally similar to the human enzyme despite their only ~10% sequence identity. In addition, the C-terminal extension is bound to the N-terminal domain by an unusual [2Fe–2S] cluster that is coordinated by C196 of the N-terminal domain and C403, C406, and C411 of the C-terminal extension. The function of this [2Fe–2S] cluster, which is distant from the active site, is unclear although it appears likely that it only has a structural role. Nevertheless, three mutations, C406Y, C406S, and C411G, that inactivate the enzyme and thereby cause the rare inherited disease **erythropoietic protoporphyria** (see below) demonstrate the importance of the [2Fe–2S] cluster for activity.

The ferrochelatase active site (Fig. 26-40) consists of two hydrophobic lips that, it has been proposed, participate in the enzyme's association with the inner mitochondrial membrane. The ferrochelatase reaction follows an ordered mechanism in which the Fe(II) binds to the enzyme before the porphyrin. The reaction requires that the two pyrrole NH protons be removed from the porphyrin prior to the binding of the Fe(II) (Fig. 26-39). The invariant H263 appears properly positioned to abstract these protons from the porphyrin (Fig. 26-40), a hypothesis that is supported by mutagenesis studies. Structural and spectroscopic studies indicate that the metalation reaction is accompanied by the folding of the porphyrin by ~12° to a nonplanar conformation. Product release is then facilitated by the partial unwinding of a structurally conserved  $\pi$  helix (Fig. 26-40;  $\pi$  helices are discussed in Section 8-1Bb).

**Figure 26-40** X-ray structure of human ferrochelatase in complex with its heme product. A subunit of this homodimeric protein is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red), but with its conserved  $\pi$  helix (residues 340–360) magenta. The bound heme and [2Fe–2S] cluster are shown in space-filling form with C green, N blue, O red, S yellow, and Fe orange. The side chain of the catalytically essential His 263 is drawn in stick form with C cyan and N blue. [Based on an X-ray structure by Harry Dailey and William Lanzilotta, University of Georgia. PDBid 2QD3.]

#### h. Heme Biosynthesis Is Regulated Differently in Erythroid and Liver Cells

The two major sites of heme biosynthesis are erythroid cells, which synthesize ~85% of the body's heme groups, and the liver, which synthesizes ~80% of the remainder. An important function of heme in liver is as the prosthetic groups of the **cytochromes P450**, a family of oxidative enzymes involved in detoxification (Section 15-4Bc), whose members are required throughout a liver cell's lifetime in amounts that vary with conditions. In contrast, erythroid cells, in which heme is, of course, a hemoglobin component, engage in heme synthesis only on differentiation, when they synthesize hemoglobin in vast quantities. This is a one-time synthesis; the heme must last the erythrocyte's lifetime (normally 120 days) since heme and hemoglobin synthesis stop on red cell maturation (protein synthesis stops on the loss of nuclei and ribosomes). The different ways in which heme biosynthesis is regulated in liver and in erythroid cells reflect these different demands: In liver, heme biosynthesis must really be "controlled," whereas in erythroid cells, the process is more like breaking a dam.

In liver, the main control target in heme biosynthesis is ALA synthase, the enzyme catalyzing the pathway's first committed step. Heme, or its Fe(III) oxidation product **hemin**, controls this enzyme's activity through three mechanisms: (1) feedback inhibition, (2) inhibition of the transport of ALA synthase (ALAS) from its site of synthesis in the cytosol to its reaction site in the mitochondrion (Fig. 26-39), and (3) repression of ALAS synthesis.

In erythroid cells, heme exerts quite a different effect on its biosynthesis. Heme induces, rather than represses, protein synthesis in reticulocytes (immature erythrocytes). Although the vast majority of the protein synthesized by reticulocytes is globin, heme may also induce these cells to synthesize the enzymes of the heme biosynthesis pathway. Moreover, the rate-determining step of heme biosynthesis in erythroid cells may not be the ALA synthase reaction, which in mammalian reticulocytes is catalyzed by a different isozyme (**ALAS-2**) than the ALA synthase that is expressed in other cells (**ALAS-1**). Experiments on various systems of differentiating erythroid cells implicate ferrochelatase and porphobilinogen deaminase in the control of heme biosynthesis in these cells. There are also indications that cellular uptake of iron may be rate limiting. Iron is transported in the plasma complexed with the iron transport protein **transferrin**. The rate at which the iron–transferrin complex enters most cells, including those of liver, is controlled by receptor-mediated endocytosis (Section 12-5Bc). However, lipid-soluble iron complexes that diffuse directly into reticulocytes stimulate *in vitro* heme biosynthesis. The existence of several control points supports the supposition that when erythroid heme biosynthesis is “switched on,” all of its steps function at their maximal rates rather than any one step limiting the flow through the pathway. Heme-stimulated synthesis of globin also ensures that heme and globin are synthesized in the correct ratio for assembly into hemoglobin (Section 32-4Aa).

#### i. Porphyrins Have Bizarre Symptoms

Seven sets of genetic defects in heme biosynthesis, in liver or erythroid cells, are recognized. All involve the accumulation of porphyrin and/or its precursors and are therefore known as **porphyrias** (Greek: *porphyra*, purple). Two such defects are known to affect erythroid cells: uroporphyrinogen III synthase deficiency (**congenital erythropoietic porphyria**) and ferrochelatase deficiency (**erythropoietic protoporphyria**). The former results in accumulation of uroporphyrinogen I and its decarboxylation product **coproporphyrinogen I**. Excretion of these compounds colors the urine red, their deposition in the teeth turns them a fluorescent reddish brown, and their accumulation in the skin renders it extremely photosensitive such that it ulcerates and forms disfiguring scars. Increased hair growth is also observed in afflicted individuals such that fine hair may cover much of the face and extremities. These symptoms have prompted speculation that the werewolf legend has a biochemical basis.

The most common porphyria that primarily affects liver is porphobilinogen deaminase deficiency (**acute intermittent porphyria**). This disease is marked by intermittent attacks of abdominal pain and neurological dysfunction, often brought about by infection, fasting, certain drugs, alcohol, steroids, and other chemicals, all of which induce the expression of ALAS-1. Excessive amounts of ALA and PBG are excreted in the urine during and after such attacks. The urine may become red resulting from the excretion of excess porphyrins synthesized from PBG in nonhepatic cells although the skin does not become unusually photosensitive. King George III,

who ruled England during the American Revolution, and who has been widely portrayed as being mad, in fact had attacks characteristic of acute intermittent porphyria, was reported to have urine the color of port wine, and had several descendants who were diagnosed as having this disease. American history might have been quite different had George III not inherited this metabolic defect.

#### j. Heme Is Degraded to Bile Pigments

At the end of their lifetime, red cells are removed from the circulation and their components degraded. Heme catabolism (Fig. 26-41) begins with oxidative cleavage, by **heme oxygenase**, of the porphyrin between rings A and B to form **biliverdin**, a green linear tetrapyrrole. Biliverdin's central methenyl bridge (between rings C and D) is then reduced to form the red-orange **bilirubin**. The changing colors of a healing bruise are a visible manifestation of heme degradation.

The highly lipophilic bilirubin is insoluble in aqueous solutions. Like other lipophilic metabolites, such as free fatty acids, it is transported in the blood in complex with serum albumin. In the liver, its aqueous solubility is increased by esterification of its two propionate side groups with glucuronic acid, yielding **bilirubin diglucuronide**, which is secreted into the bile. Bacterial enzymes in the large intestine hydrolyze the glucuronic acid groups and, in a multistep process, convert bilirubin to several products, most notably **urobilinogen**. Some urobilinogen is reabsorbed and transported via the bloodstream to the kidney, where it is converted to the yellow **urobilin** and excreted, thus giving urine its characteristic color. Most of the urobilinogen, however, is microbially converted to the deeply red-brown **stercobilin**, the major pigment of feces.

When the blood contains excessive amounts of bilirubin, the deposition of this highly insoluble substance colors the skin and the whites of the eyes yellow. This condition, called **jaundice** (French: *jaune*, yellow), signals either an abnormally high rate of red cell destruction, liver dysfunction, or bile duct obstruction. Newborn infants, particularly when premature, often become jaundiced because their livers do not yet make sufficient **bilirubin UDP-glucuronosyltransferase** to glucuronidate the incoming bilirubin. Jaundiced infants are treated by bathing them with light from a fluorescent lamp; this photochemically converts bilirubin to more soluble isomers that the infant can degrade and excrete.

#### k. Hemoglobin's Reduced Affinity for CO Prevents Asphyxiation

In the reaction forming biliverdin, the methenyl bridge carbon between porphyrin rings A and B is released as CO (Fig. 26-41, *top*), which, we have seen, is a tenacious heme ligand (with 200-fold greater affinity for hemoglobin and myoglobin than O<sub>2</sub>; Section 10-1A). Consequently, ~1% of hemoglobin's O<sub>2</sub>-binding sites are blocked by CO, even in the absence of air pollution. However, free heme in solution binds CO with 20,000-fold greater affinity than it binds O<sub>2</sub>. Thus, the globin (protein) portion of hemoglobin (and likewise myoglobin) somehow lowers the affinity of its bound heme for CO, thereby making O<sub>2</sub> transport possible. How does the globin do so?

**Figure 26-41** The heme degradation pathway. M, V, P, and E, respectively, represent methyl, vinyl, propionyl, and ethyl groups.

Early X-ray structures of **carboxymyoglobin** (myoglobin with a CO ligand) indicated that the bound CO was inclined from the normal to the heme plane by  $40^\circ$  to  $60^\circ$  (the  $Fe-C-O$  bond angle appeared to be  $120^\circ$  to  $140^\circ$ ), approximately the same angle with which  $O_2$  binds to heme (Fig. 10-12). Yet, in complexes of CO with porphyrins in the absence of protein, the CO is normal to the heme plane. This suggested that the globin (in both myoglobin and

hemoglobin) sterically bends the bound CO away from its preferred linear geometry, thereby reducing its affinity for CO and hence permitting the CO to be slowly exhaled. However, a variety of spectroscopic investigations together with highly accurate X-ray structures of carboxymyoglobin revealed that the bound CO is, in fact, inclined from the normal to the heme plane by  $\sim 7^\circ$ , a distortion that is too small to explain the reduced affinity of myoglobin for CO.

Of course, this reduced affinity might instead be explained by the distortions that the upright CO ligand imposes on the globin, presumably via the distal His (E7, the His residue that hydrogen bonds to the bound O<sub>2</sub>; Section 10-2A). However, studies of the energetics of binding of CO and O<sub>2</sub> to myoglobins in which His E7 has been mutated to nonpolar residues of comparable bulk (e.g., Leu) indicate that this is not the main determinant of the ligand affinity changes. Rather, the reduction in affinity of myoglobin for CO relative to that for O<sub>2</sub> has been shown to arise from the greater hydrogen bonding affinity that His E7 has for O<sub>2</sub> relative to CO together with electrostatic effects due to the differing charge distributions in the O<sub>2</sub> and CO ligands.

### I. Chloroquine Prevents Malaria by Inhibiting Plasmodial Heme Sequestration

Malaria is caused by the mosquito-borne parasite *Plasmodium falciparum* (Section 7-3Ab), which multiplies within and destroys red blood cells in a 2-day cycle. During the intraerythrocytic stages of its life cycle, the parasite partially meets its nutritional needs by proteolyzing up to ~80% of the host cell's hemoglobin in its so-called acid food vacuole, whose pH is 4.7. This process releases heme, which in its soluble form, is toxic to the parasite because it damages cell membranes and inhibits a variety of enzymes. Since, unlike their human hosts, plasmodia cannot degrade heme, they sequester it within their food vacuoles in the form of harmless dark brown granules known as **hemozoin**, which consist of crystals of dimerized hemes linked together by reciprocal iron-carboxylate bonds between the ferric ions and the propionate side chains of adjacent molecules. Hemozoin has been found to be identical to **β-hematin**,

whose X-ray structure has been determined. Dimers interact in the crystals through hydrogen bonds between the remaining carboxyl groups.

### Chloroquine,

a member of the quinoline ring-containing family of antimalarials, which includes **quinine**, is one of the most successful antimicrobial agents that has been produced. It is effective against plasmodia only during their intraerythrocytic stages. This drug, being a weak base that can readily pass through membranes in its uncharged form, accumulates in the plasmodial acid food vacuole in its acidic (charged) form in millimolar concentrations. Chloroquine and several other quinoline-containing antimalarials inhibit the crystallization of hemes to form hemozoin. This inhibition *in vivo* is almost certainly responsible for the antimalarial properties of these drugs. The mechanism of inhibition is as yet unclear although a plausible hypothesis is that the drug adsorbs onto crystallized hemozoin, inhibiting further crystallization.

The massive use of chloroquine has, unfortunately, led to the appearance of chloroquine-resistant plasmodia in nearly every malarial region of the world. Resistant plasmodia do not concentrate chloroquine in their food vacuoles to the high levels found in sensitive parasites. Rather, they export this drug out of their food vacuoles at an ~50-fold higher rate than do sensitive organisms. Since chloroquine activity and chloroquine resistance have different mechanisms, it has been possible to modify existing quinoline-containing structures and to develop new hemozoin crystallization inhibitors that are effective antimalarial agents but to which plasmodia are not (yet) resistant.

### B. Biosynthesis of Physiologically Active Amines

*Epinephrine, norepinephrine, dopamine, serotonin (5-hydroxytryptamine), γ-aminobutyric acid (GABA), and*

## histamine

X = OH, R = CH<sub>3</sub> **Epinephrine (Adrenalin)**  
 X = OH, R = H **Norepinephrine**  
 X = H, R = H **Dopamine**

**Serotonin**  
(5-hydroxytryptamine)

**Histamine**

are hormones and/or neurotransmitters derived from amino acids. For instance, epinephrine, as we have seen, activates muscle adenylate cyclase, thereby stimulating glycogen breakdown (Section 18-3E); deficiency in dopamine production is associated with **Parkinson's disease**, a degenerative condition causing "shaking palsy"; serotonin causes smooth muscle contraction; GABA is one of the brain's major inhibitory neurotransmitters (Section 20-5Cf), being released at 30% of its synapses; and histamine is involved in allergic responses (as allergy sufferers who take antihistamines will realize), as well as in the control of acid secretion by the stomach (Section 20-3C).

The biosynthesis of each of these physiologically active amines involves decarboxylation of the corresponding precursor amino acid. Amino acid decarboxylases are PLP-dependent enzymes that form a PLP-Schiff base with the

substrate so as to stabilize the C <sub>$\alpha$</sub>  carbanion formed on C <sub>$\alpha$</sub> -COO<sup>-</sup> bond cleavage (Section 26-1Aa):

Formation of histamine and GABA are one-step processes (Fig. 26-42). In the synthesis of serotonin from tryptophan, the decarboxylation is preceded by a hydroxylation (Fig. 26-43) by **tryptophan hydroxylase**, one of three mammalian enzymes that has a 5,6,7,8-tetrahydrobiopterin cofactor (Section 26-3Ha). This hydroxylation involves an NIH shift similar to that occurring in phenylalanine hydroxylase (Fig. 26-30), although no epoxide intermediate has been observed in this case. Dopamine, norepinephrine, and epinephrine are all termed **catecholamines** because they are amine derivatives of **catechol**:

**Catechol**

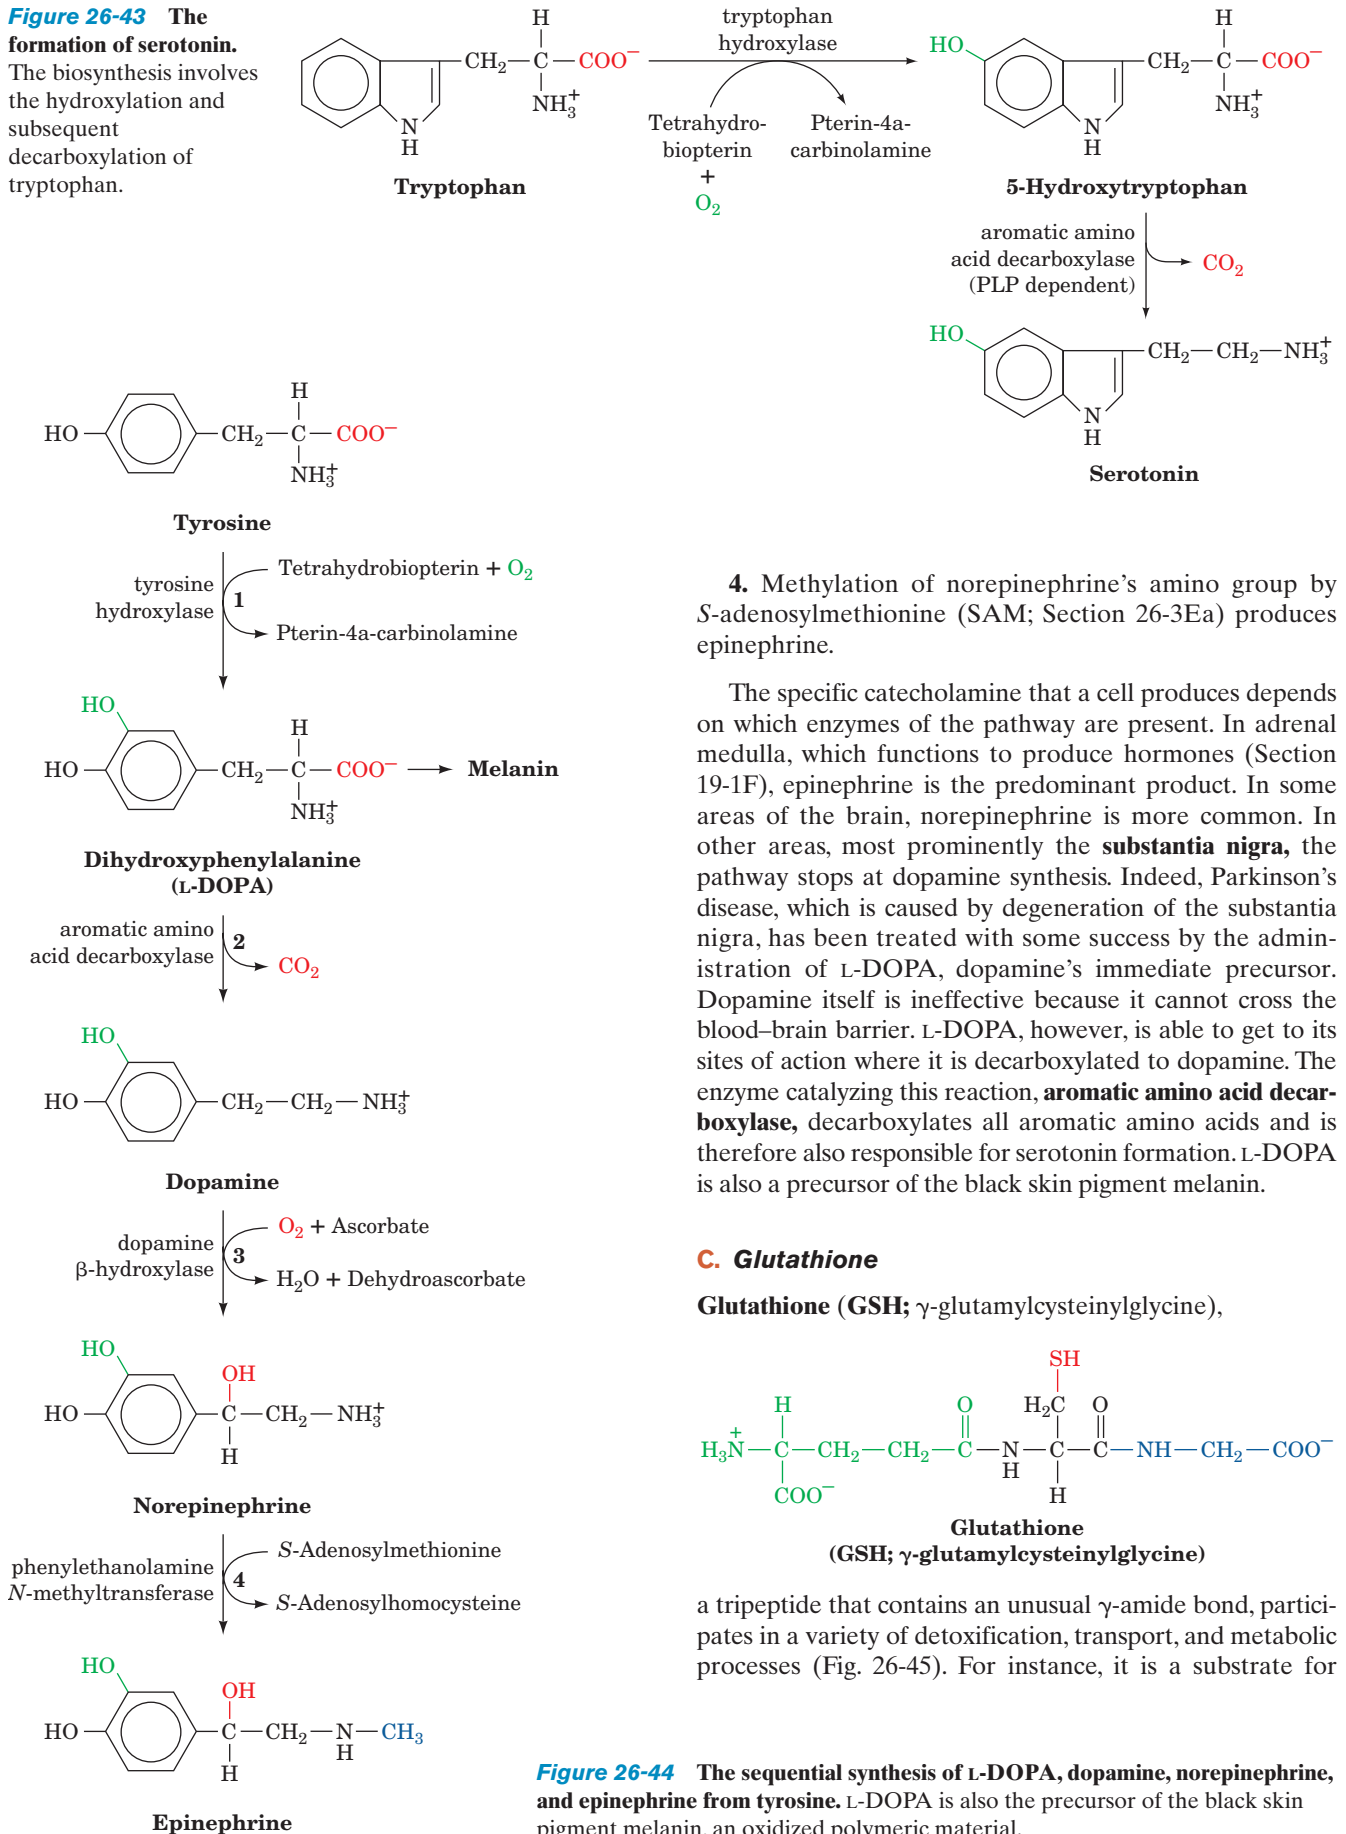

The conversion of tyrosine to these various catecholamines occurs as follows (Fig. 26-44):

1. Tyrosine is hydroxylated to **3,4-dihydroxyphenylalanine (L-DOPA)** by **tyrosine hydroxylase**, another 5,6,7,8-tetrahydrobiopterin-requiring enzyme.
2. L-DOPA is decarboxylated to dopamine.
3. A second hydroxylation yields norepinephrine.

**Figure 26-42** The formation of  $\gamma$ -aminobutyric acid (GABA) and histamine. The reactions involve the decarboxylations of glutamate to form GABA and of histidine to form histamine.

**Figure 26-43** The formation of serotonin. The biosynthesis involves the hydroxylation and subsequent decarboxylation of tryptophan.

4. Methylation of norepinephrine's amino group by S-adenosylmethionine (SAM; Section 26-3Ea) produces epinephrine.

The specific catecholamine that a cell produces depends on which enzymes of the pathway are present. In adrenal medulla, which functions to produce hormones (Section 19-1F), epinephrine is the predominant product. In some areas of the brain, norepinephrine is more common. In other areas, most prominently the **substantia nigra**, the pathway stops at dopamine synthesis. Indeed, Parkinson's disease, which is caused by degeneration of the substantia nigra, has been treated with some success by the administration of L-DOPA, dopamine's immediate precursor. Dopamine itself is ineffective because it cannot cross the blood-brain barrier. L-DOPA, however, is able to get to its sites of action where it is decarboxylated to dopamine. The enzyme catalyzing this reaction, **aromatic amino acid decarboxylase**, decarboxylates all aromatic amino acids and is therefore also responsible for serotonin formation. L-DOPA is also a precursor of the black skin pigment melanin.

### C. Glutathione

**Glutathione (GSH;  $\gamma$ -glutamylcysteinylglycine)**,

a tripeptide that contains an unusual  $\gamma$ -amide bond, participates in a variety of detoxification, transport, and metabolic processes (Fig. 26-45). For instance, it is a substrate for

**Figure 26-44** The sequential synthesis of L-DOPA, dopamine, norepinephrine, and epinephrine from tyrosine. L-DOPA is also the precursor of the black skin pigment melanin, an oxidized polymeric material.

**Figure 26-45** Some reactions involving glutathione. The reactions and enzymes are (1) peroxide detoxification by **glutathione peroxidase**, (2) regeneration of GSH from GSSG by glutathione reductase (Section 21-2Ba), (3) thiol transferase modulation of protein thiol–disulfide balance, and (4) leukotriene biosynthesis by a glutathione-*S*-transferase.

peroxidase reactions, helping to destroy peroxides generated by oxidases; it is involved in leukotriene biosynthesis (Section 25-7Cb); and the balance between its reduced (GSH) and oxidized (GSSG) forms maintains the sulfhydryl groups of intracellular proteins in their correct oxidation states.

The  **$\gamma$ -glutamyl cycle**, which was elucidated by Alton Meister, provides a vehicle for the energy-driven transport

of amino acids into cells through the synthesis and breakdown of GSH (Fig. 26-46). GSH is synthesized from glutamate, cysteine, and glycine by the consecutive action of  **$\gamma$ -glutamylcysteine synthetase** and **GSH synthetase** (Fig. 26-46, Reactions 1 and 2). ATP hydrolysis provides the free energy for each reaction. The carboxyl group is activated for peptide bond synthesis by formation of an acyl phosphate intermediate:

The breakdown of GSH is catalyzed by  **$\gamma$ -glutamyl transpeptidase**,  **$\gamma$ -glutamyl cyclotransferase**, **5-oxoprolinase**, and an intracellular protease (Fig. 26-46, Reactions 3–6).

Amino acid transport occurs because, whereas GSH is synthesized intracellularly and is located largely within the cell,  $\gamma$ -glutamyl transpeptidase, which catalyzes GSH breakdown (Fig. 26-46, Reaction 3), is situated on the cell membrane's external surface and accepts amino acids, notably cysteine and methionine. GSH is first transported to the

**Figure 26-46** Glutathione synthesis as part of the  **$\gamma$ -glutamyl cycle of glutathione metabolism**. The cycle's reactions are catalyzed by (1)  **$\gamma$ -glutamylcysteine synthetase**, (2) **glutathione**

**synthetase**, (3)  **$\gamma$ -glutamyl transpeptidase**, (4)  **$\gamma$ -glutamyl cyclotransferase**, (5) **5-oxoprolinase**, and (6) an intracellular protease.

**Figure 26-47** Tetrahydrofolate (THF).

external surface of the cell membrane, where the transfer of the  $\gamma$ -glutamyl group from GSH to an external amino acid occurs. The  $\gamma$ -glutamyl amino acid is then transported back into the cell and converted to glutamate by a two-step process in which the transported amino acid is released and **5-oxoproline** is formed as an intermediate. The last step in the cycle, the hydrolysis of 5-oxoproline, requires ATP hydrolysis. This surprising observation (amide bond hydrolysis is almost always an exergonic process) is a consequence of 5-oxoproline's unusually stable internal amide bond.

#### D. Tetrahydrofolate Cofactors: The Metabolism of $C_1$ Units

Many biosynthetic processes involve the addition of a  $C_1$  unit to a metabolic precursor. A familiar example is carboxylation. For instance, gluconeogenesis from pyruvate begins with the addition of a carboxyl group to form oxaloacetate (Section 23-1Aa). The coenzyme involved in this and most other carboxylation reactions is biotin (Section 23-1Ab). In contrast, *S*-adenosylmethionine functions as a methylating agent (Section 26-3Ea).

**Tetrahydrofolate (THF)** is more versatile than the above cofactors in that it functions to transfer  $C_1$  units in several oxidation states. THF is a 6-methylpterin derivative linked in sequence to *p*-aminobenzoic acid and Glu residues (Fig. 26-47). Up to five additional Glu residues may be linked to the first glutamate via isopeptide bonds to form a polyglutamyl tail.

THF is derived from **foliac acid** (Latin: *folium*, leaf), a doubly oxidized form of THF that must be enzymatically reduced before it becomes an active coenzyme (Fig. 26-48). Both reductions are catalyzed by **dihydrofolate reductase (DHFR)**. Mammals cannot synthesize folic acid and so must obtain it from their diets or from intestinal microorganisms.

$C_1$  units are covalently attached to THF at its positions N5, N10, or both N5 and N10. These  $C_1$  units, which may be at the oxidation levels of formate, formaldehyde, or methanol (Table 26-1), are all interconvertible by enzymatic redox reactions (Fig. 26-49).

The main entry of  $C_1$  units into the THF pool is as  **$N^5, N^{10}$ -methylene-THF** through the conversion of serine to glycine by serine hydroxymethyltransferase (Sections 26-3Bb and 26-5Ae) and the cleavage of glycine by glycine synthase (the glycine cleavage system; Section 26-3Ba, Fig. 26-14). Histidine also contributes  $C_1$  units through its degradation with the formation of  **$N^5$ -formimino-THF** (Fig. 26-17, Reaction 11).

A  $C_1$  unit in the THF pool can have several fates (Fig. 26-50):

1. It may be used directly as  $N^5, N^{10}$ -methylene-THF in the conversion of the deoxynucleotide dUMP to dTMP by **thymidylate synthase** (Section 28-3Bb).
2. It may be reduced to  **$N^5$ -methyl-THF** for the synthesis of methionine from homocysteine (Section 26-3Ea).
3. It may be oxidized through  $N^5, N^{10}$ -methenyl-THF to  **$N^{10}$ -formyl-THF** for use in the synthesis of purines (Section

**Figure 26-48** The two-stage reduction of folate to THF. Both reactions are catalyzed by dihydrofolate reductase (DHFR).

**Table 26-1** Oxidation Levels of C<sub>1</sub> Groups Carried by THF

Oxidation Level	Group Carried	THF Derivative(s)
Methanol	Methyl (—CH <sub>3</sub> )	N <sup>5</sup> -Methyl-THF
Formaldehyde	Methylene (—CH <sub>2</sub> —)	N <sup>5</sup> ,N <sup>10</sup> -Methylene-THF
Formate	Formyl (—CH=O)	N <sup>5</sup> -Formyl-THF, N <sup>10</sup> -formyl-THF
	Formimino (—CH=NH)	N <sup>5</sup> -Formimino-THF
	Methenyl (—CH=)	N <sup>5</sup> ,N <sup>10</sup> -Methenyl-THF

28-1A). Since the purine ring of ATP is involved in histidine biosynthesis in microorganisms and plants (Section 26-5Be), N<sup>10</sup>-formyl-THF is indirectly involved in this pathway as

well. Prokaryotes use N<sup>10</sup>-formyl-THF in a formylation reaction yielding **formylmethionyl-tRNA**, which they require for the initiation of protein synthesis (Section 32-3Ca).

**Figure 26-49** Interconversion of the C<sub>1</sub> units carried by THF.

**Figure 26-50** The biosynthetic fates of the C<sub>1</sub> units in the THF pool.

A deficiency in folic acid results in **megaloblastic anemia**, a condition in which erythrocytes in the blood are replaced by fewer abnormally large erythrocytes known as **macrocytes**. This occurs as a consequence of the lack of  $N^5,N^{10}$ -methylene-THF, which is required for the synthesis of the DNA precursor deoxythymidine monophosphate from deoxyuridine monophosphate (Section 28-3Bb). Pernicious anemia (vitamin B<sub>12</sub> deficiency; Section 25-2Ee) has similar anemic symptoms. This is because the irreversibility of the reaction forming  $N^5$ -methyl-THF and the now inactive coenzyme B<sub>12</sub>-dependent methionine synthase (top of Fig. 26-49), the only mammalian enzyme that utilizes  $N^5$ -methyl-THF, result in folates becoming trapped in their  $N^5$ -methyl-THF form. Consequently, the anemic symptoms of pernicious anemia may be alleviated by the administration of folic acid but this does not relieve its neurological symptoms.

**Sulfonamides (sulfa drugs)** such as **sulfanilamide** are antibiotics that are structural analogs of the *p*-aminobenzoic acid constituent of THF:

They competitively inhibit bacterial synthesis of THF at the *p*-aminobenzoic acid incorporation step, thereby blocking the above THF-requiring reactions. The inability of mammals to synthesize folic acid leaves them unaffected by sulfonamides, which accounts for the medical utility of these widely used antibacterial agents.

## 5 AMINO ACID BIOSYNTHESIS

Many amino acids are synthesized by pathways that are present only in plants and microorganisms. Since mammals must obtain these amino acids in their diets, these substances are known as **essential amino acids**. The other amino acids, which can be synthesized by mammals from common intermediates, are termed **nonessential amino**

**acids**. Their  $\alpha$ -keto acid carbon skeletons are converted to amino acids by transamination reactions (Section 26-1A) utilizing the preformed  $\alpha$ -amino nitrogen of another amino acid, usually glutamate. Yet, although it was originally presumed that glutamate can be synthesized from ammonia and  $\alpha$ -ketoglutarate by glutamate dehydrogenase acting in reverse, it now appears that the predominant physiological direction of this enzyme is glutamate breakdown (Section 26-1B). Consequently, *preformed  $\alpha$ -amino nitrogen should also be considered to be an essential nutrient*. In this context, it is interesting to note that, in addition to the four well-known taste receptors, those for sweet, sour, salty, and bitter tastes, a fifth taste receptor has been characterized, that for the meaty taste of **monosodium glutamate (MSG)**, which is known as **umami** (Japanese: flavor).

The essential and nonessential amino acids for humans are listed in Table 26-2. Arginine is classified as essential, even though it is synthesized by the urea cycle (Section 26-2D), because it is required in greater amounts than can be produced by this route during the normal growth and development of children (but not adults). The essential amino acids occur in animal and vegetable proteins. Different proteins, however, contain different proportions of the essential amino acids. Milk proteins, for example, contain them all in the proportions required for proper human nutrition. Bean protein, on the other hand, contains an abundance of lysine but is deficient in methionine, whereas wheat is deficient in lysine but contains ample methionine. A balanced protein diet therefore must contain a variety of different protein sources that complement each other to supply the proper proportions of all the essential amino acids.

In this section we study the pathways involved in the formation of the nonessential amino acids. We also briefly consider such pathways for the essential amino acids as they occur in plants and microorganisms. You should note, however, that although we discuss some of the most common pathways for amino acid biosynthesis, there is considerable variation in these pathways among different species. In contrast, as we have seen, the basic pathways of carbohydrate and lipid metabolism are all but universal.

### A. Biosynthesis of the Nonessential Amino Acids

*All the nonessential amino acids except tyrosine are synthesized by simple pathways leading from one of four common metabolic intermediates: pyruvate, oxaloacetate,  $\alpha$ -ketoglutarate, and 3-phosphoglycerate.* Tyrosine, which is really misclassified as nonessential, is synthesized by the one-step hydroxylation of the essential amino acid phenylalanine (Section 26-3H). Indeed, the dietary requirement for phenylalanine reflects the need for tyrosine as well. The presence of dietary tyrosine therefore decreases the need for phenylalanine. Since preformed  $\alpha$ -amino nitrogen in the form of glutamate is an essential nutrient for nonessential

**Table 26-2 Essential and Nonessential Amino Acids in Humans**

Essential	Nonessential
Arginine <sup>a</sup>	Alanine
Histidine	Asparagine
Isoleucine	Aspartate
Leucine	Cysteine
Lysine	Glutamate
Methionine	Glutamine
Phenylalanine	Glycine
Threonine	Proline
Tryptophan	Serine
Valine	Tyrosine

<sup>a</sup>Although mammals synthesize arginine, they cleave most of it to form urea (Sections 26-2D and 26-2E).

amino acid biosynthesis, we first discuss its production by plants and microorganisms.

#### a. Glutamate Is Synthesized by Glutamate Synthase

**Glutamate synthase**, an enzyme that occurs only in microorganisms, plants, and lower animals, converts

$\alpha$ -ketoglutarate and ammonia originating in glutamine to glutamate. The electrons required for this reductive amination come from NADPH or ferredoxin, depending on the organism. The NADPH-dependent glutamate synthase from the nitrogen-fixing bacterium *Azospirillum brasilense*, the best characterized such enzyme, is an  $\alpha_2\beta_2$  heterotetramer that binds an FAD and two [4Fe-4S] clusters on each  $\beta$  subunit, and an FMN and a [3Fe-4S] cluster on each  $\alpha$  subunit. The overall reaction is

and involves five steps that occur at three distinct active sites (Fig. 26-51):

1. Electrons are transferred from NADPH to FAD at active site 1 on the  $\beta$  subunit to yield  $\text{FADH}_2$ .
2. The electrons are transferred from the  $\text{FADH}_2$  to FMN at site 2 on a specific  $\alpha$  subunit through the iron-sulfur clusters to yield  $\text{FMNH}_2$ .
3. Glutamine is hydrolyzed to  $\alpha$ -glutamate and ammonia at site 3 on the  $\alpha$  subunit.
4. The ammonia produced is transferred to site 2 where it reacts with  $\alpha$ -ketoglutarate to form  $\alpha$ -iminoglutarate.

**Figure 26-51** The sequence of reactions catalyzed by glutamate synthase.

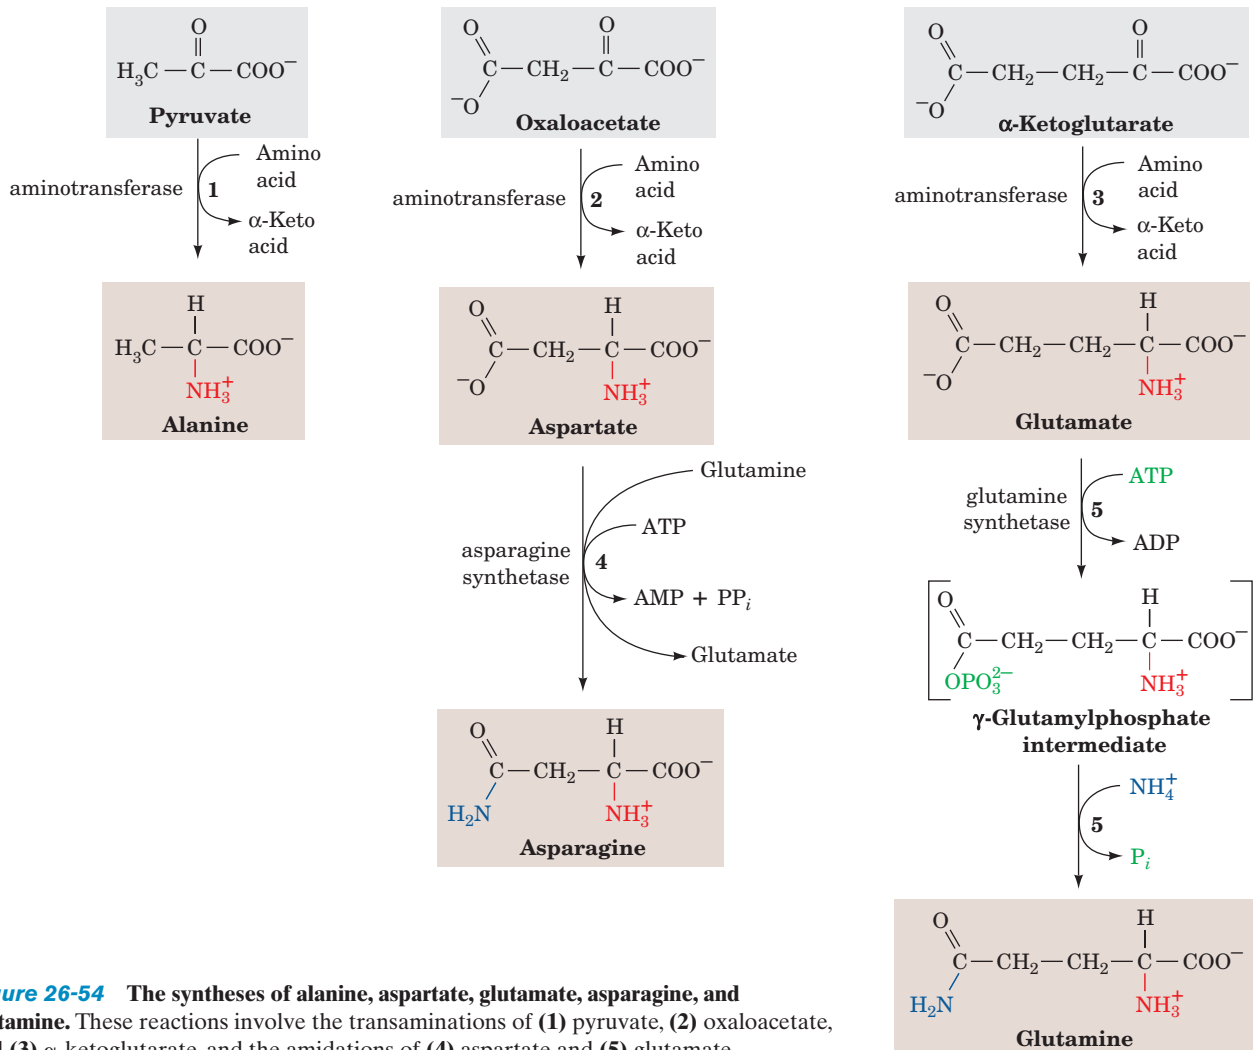

**Figure 26-53** The  $\beta$  helix of *A. brasilense* glutamate synthase. The polypeptide backbone (residues 1225–1416) is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). Neighboring turns of polypeptide chain within the  $\beta$  helix interact as do the strands of parallel  $\beta$  sheets. Nevertheless, the conformations of many of these segments lie outside the normal range for  $\beta$  strands, and hence they are drawn in coil form. [Based on an X-ray structure by Andrea Mattevi, Università degli Studi di Pavia, Italy. PDBid 1EA0.]

amino acid biosynthesis and having a glutamine amidotransferase domain include asparagine synthetase (Fig. 26-54, Reaction 4; see below), a member of the Ntn family, and imidazole glycerol phosphate synthase (Fig. 26-65, Reaction 5), which belongs to the triad family. All of these enzymes have an ammonia-channeling tunnel that connects the amidotransferase site with the ammonia-utilizing site.

**b. Alanine, Asparagine, Aspartate, Glutamate, and Glutamine Are Synthesized from Pyruvate, Oxaloacetate, and  $\alpha$ -Ketoglutarate**

Pyruvate, oxaloacetate, and  $\alpha$ -ketoglutarate are the keto acids that correspond to alanine, aspartate, and glutamate, respectively. Indeed, as we have seen (Section 26-1), the synthesis of each of these amino acids is a one-step

**Figure 26-54** The syntheses of alanine, aspartate, glutamate, asparagine, and glutamine. These reactions involve the transaminations of (1) pyruvate, (2) oxaloacetate, and (3)  $\alpha$ -ketoglutarate, and the amidations of (4) aspartate and (5) glutamate.

transamination reaction (Fig. 26-54, Reactions 1–3). Asparagine and glutamine are, respectively, synthesized from aspartate and glutamate by amidation (Fig. 26-54, Reactions 4 and 5). **Glutamine synthetase** catalyzes the formation of glutamine in a reaction in which ATP is hydrolyzed to ADP

**Figure 26-55** X-ray structure of *S. typhimurium* glutamine synthetase. The enzyme consists of 12 identical subunits, here represented by their C<sub>α</sub> backbones, arranged with D<sub>6</sub> symmetry (the symmetry of a hexagonal prism). (a) View down the 6-fold axis of symmetry showing only the six subunits of the upper ring in alternating blue and green. The subunits of the lower ring are roughly directly below those of the upper ring. The protein, including its side chains (not shown), has a diameter of 143 Å. The six active sites shown are marked by the pairs of Mn<sup>2+</sup> ions (magenta spheres; divalent metal ions, physiologically Mg<sup>2+</sup>, are required for enzymatic activity). Each adenylylation site, Tyr 397 (yellow), lies between two subunits at a higher radius than the corresponding active site. Also drawn in one active site are ADP (cyan) and phosphinothricin (orange), a competitive inhibitor of glutamate. (b) Side view along one of the enzyme's 2-fold axes showing only the eight nearest subunits. The molecule extends 103 Å along the 6-fold axis, which is vertical in this view. [Based on an X-ray structure by David Eisenberg, UCLA. PDBid 1FPY.]

and P<sub>i</sub> via the intermediacy of **γ-glutamylphosphate** and NH<sub>4</sub><sup>+</sup> is the amino group donor (Fig. 26-54, Reaction 5). Curiously, aspartate amidation by **asparagine synthetase** to form asparagine follows a different route; it utilizes glutamine as its amino group donor and hydrolyzes ATP to AMP+PP<sub>i</sub> (Fig. 26-54, Reaction 4). This enzyme is composed of a glutamine amidotransferase domain of the Ntn family (see above) and a second domain in which β-aspartyl-AMP

**β-Aspartyl-AMP**

is synthesized from Asp and ATP and then reacts with ammonia to form Asn. As with other glutamine amidotransferase-containing enzymes, the two domains are connected by a tunnel that channels ammonia between their two active sites.

### c. Glutamine Synthetase Is a Central Control Point in Nitrogen Metabolism

Glutamine, as we have seen, is the amino group donor in the formation of many biosynthetic products, as well as being a storage form of ammonia. Glutamine synthetase's consequent pivotal position in nitrogen metabolism makes its control a vital aspect of this process. In fact, mammalian glutamine synthetases are activated by α-ketoglutarate, the product of glutamate's oxidative deamination. This control presumably prevents the accumulation of the ammonia produced by that reaction.

Bacterial glutamine synthetase, as Earl Stadtman showed, has a much more elaborate control system. This enzyme, which consists of 12 identical 469-residue subunits arranged with D<sub>6</sub> symmetry (Fig. 26-55), is regulated by several effectors as well as by covalent modification. Although a complete description of this complex enzyme is not given here, several aspects of its catalytic and control systems bear note.

The X-ray structure of *Salmonella typhimurium* glutamine synthetase in complex with the glutamate structural analog **phosphinothricin**,

**Phosphinothricin**

**Glutamate**

determined by David Eisenberg, reveals that its catalytic sites occur at the interface between the C-terminal domain

of one subunit and the N-terminal domain of an adjacent subunit. These catalytic sites have a shape described as a “bifunnel” that opens at both the exposed top (ATP binding) and bottom (Glu and  $\text{NH}_4^+$  binding) of the molecule (between the two hexameric rings) and is narrow in the plane of its essential metal ions (two per subunit). Nucleotide binding induces conformational changes that increase the enzyme’s affinity for glutamate and ammonium ion, leading to an ordered sequential mechanism.

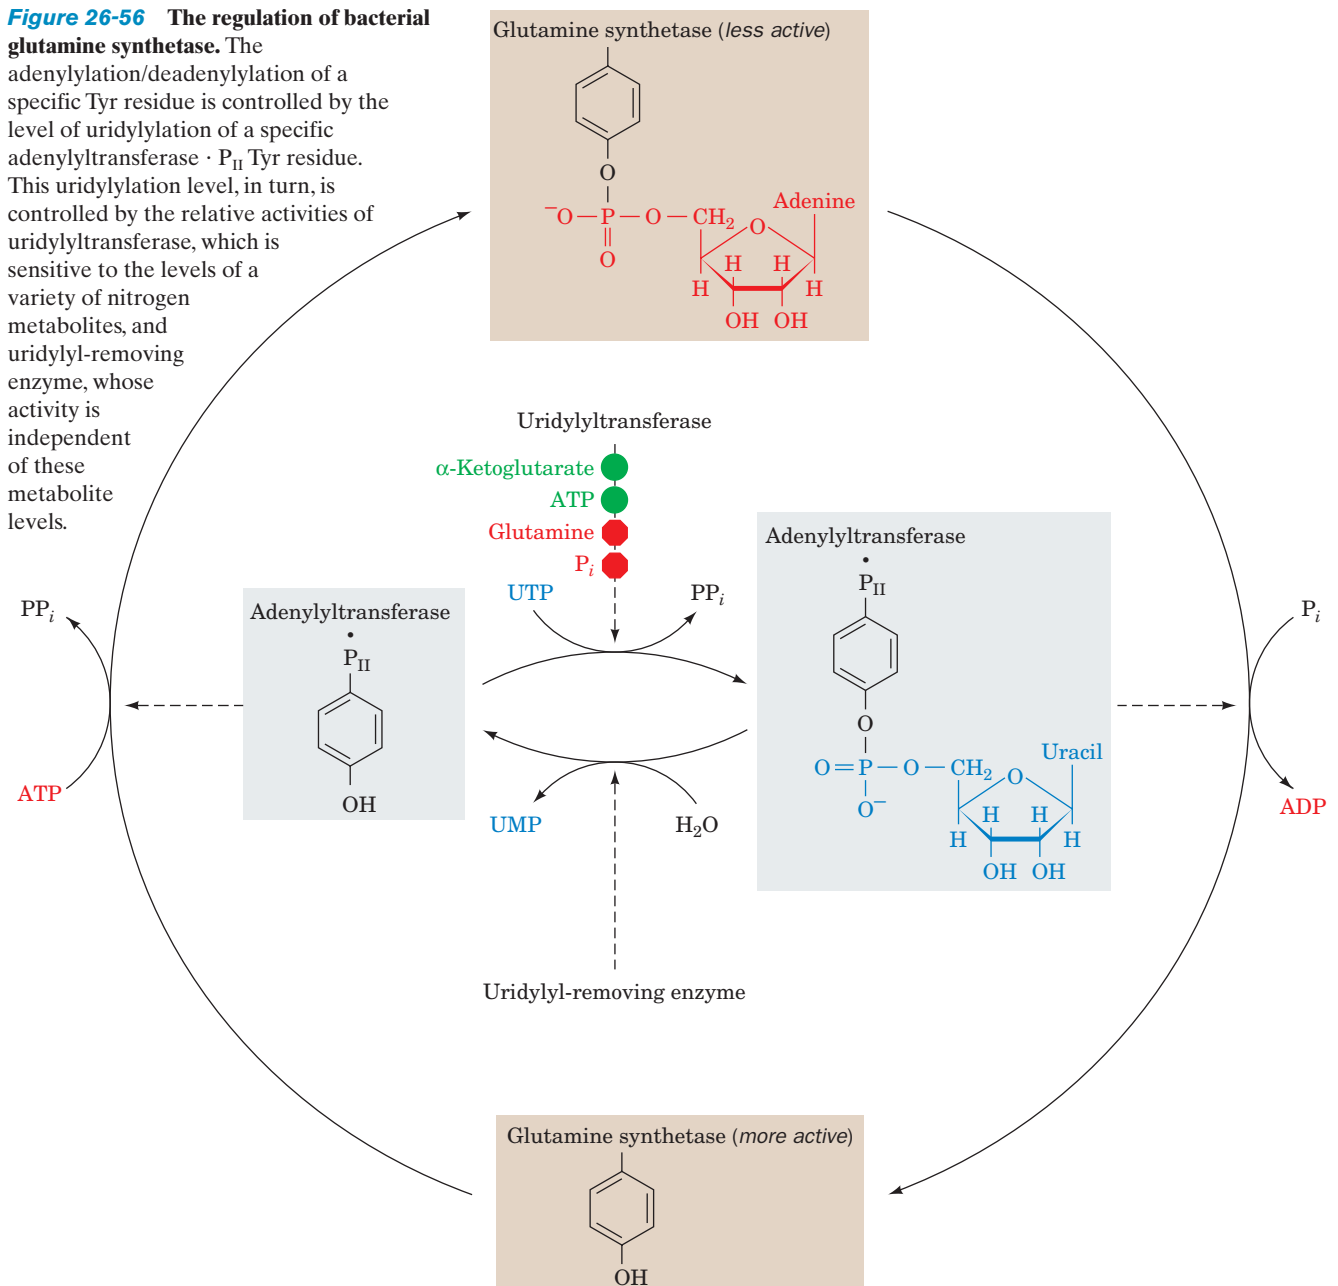

*Nine feedback inhibitors cumulatively control the activity of bacterial glutamine synthetase:* histidine, tryptophan, carbamoyl phosphate (as synthesized by carbamoyl phosphate synthetase II), glucosamine-6-phosphate, AMP, and CTP are all end products of pathways leading from glutamine, whereas alanine, serine, and glycine reflect the cell’s nitrogen

level. Several of these inhibitors act in a competitive manner, binding either to the glutamate binding site (serine, glycine, and alanine) or to the ATP binding site (AMP and CTP).

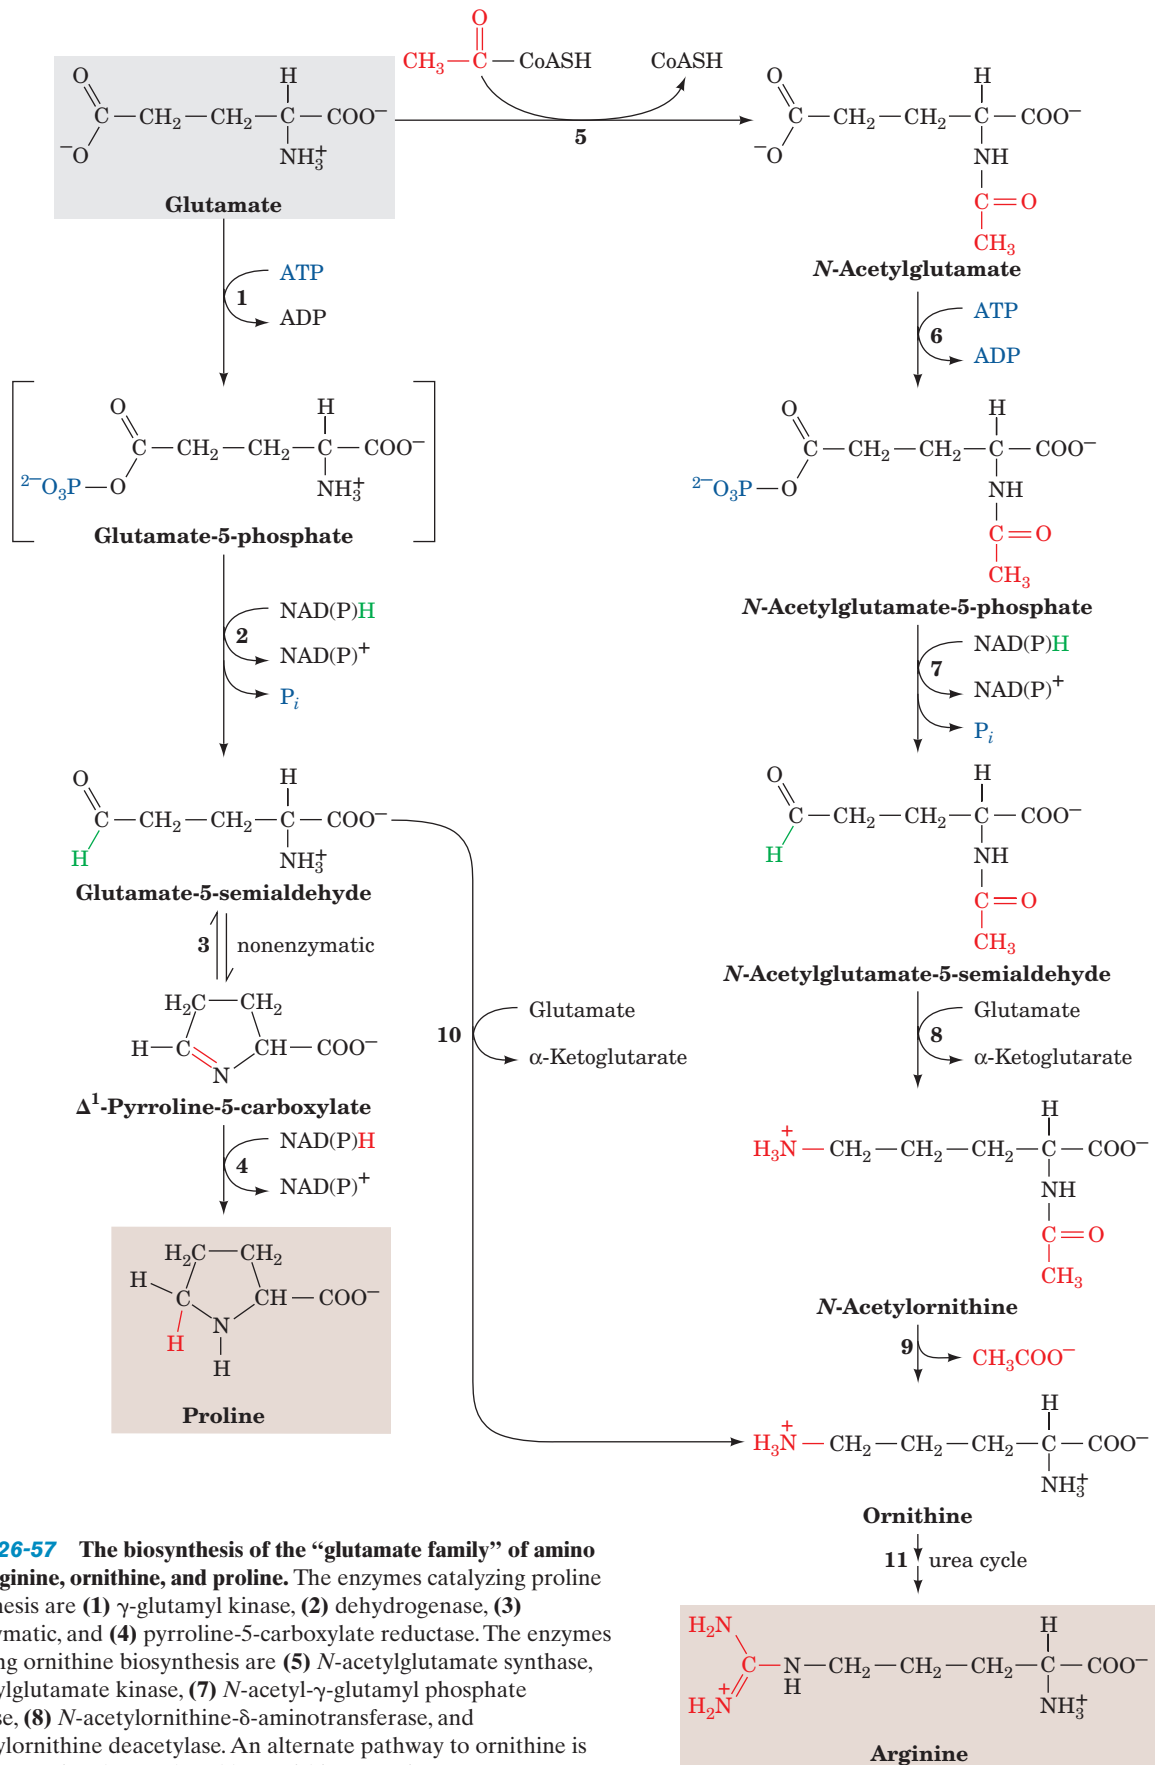

*E. coli glutamine synthetase is covalently modified by adenylation of a specific Tyr residue* (Fig. 26-56). The enzyme’s susceptibility to cumulative feedback inhibition increases, and its activity therefore decreases, with its degree of adenylation. The level of adenylation is controlled by a complex metabolic cascade that is conceptually similar to the one controlling glycogen phosphorylase (although the type of covalent modification differs in that glycogen phosphorylase is phosphorylated at a specific Ser residue; Section 18-3Ca). Both adenylation and deadenylation of glutamine synthetase are catalyzed by **adenylyltransferase** in complex with a tetrameric regulatory protein, **P<sub>II</sub>**. This

**Figure 26-56** The regulation of bacterial glutamine synthetase. The

adenylylation/deadenylylation of a specific Tyr residue is controlled by the level of uridylylation of a specific adenylyltransferase · P<sub>II</sub> Tyr residue. This uridylylation level, in turn, is controlled by the relative activities of uridylyltransferase, which is sensitive to the levels of a variety of nitrogen metabolites, and uridylyl-removing enzyme, whose activity is independent of these metabolite levels.

**Figure 26-57** The biosynthesis of the “glutamate family” of amino acids: arginine, ornithine, and proline. The enzymes catalyzing proline biosynthesis are (1)  $\gamma$ -glutamyl kinase, (2) dehydrogenase, (3) nonenzymatic, and (4) pyrroline-5-carboxylate reductase. The enzymes catalyzing ornithine biosynthesis are (5) *N*-acetylglutamate synthase, (6) acetylglutamate kinase, (7) *N*-acetyl- $\gamma$ -glutamyl phosphate reductase, (8) *N*-acetylornithine- $\delta$ -aminotransferase, and (9) acetylornithine deacetylase. An alternate pathway to ornithine is through Reaction 10, catalyzed by ornithine- $\delta$ -aminotransferase. Ornithine is converted to arginine (11) via the urea cycle (Fig. 26-7, Reactions 2–4).

complex deadenylylates glutamine synthetase when  $P_{II}$  is uridylylated (also at a Tyr residue) and adenylylates glutamine synthetase when  $P_{II}$  lacks UMP residues. The level of  $P_{II}$  uridylylation, in turn, depends on the relative activities of two enzymatic activities located on the same protein: a **uridylyltransferase** that uridylylates  $P_{II}$  and a **uridylyl-removing enzyme** that hydrolytically excises the attached UMP groups of  $P_{II}$  (Fig. 26-56). The uridylyltransferase is activated by  $\alpha$ -ketoglutarate and ATP and inhibited by glutamine and  $P_i$ , whereas uridylyl-removing enzyme is insensitive to these metabolites. This complex metabolic cascade therefore renders the activity of *E. coli* glutamine synthetase extremely responsive to the cell's nitrogen requirements.

#### d. Glutamate Is the Precursor of Proline, Ornithine, and Arginine

Conversion of glutamate to proline (Fig. 26-57, Reactions 1–4) involves the reduction of the  $\gamma$ -carboxyl group to an aldehyde followed by the formation of an internal Schiff base whose further reduction yields proline. Reduction of the glutamate  $\gamma$ -carboxyl group to an aldehyde is an endergonic process that is facilitated by the carboxyl group's prior phosphorylation by  **$\gamma$ -glutamyl kinase**. The unstable product, **glutamate-5-phosphate**, has not been isolated from reaction mixtures but is presumed to be the substrate for the reduction that follows. The resulting **glutamate-5-semialdehyde** cyclizes spontaneously to form the internal Schiff base  **$\Delta^1$ -pyrroline-5-carboxylate**. The final reduction to proline is catalyzed by **pyrroline-5-carboxylate reductase**. Whether the enzyme requires NADH or NADPH is unclear.

The *E. coli* pathway from glutamate to ornithine and hence to arginine likewise involves the ATP-driven reduction of the glutamate  $\gamma$ -carboxyl group to an aldehyde (Fig. 26-57, Reactions 6 and 7). Spontaneous cyclization of this intermediate, ***N*-acetylglutamate-5-semialdehyde**, is prevented by prior acetylation of its amino group by ***N*-acetylglutamate synthase** to form ***N*-acetylglutamate** (Fig. 26-57, Reaction 5). *N*-Acetylglutamate-5-semialdehyde, in turn, is converted to the corresponding amine by transamination (Fig. 26-57, Reaction 8). Hydrolysis of the acetyl protecting group finally yields ornithine, which, as we have seen (Section 26-2), is converted to arginine via the urea cycle. In humans, however, the pathway to ornithine is more direct. The *N*-acetylation of glutamate that protects it from cyclization does not occur. Rather, glutamate-5-semialdehyde, which is in equilibrium with  $\Delta^1$ -pyrroline-5-carboxylate, is directly transaminated to yield ornithine in a reaction catalyzed by **ornithine- $\delta$ -aminotransferase** (Fig. 26-57, Reaction 10).

#### e. Serine, Cysteine, and Glycine Are Derived from 3-Phosphoglycerate

Serine is formed from the glycolytic intermediate 3-phosphoglycerate in a three-reaction pathway (Fig. 26-58):

1. Conversion of 3-phosphoglycerate's 2-OH group to a ketone yielding **3-phosphohydroxypyruvate**, serine's phosphorylated keto acid analog.
2. Transamination of 3-phosphohydroxypyruvate to phosphoserine.
3. Hydrolysis of phosphoserine to yield serine.

**Figure 26-58** The conversion of 3-phosphoglycerate to serine. The pathway enzymes are (1) 3-phosphoglycerate dehydrogenase, (2) a PLP-dependent aminotransferase, and (3) phosphoserine phosphatase.

Serine participates in glycine synthesis in two ways (Section 26-3B):

1. Direct conversion of serine to glycine by serine hydroxymethyl transferase in a reaction that also yields  $N^5,N^{10}$ -methylene-THF (Fig. 26-12, Reaction 4 in reverse).
2. Condensation of the  $N^5,N^{10}$ -methylene-THF with  $CO_2$  and  $NH_4^+$  by the glycine cleavage system (Fig. 26-12, Reaction 3 in reverse).

We have already discussed the synthesis, in animals, of cysteine from serine and homocysteine, a breakdown product of methionine (Section 26-3Ea). Homocysteine combines with serine to yield cystathionine, which subsequently forms cysteine and  $\alpha$ -ketobutyrate (Fig. 26-18, Reactions 5 and 6). Since cysteine's sulfhydryl group is derived from the essential amino acid methionine, cysteine is really an essential amino acid. In plants and microorganisms, however, cysteine is synthesized from serine in a two-step reaction involving the activation of the serine —OH by converting it to ***O*-acetylserine** followed by the displacement of acetate by sulfide (Fig. 26-59a). The sulfide required is produced from sulfate in an 8-electron reduction that occurs in *E. coli* as shown in Fig. 26-59b. Sulfate is first activated by the

**Figure 26-59** Cysteine biosynthesis. (a) The synthesis of cysteine from serine in plants and microorganisms. (b) The 8-electron reduction of sulfate to sulfide in *E. coli*.

enzymes **ATP sulfurylase** (which is used in the pyrosequencing of DNA; Section 7-2Ca) and **adenosine-5'-phosphosulfate (APS) kinase**. The activated sulfate is then reduced to sulfite by **3'-phosphoadenosine-5'-phosphosulfate (PAPS) reductase** and to sulfide by **sulfite reductase**.

### B. Biosynthesis of the Essential Amino Acids

Essential amino acids, like nonessential amino acids, are synthesized from familiar metabolic precursors. Their synthetic pathways are present only in microorganisms and plants, however, and usually involve more steps than those of the nonessential amino acids. For example, lysine, methionine, and threonine are all synthesized from aspartate in pathways whose common first reaction is catalyzed by **aspartokinase**, an enzyme that is present only in plants and microorganisms. Similarly, valine and leucine are formed from pyruvate; isoleucine is formed from pyruvate and  $\alpha$ -ketobutyrate; and tryptophan, phenylalanine, and tyrosine are formed from phosphoenolpyruvate and erythrose-4-phosphate. The enzymes that synthesize essential amino acids were apparently lost early in animal evolution, possibly because of the ready availability of these amino acids in the diet.

Time and space prevent a detailed discussion of the many interesting reactions that occur in these pathways. The biosynthetic pathways of the aspartate family of amino acids, the pyruvate family, the aromatic family, and histidine are presented in Figs. 26-60 through 26-63 and 26-65 together with lists of the enzymes involved. Several agriculturally useful

**Figure 26-60** (Opposite) The biosynthesis of the “aspartate family” of amino acids: lysine, methionine, and threonine. The pathway enzymes are (1) aspartokinase, (2)  $\beta$ -aspartate semialdehyde dehydrogenase, (3) homoserine dehydrogenase, (4) homoserine kinase, (5) threonine synthase (a PLP enzyme), (6) homoserine acyltransferase, (7) cystathionine  $\gamma$ -synthase, (8) cystathionine  $\beta$ -lyase, (9) methionine synthase (alternatively homocysteine methyltransferase, which also occurs in mammals; Section 26-3Ec), (10) dihydrodipicolinate synthase, (11) dihydrodipicolinate reductase, (12) *N*-succinyl-2-amino-6-ketopimelate synthase, (13) succinyl-diaminopimelate aminotransferase (a PLP enzyme), (14) succinyl-diaminopimelate desuccinylase, (15) diaminopimelate epimerase, and (16) diaminopimelate decarboxylase.

herbicides are specific inhibitors of some of these enzymes. Such herbicides have little toxicity toward animals and hence pose minimal risk to human health and the environment.

### a. The Aspartate Family: Lysine, Methionine, and Threonine

In bacteria, aspartate is the common precursor of lysine, methionine, and threonine (Fig. 26-60). The biosyntheses of these essential amino acids all begin with the aspartokinase-catalyzed phosphorylation of aspartate to yield **aspartyl- $\beta$ -phosphate**. We have seen that the control of metabolic pathways commonly occurs at the first committed step of the pathway. One might therefore expect lysine, methionine, and threonine biosynthesis to be controlled as a group. Each of these pathways is, in fact, independently controlled. *E. coli* does so via three isozymes of aspartokinase that respond differently to the three amino acids in terms both of feedback inhibition of enzyme activity and repression of enzyme synthesis. Table 26-3 summarizes this differential control. In addition, the pathway direction is controlled by feedback inhibition at the branch points by the individual amino acids. Thus methionine inhibits the *O*-acylation of homoserine (Fig. 26-60, Reaction 6), and lysine inhibits dihydrodipicolinate synthase (Fig. 26-60, Reaction 10).

### b. The Pyruvate Family: Leucine, Isoleucine, and Valine

Valine and isoleucine are both synthesized via the same five-step pathway (Fig. 26-61), the only difference being in the first step of the series. In this TPP-dependent reaction, which resembles those catalyzed by pyruvate decarboxylase (Section 17-3Ba) and transketolase (Section 23-4Ca), pyruvate forms an adduct with TPP, which is decarboxylated to hydroxyethyl-TPP. This resonance-stabilized carbanion adds either to the keto group of a second pyruvate to form **acetolactate** on the way to valine, or to the keto group of threonine-derived  **$\alpha$ -ketobutyrate** to form  **$\alpha$ -aceto- $\alpha$ -hydroxybutyrate** on the way to isoleucine. The leucine biosynthetic pathway branches off from the valine pathway at  $\alpha$ -ketoisovalerate (Fig. 26-61, Reaction 6). Reactions 6 to 8 in Fig. 26-61 are reminiscent of the first three reactions of the citric acid cycle (Sections 21-3A–C). Here, acetyl-CoA condenses with  **$\alpha$ -ketoisovalerate** to form  **$\alpha$ -isopropylmalate**, which then undergoes a dehydration/

**Figure 26-61** (Opposite) The biosynthesis of the “pyruvate family” of amino acids: isoleucine, leucine, and valine. The pathway enzymes are (1) acetolactate synthase (a TPP enzyme), (2) acetolactate mutase, (3) reductase, (4) dihydroxy acid dehydratase, (5) valine aminotransferase (a PLP enzyme), (6)  $\alpha$ -isopropylmalate synthase, (7)  $\alpha$ -isopropylmalate dehydratase, (8) isopropylmalate dehydrogenase, (9) leucine aminotransferase (a PLP enzyme), and (10) threonine deaminase (serine dehydratase, a PLP enzyme).

**Table 26-3** Differential Control of Aspartokinase Isoenzymes in *E. Coli*

Enzyme	Feedback	
	Inhibitor	Corepressor(s) <sup>a</sup>
Aspartokinase I	Threonine	Threonine and isoleucine
Aspartokinase II	None	Methionine
Aspartokinase III	Lysine	Lysine

hydration reaction, followed by oxidative decarboxylation and transamination, to yield leucine.

### c. The Aromatic Amino Acids: Phenylalanine, Tyrosine, and Tryptophan

The precursors to the aromatic amino acids are the glycolytic intermediate phosphoenolpyruvate (PEP) and erythrose-4-phosphate (an intermediate in the pentose phosphate pathway; Section 23-4Cb). Their condensation forms **2-keto-3-deoxy-D-arabinoheptulosonate-7-phosphate**, a C<sub>7</sub> compound that cyclizes and is ultimately converted to **chorismate** (Fig. 26-62), the branch point for tryptophan biosynthesis. Chorismate is converted either to **anthranilate** and then on to tryptophan, or to **prephenate** and on to either tyrosine or phenylalanine (Fig. 26-63). Although mammals synthesize tyrosine by the hydroxylation of phenylalanine (Section 26-3Ha), many microorganisms synthesize it directly from prephenate.

Since the synthesis of aromatic amino acids only occurs in plants and microorganisms, this pathway is a natural target for herbicides that will not be toxic to animals. For example, **glyphosate**,

the active ingredient in one of the most widely used weed killers, Roundup, is a competitive inhibitor with respect to PEP in the **5-enolpyruvylshikimate-3-phosphate (EPSP) synthase** reaction (Reaction 6 of Fig. 26-62).

### d. A Protein Tunnel Channels the Intermediate Product of Tryptophan Synthase between Two Active Sites

The final two reactions in tryptophan biosynthesis, Reactions 5 and 6 in Fig. 26-63, are both catalyzed by **tryptophan synthase**:

1. The  $\alpha$  subunit (268 residues) of this  $\alpha_2\beta_2$  bifunctional enzyme cleaves **indole-3-glycerol phosphate**, yielding **indole** and glyceraldehyde-3-phosphate (Reaction 5).

2. The  $\beta$  subunit (396 residues) joins indole with L-serine in a PLP-dependent reaction to form L-tryptophan (Reaction 6).

Either subunit alone is enzymatically active, but when they are joined in the  $\alpha_2\beta_2$  tetramer, the rates of both reactions

**Figure 26-62** The biosynthesis of chorismate, the aromatic amino acid precursor. The pathway enzymes are (1) 2-keto-3-deoxy-D-arabinoheptulosonate-7-phosphate synthase, (2) dehydroquinase (an  $\text{NAD}^+$ -requiring reaction that yields an unchanged  $\text{NAD}^+$  product and is thereby indicative of

an oxidized intermediate as similarly occurs in the UDP-galactose-4-epimerase reaction; Section 17-5B), (3) 5-dehydroquinase, (4) shikimate dehydrogenase, (5) shikimate kinase, (6) 5-enolpyruvylshikimate-3-phosphate synthase, and (7) chorismate synthase.

and their substrate affinities are increased by 1 to 2 orders of magnitude. Indole, the intermediate product, does not appear free in solution; the enzyme apparently sequesters it.

The X-ray structure of tryptophan synthase from *Salmonella typhimurium*, determined by Craig Hyde, Edith Miles, and David Davies, explains the latter observation. The protein forms a 150-Å-long, 2-fold symmetric  $\alpha$ - $\beta$ - $\beta$ - $\alpha$  complex (Fig. 26-64) in which the active sites of neighboring  $\alpha$  and  $\beta$  subunits are separated by  $\sim 25$  Å. These active sites are joined by a solvent-filled tunnel that is

wide enough to permit the passage of the intermediate substrate, indole. This structure, the first in which the presence of a tunnel between active sites was observed, suggests the following series of events. The indole-3-glycerol phosphate substrate binds to the  $\alpha$  subunit through an opening into its active site, its “front door,” and the glyceraldehyde-3-phosphate product leaves via the same route. Similarly, the  $\beta$  subunit active site has a “front door” opening to the solvent through which serine enters and tryptophan leaves. Both active sites also have “back doors” that are connected

**Figure 26-63** The biosynthesis of phenylalanine, tryptophan, and tyrosine from chorismate. The pathway enzymes are (1) anthranilate synthase, (2) anthranilate phosphoribosyltransferase, (3) *N*-(5'-phosphoribosyl)anthranilate isomerase, (4) indole-3-glycerol phosphate synthase,

(5) tryptophan synthase,  $\alpha$  subunit, (6) tryptophan synthase,  $\beta$  subunit, (7) chorismate mutase, (8) prephenate dehydrogenase, (9) aminotransferase, (10) prephenate dehydratase, and (11) aminotransferase.

by the tunnel. The indole intermediate presumably diffuses between the two active sites via the tunnel and hence does not escape to the solvent.

Allosteric interactions between the subunits to control the activity of the  $\alpha$  subunit also serve to ensure that indole is only released when the  $\beta$  subunit is ready to accept it.

**Figure 26-64** A ribbon diagram of the bifunctional enzyme **tryptophan synthase** from *S. typhimurium*. Only one  $\alpha\beta$  protomer of this 2-fold symmetric  $\alpha\beta\alpha$  heterotetramer is shown. The  $\alpha$  subunit is blue, the  $\beta$  subunit's N-terminal domain is orange, its C-terminal domain is red-orange, and all  $\beta$  sheets are tan. The active site of the  $\alpha$  subunit is located by its bound competitive inhibitor, **indolepropanol phosphate (IPP; red ball-and-stick model)**, whereas that of the  $\beta$  subunit is marked by its PLP coenzyme (**yellow ball-and-stick model**). The solvent-accessible surface of the  $\sim 25$ -Å-long “tunnel” connecting the active sites of the  $\alpha$  and  $\beta$  subunits is outlined by a yellow dot surface. Several indole molecules (**green ball-and-stick models**) have been modeled into the tunnel in head to tail fashion, thereby demonstrating that the tunnel has sufficient width to permit the indole product of the  $\alpha$  subunit to pass through the tunnel to the  $\beta$  subunit's active site. [Courtesy of Craig Hyde, Edith Miles, and David Davies, National Institutes of Health.]  See Interactive Exercise 25

Michael Dunn has shown that the elimination of water from the serine–PLP Schiff base on the  $\beta$  subunit to form an aminoacrylate–PLP Schiff base intermediate

**Aminoacrylate–PLP Schiff base**

triggers a conformational change that activates the  $\alpha$  subunit to produce indole. The diffusion of the indole to the  $\beta$

**Figure 26-65** (Opposite) **The biosynthesis of histidine.** The pathway enzymes are (1) ATP phosphoribosyltransferase, (2) pyrophosphohydrolase, (3) phosphoribosyl–AMP cyclohydrolase, (4) phosphoribosylformimino-5-aminoimidazole carboxamide ribonucleotide isomerase, (5) imidazole glycerol phosphate synthase (a glutamine amidotransferase), (6) imidazole glycerol phosphate dehydratase, (7) L-histidinol phosphate aminotransferase, (8) histidinol phosphate phosphatase, and (9) histidinol dehydrogenase.

subunit to react with this intermediate then results in the formation of tryptophan.

Channeling may be particularly important for indole since this nonpolar molecule otherwise can escape the bacterial cell by diffusing through its plasma and outer membranes. We have seen similar phenomena in reactions involving glutamine amidotransferases (Sections 26-2Aa and 26-5Aa), as well as in the series of reactions catalyzed by fatty acid synthase, in which the growing product is kept in the vicinity of the multifunctional enzyme's active site by covalent attachment to the enzyme's flexible phosphopantetheine arm (Section 25-4Ca). Channeling is also implicated in the multistep biosyntheses of purines and pyrimidines (Sections 28-1A and 28-2A).

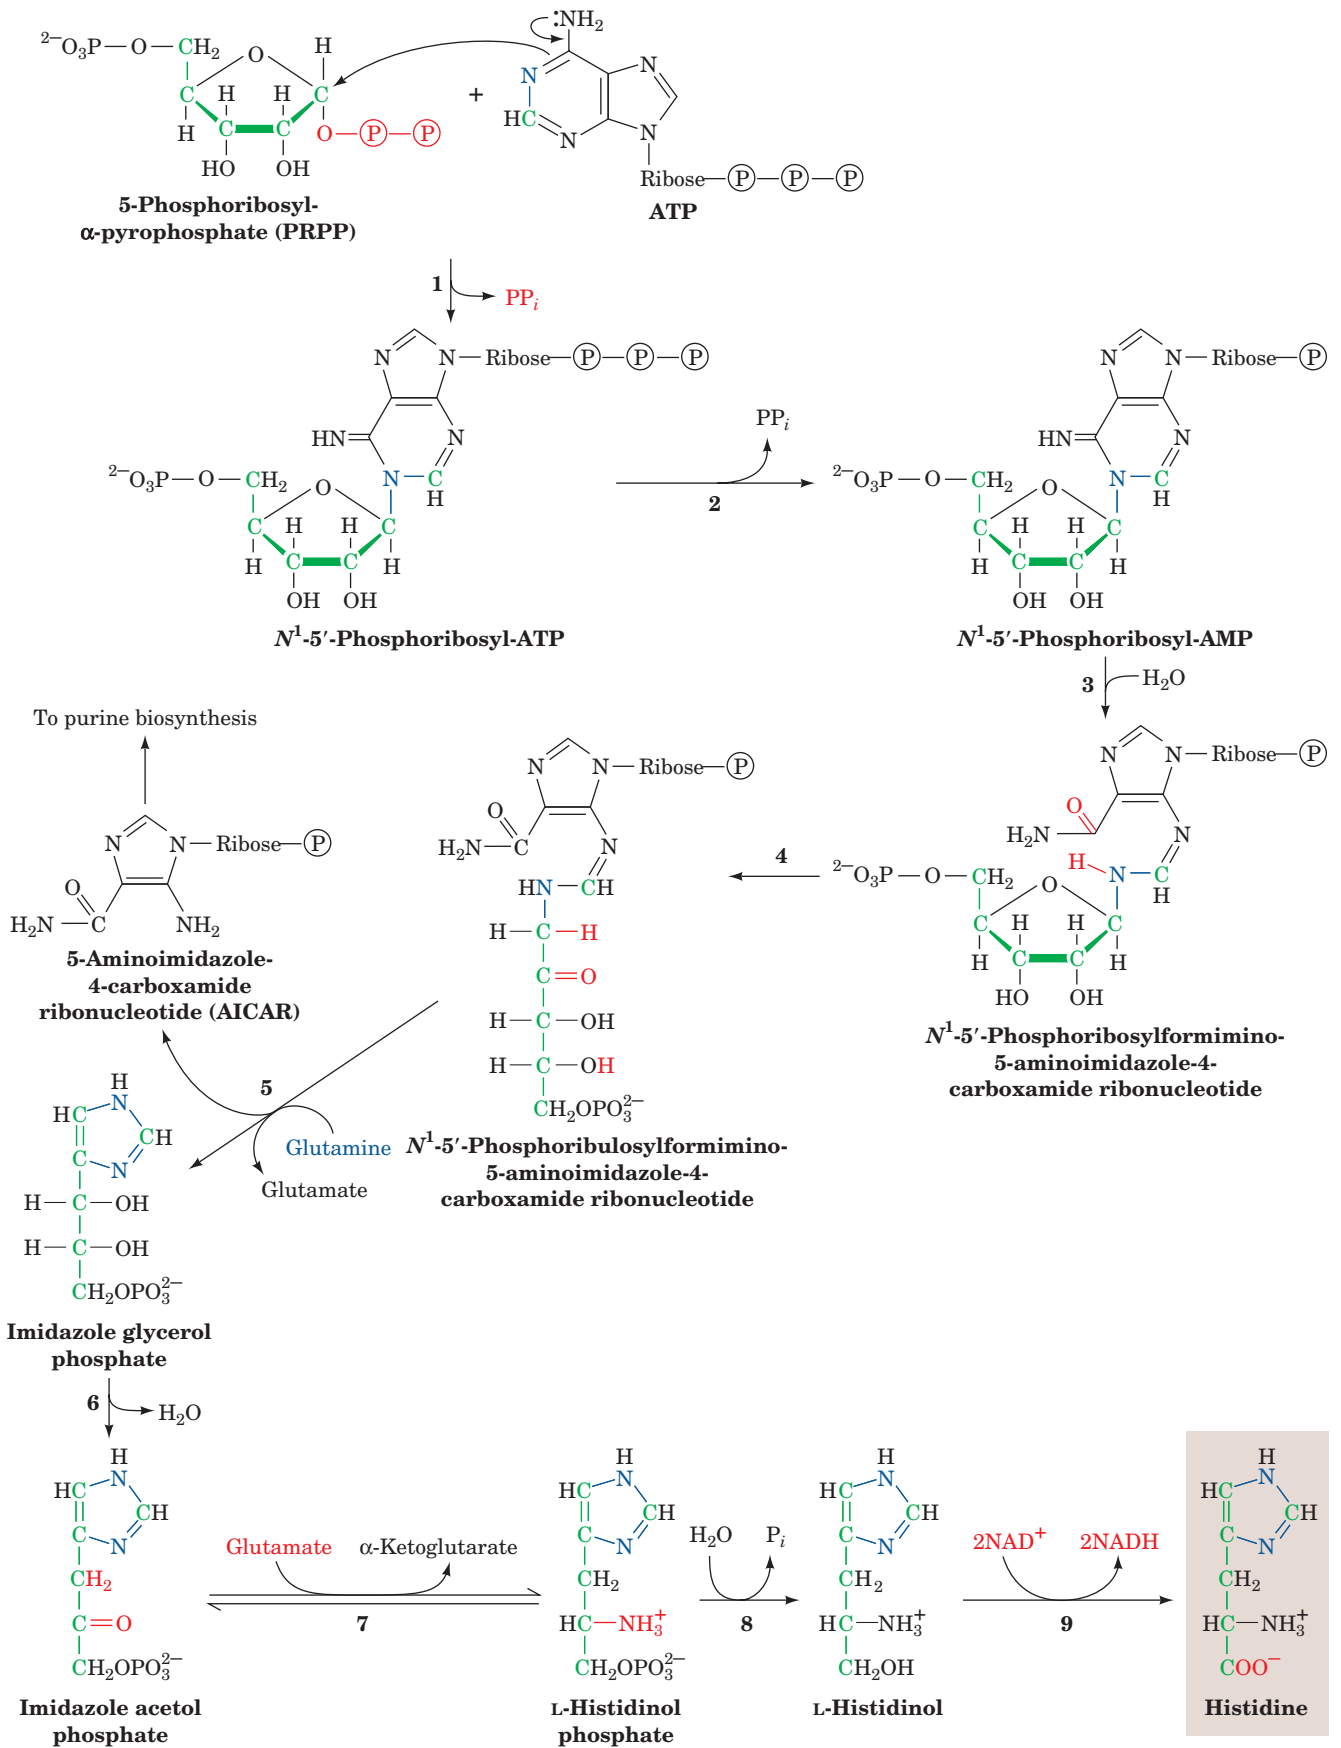

#### e. Histidine Biosynthesis

Five of histidine's six C atoms are derived from **5-phosphoribosyl- $\alpha$ -pyrophosphate (PRPP; Fig. 26-65)**, an intermediate also involved in the biosynthesis of tryptophan (Fig. 26-63, Reaction 2), purine nucleotides (Section 28-1A), and pyrimidine nucleotides (Section 28-2A). The histidine's sixth carbon originates from ATP. The ATP atoms that are not incorporated into histidine are eliminated as **5-aminoimidazole-4-carboxamide ribonucleotide (AICAR; Fig. 26-65, Reaction 5)**, which is also an intermediate in purine biosynthesis (Section 28-1A).

The unusual biosynthesis of histidine from a purine has been cited as evidence supporting the hypothesis that life was originally RNA based (Section 1-5Ca). His residues, as we have seen, are often components of enzyme active sites, where they act as nucleophiles and/or general acid–base catalysts. The discovery that RNA can have catalytic properties (Section 31-4Ae) therefore suggests that the imidazole moiety of purines plays a similar role in these RNA enzymes (**ribozymes**). This further suggests that the histidine biosynthesis pathway is a “fossil” of the transition to more efficient protein-based life-forms.

## 6 NITROGEN FIXATION

The most prominent chemical elements in living systems are O, H, C, N, and P. The elements O, H, and P occur widely in metabolically available forms (e.g.,  $H_2O$ ,  $O_2$ , and  $P_i$ ). However, the major available forms of C and N,  $CO_2$  and  $N_2$ , are extremely stable (unreactive); for example, the  $N\equiv N$  triple bond has a bond energy of  $945 \text{ kJ} \cdot \text{mol}^{-1}$

(versus  $351 \text{ kJ} \cdot \text{mol}^{-1}$  for a C—O single bond).  $\text{CO}_2$ , with only minor exceptions, is metabolized (fixed) only by photosynthetic organisms (Chapter 24).  $\text{N}_2$  fixation is even less common; this element is converted to metabolically useful forms by only a few strains of bacteria, named **diazotrophs**.

Diazotrophs of the genus *Rhizobium* live in symbiotic relationship with root nodule cells of legumes (plants belonging to the pea family, including beans, clover, and alfalfa; Fig. 26-66) where they convert  $\text{N}_2$  to  $\text{NH}_3$ :

The  $\text{NH}_3$  thus formed can be incorporated either into glutamate by glutamate dehydrogenase (Section 26-1B) or into glutamine by glutamine synthetase (Section 26-5Ab). This nitrogen-fixing system produces more metabolically useful nitrogen than the legume needs; the excess is excreted into the soil, enriching it. It is therefore common agricultural practice to plant a field with alfalfa every few years to build up the supply of usable nitrogen in the soil for later use in growing other crops.

#### a. Nitrogenase Contains Novel Redox Centers

**Nitrogenase**, which catalyzes the reduction of  $\text{N}_2$  to  $\text{NH}_3$ , is a complex of two proteins:

1. The **Fe-protein**, a homodimer that contains one  $[4\text{Fe}-4\text{S}]$  cluster and two ATP binding sites.

**Figure 26-66** Photograph showing the root nodules of the legume bird's-foot trefoil. [Vu/Cabisco/Visuals Unlimited.]

2. The **MoFe-protein**, an  $\alpha_2\beta_2$  heterotetramer that contains Fe and Mo.

The X-ray structure of *Azotobacter vinelandii* nitrogenase in complex with the inhibitor  $\text{ADP} \cdot \text{AlF}_4^-$  (which mimics the transition state in ATP hydrolysis), determined by Douglas Rees, reveals that each MoFe-protein associates with two molecules of Fe-protein (Fig. 26-67).

Each Fe-protein dimer's single  $[4\text{Fe}-4\text{S}]$  cluster is located in a solvent-exposed cleft between the two subunits

**Figure 26-67** X-ray structure of the *A. vinelandii* nitrogenase in complex with  $\text{ADP} \cdot \text{AlF}_4^-$ . The enzyme, which is viewed along its molecular 2-fold axis, is an  $(\alpha\beta\gamma_2)_2$  heterooctamer in which the  $\beta$ - $\alpha$ - $\alpha$ - $\beta$  assembly, the MoFe-protein, is flanked by two  $\gamma_2$  Fe-proteins whose 289-residue subunits are related by local 2-fold symmetry. The homologous  $\alpha$  subunits (cyan and magenta; 491 residues) and  $\beta$  subunits (light red and light blue; 522 residues) are related by pseudo-2-fold symmetry. The two  $\gamma$  subunits forming each Fe-protein (pink and green with their

Switch I and Switch II segments red and blue) bind to the MoFe-protein with the 2-fold axis relating them coincident with the pseudo-2-fold axis relating the MoFe-protein's  $\alpha$  and  $\beta$  subunits. The  $\text{ADP} \cdot \text{AlF}_4^-$ ,  $[4\text{Fe}-4\text{S}]$  cluster, FeMo-cofactor, and P-cluster are drawn in space-filling form with C green, N blue, O red, S yellow, Fe orange, Mo pink, and the  $\text{AlF}_4^-$  ion purple. [Based on an X-ray structure by Douglas Rees, California Institute of Technology. PDBid 1N2C.]  See Interactive Exercise 26

and is symmetrically linked to Cys 97 and Cys 132 from both subunits such that an Fe-protein resembles an “iron butterfly” with the [4Fe–4S] cluster at its head. Its two identical nucleotide binding sites are located at the interface between its two subunits. The [4Fe–4S] cluster cycles between its +1 and +2 oxidation states.

The MoFe-protein’s  $\alpha$  and  $\beta$  subunits assume similar folds and extensively associate to form a pseudo-2-fold symmetric  $\alpha\beta$  dimer, two of which more loosely associate to form the 2-fold symmetric  $\alpha_2\beta_2$  tetramer (Fig. 26-67). Each  $\alpha\beta$  dimer has two bound redox centers:

**1. The P-cluster** (Fig. 26-68*a,b*), which consists of two [4Fe–3S] clusters linked through an additional sulfide ion forming the eighth corner of each of the clusters to make cubane-like structures, and bridged by two Cys thiol ligands, each coordinating one Fe from each cluster. Four additional Cys thiols coordinate the remaining four Fe atoms. The positions of two of the Fe atoms in one of the [4Fe–3S] clusters change on oxidation, rupturing the bonds from these Fe atoms to the linking sulfide ion. These bonds are replaced in the oxidized state by a Ser oxygen ligand to one of the Fe atoms, and by a bond to the amide N of a Cys from the other Fe atom.

**2. The FeMo-cofactor** (Fig. 26-68*c*), which consists of a [4Fe–3S] cluster and a [1Mo–3Fe–3S] cluster bridged by

three sulfide ions. The FeMo-cofactor’s Mo atom is approximately octahedrally coordinated by three cofactor sulfide ions, a His imidazole nitrogen, and two oxygens from a bound **homocitrate** ion:

**Homocitrate**

(an essential component of the FeMo-cofactor). The FeMo-cofactor contains a central cavity that a high resolution (1.16 Å) X-ray structure of *A. vinelandii* MoFe-protein, also determined by Rees, reveals contains what most probably is a nitrogen atom (although a C or an O atom cannot be ruled out). This putative N atom is liganded to the FeMo-cofactor’s central six Fe atoms such that it completes the approximate tetrahedral coordination environment of each of these Fe atoms.

The FeMo-cofactor is located  $\sim 10$  Å below the  $\alpha$  subunit surface, and hence the  $\text{N}_2$  is thought to gain access to its binding site through conformational fluctuations of the protein (recall that myoglobin and hemoglobin likewise have no clear path for  $\text{O}_2$  to approach its heme binding

**Figure 26-68** The prosthetic groups of the nitrogenase MoFe-protein. The molecules are drawn in ball-and-stick form with C green, N blue, O red, S yellow, Fe orange, and Mo pink. (a) The reduced *Klebsiella pneumoniae* P-cluster. It consists of two [4Fe–3S] complexes linked by an additional sulfide ion forming the eighth corner of each cubane-like structure, and bridged by two Cys thiol ligands, each coordinating one Fe from each cluster. Four additional Cys thiols coordinate the remaining 4 Fe atoms. (b) The 2-electron-oxidized *K. pneumoniae* P-cluster. In comparison with the reduced complex in Part a, two of the Fe–S bonds from the centrally located sulfide ion that bridges the two [4Fe–3S] clusters have been replaced by ligands from the Cys 87 $\alpha$  amide N and the Ser 186 $\beta$  side chain O yielding a [4Fe–3S] cluster (left) and a [4Fe–4S] cluster (right) that remain linked by a direct Fe–S bond and two bridging Cys thiols. (c) The *A. vinelandii* FeMo-cofactor. It consists of a [4Fe–3S] cluster and a [1Mo–3Fe–3S] cluster that are bridged by three sulfide ions. The FeMo-cofactor is linked to the protein by only two ligands at its opposite ends, one from His 442 $\alpha$  to the Mo atom and the other from Cys 275 $\alpha$  to an Fe atom. The Mo atom is

additionally doubly liganded by homocitrate. What is most likely an N atom (blue sphere) is liganded to the FeMo-cluster’s six central Fe atoms (dashed black lines). [Parts a and b based on X-ray structures by David Lawson, John Innes Centre, Norwich, U.K. Part c based on an X-ray structure by Douglas Rees, California Institute of Technology. PDBids (a) 1QGU, (b) 1QH1, and (c) 1M1N.]

sites in these proteins; Section 10-2). The P-cluster, which is also  $\sim 10$  Å below the protein surface, is at the interface between the  $\alpha$  and  $\beta$  subunits on the pseudo-2-fold axis that roughly relates these two subunits. The 2-fold axis of the Fe-protein and the pseudo-2-fold axis of the MoFe-proteins coincide in their complex.

The Fe-protein hydrolyzes two ATP molecules for each electron it transfers from its  $[4\text{Fe-4S}]^{+1}$  cluster to the P-cluster. Since the nucleotide binding sites and the  $[4\text{Fe-4S}]$  cluster on the Fe-protein are separated by  $\sim 20$  Å, a distance too large for direct coupling between electron transfer and ATP hydrolysis, it appears that these processes are allosterically coupled through conformational changes at the subunit interface. Indeed, portions of the Fe-protein resemble those of G-proteins, in which nucleotide hydrolysis is coupled to conformational changes controlling the protein's actions (Sections 19-2Cb and 19-3Cf). Specifically, two regions of the Fe-protein, designated Switch I and Switch II (Fig. 26-67), are homologous with those of Ras (Section 19-3Cf). The binding of  $\text{ADP} \cdot \text{AlF}_4^-$  to Fe-protein induces conformational changes in Switch I that affect the interactions between the Fe-protein and the MoFe-protein, and in Switch II that affect the environment of the  $[4\text{Fe-4S}]$  cluster.

In nitrogenase, the  $[4\text{Fe-4S}]$  cluster of the Fe-protein approaches within  $\sim 14$  Å of the P-cluster in the MoFe-protein, whereas the P-cluster and the FeMo-cofactor are  $\sim 13$  Å apart. Hence, the sequence of the electron-transfer steps in the nitrogenase reaction appears to be

It therefore seems that the role of ATP hydrolysis is to stabilize a conformation in the Fe-protein that it cannot achieve on its own and which facilitates electron transfer from the  $[4\text{Fe-4S}]$  cluster on the Fe-protein to the P-cluster on the MoFe-protein.

### b. $\text{N}_2$ Reduction Is Energetically Costly

Nitrogen fixation requires two participants in addition to  $\text{N}_2$  and nitrogenase: (1) a source of electrons and (2) ATP. Electrons are generated either oxidatively or photosynthetically, depending on the organism. These electrons are transferred to ferredoxin (Section 22-2C1a), a  $[4\text{Fe-4S}]$ -containing electron carrier that transfers an electron to the Fe-protein of nitrogenase, beginning the nitrogen fixation process (Fig. 26-69). Two molecules of ATP bind to the

reduced Fe-protein and are hydrolyzed as each electron is passed from the Fe-protein to the MoFe-protein. The ATP hydrolysis-induced conformational change in the Fe-protein alters its redox potential from  $-0.29$  to  $-0.40$  V, making the electron capable of  $\text{N}_2$  reduction ( $\mathcal{E}^{\circ'} = -0.34$  V for the half-cell  $\text{N}_2 + 6\text{H}^+ + 6e^- \rightleftharpoons 2\text{NH}_3$ ).

The actual reduction of  $\text{N}_2$  occurs on the MoFe-protein in three discrete steps, each involving an electron pair:

An electron transfer must occur six times per  $\text{N}_2$  molecule fixed so that a total of 12 ATPs are required to fix one  $\text{N}_2$  molecule. Although the  $\text{N}_2$  binding site is almost certainly the FeMo-cofactor, exactly how the  $\text{N}_2$  is bound and reduced are largely a matter of speculation. Theoretical studies suggest that the FeMo-cofactor's prismatically arranged Fe atoms provide favorable interaction sites for  $\text{N}_2$  and its reduction products. Indeed, it seems highly likely that the putative N atom that is liganded to the FeMo-cofactor (Fig. 26-68c) participates in  $\text{N}_2$  reduction.

Nitrogenase also reduces  $\text{H}_2\text{O}$  to  $\text{H}_2$ , which in turn reacts with **diimine** to reform  $\text{N}_2$ :

The resulting futile cycle is favored when the ATP level is low and/or the reduction of the Fe-protein is sluggish. Even when ATP is plentiful, however, the cycle cannot be suppressed beyond about one  $\text{H}_2$  molecule produced per  $\text{N}_2$  reduced and hence appears to be a requirement of the nitrogenase reaction. The total cost of  $\text{N}_2$  reduction is therefore 8 electrons transferred and 16 ATPs hydrolyzed (physiologically, 20–30 ATPs). Hence nitrogen fixation is an energetically expensive process; indeed, the nitrogen-fixing bacteria in the root nodules of pea plants consume nearly 20% of the ATP that the plant produces.

### c. Leghemoglobin Protects Nitrogenase from Oxygen Inactivation

Nitrogenase is rapidly inactivated by  $\text{O}_2$ , so the enzyme must be protected from this reactive substance. Cyanobacteria

**Figure 26-69** The flow of electrons in the nitrogenase-catalyzed reduction of  $\text{N}_2$ .

(photosynthetic oxygen-evolving bacteria; Section 1-1Ab) provide protection by carrying out nitrogen fixation in specialized nonphotosynthetic cells called **heterocysts**, which have Photosystem I but lack Photosystem II (Section 24-2Ca). In the root nodules of legumes (Fig. 26-66), however, protection is afforded by the symbiotic synthesis of **leghemoglobin**. The globin portion of this ~145-residue monomeric oxygen-binding protein is synthesized by the plant (an evolutionary curiosity since globins are otherwise known to occur only in animals), whereas the heme is synthesized by the *Rhizobium*. Leghemoglobin has a very high O<sub>2</sub> affinity, thus keeping the pO<sub>2</sub> low enough to protect the nitrogenase while providing passive O<sub>2</sub> transport for the aerobic bacterium.

#### d. Installing the Nitrogen Fixation Machinery in Nonleguminous Plants Would Revolutionize Agriculture

Although atmospheric N<sub>2</sub> is the ultimate nitrogen source for all living things, most plants do not support the symbiotic growth of nitrogen-fixing bacteria. They must therefore depend on a source of “prefixed” nitrogen such as nitrate or ammonia. These nutrients come from lightning discharges (the source of ~10% of naturally fixed N<sub>2</sub>), decaying organic matter in the soil, or from fertilizer applied to it. The Haber process, which was invented by Fritz Haber in 1910, is a chemical process for N<sub>2</sub> fixation that is still widely used in fertilizer manufacture. This direct reduction of N<sub>2</sub> by H<sub>2</sub> to form NH<sub>3</sub> requires temperatures of 300 to 500°C, pressures of >300 atm, and an Fe catalyst. Intriguingly, the spacing of the Fe atoms on the surface of this catalyst resembles that of the FeMo-cofactor’s central Fe atoms (Fig. 26-68c).

One of the major long-term goals of genetic engineering is to induce agriculturally useful nonleguminous plants to

fix their own nitrogen, a complex undertaking in which the plant must be made to provide a hospitable environment for nitrogen fixation as well as to acquire the enzymatic machinery to do so. This would free farmers, particularly those in developing countries, from the need for either purchasing fertilizers, periodically letting their fields lie fallow (giving legumes the opportunity to grow), or following the slash-and-burn techniques that are rapidly destroying the world’s tropical forests and contributing significantly to the greenhouse effect (atmospheric CO<sub>2</sub> pollution causing long-term global warming).

#### e. The Nitrogen Cycle Describes the Interconversion of Nitrogen in the Biosphere

The ammonia produced by the nitrogenase reaction and incorporated into amino acids is eventually recycled in the biosphere as described by the **nitrogen cycle** (Fig. 26-70). Nitrate is produced by certain bacteria that oxidize NH<sub>3</sub> to NO<sub>2</sub><sup>-</sup> and then NO<sub>3</sub><sup>-</sup>, a process called **nitrification**. Still other organisms convert nitrate back to N<sub>2</sub>, which is known as **denitrification**. In addition, nitrate is reduced to NH<sub>3</sub> by plants, fungi, and many bacteria, a process called **ammonification** in which **nitrate reductase** catalyzes the two-electron reduction of nitrate to nitrite (NO<sub>2</sub><sup>-</sup>):

and then **nitrite reductase** converts nitrite to ammonia,

The direct anaerobic oxidation of NH<sub>3</sub> back to N<sub>2</sub> without the intermediacy of nitrate, the reverse of nitrogen fixation, has recently been discovered in certain bacteria.

**Figure 26-70 The nitrogen cycle.** Nitrogen fixation by nitrogenase converts N<sub>2</sub> to the biologically useful ammonia. Nitrate can also be converted to ammonia by the sequential actions of nitrate reductase and nitrite reductase. Ammonia is transformed to N<sub>2</sub> by nitrification followed by denitrification. Ammonia may be assimilated into nitrogen-containing biomolecules, which may be decomposed back to ammonia.

## CHAPTER SUMMARY

**1 Amino Acid Deamination** Amino acids are the precursors for numerous nitrogen-containing compounds such as heme, physiologically active amines, and glutathione. Excess amino acids are converted to common metabolic intermediates for use as fuels. The first step in amino acid breakdown is removal of the  $\alpha$ -amino group by transamination. Transaminases require pyridoxal phosphate (PLP) and convert amino acids to their corresponding  $\alpha$ -keto acids. The amino group is transferred to  $\alpha$ -ketoglutarate to form glutamate, oxaloacetate to form aspartate, or pyruvate to form alanine. Glutamate is subsequently oxidatively deaminated by glutamate dehydrogenase (GDH) to form ammonia and regenerate  $\alpha$ -ketoglutarate. Hyperinsulinism/hyperammonemia (HI/HA), a genetic disease, is caused by a mutation of the GDH gene that decreases GTP's ability to inhibit GDH.

**2 The Urea Cycle** In the urea cycle, amino groups from  $\text{NH}_3$  and aspartate combine with  $\text{HCO}_3^-$  to form urea. This pathway takes place in the liver, partially in the mitochondrion and partially in the cytosol. It begins with the ATP-dependent condensation of  $\text{NH}_3$  and  $\text{HCO}_3^-$  by carbamoyl phosphate synthetase, an enzyme with a 96-Å-long tunnel connecting its three active sites through which its highly reactive intermediate products are channeled. The resulting carbamoyl phosphate then combines with ornithine to yield citrulline, which combines with aspartate to form argininosuccinate, which in turn is cleaved to fumarate and arginine. The arginine is then hydrolyzed to urea, which is excreted, and ornithine, which reenters the urea cycle. *N*-Acetylglutamate regulates the urea cycle by activating carbamoyl phosphate synthetase allosterically.

**3 Metabolic Breakdown of Individual Amino Acids** The  $\alpha$ -keto acid products of transamination reactions are degraded to citric acid cycle intermediates or their precursors. The amino acids leucine and lysine are ketogenic in that they are converted only to the ketone body precursors acetyl-CoA and acetoacetate. The remaining amino acids are, at least in part, glucogenic in that they are converted to the glucose precursors pyruvate, oxaloacetate,  $\alpha$ -ketoglutarate, succinyl-CoA, or fumarate. Alanine, cysteine, glycine, serine, and threonine are converted to pyruvate. Serine hydroxymethyltransferase catalyzes the PLP-dependent  $\text{C}_\alpha\text{—C}_\beta$  bond cleavage of serine to form glycine. This reaction requires the transfer of a methylene group from  $N^5, N^{10}$ -methylene-tetrahydrofolate, which the tetrahydrofolate (THF) obtains from the glycine cleavage system, a multienzyme system. Asparagine and aspartate are converted to oxaloacetate.  $\alpha$ -Ketoglutarate is a product of arginine, glutamate, glutamine, histidine, and proline degradation. Methionine, isoleucine, and valine are degraded to succinyl-CoA. Methionine breakdown involves the synthesis of *S*-adenosylmethionine (SAM), a sulfonium ion that acts as a methyl donor in many biosynthetic reactions. Hyperhomocysteinemia, a risk factor for cardiovascular disease, cognitive im-

pairment, and neural tube defects, is caused by a deficiency in its folate-dependent degradation. Maple syrup urine disease (MSUD) is caused by an inherited defect in branched-chain amino acid degradation. Branched-chain amino acid degradation pathways contain reactions common to all acyl-CoA oxidations. Tryptophan is degraded to alanine and acetoacetate. Phenylalanine and tyrosine are degraded to fumarate and acetoacetate. Most individuals with the hereditary disease phenylketonuria lack phenylalanine hydroxylase (PAH), which converts phenylalanine to tyrosine.

**4 Amino Acids as Biosynthetic Precursors** Heme is synthesized from glycine and succinyl-CoA. These precursors condense to form  $\delta$ -aminolevulinic acid (ALA), which cyclizes to form the pyrrole porphobilinogen (PBG). Four molecules of PBG condense to form uroporphyrinogen III, which then goes on to form heme, with the final reaction, the insertion of Fe(II) into protoporphyrin IX, catalyzed by ferrochelatase. Defects in heme biosynthesis, which are known as porphyrias, have a variety of bizarre symptoms. Heme is degraded to form linear tetrapyrroles, which are subsequently excreted as bile pigments. The hormones and neurotransmitters L-DOPA, epinephrine, norepinephrine, serotonin,  $\gamma$ -aminobutyric acid (GABA), and histamine are all synthesized from amino acid precursors. Glutathione, a tripeptide that is synthesized from glutamate, cysteine, and glycine, is involved in a variety of protective, transport, and metabolic processes. Tetrahydrofolate is a coenzyme that participates in the transfer of  $\text{C}_1$  units.

**5 Amino Acid Biosynthesis** Amino acids are required for many vital functions of an organism. Those amino acids that mammals can synthesize from common  $\alpha$ -keto acid carbon skeletons and preformed  $\alpha$ -amino nitrogen such as that of glutamate are known as nonessential amino acids; those that mammals must obtain from their diets are called essential amino acids. The biosynthesis of nonessential amino acids involves relatively simple pathways, whereas those forming the essential amino acids are generally more complex.

**6 Nitrogen Fixation** Although the ultimate source of nitrogen for amino acid biosynthesis is atmospheric  $\text{N}_2$ , this nearly inert gas must first be reduced to a metabolically useful form,  $\text{NH}_3$ , by nitrogen fixation. This process occurs only in certain types of bacteria, one genus of which occurs in symbiotic relationship with legumes.  $\text{N}_2$  is fixed in these organisms by an oxygen-sensitive enzyme, nitrogenase, that consists of two proteins: the Fe-protein dimer, which contains one [4Fe-4S] cluster and two ATP binding sites, and the MoFe-protein  $\alpha_2\beta_2$  tetramer, which contains one P-cluster (consisting of two [4Fe-3S] clusters linked by a sulfide ion) and one FeMo-cofactor (a [4Fe-3S] cluster and a [1Mo-3Fe-3S] cluster bridged by three sulfide ions and coordinated with homocitrate) in each  $\alpha\beta$  dimer. These cofactors each function as two-electron carriers for the ATP-driven reduction of  $\text{N}_2$  to  $\text{NH}_3$ .

## PROBLEMS

- Write the reaction for the transamination of an amino acid in terms of Cleland notation (Section 14-5A).
- Explain why the symptoms of the partial deficiency of a urea cycle enzyme may be attenuated by a low-protein diet.
- Why are people on a high-protein diet instructed to drink lots of water?
- A student on a particular diet expends  $10,000 \text{ kJ} \cdot \text{day}^{-1}$  while excreting 40 g of urea. Assuming that protein is 16% N by weight and that its metabolism yields  $18 \text{ kJ} \cdot \text{g}^{-1}$ , what percentage of the student's energy requirement is met by protein?
- Production of the enzymes that catalyze the reactions of the urea cycle can increase or decrease according to the metabolic needs of the organism. High levels of these enzymes are associated with high-protein diets as well as starvation. Explain this apparent paradox.
- Helicobacter pylori*, the bacterium responsible for gastric ulcers, can survive in the stomach (where the pH is as low as 1.5) in part because it synthesizes large amounts of the enzyme urease. (a) Write the reaction for urea hydrolysis by urease. (b) Explain why this reaction could help establish a more hospitable environment for *H. pylori*, which tolerates acid but prefers to grow at near-neutral pH.
- Why are phenylketonurics warned against eating products containing the artificial sweetener **aspartame** (NutraSweet; chemical name L-aspartyl-L-phenylalanine methyl ester)?
- Demonstrate that the synthesis of heme from PBG as labeled in Fig. 26-35 results in the heme-labeling pattern given in Fig. 26-32.
- Explain why certain drugs and other chemicals can precipitate an attack of acute intermittent porphyria.
- Heterozygotes for erythropoietic protoporphyria show only 20 to 30% residual ferrochelatase activity rather than the 50% that is normally expected for an autosomal dominant inherited disease. Provide a plausible explanation for this observation.
- One of the symptoms of **kwashiorkor**, the dietary protein deficiency disease in children, is the depigmentation of the skin and hair. Explain the biochemical basis of this symptom.
- What are the metabolic consequences of a defective uridylyl-removing enzyme in *E. coli*?
- Figure 26-60, Reaction 9, indicates that methionine is synthesized in microorganisms by the methylation of homocysteine in a reaction in which  $N^5$ -methyl-THF is the methyl donor. Yet, in the breakdown of methionine (Fig. 26-18), its demethylation occurs in three steps in which SAM is an intermediate. Discuss why this reaction does not occur via the simpler one-step reversal of the methylation reaction.
- In the glucose-alanine cycle (Fig. 26-3), glycolytically derived pyruvate is transaminated to alanine and exported to the liver for conversion to glucose and return to the cell. Explain how a muscle cell is able to participate in this cycle under anaerobic (vigorously contracting) conditions. (*Hint*: The breakdown of many amino acids yields  $\text{NH}_3$ .)
- Draw the activated intermediates involved in (a) glutamine and (b) asparagine biosynthesis from glutamate and aspartate, respectively. (c) Provide an example of another metabolic activation of a carboxylic acid group analogous to each of these reactions.
- The  $\alpha_2\beta_2$  tetramer of tryptophan synthase catalyzes the PLP-dependent reaction of indole-3-glycerol phosphate and serine to form tryptophan (Fig. 26-63, Reactions 5 and 6). Draw the chemical reactions involved in this synthesis, including the participation of PLP, and use curved arrows to show the flow of electrons. What role does PLP play in the reaction?
- Suggest a reason why the nitrogen-fixing heterocysts of cyanobacteria have lost Photosystem II but retain Photosystem I.

# Energy Metabolism: Integration and Organ Specialization

## CHAPTER 27

### 1 Major Pathways and Strategies of Energy Metabolism: A Summary

#### 2 Organ Specialization

- A. Brain
- B. Muscle
- C. Adipose Tissue
- D. Liver
- E. Kidney

#### 3 Metabolic Homeostasis: Regulation of Appetite, Energy Expenditure, and Body Weight

- A. AMP-Dependent Protein Kinase Is the Cell's Fuel Gauge
- B. Adiponectin Regulates AMPK Activity
- C. Leptin
- D. Insulin
- E. Ghrelin and PYY<sub>3-36</sub>
- F. Hypothalamic Integration of Hormonal Signals
- G. Control of Energy Expenditure by Adaptive Thermogenesis
- H. Did Leptin Evolve as a Thrifty Gene?

#### 4 Metabolic Adaptation

- A. Starvation
- B. Diabetes Mellitus

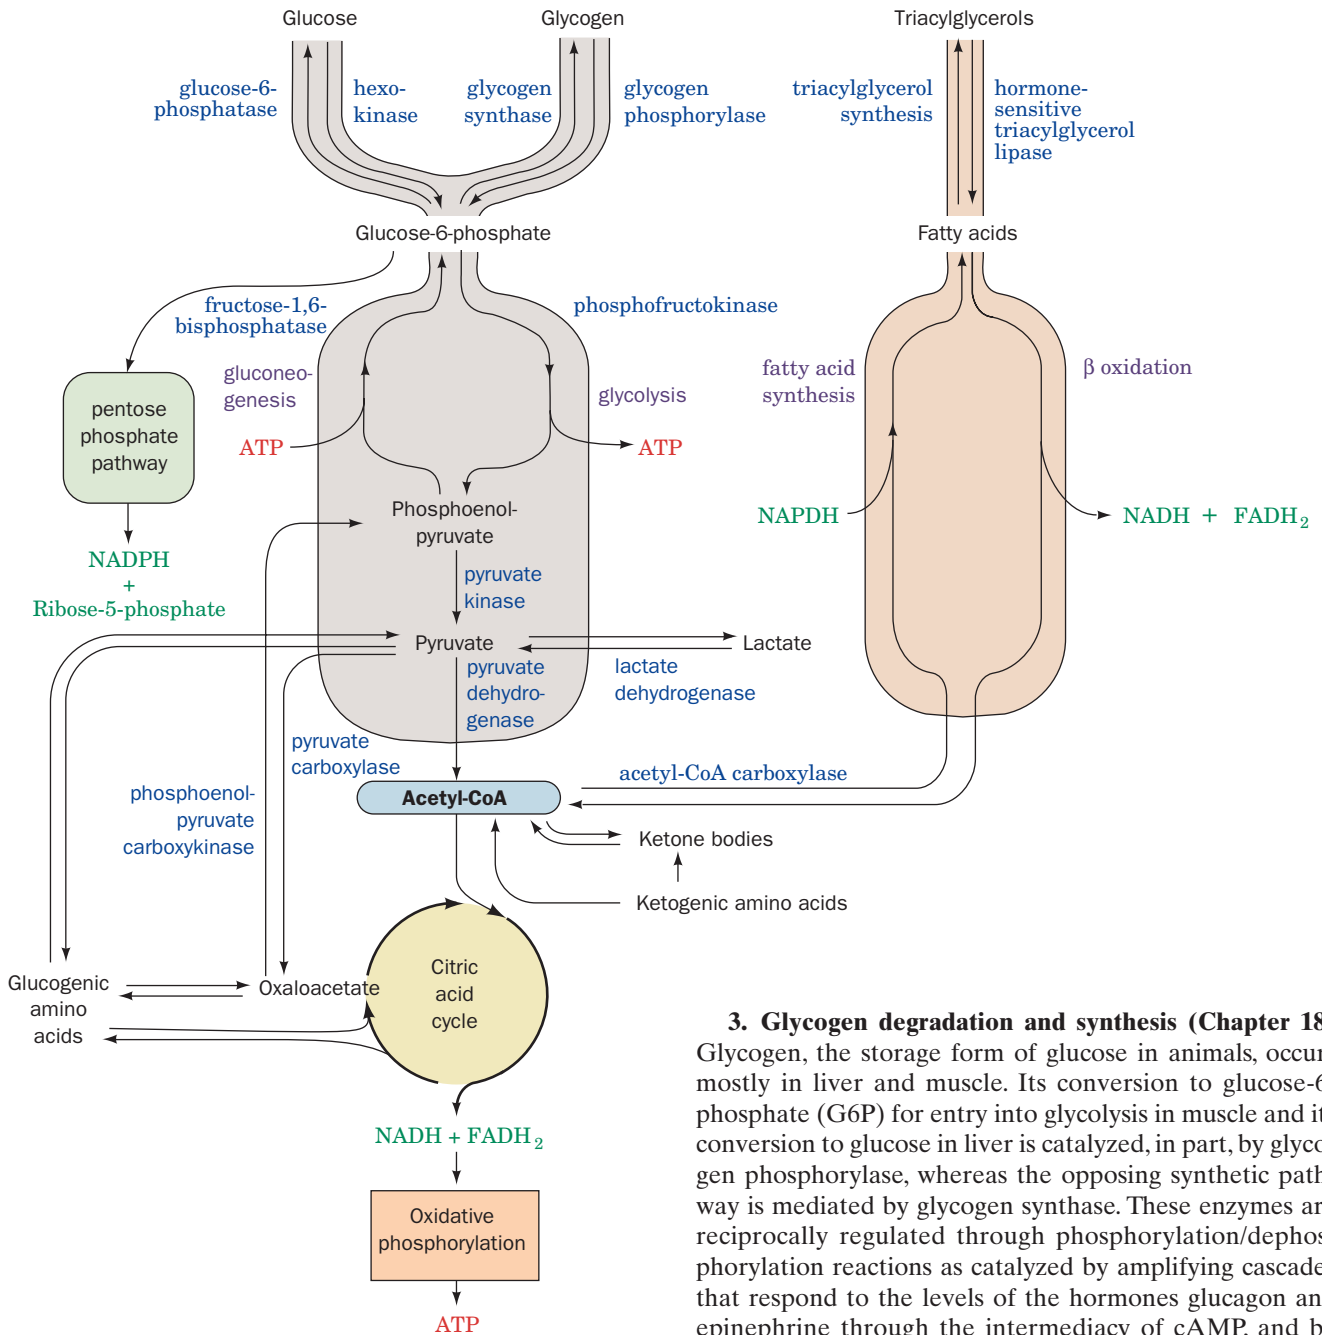

At this point in our narrative we have studied all of the major pathways of energy metabolism. Consequently, we are now in a position to consider how organisms, mammals in particular, orchestrate the metabolic symphony to meet their energy needs. This chapter therefore begins with a recapitulation of the major metabolic pathways and their control systems, then considers how these processes are apportioned among the various organs of the body, and ends with a discussion of metabolic adaptation, including how the body maintains energy balance (homeostasis), how it deals with the metabolic challenges of starvation and obesity, and how it responds to the loss of control resulting from diabetes mellitus.

### 1 MAJOR PATHWAYS AND STRATEGIES OF ENERGY METABOLISM: A SUMMARY

Figure 27-1 indicates the interrelationships among the major pathways involved in energy metabolism. Let us review these pathways and their control mechanisms.

**1. Glycolysis (Chapter 17)** The metabolic degradation of glucose begins with its conversion to two molecules of pyruvate with the net generation of two molecules each of ATP and NADH. Under anaerobic conditions, pyruvate is converted to lactate (or, in yeast, to ethanol) so as to recycle the NADH. Under aerobic conditions, however, when glycolysis serves to prepare glucose for further oxidation, the NAD<sup>+</sup> is regenerated through oxidative phosphorylation (see below). The flow of metabolites through the glycolytic pathway is largely controlled by the activity of phosphofructokinase (PFK). This enzyme is activated by AMP and ADP, whose concentrations rise as the need for energy metabolism increases, and is inhibited by ATP and citrate, whose concentrations increase when the demand for energy metabolism has slackened. Citrate, a citric acid cycle intermediate, also inhibits PFK and glycolysis when aerobic metabolism takes over from anaerobic metabolism, making glucose oxidation more efficient (the Pasteur effect; Section 22-4C), and when fatty acid and/or ketone body oxidation (which are also aerobic pathways) are providing for energy needs (the glucose–fatty acid or Randle cycle; Section 22-4Bb). PFK is also activated by fructose-2,6-bisphosphate, whose concentration is regulated by the levels of glucagon, epinephrine, and norepinephrine through the intermediacy of cAMP (Section 18-3Fc). Liver and heart muscle F<sub>2,6</sub>P levels are regulated oppositely: A [cAMP] increase causes an [F<sub>2,6</sub>P] decrease in liver and an [F<sub>2,6</sub>P] increase in heart muscle. However, skeletal muscle [F<sub>2,6</sub>P] does not respond to changes in [cAMP].

**2. Gluconeogenesis (Section 23-1)** Mammals can synthesize glucose from a variety of precursors, including pyruvate, lactate, glycerol, and gluconic amino acids (but not fatty acids), through pathways that occur mainly in liver and kidney. Many of these precursors are converted to oxaloacetate which, in turn, is converted to phosphoenolpyruvate and then, through a series of reactions that largely reverse the path of glycolysis, to glucose. The irreversible steps of glycolysis, those catalyzed by PFK and hexokinase, are bypassed in gluconeogenesis by hydrolytic reactions catalyzed, respectively, by fructose-1,6-bisphosphatase (FBPase) and glucose-6-phosphatase. FBPase and PFK may both be at least partially active simultaneously, creating a substrate cycle. This cycle, and the reciprocal regulation of PFK and FBPase, are important in regulating both the rate and direction of flux through glycolysis and

**Figure 27-1** The major energy metabolism pathways.

gluconeogenesis (Sections 17-4F and 23-1B). Fatty acid and ketone body oxidation can increase the rate of gluconeogenesis in liver by decreasing the concentration of F2,6P (Section 18-3Fc). This occurs because the increased citrate concentration accompanying activation of the citric acid cycle during fatty acid oxidation inhibits PFK-2 as well as PFK (Table 23-1). Phosphoenolpyruvate carboxykinase (PEPCK) bypasses the third irreversible reaction of glycolysis, that catalyzed by pyruvate kinase (PK), and is controlled exclusively by long-term transcriptional regulation.

### 3. Glycogen degradation and synthesis (Chapter 18)

Glycogen, the storage form of glucose in animals, occurs mostly in liver and muscle. Its conversion to glucose-6-phosphate (G6P) for entry into glycolysis in muscle and its conversion to glucose in liver is catalyzed, in part, by glycogen phosphorylase, whereas the opposing synthetic pathway is mediated by glycogen synthase. These enzymes are reciprocally regulated through phosphorylation/dephosphorylation reactions as catalyzed by amplifying cascades that respond to the levels of the hormones glucagon and epinephrine through the intermediacy of cAMP, and by insulin (Sections 18-3E and 19-4F). The glucagon–insulin ratio is therefore a crucial factor in determining the rate and direction of glycogen metabolism.

### 4. Fatty acid degradation and synthesis (Sections 25-1 through 25-5)

Fatty acids are broken down in increments of  $C_2$  units through  $\beta$  oxidation to form acetyl-CoA. They are synthesized from this compound via a separate pathway. The activity of the  $\beta$ -oxidation pathway varies with the fatty acid concentration. This, in turn, depends on the activity of “hormone-sensitive” triacylglycerol lipase in adipose tissue that is stimulated, through cAMP-regulated phosphorylation/dephosphorylation reactions, by glucagon and epinephrine but inhibited by insulin. The fatty acid synthesis rate varies with the activity of acetyl-CoA carboxylase,

which is activated by citrate and insulin-dependent dephosphorylation, and inhibited by the pathway product palmitoyl-CoA and by cAMP- and AMP-dependent phosphorylation. Fatty acid synthesis is also subject to long-term regulation through alterations in the rates of synthesis of the enzymes mediating this process as stimulated by insulin and inhibited by fasting. *The glucagon–insulin ratio is therefore of prime importance in determining the rate and direction of fatty acid metabolism.*

**5. Citric acid cycle (Chapter 21)** The citric acid cycle oxidizes acetyl-CoA, the common degradation product of glucose, fatty acids, ketone bodies, and ketogenic amino acids, to CO<sub>2</sub> and H<sub>2</sub>O with the concomitant production of NADH and FADH<sub>2</sub>. Many glucogenic amino acids can also be oxidized via the citric acid cycle through their breakdown, ultimately to pyruvate and then to acetyl-CoA, sometimes via the **cataplerosis** (using up) of a citric acid cycle intermediate (Section 21-5). The activities of the citric acid cycle regulatory enzymes citrate synthase, isocitrate dehydrogenase, and  $\alpha$ -ketoglutarate dehydrogenase are controlled by substrate availability and feedback inhibition by cycle intermediates, NADH, and ATP.

**6. Oxidative phosphorylation (Chapter 22)** This mitochondrial pathway oxidizes NADH and FADH<sub>2</sub> to NAD<sup>+</sup> and FAD with the coupled synthesis of ATP. The rate of oxidative phosphorylation, which is tightly coordinated with the metabolic fluxes through glycolysis and the citric acid cycle, is largely dependent on the concentrations of ATP, ADP, and P<sub>i</sub>, as well as O<sub>2</sub>.

**7. Pentose phosphate pathway (Section 23-4)** This pathway functions to generate NADPH for use in reductive biosynthesis, as well as the nucleotide precursor ribose-5-phosphate, through the oxidation of G6P. Its flux-generating step is catalyzed by glucose-6-phosphate dehydrogenase, which is controlled by the level of NADP<sup>+</sup>. *The ability of enzymes to distinguish between NADH, which is mainly utilized in energy metabolism, and NADPH permits energy metabolism and biosynthesis to be regulated independently.*

**8. Amino acid degradation and synthesis (Sections 26-1 through 26-5)** Excess amino acids may be degraded to common metabolic intermediates. Most of these pathways begin with an amino acid's transamination to its corresponding  $\alpha$ -keto acid with the eventual transfer of the amino group to urea via the urea cycle. Leucine and lysine are ketogenic amino acids in that they can be converted only to acetyl-CoA or acetoacetate and hence cannot be glucose precursors. The other amino acids are glucogenic in that they may be, at least in part, converted to one of the glucose precursors pyruvate, oxaloacetate,  $\alpha$ -ketoglutarate, succinyl-CoA, or fumarate. Five amino acids are both ketogenic and glucogenic. Essential amino acids are those that an animal cannot synthesize itself; they must be obtained from plant and microbial sources. Nonessential amino acids can be synthesized by animals utilizing preformed amino groups via pathways that are generally simpler than those synthesizing essential amino acids.

Two compounds lie at the crossroads of the foregoing metabolic pathways: acetyl-CoA and pyruvate (Fig. 27-1).

Acetyl-CoA is the common degradation product of most metabolic fuels, including polysaccharides, lipids, and proteins. Its acetyl group may be oxidized to CO<sub>2</sub> and H<sub>2</sub>O via the citric acid cycle and oxidative phosphorylation or used to synthesize fatty acids. Pyruvate is the product of glycolysis, the dehydrogenation of lactate, and the breakdown of certain glucogenic amino acids. It may be oxidatively decarboxylated to yield acetyl-CoA, thereby committing its atoms either to oxidation or to the biosynthesis of fatty acids. Alternatively, it may be carboxylated via the pyruvate carboxylase reaction to form oxaloacetate, which, in turn, either replenishes citric acid cycle intermediates or enters gluconeogenesis via phosphoenolpyruvate, thereby bypassing an irreversible step in glycolysis. Pyruvate is therefore a precursor of several amino acids as well as of glucose.

The foregoing pathways occur in specific cellular compartments. Glycolysis, glycogen synthesis and degradation, fatty acid synthesis, and the pentose phosphate pathway are largely or entirely cytosolically based, whereas fatty acid degradation, the citric acid cycle, and oxidative phosphorylation occur in the mitochondrion. Different phases of gluconeogenesis and amino acid degradation occur in each of these compartments. *The flow of metabolites across compartment membranes is mediated, in most cases, by specific carriers that are also subject to regulation.*

The enormous number of enzymatic reactions that simultaneously occur in every cell (Fig. 16-1) must be coordinated and strictly controlled to meet the cell's needs. Such regulation occurs on many levels. Intercellular communications regulating metabolism occur via certain hormones, including epinephrine, norepinephrine, glucagon, and insulin, as well as through a series of steroid hormones known as **glucocorticoids** (whose effects are discussed in Section 19-1Ga). These hormonal signals trigger a variety of cellular responses, including the synthesis of second messengers such as cAMP in the short term and the modulation of protein synthesis rates in the long term. On the molecular level, enzymatic reaction rates are controlled by phosphorylation/dephosphorylation via amplifying reaction cascades, by allosteric responses to the presence of effectors, which are usually precursors or products of the reaction pathway being controlled, and by substrate availability. The regulatory machinery of opposing catabolic and anabolic pathways is generally arranged such that these pathways are reciprocally regulated.

## 2 ORGAN SPECIALIZATION

Different organs have different metabolic functions and capabilities. In this section we consider how the special needs of the mammalian body organs are met and how their metabolic capabilities are coordinated to meet these needs. In particular, we discuss brain, muscle, adipose tissue, liver, and kidney (Fig. 27-2).

### A. Brain

Brain tissue has a remarkably high respiration rate. For instance, the human brain constitutes only ~2% of the adult

**Figure 27-2** The metabolic interrelationships among brain, adipose tissue, muscle, liver, and kidney. The red-outlined arrows indicate pathways that predominate in the well-fed state when

glucose, amino acids, and fatty acids are directly available from the intestines.

body mass but is responsible for ~20% of its resting  $O_2$  consumption. This consumption, moreover, is independent of the state of mental activity; it varies little between sleep and the intense concentration required of, say, the study of biochemistry. Most of the brain's energy production serves to power the plasma membrane ( $Na^+ - K^+$ )-ATPase (Section 20-3A), which maintains the membrane potential required for nerve impulse transmission (Section 20-5). In fact, the respiration of brain slices is over 50% reduced by the ( $Na^+ - K^+$ )-ATPase inhibitor ouabain (Section 20-3Af).

Under usual conditions, glucose serves as the brain's only fuel (although, with extended fasting, the brain gradually switches to ketone bodies; Section 27-4A). Indeed, since brain cells store very little glycogen, they require a

steady supply of glucose from the blood. A blood glucose concentration of less than half of the normal value of ~5 mM results in brain dysfunction. Levels much below this, for example, caused by severe insulin overdose, result in coma, irreversible damage, and ultimately death. One of the liver's major functions, therefore, is to maintain the blood glucose level (Sections 18-3F and 27-2D).

### B. Muscle

Muscle's major fuels are glucose from glycogen, fatty acids, and ketone bodies. Rested, well-fed muscle, in contrast to brain, synthesizes a glycogen store comprising 1 to 2% of its mass. The glycogen serves muscle as a readily available

fuel depot since it can be rapidly converted to G6P for entry into glycolysis (Section 18-1).

Muscle cannot export glucose because it lacks glucose-6-phosphatase. Nevertheless, muscle serves the body as an energy reservoir because, during the fasting state, its proteins are degraded to amino acids, many of which are converted to pyruvate, which in turn, is transaminated to alanine. The alanine is then exported via the bloodstream to the liver, which transaminates it back to pyruvate, a glucose precursor. This process is known as the glucose-alanine cycle (Section 26-1Ad).

Since muscle does not participate in gluconeogenesis, it lacks the machinery that regulates this process in such gluconeogenic organs as liver and kidney. Muscle does not have receptors for glucagon, which, it will be recalled, stimulates an increase in blood glucose levels (Section 18-3F). However, muscle possesses epinephrine receptors ( $\beta$ -adrenergic receptors; Section 19-1F), which through the intermediacy of cAMP control the phosphorylation/dephosphorylation cascade system that regulates glycogen breakdown and synthesis (Section 18-3). This is the same cascade system that controls the competition between glycolysis and gluconeogenesis in liver in response to glucagon.

Heart muscle and skeletal muscle contain different isozymes of PFK-2/FBPase-2. The heart muscle isozyme is controlled by phosphorylation oppositely to that in liver, whereas skeletal muscle PFK-2/FBPase-2 is not controlled by phosphorylation at all (Section 18-3Fc). Thus the concentration of F2,6P rises in heart muscle but falls in liver in response to an increase in [cAMP]. Moreover the muscle isozyme of pyruvate kinase, which, it will be recalled, catalyzes the final step of glycolysis, is not subject to phosphorylation/dephosphorylation as is the liver isozyme (Section 23-1Ba). Thus, *whereas an increase in liver cAMP stimulates glycogen breakdown and gluconeogenesis, resulting in glucose export, an increase in heart muscle cAMP activates glycogen breakdown and glycolysis, resulting in glucose consumption. Consequently, epinephrine, which prepares the organism for action (fight or flight), acts independently of glucagon which, acting reciprocally with insulin, regulates the general level of blood glucose.*

#### a. Muscle Contraction Is Anaerobic Under Conditions of High Exertion

Muscle contraction is driven by ATP hydrolysis (Section 35-3Bb) and is therefore ultimately dependent on respiration. Skeletal muscle at rest utilizes  $\sim 30\%$  of the  $O_2$  consumed by the human body. A muscle's respiration rate may increase in response to a heavy workload by as much as 25-fold. Yet, its rate of ATP hydrolysis can increase by a much greater amount. The ATP is initially regenerated by the reaction of ADP with phosphocreatine as catalyzed by creatine kinase (Section 16-4Cd):

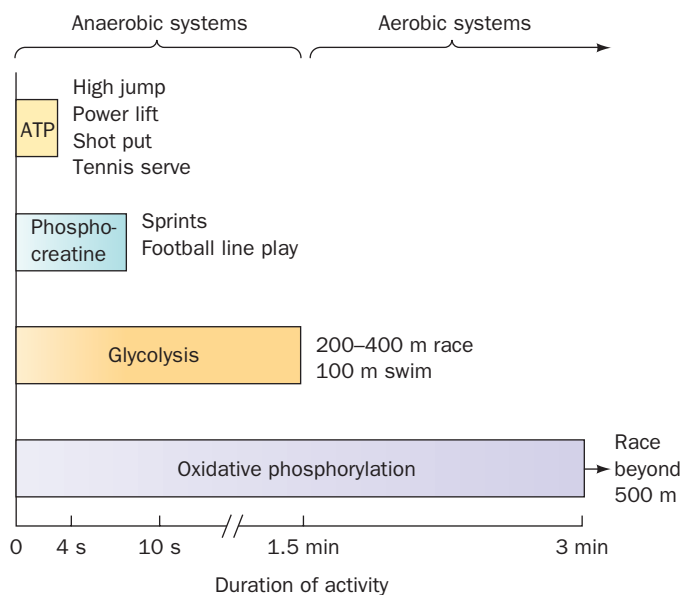

(phosphocreatine is resynthesized in resting muscle by the reversal of this reaction). Under conditions of maximum exertion, however, such as occurs in a sprint, a muscle has

only an  $\sim 5$ -s supply of phosphocreatine. It must then shift to ATP production via glycolysis of G6P resulting from glycogen breakdown, a process whose maximum flux greatly exceeds those of the citric acid cycle and oxidative phosphorylation. Much of this G6P is therefore degraded anaerobically to lactate (Section 17-3A) which, in the Cori cycle (Section 23-1C), is exported via the bloodstream to the liver, where it is reconverted to glucose through gluconeogenesis. Gluconeogenesis requires ATP generated by oxidative phosphorylation. Muscles thereby shift much of their respiratory burden to the liver and consequently also delay the  $O_2$ -consumption process, a phenomenon known as oxygen debt. The source of ATP during exercise of varying duration is summarized in Fig. 27-3.

#### b. Muscle Fatigue Has a Protective Function

**Muscle fatigue**, defined as the inability of a muscle to maintain a given power output, occurs in  $\sim 20$  s under conditions of maximum exertion. Such fatigue is not caused by the exhaustion of the muscle's glycogen supply. Rather, it may result from glycolytic proton generation that can drop the intramuscular pH from its resting value of 7.0 to as low as 6.4 (fatigue does not, as is widely believed, result from the buildup of lactate itself, as is demonstrated by the observation that muscles can sustain a large power output under high lactate concentrations if the pH is maintained near 7.0). Nevertheless, how acidification might cause muscle fatigue is unclear. Two other proposed causes for muscle fatigue are (1) the increased  $[P_i]$  arising largely from the

**Figure 27-3** Source of ATP during exercise in humans. The supply of endogenous ATP is extended for a few seconds by phosphocreatine, after which anaerobic glycolysis generates ATP. The shift from anaerobic to aerobic metabolism (oxidative phosphorylation) occurs after about 90 s, or slightly later in trained athletes. [Adapted from McArdle, W.D., Katch, F.I., and Katch, V.L., *Exercise Physiology*, 2nd ed., Lea & Febiger (1986), p. 348.]

utilization of ATP may precipitate  $\text{Ca}^{2+}$  as calcium phosphate (which is highly insoluble), thereby decreasing contractile force (muscle contraction is triggered by the release of  $\text{Ca}^{2+}$  ion; Section 35-3Cb); and (2) the  $\text{K}^+$  ion known to be released from contracting muscle cells may result in their depolarization (Section 20-5Ba) and hence a reduction in their contraction. Whatever its cause(s), it seems likely that muscle fatigue is an adaptation that prevents muscle cells from committing suicide by exhausting their ATP supply (recall that glycolysis and other ATP-generating pathways must be primed by ATP).

### c. The Heart Is a Largely Aerobic Organ

The heart is a muscular organ but one that must maintain continuous rather than intermittent activity. Thus heart muscle, except for short periods of extreme exertion, relies entirely on aerobic metabolism. It is therefore richly endowed with mitochondria; they comprise up to 40% of its cytoplasmic space, whereas some types of skeletal muscle are nearly devoid of mitochondria. The heart can metabolize fatty acids, ketone bodies, glucose, pyruvate, and lactate. Fatty acids are the resting heart's fuel of choice but, on the imposition of a heavy workload, the heart greatly increases its rate of consumption of glucose, which is derived mostly from its relatively limited glycogen store.

## C. Adipose Tissue

Adipose tissue, which consists of cells known as adipocytes (Fig. 12-2), is widely distributed about the body but occurs most prominently under the skin, in the abdominal cavity, in skeletal muscle, around blood vessels, and in mammary gland. The adipose tissue of a normal 70-kg man contains ~15 kg of fat. This amount represents some 590,000 kJ of energy (141,000 dieter's Calories), which is sufficient to maintain life for ~3 months. Yet, adipose tissue is by no means just a passive storage depot. In fact, it is second in importance only to liver in the maintenance of metabolic homeostasis (Section 27-3).

Adipose tissue obtains most of its fatty acids from the liver or from the diet as described in Section 25-1. Fatty acids are activated by the formation of the corresponding fatty acyl-CoA and then esterified with glycerol-3-phosphate to form the stored triacylglycerols (Section 25-4F). The glycerol-3-phosphate arises from the reduction of dihydroxyacetone phosphate, which must be glycolytically generated from glucose or gluconeogenically generated from pyruvate or oxaloacetate (a process called **glyceroneogenesis**; Section 25-4Fa) because adipocytes lack a kinase that phosphorylates endogenous glycerol.

Adipocytes hydrolyze triacylglycerols to fatty acids and glycerol in response to the levels of glucagon, epinephrine, and insulin through a reaction catalyzed by hormone-sensitive triacylglycerol lipase (Section 25-5). If glycerol-3-phosphate is abundant, many of the fatty acids so formed are reesterified to triacylglycerols. Indeed, the average turnover time for triacylglycerols in adipocytes is only a few days. If, however, glycerol-3-phosphate is in short supply, the fatty acids are released into the bloodstream. *The rate of*

*glucose uptake by adipocytes, which is regulated by insulin as well as by glucose availability, is therefore also an important factor in triacylglycerol formation and mobilization.* However, glycerol-3-phosphate is also produced via glyceroneogenesis under the control of PEPCK, allowing triacylglycerol turnover even when glucose concentration is low.

### a. Obesity Results from Aberrant Metabolic Control

The human body regulates glycogen and protein levels within relatively narrow limits, but fat reserves, which are much larger, can become enormous. The accumulation of fatty acids as triacylglycerols in adipose tissue is largely a result of excess fat or carbohydrate intake compared to energy expenditure. Fat synthesis from carbohydrates occurs when the carbohydrate intake is high enough that glycogen stores, to which excess carbohydrate is normally directed, approach their maximum capacity.

Obesity is one of the major health-related problems in industrial countries. An estimated 30% of adults in the United States are obese (are at least 20% above their desirable weights) and another 35% are overweight. Most obese people find it inordinately difficult to lose weight or, having done so, to keep it off. Yet most animals, including humans, tend to have stable weights; that is, if they are given free access to food, they eat just enough to maintain this so-called set point weight. The nature of the regulatory machinery that controls the set point, which in obese individuals seems to be aberrantly high, is just beginning to come to light (see Section 27-3).

Formerly grossly obese individuals who have lost at least 100 kg to reach their normal weights exhibit some of the metabolic symptoms of starvation: they are obsessed with food, have low heart rates, are cold intolerant, and require 25% less caloric intake than normal individuals of similar heights and weights. In both normal and obese individuals, some 50% of the fatty acids liberated by the hydrolysis of triacylglycerols are reesterified before they can leave the adipocytes. In formerly obese subjects, this reesterification rate is only 35 to 40%, a level similar to that observed in normal individuals after a several day fast. The fat cells in normal and obese individuals, moreover, are of roughly the same size; obese people just have more of them. In fact, adipocyte precursor cells from massively obese individuals proliferate excessively in tissue culture compared to those from normal or even moderately obese subjects (adipocytes themselves do not replicate). Since fat cells, once gained, are never lost, this suggests that adipocytes, although highly elastic in size, tend to maintain a certain fixed volume and in doing so influence the metabolism and thus the appetite. This insight, unfortunately, has not yet led to a method for lowering the set points of individuals with a tendency toward obesity.

## D. Liver

*The liver is the body's central metabolic clearinghouse.* It functions to maintain the proper levels of nutrients in the blood for use by the brain, muscles, and other tissues. The liver is uniquely situated to carry out this task because all the

nutrients absorbed by the intestines except fatty acids are released into the portal vein, which drains directly into the liver.

*One of the liver's major functions is to act as a blood glucose "buffer."* It does so by taking up or releasing glucose in response to the levels of glucagon, epinephrine, and insulin as well as to the concentration of glucose itself. After a carbohydrate-containing meal, when the blood glucose concentration reaches  $\sim 6$  mM, the liver takes up glucose by converting it to G6P. The process is catalyzed by glucokinase (Section 18-3Fa), which differs from hexokinase, the analogous glycolytic enzyme in other cells, in that glucokinase has a much lower affinity for glucose (glucokinase reaches half-maximal velocity at  $\sim 5$  mM glucose vs  $< 0.1$  mM glucose for hexokinase) and is not inhibited by G6P. Liver cells, in contrast to muscle and adipose cells, are permeable to glucose, and thus insulin has no direct effect on their glucose uptake. Since the blood glucose concentration is normally less than glucokinase's  $K_M$ , the rate of glucose phosphorylation in the liver is more or less proportional to the blood glucose concentration. The other intestinally absorbed sugars, mostly fructose, galactose, and mannose, are also converted to G6P in the liver (Section 17-5). After an overnight fast, the blood glucose level drops to  $\sim 4$  mM. The liver keeps it from dropping below this level by releasing glucose into the blood as is described below. In addition, lactate, the product of anaerobic glucose metabolism in the muscle, is taken up by the liver for use in gluconeogenesis and lipogenesis as well as in oxidative phosphorylation (the Cori cycle; Section 23-1C). Alanine produced in the muscle is taken up by the liver and converted to pyruvate for gluconeogenesis as well (the glucose-alanine cycle; Section 26-1Ad).

#### a. The Fate of Glucose-6-Phosphate Varies with Metabolic Requirements

*G6P is at the crossroads of carbohydrate metabolism; it can have several alternative fates depending on the glucose demand (Fig. 27-1):*

1. G6P can be converted to glucose by the action of glucose-6-phosphatase for transport via the bloodstream to the peripheral organs.
2. G6P can be converted to glycogen (Section 18-2) when the body's demand for glucose is low. Yet, increased glucose demand, as signaled by higher levels of glucagon and/or epinephrine, reverses this process (Section 18-1).
3. G6P can be converted to acetyl-CoA via glycolysis and the action of pyruvate dehydrogenase (Chapter 17 and Section 21-2). Most of this glucose-derived acetyl-CoA is used in the synthesis of fatty acids (Section 25-4), whose fate is described below, and in the synthesis of phospholipids (Section 25-8) and cholesterol (Section 25-6A). Cholesterol, in turn, is a precursor of bile salts, which are produced by the liver (Section 25-6C) for use as emulsifying agents in the intestinal digestion and absorption of fats (Section 25-1).
4. G6P can be degraded via the pentose phosphate pathway (Section 23-4) to generate the NADPH required

for fatty acid biosynthesis and the liver's many other biosynthetic functions, as well as ribose-5-phosphate (R5P) for nucleotide biosynthesis (Sections 28-1A and 28-2A).

#### b. The Liver Can Synthesize or Degrade Triacylglycerols

Fatty acids are also subject to alternative metabolic fates in the liver (Fig. 27-1):

1. When the demand for metabolic fuels is high, fatty acids are degraded to acetyl-CoA and then to ketone bodies (Section 25-3) for export via the bloodstream to the peripheral tissues.
2. When the demand for metabolic fuels is low, fatty acids are used to synthesize triacylglycerols that are secreted into the bloodstream as VLDL for uptake by adipose tissue. Fatty acids may also be incorporated into phospholipids (Section 25-8).

Since the rate of fatty acid oxidation varies only with fatty acid concentration (Section 25-5), fatty acids produced by the liver might be expected to be subject to reoxidation before they can be exported. Such a futile cycle is prevented by the compartmentalization of fatty acid oxidation in the mitochondrion and fatty acid synthesis in the cytosol. Carnitine palmitoyltransferase I, a component of the system that transports fatty acids into the mitochondrion (Section 25-2B), is inhibited by malonyl-CoA, the key intermediate in fatty acid biosynthesis (Section 25-4A). Hence, when the demand for metabolic fuels is low so that fatty acids are being synthesized, they cannot enter the mitochondrion for conversion to acetyl-CoA. Rather, the liver's biosynthetic demand for acetyl-CoA is met through the degradation of glucose.

When the demand for metabolic fuel rises so as to inhibit fatty acid biosynthesis, however, fatty acids are transported into the liver mitochondria for conversion to ketone bodies. Under such conditions of low blood glucose concentrations, glucokinase has reduced activity so that there is net glucose export (there is, however, always a futile cycle between the reactions catalyzed by glucokinase and glucose-6-phosphatase; Section 18-3Fb). The liver cannot use ketone bodies for its own metabolic purposes because liver cells lack 3-ketoacyl-CoA transferase (Section 25-3). Fatty acids rather than glucose or ketone bodies are therefore the liver's major acetyl-CoA source under conditions of high metabolic demand. The liver generates its ATP from this acetyl-CoA through the citric acid cycle and oxidative phosphorylation. The aerobic oxidation of fatty acids inhibits glucose utilization since activation of the citric acid cycle and oxidative phosphorylation increases the concentration of citrate, which inhibits glycolysis (the glucose-fatty acid or Randle cycle; Section 22-4Bb).

#### c. Amino Acids Are Important Metabolic Fuels

The liver degrades amino acids to a variety of metabolic intermediates (Section 26-3). These pathways mostly begin with amino acid transamination to yield the corresponding  $\alpha$ -keto acid (Section 26-1A) with the amino group being

ultimately converted, via the urea cycle (Section 26-2), to the subsequently excreted urea. Glucogenic amino acids can be converted in this manner to pyruvate or citric acid cycle intermediates such as oxaloacetate and are thereby gluconeogenic precursors (Section 23-1). Ketogenic amino acids, many of which are also glucogenic, may be converted to ketone bodies.

The liver's glycogen store is insufficient to supply the body's glucose needs for more than ~6 h after a meal. After that, glucose is supplied through gluconeogenesis from amino acids arising mostly from muscle protein degradation to alanine (the glucose–alanine cycle; Section 26-1Ad) and glutamine (the transport form of ammonia; Section 26-1B). Thus proteins, in addition to their structural and functional roles, are important fuel resources. (Animals cannot convert fat to glucose because they lack a pathway for the net conversion of acetyl-CoA to oxaloacetate; Section 23-2).

#### d. The Liver Is the Body's Major Metabolic Processing Unit

The liver has numerous specialized biochemical functions in addition to those already mentioned. Prominent among them are the synthesis of blood plasma proteins, the degradation of porphyrins (Section 26-4A) and nucleic acid bases (Section 28-4), the storage of iron, and the detoxification of biologically active substances such as drugs, poisons, and hormones by a variety of oxidation (e.g., by cytochromes P450; Section 15-4Bc), reduction, hydrolysis, conjugation, and methylation reactions.

#### E. Kidney

The kidney functions to filter out the waste product urea from the blood and concentrate it for excretion, to recover important metabolites such as glucose, and to maintain the blood's pH. Blood pH is maintained by regenerating depleted blood buffers such as bicarbonate (lost by the exhalation of CO<sub>2</sub>) and by removing for excretion excess H<sup>+</sup> together with the conjugate bases of excess metabolic acids such as the ketone bodies acetoacetate and β-hydroxybutyrate. Phosphate, the major buffer in urine for moderate acid excretion, is accompanied by equivalent quantities of cations such as Na<sup>+</sup> and K<sup>+</sup>. However, large losses of Na<sup>+</sup> and K<sup>+</sup> would upset the body's electrolyte balance, so on the production of large amounts of acids such as lactic acid or ketone bodies, the kidney produces NH<sub>4</sub><sup>+</sup> to aid in the excretion of the excess H<sup>+</sup> (utilizing Cl<sup>-</sup> or the conjugate base of a metabolic acid as the counterion). This NH<sub>4</sub><sup>+</sup> is generated from glutamine, which is converted first to glutamate and then to α-ketoglutarate by glutaminase and glutamate dehydrogenase. The overall reaction is

The α-ketoglutarate is converted to malate by the citric acid cycle and then is exported from the mitochondrion and converted either to pyruvate, which is oxidized completely to CO<sub>2</sub>, or via oxaloacetate to PEP and then to glucose via gluconeogenesis. High fat diets, which produce

high blood concentrations of free fatty acids and ketone bodies and hence high acidic loads, cause α-ketoglutarate to be converted completely to CO<sub>2</sub>, and then to bicarbonate, thereby increasing the blood's buffering capacity. During starvation, the α-ketoglutarate enters gluconeogenesis, to the extent that the kidneys generate as much as 50% of the body's glucose supply.

### 3 METABOLIC HOMEOSTASIS: REGULATION OF APPETITE, ENERGY EXPENDITURE, AND BODY WEIGHT

When a normal animal overeats, the resulting additional fat somehow signals the brain to induce the animal to eat less and to expend more energy. Conversely, the loss of fat stimulates increased eating until the lost fat is replaced. Evidently, animals have a “lipostat” that can keep the amount of body fat constant to within 1% over many years. At least a portion of the lipostat resides in the hypothalamus (a part of the brain that hormonally controls numerous physiological functions; Section 19-1H), since damaging it can yield a grossly obese animal.

Despite this obvious set of controls in animals, there has been an explosion of obesity in many industrial nations. It has, in fact, become a world health problem, leading to diabetes and heart disease. As a result of numerous studies in recent years, researchers have been able to outline the mechanisms involved in **metabolic homeostasis**, the balance between energy influx and energy expenditure, and to identify some of the irregularities that lead to obesity. A variety of mutant strains of rodents have been generated that cause obesity. The study of these mutants has resulted in the identification of several hormones that act in a coordinated manner to regulate appetite.

#### A. AMP-Dependent Protein Kinase Is the Cell's Fuel Gauge

All of the metabolic pathways discussed in Section 27-1 are affected in one way or another by the need for ATP, as is indicated by the cell's AMP-to-ATP ratio (Section 17-4Fd). Several enzymes are either activated or inhibited allosterically by AMP, and several others are phosphorylated by **AMP-dependent protein kinase (AMPK)**, a major regulator of metabolic homeostasis. *AMPK activates metabolic breakdown pathways that generate ATP while inhibiting biosynthetic pathways so as to conserve ATP for more vital processes.* AMPK is an αβγ heterotrimer found in all eukaryotic organisms from yeast to humans. The α subunit contains a Ser/Thr protein kinase domain, and the γ subunit contains sites for allosteric activation by AMP and inhibition by ATP. Like other protein kinases, AMPK's kinase domain must be phosphorylated for activity. Binding of AMP to the γ subunit causes a conformational change that exposes Thr 172 in the activation loop of the α subunit, promoting its phosphorylation and increasing its activity at least 100-fold. AMP can activate the phosphorylated enzyme up to 5-fold more. There are two isoforms of the α

subunit, two of the  $\beta$  subunit, and three of the  $\gamma$  subunit, giving rise to 12 possible heterotrimeric combinations, with splice variants yielding further diversity. The major kinase that phosphorylates AMPK is named **LKB1**. The knockout of LKB1 in mouse liver results in the loss of the phosphorylated form of AMPK.

#### a. AMPK Activates Glycolysis in Ischemic Cardiac Muscle

AMPK's targets include the heart isozyme of the bifunctional enzyme PFK-2/FBPase-2, which controls the fructose-2,6-bisphosphate (F2,6P) concentration (Section 18-3Fc). The phosphorylation of this isozyme activates the PFK-2 activity, increasing [F2,6P], which in turn activates PFK-1, the rate-determining enzyme of glycolysis (Section 17-4Fb). Consequently, in ischemic (blood-starved) heart muscle cells, which receive insufficient oxygen for oxidative phosphorylation to maintain adequate concentrations of ATP, the resulting AMP buildup causes the cells to switch to anaerobic glycolysis for ATP production.

#### b. AMPK Inhibits Lipogenesis, Cholesterol Synthesis, and Gluconeogenesis in Liver

AMPK-mediated phosphorylation also inhibits acetyl-CoA carboxylase (ACC), which catalyzes the first committed step of fatty acid synthesis (Section 25-4B), and hydroxymethylglutaryl-CoA reductase (HMG-CoA reductase), which catalyzes the rate-determining step in cholesterol biosynthesis (Section 25-6Aa). Activated AMPK inhibits gluconeogenesis in a more complicated way: It phosphorylates and thereby inactivates the transcriptional coactivator **TORC2** (for *transducer of regulated CREB activity-2*), which in concert with the transcriptional activator CREB, would otherwise induce the transcription of the gene encoding PEP carboxykinase (PEPCK), the enzyme that catalyzes the rate-determining step of gluconeogenesis (Sections 23-1Af and 23-1Bb). Consequently, when the rate of ATP production is inadequate, these biosynthetic pathways are turned off, thereby conserving ATP for more vital cellular functions.

#### c. AMPK Promotes Fatty Acid Oxidation and Glucose Uptake but Inhibits Glycogen Synthesis in Skeletal Muscle

The inhibition of ACC results in a decrease in the concentration of malonyl-CoA, the starting material for fatty acid biosynthesis. Malonyl-CoA has an additional role, however. It is an inhibitor of carnitine palmitoyltransferase I (Section 25-2B), which is required to transfer cytosolic palmitoyl-CoA into mitochondria for oxidation. The decrease in malonyl-CoA concentration therefore allows more palmitoyl-CoA to be oxidized. AMPK also increases the recruitment of GLUT4 to muscle cell plasma membranes (Section 20-2Ec), as well as stimulating its expression, thus facilitating the insulin-independent entry of glucose into these cells. In addition, AMPK inhibits glycogen synthase (which catalyzes the rate-limiting reaction in glycogen synthesis; Section 18-3B). In fact, the  $\beta$  subunit of AMPK has a glycogen-binding domain that presumably recruits AMPK to the vicinity of glycogen synthase.

#### d. AMPK Inhibits Fatty Acid Synthesis and Lipolysis in Adipocytes

AMPK inhibits fatty acid synthesis in adipocytes by phosphorylating ACC as described above. Moreover, AMPK phosphorylates hormone-sensitive triacylglycerol lipase in adipose tissue (Section 25-5). This phosphorylation inhibits rather than activates the enzyme, in part by preventing the relocation of the enzyme to the lipid droplet, the cellular location of lipolysis. As a result, fewer triacylglycerol molecules are broken down so that fewer fatty acids are exported to the bloodstream. This latter process seems paradoxical (fatty acid oxidation would help relieve an ATP deficit), although it has been speculated that it prevents the cellular buildup of fatty acids to toxic levels. The major effects of AMPK activation on glucose and lipid metabolism in liver, skeletal muscle, heart muscle, and adipose tissue are diagrammed in Fig. 27-4.

### B. Adiponectin Regulates AMPK Activity

**Adiponectin** is a 247-residue protein hormone, secreted exclusively by adipocytes, that helps regulate energy homeostasis and glucose and lipid metabolism by controlling AMPK activity. Its monomers consist of an N-terminal collagenlike domain and a C-terminal globular domain. Adiponectin occurs in the bloodstream in several forms: a low molecular weight (LMW) trimer formed by the coiling of its collagenlike domains into a triple helix (Section 8-2Ba) as well as hexamers (MMW) and multimers (HMW) that form disulfide cross-linked bouquets (Fig. 27-5). In addition, globular adiponectin, formed by the cleavage of the collagenlike domain to release globular monomers, occurs in lower concentrations.

The binding of adiponectin to **adiponectin receptors**, which occur on the surfaces of both liver and muscle cells, acts to increase the phosphorylation and activity of AMPK. This, as we have seen (Section 27-3A), inhibits gluconeogenesis and stimulates fatty acid oxidation in liver and stimulates glucose uptake and glucose and fatty acid oxidation in muscle. All of these effects act to increase insulin sensitivity, in part because adiponectin and insulin elicit similar responses in tissues such as liver. Decreased adiponectin is associated with insulin resistance (Section 27-4B). Paradoxically, the blood concentration of adiponectin, which is secreted by adipocytes, decreases with increased amounts of adipose tissue. This may be because increased adipose tissue is also associated with increased production of **tumor necrosis factor- $\alpha$  (TNF- $\alpha$ )**, a cytokine that decreases both the expression and secretion of adiponectin from adipose tissue (Section 19-3Db).

### C. Leptin

Two of the genes whose mutations cause obesity in mice are known as *obese (ob)* and *diabetes (db)*; the wild-type genes are designated *OB* and *DB*. Homozygotes for defects in either of these recessive genes, *ob/ob* or *db/db*, are grossly obese and have nearly identical phenotypes (Fig. 27-6). Indeed, the way in which these phenotypes

**Figure 27-4** Major effects of AMP-activated protein kinase (AMPK) on glucose and lipid metabolism in liver, muscle, and adipose tissue. In skeletal muscle, AMPK stimulates glucose and fatty acid oxidation while inhibiting glycogen synthesis. In heart muscle, AMPK stimulates glycolysis. In liver, AMPK inhibits

lipid biosynthesis and gluconeogenesis while activating fatty acid oxidation. In adipose tissue, AMPK inhibits fatty acid biosynthesis, lipolysis, and fatty acid export. [After Towler, M.C. and Hardie, D.G., *Circ. Res.* **100**, 328 (2007).]

were distinguished was by surgically linking the circulation of a mutant mouse to that of a normal (*OB/OB*) mouse, a phenomenon named **parabiosis**. *ob/ob* mice so linked

exhibit normalization of body weight and reduced food intake, whereas *db/db* mice do not do so. This suggests that *ob/ob* mice are deficient in a circulating factor that regulates appetite and metabolism, whereas *db/db* mice are defective in the receptor for this circulating factor.

**Figure 27-5** Adiponectin trimers, hexamers, and multimers. These complexes are referred to as low molecular weight (LMW), medium molecular weight (MMW), and high molecular weight (HMW) forms. [After Kadowaki, T., and Yamauchi, T., *Endocr. Rev.* **26**, 439 (2005).]

**Figure 27-6** Normal (*OB/OB*, left) and obese (*ob/ob*, right) mice. [Courtesy of Richard D. Palmiter, University of Washington.]

The mouse *OB* gene encodes a 146-residue monomeric protein named **leptin** (Greek: *leptos*, thin; Fig. 27-7) that has no apparent homology with proteins of known sequence. Leptin, which was discovered by Jeffrey Friedman, is expressed only by adipocytes, which in doing so appear to inform the brain of how much fat the body carries. Thus, injecting leptin into *ob/ob* mice causes them to eat less and to lose weight. In fact, leptin-treated *ob/ob* mice on a restricted diet lost 50% more weight than untreated *ob/ob* mice on the same diet, which suggests that reduced food intake alone is insufficient to account for leptin-induced weight loss. Leptin appears to control energy expenditure as well.

Leptin injection has no effect on *db/db* mice. The leptin receptor gene was identified by making a cDNA library from mouse brain tissue that specifically bound leptin and then identifying a receptor-expressing clone by its ability to bind leptin (gene cloning techniques are discussed in Section 5-5). This gene, which has been shown to be the *DB* gene, encodes a protein named **OB-R** (for *OB* receptor) that appears to have a single transmembrane segment and an extracellular domain that resembles the receptors for certain cytokines (proteins that regulate the differentiation, proliferation, and activities of various blood cells; Section 19-3Eb).

OB-R protein, which was discovered by Louis Tartaglia, has at least six alternatively spliced forms that appear to be expressed in a tissue-specific manner (alternative gene splicing is discussed in Section 31-4Am). In normal mice, the hypothalamus expresses high levels of a splice variant of OB-R that has a 302-residue cytoplasmic segment. However, in *db/db* mice, this segment has an abnormal splice site that truncates it to only 34 residues, which almost certainly renders this OB-R variant unable to transmit leptin signals. Thus, it appears that leptin's weight-controlling effects are mediated by signal transduction resulting from its binding to the OB-R protein in the hypothalamus.

Human leptin is 84% identical in sequence to that of mice. The use of a radioimmunoassay (Section 19-1A) to measure the serum levels of leptin in normal-weight and obese humans established that in both groups serum leptin concentrations increase with their percentage of body fat as does the *ob* mRNA content of their adipocytes. Moreover, after obese individuals had lost weight, their serum leptin concentrations and adipocyte *ob* mRNA content declined. This suggests that most obese persons produce sufficient amounts of leptin but have developed "leptin resistance." Since leptin must cross the blood-brain barrier in order to exert its effects on the hypothalamus, it has been suggested that this crossing is somehow saturatable, thus limiting the concentration of leptin in the brain. The high concentration of leptin in obese individuals is not without affect, however. OB-R is also expressed in peripheral tissues where leptin has been shown to function as well. While not preventing obesity, the hormone has been shown to directly stimulate the oxidation of fatty acids as well as to inhibit the accumulation of lipids in non-adipose tissue. It does so by activating AMP-dependent protein kinase (AMPK), which in turn phosphorylates and thereby inacti-

**Figure 27-7 X-ray structure of human leptin-E100.** This mutant form of leptin (W100E) has comparable biological activity to the wild-type protein but crystallizes more readily. The protein, which is colored in rainbow order from its N-terminus (blue) to its C-terminus (red), forms a four-helix bundle, as do many protein growth factors (e.g., human growth hormone; Fig. 19-10). Residues 25 to 38 are not visible in the X-ray structure. [Based on an X-ray structure by Faming Zhang, Eli Lilly & Co., Indianapolis, Indiana. PDBid 1AX8.]

 See Interactive Exercise 27.

vates acetyl-CoA carboxylase (ACC). This reduces the malonyl-CoA concentration, thereby decreasing its inhibition of carnitine palmitoyltransferase I, which then transports fatty acyl-CoA into the mitochondrion for oxidation (Section 25-5). We discuss the function of leptin in peripheral tissues in Section 27-3H.

A small minority of obese individuals have been found to be leptin deficient in a manner similar to *ob/ob* mice. Two grossly obese children who are members of the same highly consanguineous (descended from the same ancestors) family (they are cousins and both sets of parents are cousins) have been shown to be homozygous for a defective OB gene. The children, at the ages of 8 and 2 years old, respectively, weighed 86 and 29 kg and were noted to have remarkably large appetites. Their OB genes have a deletion of a single guanine nucleotide in codon 133, thereby causing a frameshift mutation that, it is likely, renders the

mutant leptin biologically inactive. Moreover, their leptin serum levels were only ~10% of normal. Leptin injections have relieved their symptoms.

#### D. Insulin

We have discussed the insulin signaling cascade (Section 19-4F) and the role of insulin in peripheral tissues such as muscle and adipose tissue in stimulating the uptake of glucose (Fig. 20-11) and its storage as glycogen (Section 18-3) or fat (Section 25-5). Insulin receptors also occur in the hypothalamus. Consequently, the infusion of insulin into rats with insulin-deficient diabetes inhibits food intake, reversing the overeating behavior characteristic of the disease. Knock-out mice have been developed with a central nervous system-specific disruption of the insulin receptor gene. These mice have no alteration in brain development or survival but become obese, with increased body fat, increased leptin levels, increased serum triacylglycerol, and the elevated plasma insulin levels characteristic of insulin resistance (Section 27-4B). Evidently, insulin also plays a role in the neuronal regulation of food intake and body weight. As we discuss in Section 27-3F, insulin and leptin both act through receptors in the hypothalamus to decrease food intake.

#### E. Ghrelin and PYY<sub>3-36</sub>

##### a. Ghrelin and PYY<sub>3-36</sub> Act as Short-Term Regulators of Appetite

**Ghrelin**, which was discovered by Masayasu Kojima and Kenji Kanagawa, is an appetite-stimulating gastric peptide that is secreted by the empty stomach. This 28-residue peptide was first discovered and named for its function as a growth hormone-releasing peptide (ghrelin is an abbreviation for *growth-hormone-release*). Octanoylation of its Ser 3 is required for activity.

##### Human ghrelin

X = Ser modified with *n*-octanoic acid

Injection of ghrelin has been shown to induce adiposity (increased adipose tissue) in rodents by stimulating an increase in food intake while reducing fat utilization. In humans in states of positive energy balance such as obesity or high caloric intake, circulating ghrelin levels are decreased, whereas during fasting, circulating ghrelin levels increase.

##### PYY<sub>3-36</sub>

##### Human PYY<sub>3-36</sub>

is a peptide secreted by the gastrointestinal tract in proportion to the caloric intake of a meal, which acts to inhibit further food intake. Both rodents and humans have been shown to respond to the presence of this peptide by decreasing their food intake for up to 12 hours. Human subjects receiving a 90-minute infusion of PYY<sub>3-36</sub> ate only 1500 kcal of

food during the next 24-hour period, whereas those receiving saline controls ate 2200 kcal during the same period.

#### F. Hypothalamic Integration of Hormonal Signals

##### a. Neurons of the Arcuate Nucleus Region of the Hypothalamus Integrate and Transmit Hunger Signals

About half of the length of the hypothalamus is taken up by the **arcuate nucleus**, a collection of neuronal cell bodies consisting of two cell types: the **NPY/AgRP** cell type and the **POMC/CART** cell type. These cell types are named after the neuropeptides they secrete. **Neuropeptide Y (NPY)**

##### Neuropeptide Y

The C-terminal carboxyl is amidated

is a potent stimulator of food intake and an inhibitor of energy expenditure, as is **Agouti related peptide (AgRP)**. **Pro-opiomelanocortin (POMC)** is post-translationally processed in the hypothalamus to release  **$\alpha$ -melanocyte stimulating hormone ( $\alpha$ -MSH; Section 34-3C)**. **Cocaine and amphetamine-regulated transcript (CART)** and  $\alpha$ -MSH are both inhibitors of food intake and stimulators of energy expenditure.

The balance of the secretions from these two cell types is controlled by leptin, insulin, ghrelin, and PYY<sub>3-36</sub> (Fig. 27-8). Leptin and insulin signal satiety and therefore decrease appetite by diffusing across the blood-brain barrier to the arcuate nucleus, where they stimulate POMC/CART neurons to produce CART and  $\alpha$ -MSH, while inhibiting the production of NPY from NPY/AgRP neurons. Leptin receptors act through the JAK-STAT signal transduction pathway (Section 19-3Eb). Ghrelin has receptors on NPY/AgRP neurons that stimulate the secretion of NPY and AgRP to increase appetite. Interestingly, PYY<sub>3-36</sub>, a peptide that is homologous to NPY, binds specifically to NPY receptor subtype Y2R on NPY/AgRP neurons. This subtype is an inhibitory receptor, however, so binding of PYY<sub>3-36</sub> causes a decrease in secretion from NPY/AgRP neurons. The integrated stimuli of all these secretions from the arcuate nucleus control appetite.

#### G. Control of Energy Expenditure by Adaptive Thermogenesis

The energy content of food is utilized by an organism either in the performance of work or the generation of heat. Excess energy is stored as glycogen or fat for future use. In well-balanced individuals, the storage of excess fuel remains constant over many years. However, when energy consumed is consistently greater than energy expended, obesity results. The body has several mechanisms for preventing obesity. One of them, as discussed above, is appetite control. The other is **diet-induced thermogenesis**, a form of **adaptive thermogenesis** (heat production in

**Figure 27-8 Hormones that control the appetite.** Leptin and insulin (*bottom*) circulate in the blood at concentrations proportional to body-fat mass. They decrease appetite by inhibiting NPY/AgRP neurons (*center*) while stimulating melanocortin-producing neurons in the arcuate nucleus region of the hypothalamus. NPY and AgRP increase the appetite, and melanocortins decrease the appetite, via other neurons (*top*). Activation of NPY/AgRP-expressing neurons inhibits

melanocortin-producing neurons. The gastric hormone ghrelin stimulates appetite by activating the NPY/AgRP-expressing neurons. PYY<sub>3-36</sub>, released from the gastrointestinal tract, inhibits NPY/AgRP-expressing neurons and thereby decreases the appetite. PYY<sub>3-36</sub> works in part through the autoinhibitory NPY receptor subtype Y2R. [After Schwartz, M.W. and Morton, G.J., *Nature* **418**, 596 (2002).]

response to environmental stress). We have previously discussed adaptive thermogenesis in response to cold, which occurs in rodents and newborn humans through the uncoupling of oxidative phosphorylation in brown adipose tissue (Section 22-3Da). The mechanism of this thermogenesis involves the release of norepinephrine from the brain in response to cold, its binding to  $\beta$ -adrenergic receptors on brown adipose tissue inducing an increase in [cAMP], which in turn initiates an enzymatic phosphorylation cascade that activates hormone-sensitive triacylglycerol lipase. The resulting increase in the concentration of free fatty acids provides fuel for oxidation as well as inducing

the opening of a proton channel, called uncoupling protein-1 (UCP1) or thermogenin, in the inner mitochondrial membrane. The opening of UCP1 discharges the proton gradient across the inner mitochondrial membrane, thus uncoupling electron transport from ATP production. The energy that would otherwise have been used to drive ATP synthesis is thereby released as heat.

Although metabolic measurements in adult humans clearly demonstrate that an increase in energy intake causes an increase in metabolic rate and thermogenesis, the cause of this increase is unclear. Adult humans have little brown adipose tissue. However, skeletal muscle represents

up to 40% of their total body weight and has high mitochondrial capacity. Homologs of UCP1 have been identified: **UCP2** occurs in many tissues including white adipose tissue, whereas **UCP3** occurs in brown adipose tissue, white adipose tissue, and muscle. Leptin has been shown to up-regulate UCP2. However, it has yet to be demonstrated that UCP3 in muscle participates in diet-induced thermogenesis. ATP-hydrolyzing substrate cycles such as that between fatty acids and triacylglycerol in adipose tissue (Section 27-2C) may also be involved.

### H. Did Leptin Evolve as a Thrifty Gene?

The unusual behavior of leptin, which serves to control weight in normal-weight individuals while its concentration continues to climb without apparent effect in obese individuals, has led to the proposal that leptin evolved as a “thrifty gene.” In hunter-gatherer societies, it was a distinct advantage to be able to survive intermittent famines. In order to do this, fat must be stored in adipose tissue in times of plenty, making short-term obesity advantageous. However, the accumulation of fatty acids and lipids in non-adipose tissue results in coronary artery disease, insulin resistance, and diabetes (Section 27-4B). Leptin, by directly stimulating the oxidation of fatty acids as well as inhibiting the accumulation of lipids in non-adipose tissue, is thought to protect against these diseases during short-term obesity, thereby providing an evolutionary advantage. However, in recent times in industrialized nations, the unprecedented availability of food and lack of famine has made obesity a long-term rather than a short-term condition, which is a liability rather than a benefit.

## 4 METABOLIC ADAPTATION

In this section we consider the body’s responses to two metabolically abnormal situations: (1) starvation and (2) the disease diabetes mellitus.

### A. Starvation

Glucose is the metabolite of choice of both brain and working muscle. Yet, the body stores less than a day’s supply of carbohydrate (Table 27-1). Thus, the low blood sugar caused by even an overnight fast results, through an increase in glucagon secretion and a decrease in insulin secretion, in the mobilization of fatty acids from adipose tissue (Section 25-5). The diminished insulin level also inhibits glucose uptake by muscle tissue. Muscles therefore switch from glucose to fatty acid metabolism for energy production. The brain, however, still remains heavily dependent on glucose.

In animals, glucose cannot be synthesized from fatty acids. This is because neither pyruvate nor oxaloacetate, the precursors of glucose in gluconeogenesis (Section 23-1), can be synthesized from acetyl-CoA (the oxaloacetate in the citric acid cycle is derived from acetyl-CoA but the cyclic nature of this process requires that the oxaloacetate be consumed as fast as it is synthesized; Section 21-1A).

**Table 27-1 Fuel Reserves for a Normal 70-kg Man**

Fuel	Mass (kg)	Calories <sup>a</sup>
<i>Tissues</i>		
Fat (adipose triacylglycerols)	15	141,000
Protein (mainly muscle)	6	24,000
Glycogen (muscle)	0.150	600
Glycogen (liver)	0.075	300
<i>Circulating fuels</i>		
Glucose (extracellular fluid)	0.020	80
Free fatty acids (plasma)	0.0003	3
Triacylglycerols (plasma)	0.003	30
<i>Total</i>		166,000

<sup>a</sup>One (dieter’s) Calorie = 1 kcal = 4.184 kJ.

Source: Cahill, G.F., Jr., *New Engl. J. Med.* **282**, 669 (1970).

During starvation, glucose must therefore be synthesized from the glycerol product of triacylglycerol breakdown and, more importantly, from the amino acids derived from the proteolytic degradation of proteins, the major source of which is muscle. Thus, after a 40-hour fast, gluconeogenesis supplies ~96% of the glucose produced by the liver. However, the continued breakdown of muscle during prolonged starvation would ensure that this process became irreversible since a large muscle mass is essential for an animal to move about in search of food. The organism must therefore make alternate metabolic arrangements.

After several days of starvation, gluconeogenesis has so depleted the liver’s oxaloacetate supply that this organ’s ability to metabolize acetyl-CoA via the citric acid cycle is greatly diminished. Rather, the liver converts the acetyl-CoA to ketone bodies (Section 25-3), which it releases into the blood. The brain gradually adapts to using ketone bodies as fuel through the synthesis of the appropriate enzymes: After a 3-day fast, only about one-third of the brain’s energy requirements are satisfied by ketone bodies but after 40 days of starvation, ~70% of its energy needs are so met. The rate of muscle breakdown during prolonged starvation consequently decreases to ~25% of its rate after a several-day fast. The survival time of a starving individual is therefore much more dependent on the size of his or her fat reserves than it is on his or her muscle mass. Indeed, highly obese individuals can survive for over a year without eating (and have occasionally done so in clinically supervised weight reduction programs).

#### a. Caloric Restriction May Increase Longevity

Caloric restriction is a modified form of starvation whereby energy intake is reduced 30–40%, while micronutrient (vitamin and mineral) levels are maintained. Rodents kept on such a diet live up to 50% longer than rodents on normal diets and exhibit fewer of the debilitating symptoms of old age. The life spans of a large range of organisms from yeast to primates are similarly extended. Considerable research effort is being expended to determine the biochemical basis of these observations.

## B. Diabetes Mellitus

The polypeptide hormone insulin acts mainly on muscle, liver, and adipose tissue cells to stimulate the synthesis of glycogen, fats, and proteins while inhibiting the breakdown of these metabolic fuels. In addition, insulin stimulates the uptake of glucose by most cells, with the notable exception of brain and liver cells. Together with glucagon, which has largely opposite effects, insulin acts to maintain the proper level of blood glucose.

In the disease **diabetes mellitus**, which is the third leading cause of death in the United States after heart disease and cancer, insulin either is not secreted in sufficient amounts or does not efficiently stimulate its target cells. As a consequence, blood glucose levels become so elevated that the glucose “spills over” into the urine, providing a convenient diagnostic test for the disease. Yet, despite these high blood glucose levels, cells “starve” since insulin-stimulated glucose entry into cells is impaired. Triacylglycerol hydrolysis, fatty acid oxidation, gluconeogenesis, and ketone body formation are accelerated and, in a condition termed **ketoacidosis**, ketone body levels in the blood become abnormally high. Since ketone bodies are acids, their high concentration puts a strain on the buffering capacity of the blood and on the kidney, which controls blood pH by excreting the excess  $H^+$  into the urine (Section 27-2E). This unusually high excess  $H^+$  excretion is accompanied by  $NH_4^+$ ,  $Na^+$ ,  $K^+$ ,  $P_i$ , and  $H_2O$  excretion, causing severe dehydration (which compounds the dehydration resulting from the osmotic effect of the high glucose concentration in the blood; excessive thirst is a classic symptom of diabetes) and a decrease in blood volume—ultimately life-threatening situations.

There are two major forms of diabetes mellitus:

**1. Insulin-dependent, type 1, or juvenile-onset diabetes mellitus**, which most often strikes suddenly in childhood.

**2. Noninsulin-dependent, type 2, or maturity-onset diabetes mellitus**, which usually develops rather gradually after the age of 40.

### a. Insulin-Dependent Diabetes Is Caused by a Deficiency of Pancreatic $\beta$ Cells

In insulin-dependent (type 1) diabetes mellitus, insulin is absent or nearly so because the pancreas lacks or has defective  $\beta$  cells. This condition results, in genetically susceptible individuals (see below), from an autoimmune response that selectively destroys their  $\beta$  cells. Individuals with insulin-dependent diabetes, as Frederick Banting and George Best first demonstrated in 1921, require daily insulin injections to survive and must follow carefully balanced diet and exercise regimens. Their life spans are, nevertheless, reduced by up to one-third as a result of degenerative complications such as kidney malfunction, nerve impairment, and cardiovascular disease, which apparently arise from the imprecise metabolic control provided by periodic insulin injections. The **hyperglycemia** (high blood [glucose]) of diabetes mellitus also leads to blindness through retinal degeneration and the glucosylation of lens proteins, which causes cataracts (Fig. 27-9).

**Figure 27-9** Photo of a diabetic cataract. The accumulation of glucose in the lens leads to swelling and precipitation of lens proteins. The resulting opacification causes blurred vision and ultimately complete loss of sight. [© Sue Ford/Photo Researchers.]

Perhaps newly developed systems that monitor blood glucose levels and continuously deliver insulin in the required amounts will rectify this situation.

The usually rapid onset of the symptoms of insulin-dependent diabetes had suggested that the autoimmune attack on the pancreatic  $\beta$  cells responsible for this disease is one of short duration. Typically, however, the disease “brews” for several years as the aberrantly aroused immune system slowly destroys the  $\beta$  cells. Only when  $>80\%$  of these cells have been eliminated do the classic symptoms of diabetes suddenly emerge. Consequently, one of the most successful treatments for insulin-dependent diabetes is a  $\beta$ -cell transplant, a procedure that became possible with the development of relatively benign immunosuppressive drugs.

Why does the immune system attack the pancreatic  $\beta$  cells? It has long been known that certain alleles (genetic variants) of the **Class II major histocompatibility complex (MHC) proteins** are particularly common in insulin-dependent diabetics [MHC proteins are highly polymorphic (variable within a species) immune system components to which cell-generated antigens such as viral proteins must bind in order to be recognized as foreign; Sections 35-2Aa and 35-2E]. It is thought that autoimmunity against  $\beta$  cells is induced in a susceptible individual by a foreign antigen, perhaps a virus, which immunologically resembles some  $\beta$  cell component. The Class II MHC protein that binds this antigen does so with such tenacity that it stimulates the immune system to launch an unusually vigorous and prolonged attack on the antigen. Some of the activated immune system cells eventually make their way to the pancreas, where they initiate an attack on the  $\beta$  cells due to the close resemblance of the  $\beta$  cell component to the foreign antigen.

### b. Noninsulin-Dependent Diabetes Is Characterized by Insulin Resistance as Well as Impaired Insulin Secretion

Noninsulin-dependent (type 2) diabetes mellitus (**NIDDM**), which accounts for over 90% of the diagnosed cases of diabetes and affects 18% of the population over 65 years of age, usually occurs in obese individuals with a genetic predisposition for this condition (although one that differs from that associated with insulin-dependent

diabetes). These individuals may have normal or even greatly elevated insulin levels. Their symptoms arise from **insulin resistance**, an apparent lack of sensitivity to insulin in normally insulin-responsive cells.

The hyperglycemia that accompanies insulin resistance induces the pancreatic  $\beta$  cells to increase their production of insulin. Yet the high basal level of insulin secretion diminishes the ability of the  $\beta$  cells to respond to further increases in blood glucose. Consequently, the hyperglycemia and its attendant complications tend to worsen over time.

A small percentage of cases of type II diabetes result from mutations in the insulin receptor that affect its insulin-binding ability or tyrosine kinase activity. However, a clear genetic cause has not been identified in the vast majority of cases. It is therefore likely that many factors play a role in the development of this disease. For example, the increased insulin production resulting from overeating may eventually suppress the synthesis of insulin receptors. This hypothesis accounts for the observation that diet alone is often sufficient to control this type of diabetes.

Insulin resistance, which may precede NIDDM by as much as 10 to 20 years, appears to be caused by an interruption in the insulin signaling pathway (Section 19-4F). Gerald Shulman has proposed that this interruption is caused by a Ser/Thr kinase cascade that phosphorylates

**Figure 27-10** The mechanism through which high concentrations of free fatty acids cause insulin resistance. Elevated concentrations of free fatty acids in the blood diffuse into muscle cells where they are converted to fatty acyl-CoA, diacylglycerols, and ceramides. These lipotoxic substances activate an isoform of protein kinase C (PKC), triggering a Ser/Thr kinase cascade that results in the phosphorylation of IRS-1 and IRS-2. This phosphorylation inhibits the Tyr phosphorylation required for transmission of the insulin signal, thereby decreasing the activation of PI3K, which decreases the rate of fusion of GLUT4-containing vesicles with the plasma membrane and hence the amount of glucose entering the cell. [Modified from Shulman, G.I., *J. Clin. Invest.* **106**, 173 (2000).]

**Figure 27-11** Twenty-four-hour plasma glucose profiles in normal and noninsulin-dependent diabetic subjects. The basal level of glucose and the peaks following meals are higher in the diabetic individuals. [After Bell, G.I., Pilkis, S.J., Weber, I.T., and Polonsky, K.S., *Annu. Rev. Physiol.* **58**, 178 (1996).]

proteins known as **insulin receptor substrates (IRSs;** Section 19-3Cg) so as to decrease their ability to be phosphorylated on their Tyr residues by activated insulin receptor. Tyrosine phosphorylation is required for IRS activation and communication with phosphoinositide 3-kinase (PI3K; Section 19-4D), which subsequently activates the translocation of GLUT4-containing vesicles to the cell surface for increased glucose transport into cells (Section 20-2Ec). The original Ser/Thr kinase cascade is triggered by the activation of an isoform of protein kinase C (PKC; Section 19-4C) caused by an increase in fatty acyl-CoA, diacylglycerol, and ceramides (Section 12-1D) resulting from elevated free fatty acids (Fig. 27-10). The failure to activate IRSs decreases the cell's response to insulin (Fig. 27-11).

### c. Substances That Activate AMPK Attenuate the Symptoms of Noninsulin-Dependent Diabetes

Other treatments for noninsulin-dependent diabetes are drugs such as **metformin** and the **thiazolidinediones (TZDs)**,

which decrease insulin resistance by either suppressing glucose release by the liver (metformin) or promoting

insulin-stimulated glucose disposal in muscle (TZDs). These drugs act by increasing AMPK activity but by different mechanisms. TZDs cause a large increase in the AMP to ATP ratio in muscle cells, with the expected concomitant increase in AMPK phosphorylation and activity. Metformin, however, stimulates LKB1 to phosphorylate and hence activate AMPK (LKB1 knockout mice are insensitive to metformin). In both cases, the increase in AMPK activity decreases gluconeogenesis in liver and increases glucose utilization in muscle (Fig. 27-4). In addition, the TZDs decrease insulin resistance by binding to and activating a transcription factor known as a **peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ )**, primarily in adipose tissue. Among other things, PPAR $\gamma$  activation induces the synthesis of adiponectin (Section 27-3B), which leads to an increase in AMPK activity. In adipose tissue, AMPK action leads to a decrease in lipolysis and fatty acid export, decreasing the concentration of free fatty acids in the blood and therefore decreasing insulin resistance (see above).

Intriguingly, Ronald Evans has shown that transgenic mice expressing an activated form of PPAR $\gamma$  in their skeletal muscles can run around twice the distance of wild-type mice and are resistant to weight gain, even on a high fat diet. This activated PPAR $\gamma$  induces an increase in the number of the aerobic and hence fatty acid-oxidizing slow-twitch (Type I) muscle fibers (Section 17-3Ca) relative to the largely anaerobic and hence less energy-efficient fast-twitch (Type II) muscle fibers.

Rodent adipocytes secrete a 108-residue polypeptide hormone called **resistin**. The hormone is named for its ability to block the action of insulin on adipocytes. In fact, resistin production is decreased by TZDs, a phenomenon that led to the discovery of resistin. Overproduction of resistin was proposed to contribute to the development of noninsulin-dependent diabetes. An interesting difference between rodents and humans is that in humans, resistin is produced by macrophages, a divergence whose evolutionary and functional implications are unclear.

#### d. Obesity Is a Contributing Factor in Metabolic Syndrome

**Metabolic syndrome** is a disturbance in metabolism characterized by insulin resistance, inflammation, and a predisposition to several disorders including type 2 diabetes, hypertension, and atherosclerosis. These disorders are accompanied by an increase in coronary heart disease. Obesity, physical inactivity, and possibly genetic determinants have been implicated in its occurrence, which affects as many as 65 million people in the United States alone. Exercise, calorie/weight reduction, adiponectin, leptin, metformin, and TZDs have all been successfully used to treat metabolic syndrome. Similarly, the PPAR $\gamma$  agonist known as **GW1516**

alleviates the symptoms of metabolic syndrome in obese men, probably by stimulating fatty acid oxidation.

Evans has shown that GW1516 greatly increases exercise endurance in mice, particularly when it is administered together with the AMPK agonist **5-aminoimidazole-4-carboxamide ribotide [AICAR]**;

#### 5-Aminoimidazole-4-carboxamide ribotide (AICAR)

which is also a product of histidine biosynthesis (Section 26-5Be) and an intermediate in purine ribonucleotide biosynthesis (Section 28-1A)]. This treatment mimics the effects of the expression of activated PPAR $\gamma$ , which suggests that the administration of GW1516 and AICAR can confer some of the benefits of exercise without actually exercising. Indeed, the World Anti-Doping Agency has placed these compounds on the list of performance-enhancing drugs that athletes are forbidden from taking.

#### e. DNA Chip Technology Permits the Integrated Study of Metabolic Regulation

Our ability to understand the integrated nature of metabolism and its genetic regulation in health and disease has taken a giant step forward with the advent of DNA chips (microarrays; Section 7-6B). For example, Ronald Kahn has used this technology to study the genetic basis of the metabolic abnormalities underlying both obesity and diabetes. To do so, he isolated the mRNA from the skeletal muscle of normal, diabetic, and insulin-treated diabetic mice and reverse-transcribed it to cDNA (Section 5-5Fa), which was then hybridized to oligonucleotide microarrays that represented 14,288 mouse genes. Thereby, 129 up-regulated and 106 down-regulated genes were identified in diabetic mice. Not surprisingly, the expression of the mRNAs encoding enzymes of the fatty acid  $\beta$ -oxidation pathway were increased, whereas those for GLUT4, glucokinase, the E1 component of the pyruvate dehydrogenase multienzyme complex, and the subunits of all four mitochondrial electron-transport chain complexes were coordinately decreased. Intriguingly, only about half of these changes in gene expression could be reversed by insulin treatment. Thus, the post-genomic era will almost certainly witness an explosion in our knowledge of metabolic regulation that should yield major health benefits. Nevertheless, our ability to sensibly interpret this huge influx of information may prove to be the greatest challenge.

## CHAPTER SUMMARY

**1 Major Pathways and Strategies of Energy Metabolism:**

**A Summary** The complex network of processes involved in energy metabolism are distributed among different compartments within cells and in different organs of the body. These processes function to generate ATP “on demand,” to generate and store glucose, triacylglycerols, and proteins in times of plenty for use when needed, and to keep the concentration of glucose in the blood at the proper level for use by organs such as the brain, whose sole fuel source, under normal conditions, is glucose. The major energy metabolism pathways include glycolysis, glycogen degradation and synthesis, gluconeogenesis, the pentose phosphate pathway, and triacylglycerol and fatty acid synthesis, which are cytosolically based, and fatty acid oxidation, the citric acid cycle, and oxidative phosphorylation, which are confined to the mitochondrion. Amino acid degradation occurs, in part, in both compartments. The mediated membrane transport of metabolites therefore also plays an essential metabolic role.

**2 Organ Specialization** The brain normally consumes large amounts of glucose. Muscle, under intense ATP demand such as in sprinting, degrades glucose and glycogen anaerobically, thereby producing lactate, which is exported via the blood to the liver for reconversion to glucose through gluconeogenesis. During moderate activity, muscle generates ATP by oxidizing glucose from glycogen, fatty acids, and ketone bodies completely to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  via the citric acid cycle and oxidative phosphorylation. Adipose tissue stores triacylglycerols and releases fatty acids into the bloodstream in response to the organism’s metabolic needs. These metabolic needs are communicated to adipose tissue by means of the hormones insulin, which indicates a fed state in which storage is appropriate, and glucagon, epinephrine, and norepinephrine, which signal a need for fatty acid release to provide fuel for other tissues. The liver, the body’s central metabolic clearinghouse, maintains blood glucose concentrations by storing glucose as glycogen in times of plenty and releasing glucose in times of need both by glycogen breakdown and by gluconeogenesis. It also converts fatty acids to ketone bodies for use by peripheral tissues. During a fast, it breaks down amino acids resulting from protein degradation to metabolic intermediates that can

be used to generate glucose. The kidney filters out urea from the blood, recovers important metabolites, and maintains pH balance. To do so, glutamine is broken down to produce  $\text{NH}_4^+$  for  $\text{H}^+$  excretion. The resulting  $\alpha$ -ketoglutarate product is converted to  $\text{CO}_2$  to resupply  $\text{HCO}_3^-$  to the blood to maintain its buffering capacity. During starvation, the kidney uses the  $\alpha$ -ketoglutarate from glutamine breakdown for gluconeogenesis.

**3 Metabolic Homeostasis: Regulation of Appetite, Energy Expenditure, and Body Weight** AMP-dependent protein kinase (AMPK), the cell’s fuel gauge, senses the cell’s need for ATP and activates metabolic breakdown pathways while inhibiting biosynthetic pathways. Adiponectin, an adipocyte hormone that increases insulin sensitivity, acts by activating AMPK. Appetite is suppressed by the actions of leptin, a hormone produced by adipose tissue, insulin, produced by the  $\beta$  cells of the pancreas, and  $\text{PYY}_{3-36}$ , produced by the gastrointestinal tract, which act in the hypothalamus to inhibit the secretion of neuropeptide Y (NPY) and stimulate the secretion of  $\alpha$ -MSH and CART. This decreases the appetite and hence food intake. Ghrelin, a hormone secreted by the empty stomach, opposes the actions of leptin, insulin, and  $\text{PYY}_{3-36}$ , stimulating appetite and food intake. Leptin also acts in peripheral tissues to stimulate energy expenditure by fatty acid oxidation and thermogenesis.

**4 Metabolic Adaptation** During prolonged starvation, the brain slowly adapts from the use of glucose as its sole fuel source to the use of ketone bodies, thereby shifting the metabolic burden from protein breakdown to fat breakdown. Diabetes mellitus is a disease in which insulin either is not secreted or does not efficiently stimulate its target tissues, leading to high concentrations of glucose in the blood and urine. Cells “starve” in the midst of plenty since they cannot absorb blood glucose and their hormonal signals remain those of starvation. Abnormally high production of ketone bodies is one of the most dangerous effects of uncontrolled diabetes. Metabolic syndrome is caused by obesity, physical inactivity, and possibly genetic determinants. Its symptoms can be relieved by substances that activate AMPK.

## PROBLEMS

- Describe the metabolic effects of liver failure.
- What is the basis of the hypothesis that athletes' muscles are more heavily buffered than those of normal individuals?
- Experienced runners know that it is poor practice to ingest large amounts of glucose prior to running a long-distance race such as a marathon. What is the metabolic basis of this apparent paradox?
- Explain why urea output is vastly decreased during starvation.
- Explain why people survive longer by total fasting than on a diet consisting only of carbohydrates.
- Explain why the breath of an untreated diabetic smells of acetone.
- Among the many eat-all-you-want-and-lose-weight diets that have been popular for a time is one that eliminates all carbohydrates but permits the consumption of all the protein and fat desired. Would such a diet be effective? (*Hint*: Individuals on such a diet often complain that they have bad breath.)
- Pancreatic  $\beta$  cells express a receptor for fatty acids. Fatty acid binding to this protein appears to stimulate insulin secretion. (a) Does this phenomenon make metabolic sense? (b) Fatty acids appear to stimulate insulin secretion to a much greater extent when glucose is also present. Why is this significant?
- High concentrations of free fatty acids in the blood are known to cause insulin resistance in muscle, but only after 5 hours. This suggests that a metabolite of these fatty acids may be responsible for this phenomenon. It is also known that an isoform of protein kinase C is activated during the process and that high concentrations of free fatty acids result in intramuscular accumulation of triacylglycerols. With this information, review the mechanism of activation of PKC and the pathway of triacylglycerol biosynthesis and suggest a metabolite that may be responsible for PKC activation.
- Discuss, in molecular terms, how physical inactivity might lead to insulin resistance.

# Nucleotide Metabolism

## CHAPTER 28

### 1 Synthesis of Purine Ribonucleotides

- A. Synthesis of Inosine Monophosphate
- B. Synthesis of Adenine and Guanine Ribonucleotides
- C. Regulation of Purine Nucleotide Biosynthesis
- D. Salvage of Purines

### 2 Synthesis of Pyrimidine Ribonucleotides

- A. Synthesis of UMP
- B. Synthesis of UTP and CTP
- C. Regulation of Pyrimidine Nucleotide Biosynthesis

### 3 Formation of Deoxyribonucleotides

- A. Production of Deoxyribose Residues
- B. Origin of Thymine

### 4 Nucleotide Degradation

- A. Catabolism of Purines
- B. Fate of Uric Acid
- C. Catabolism of Pyrimidines

### 5 Biosynthesis of Nucleotide Coenzymes

- A. Nicotinamide Coenzymes
- B. Flavin Coenzymes
- C. Coenzyme A

Nucleotides, as we have seen, are biologically ubiquitous substances that participate in nearly all biochemical processes: They are the monomeric units of DNA and RNA; the hydrolysis of ATP and GTP drives many free energy-requiring processes; the levels of ATP, ADP, and AMP regulate numerous metabolic pathways; cAMP and cGMP mediate hormonal signals; and NAD<sup>+</sup>, NADP<sup>+</sup>, FMN, FAD, and coenzyme A are essential coenzymes in a great variety of enzymatic reactions. The importance of nucleotides in cellular metabolism is indicated by the observation that nearly all cells can synthesize them both *de novo* (anew) and from the degradation products of nucleic acids. In this chapter, we consider the nature of these biosynthetic pathways. In doing so, we shall examine how they are regulated and the consequences of their blockade, both by genetic defects and through the administration of chemotherapeutic agents. We then discuss how nucleotides are degraded. Finally, we outline the biosynthesis of the nucleotide coenzymes.

### 1 SYNTHESIS OF PURINE RIBONUCLEOTIDES

In this section we commence our considerations of how nucleic acids and their components are synthesized by describing the synthesis of purine ribonucleotides. In 1948, John Buchanan obtained the first clues as to how this process occurs *de novo* by feeding a variety of isotopically labeled compounds to pigeons and chemically determining the positions of the labeled atoms in their excreted **uric acid** (a purine).

Uric acid

He used birds in these experiments because they excrete waste nitrogen almost entirely as uric acid, a water-insoluble and therefore easily isolated substance. The results of his studies, which are summarized in Fig. 28-1, demonstrated that N1 of purines arises from the amine group of aspartate; C2 and C8 originate from formate; N3 and N9 are contributed by the amide group of glutamine; C4, C5, and N7 are derived from glycine (strongly suggesting that this molecule is wholly incorporated into the purine ring); and C6 comes from HCO<sub>3</sub><sup>-</sup> (CO<sub>2</sub>).

**Figure 28-1** The biosynthetic origins of purine ring atoms. Note that C4, C5, and N7 come from a single glycine molecule but each of the other atoms is derived from an independent precursor.

The actual pathway by which these precursors are incorporated into the purine ring, the subject of Section 28-1A, was elucidated in subsequent investigations performed largely by Buchanan and by G. Robert Greenberg. These investigations showed that the initially synthesized purine derivative is **inosine monophosphate (IMP)**,

**Inosine monophosphate (IMP)**

the nucleotide of the base **hypoxanthine**. AMP and GMP are subsequently synthesized from this intermediate via separate pathways (Section 28-1B). Thus, contrary to naive expectation, purines are initially formed as ribonucleotides rather than as free bases. Additional studies have demonstrated that such widely divergent organisms as *E. coli*, yeast, pigeons, and humans have virtually identical pathways for the biosynthesis of purine nucleotides, thereby further demonstrating the biochemical unity of life.

### A. Synthesis of Inosine Monophosphate

IMP is synthesized in a pathway comprising 11 reactions (Fig. 28-2):

**1. Activation of ribose-5-phosphate.** The starting material for purine biosynthesis is  $\alpha$ -D-ribose-5-phosphate (R5P), a product of the pentose phosphate pathway (Section 23-4). In the first step of *de novo* purine biosynthesis, **ribose phosphate pyrophosphokinase** (also known as **phosphoribosylpyrophosphate synthetase**) activates R5P by reacting it with ATP to form **5-phosphoribosyl- $\alpha$ -pyrophosphate (PRPP)**. This reaction, which occurs via the nucleophilic attack of the R5P's C1—H group on the  $P_{\beta}$  of ATP, is unusual in that a pyrophosphoryl group is directly transferred from ATP to C1 of R5P and that the product has the  $\alpha$  anomeric configuration. PRPP is also a precursor in the biosynthesis of pyrimidines (Section 28-2A) and the amino acids tryptophan and histidine (Section 26-5Bd,e). Thus, as is expected for an enzyme at such an important biosynthetic crossroads, the activity of ribose phosphate pyrophosphokinase varies with the concentrations of numerous metabolites, including  $PP_i$  and 2,3-bisphosphoglycerate, which are activators, and ADP and GDP, which are mixed inhibitors (Section 14-3C). The regulation of purine nucleotide biosynthesis is further discussed in Section 28-1C.

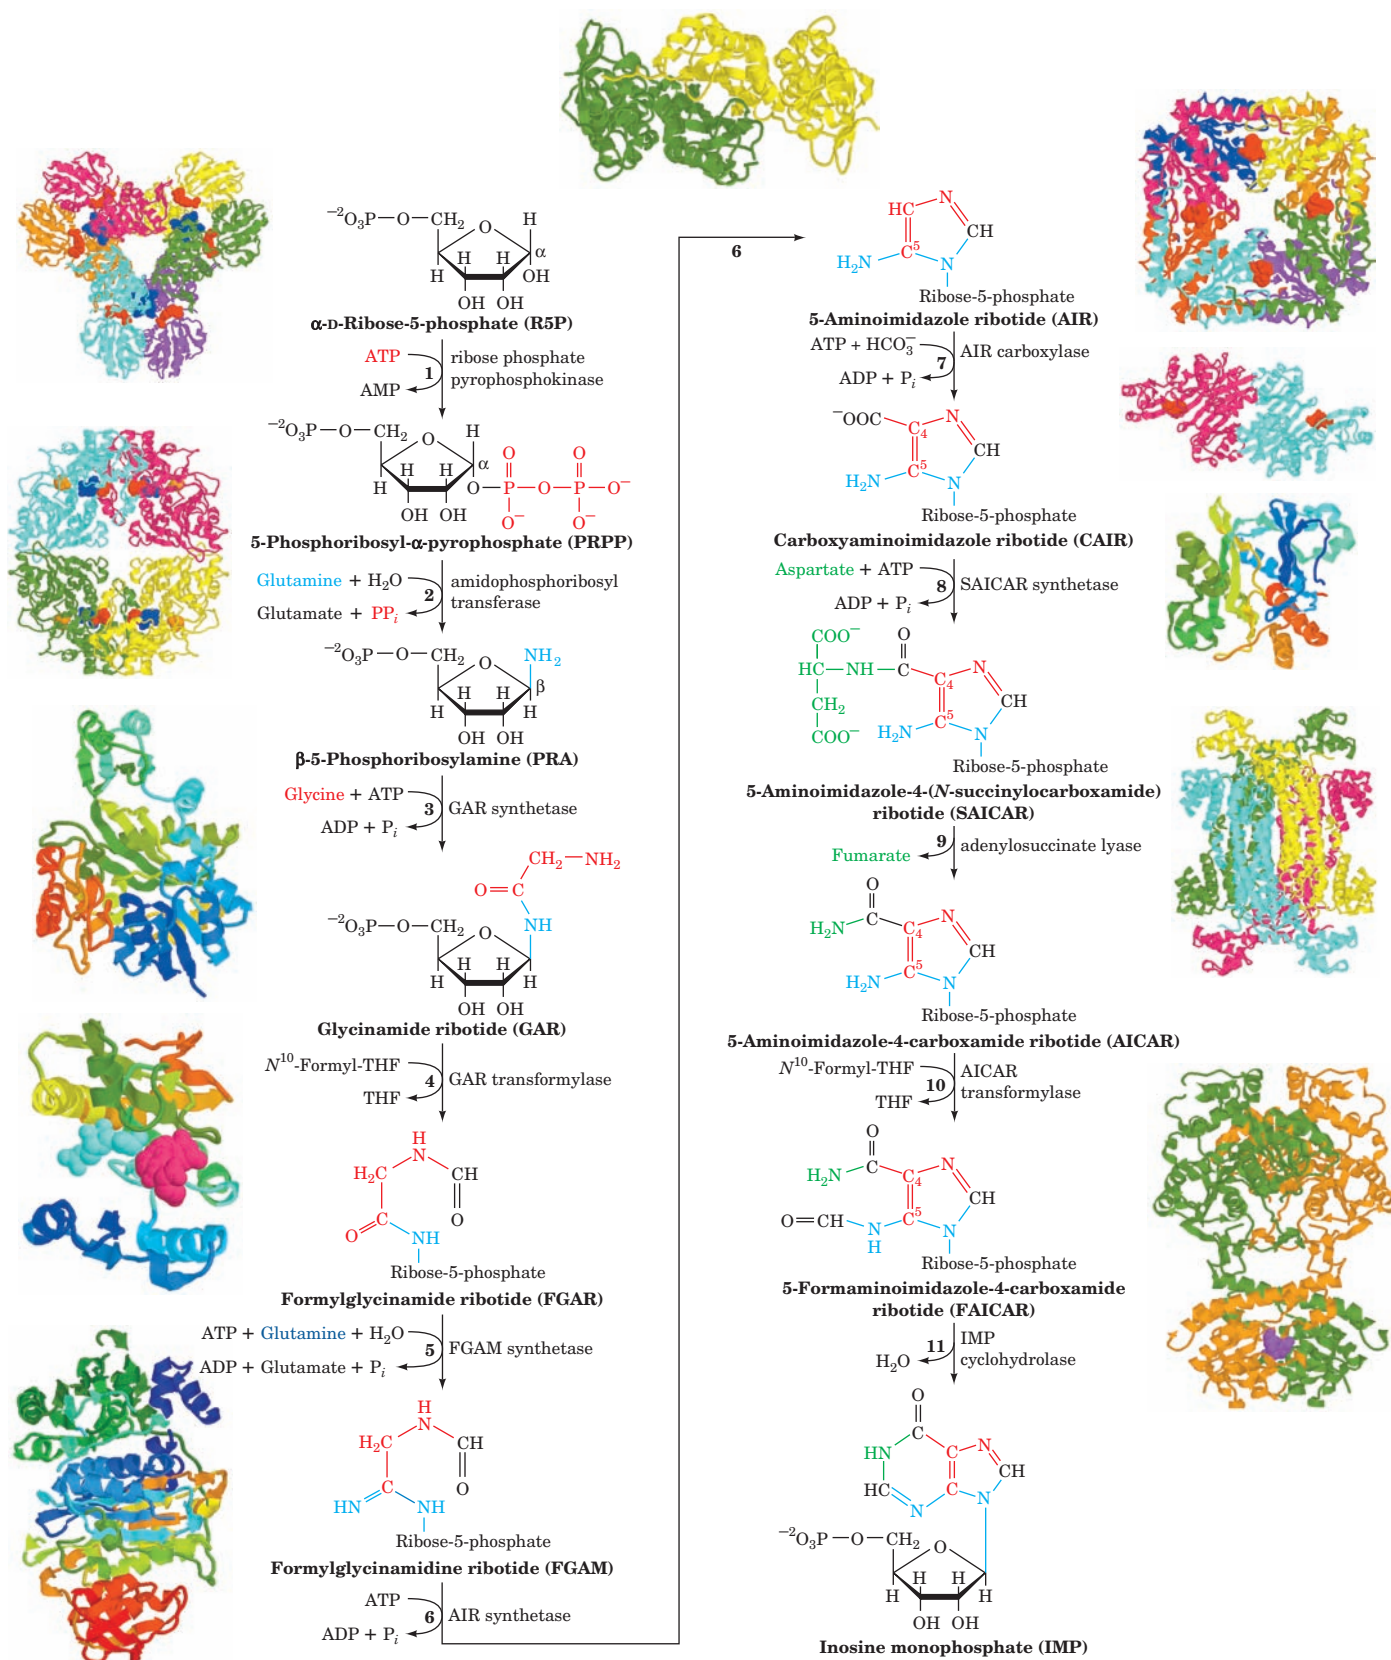

**2. Acquisition of purine atom N9. Amidophosphoribosyltransferase** (alternatively, **glutamine PRPP aminotransferase** or **PurF**; the latter being named for the *E. coli* gene encoding it, *purF*) catalyzes the displacement of PRPP's

pyrophosphate group by glutamine's amide nitrogen to yield  **$\beta$ -5-phosphoribosylamine (PRA)**. This is the first reaction in the pathway that is unique to *de novo* purine biosynthesis (and hence some sources refer to it as the first reaction of the pathway, which is then said to consist of 10 reactions). This process occurs in two consecutive reactions that take place on separate active sites on the enzyme:

1. Glutamine +  $H_2O \rightarrow$  glutamic acid +  $NH_3$
2.  $NH_3 + PRPP \rightarrow PRA + PP_i$

Step 1 is catalyzed by a member of the N-terminal nucleophile (Ntn) amidotransferase family (Section 26-5Aa). Step 2 occurs with inversion of configuration about ribose C1 and hence establishes the anomeric form of the future nucleotide. The  $NH_3$  passes between the two active sites through a 20-Å-long tunnel that is lined with conserved

**Figure 28-2 (Opposite) The metabolic pathway for the *de novo* biosynthesis of IMP.** The purine residue is built up on a ribose ring in 11 enzymatically catalyzed reactions. The X-ray structures for all enzymes are shown to the outside of the corresponding reaction arrow. The peptide chains of monomeric enzymes are colored in rainbow order from their N-termini (blue) to their C-termini (red). The oligomeric enzymes, all of which consist of identical polypeptide chains, are viewed along a rotation axis with their various chains differently colored. Bound ligands are shown in space-filling form. Enzyme 1, determined by Sine Larsen, University of Copenhagen, Denmark, is a  $D_3$  hexamer from *B. subtilis* that binds  $\alpha,\beta$ -methylene-ADP at its catalytic (red) and allosteric (blue) sites; PDBid 1DKU. Enzyme 2, determined by Janet Smith, Purdue University, is a  $D_2$  tetramer from *B. subtilis* that binds GMP (blue), ADP (red), and a [4Fe-4S] cluster (orange, which appears to have a regulatory rather than a redox function); PDBid 1AO0. Enzymes 3 and 6, both from *E. coli*, were determined by JoAnne Stubbe, MIT, and Steven Ealick, Cornell University; PDBids 1GSO and 1CCL. Enzyme 4, from *E. coli*, determined by Robert Almasy, Agouron Pharmaceuticals, San Diego, California, binds GAR (cyan) and 5-deazatetrahydrofolate (red); PDBid 1CDE. Enzyme 5, from *Thermatoga maritima*, was determined by Ian Wilson, Scripps Research Institute, La Jolla, California; PDBid 1VK3. Reaction 7, in *E. coli*, is catalyzed by two sequentially acting enzymes, Class I PurE (above) and PurK (below). Class I PurE, determined by JoAnne Stubbe, MIT, and Steven Ealick, Cornell University, is a  $D_4$  octamer that binds AIR (red); PDBid 1D7A. PurK, determined by JoAnne Stubbe, MIT, and Hazel Holden, University of Wisconsin, is a  $C_2$  dimer that binds ADP (red); PDBid 1B6S. Enzyme 8, from yeast, was determined by Victor Lamzin, Academy of Sciences, Moscow, Russia, and Keith Wilson, EMBL, Hamburg, Germany; PDBid 1A48. Enzyme 9, from *Thermatoga maritima*, determined by Todd Yeates, UCLA, is a  $D_2$  tetramer; PDBid 1C3U. Reactions 10 and 11 in chicken are catalyzed by a bifunctional enzyme that was determined by Stephen Benkovic, Pennsylvania State University, and Ian Wilson, The Scripps Research Institute, La Jolla, California. It forms a  $C_2$  dimer shown with its AICAR transformylase function above and its IMP cyclohydrolase function, which binds GMP (purple), below; PDBid 1G8M.  See the Animated Figures

nonpolar residues that lack hydrogen bonding groups and hence do not impede the diffusion of the  $\text{NH}_3$  [we have seen that  $\text{NH}_3$  generated by glutamine hydrolysis is similarly channeled to the active site that uses it in carbamoyl phosphate synthetase (Section 26-2Aa) and glutamate synthetase (Section 26-5Aa)]. These reactions, which are driven to completion by the subsequent hydrolysis of the released  $\text{PP}_i$ , constitute the pathway's flux-generating step. Not surprisingly, therefore, amidophosphoribosyltransferase is subject to feedback inhibition by purine nucleotides (Section 28-1C).

**3. Acquisition of purine atoms C4, C5, and N7.** Glycine's carboxyl group forms an amide with the amino group of PRA, yielding **glycinamide ribotide (GAR)** in a reaction, catalyzed by **GAR synthetase (PurD)**, that occurs via the intermediate phosphorylation of glycine's carboxyl group. The reaction, which is reversible despite its concomitant hydrolysis of ATP to ADP +  $\text{P}_i$ , is the only step of the purine biosynthesis pathway in which more than one purine ring atom is acquired. The observation that PRA is chemically unstable (it is hydrolyzed to R5P and  $\text{NH}_3$  with a half-life of 5 s at 37°C) suggests that GAR synthetase and amidophosphoribosyltransferase associate in a way that channels PRA between them. Indeed, a sterically and electrostatically plausible model of such a complex has been built based on the X-ray structures of these two enzymes.

**4. Acquisition of purine atom C8.** GAR's primary  $\alpha$ -amino group is formylated by **GAR transformylase (PurN)** to yield **formylglycinamide ribotide (FGAR)**. The formyl donor in this reaction is  $N^{10}$ -formyltetrahydrofolate ( $N^{10}$ -formyl-THF), a cofactor that transfers  $\text{C}_1$  units from such donors as serine, glycine, and formate to various acceptors in biosynthetic reactions (Section 26-4D). Structural and enzymological studies indicate that the reaction proceeds via the nucleophilic attack of the GAR primary amine group on the formyl carbon of  $N^{10}$ -formyl-THF to yield a tetrahedral intermediate.

**5. Acquisition of purine atom N3.** The amide amino group of a second glutamine is transferred to the growing purine ring to form **formylglycinamide ribotide (FGAM)**. This reaction, which is catalyzed by **FGAM synthetase (PurL)**, is driven by the coupled hydrolysis of ATP to ADP +  $\text{P}_i$ . It is thought to proceed by the mechanism diagrammed in Fig. 28-3. Here the oxygen of the FGAR isoamide form reacts with ATP to yield a phosphoryl ester intermediate. This intermediate then reacts with  $\text{NH}_3$  (the glutamine amide nitrogen as labilized through the transient formation of an enzyme thioester) to form a tetrahedral adduct. The adduct then eliminates  $\text{P}_i$  to yield the imine product, FGAM. Such reactions, in which a carboxamide oxygen is replaced by an imino group, are common in the biosynthesis of nucleotides. For example, Reaction 6 of this pathway and the reactions converting IMP to AMP (Section 28-1B) and UTP to CTP (Section 28-2B) follow similar mechanisms, that is, conversion of a carboxamide oxygen to a phosphoryl ester that is nucleophilically

**Figure 28-3** The proposed mechanism of formylglycinamide ribotide (FGAM) synthetase. The glutaminase domain of the enzyme contains an active site Cys residue that catalyzes the release of  $\text{NH}_3$  with the transient formation of an enzyme thioester (not shown) whose hydrolysis produces glutamate. The isoamide form of FGAR is phosphorylated by ATP and then reacts with “ $\text{NH}_3$ ” to form a tetrahedral intermediate whose collapse yields FGAM +  $\text{P}_i$ .

attacked by an amine nitrogen atom to yield a tetrahedral adduct that, in turn, expels  $\text{P}_i$  to form product.

**6. Formation of the purine imidazole ring.** The purine imidazole ring is closed in an ATP-requiring intramolecular condensation that yields **5-aminoimidazole ribotide (AIR)** in a reaction catalyzed by **AIR synthetase (PurM)**.

The aromatization of the imidazole ring is facilitated by the tautomeric shift of the reactant from its imine to its enamine form.

**7. Acquisition of C6.** In higher eukaryotes, purine C6 is introduced as  $\text{HCO}_3^-$  ( $\text{CO}_2$ ) in an ATP-dependent reaction catalyzed by **AIR carboxylase** that yields **carboxyaminoimidazole ribotide (CAIR)** and  $\text{ADP} + \text{P}_i$ . However, in yeast, plants, and most prokaryotes (including *E. coli*), this overall reaction occurs in two steps that are mediated by separate enzymatic activities: **PurK** and **Class I PurE**.

PurK catalyzes the ATP-dependent carboxylation of AIR to yield  $\text{N}^5$ -CAIR, which Class I PurE rearranges to yield CAIR. Class I PurE is homologous to AIR carboxylase, which is therefore also called **Class II PurE**. Class I PurE alone can catalyze the AIR carboxylase reaction but since its  $K_M$  for  $\text{HCO}_3^-$  is 110 mM, it requires an unphysiologically high ( $\sim 100$  mM)  $\text{HCO}_3^-$  concentration to do so at a significant rate. However, the action of PurK decreases the  $\text{HCO}_3^-$  concentration required for the PurE-catalyzed reaction by  $>1000$ -fold, presumably through the ATP-driven formation of carbonyl phosphate, as is also postulated to occur in the carbamoyl phosphate synthetase reaction (Section 26-2A). The observation that  $\text{N}^5$ -CAIR is chemically unstable (it decomposes to AIR with a half-life of 15 s at pH 7.5 and  $25^\circ\text{C}$ ) suggests that  $\text{N}^5$ -CAIR is channeled between PurK and Class I PurE. In fact, in yeast and plants, the N-terminus of Class I PurE is fused to the C-terminus of PurK. However, in *E. coli*, these two enzymatic activities occur on separate proteins for which there is no evidence of association.

**8. Acquisition of N1.** Purine atom N1 is contributed by aspartate in an amide-forming condensation reaction yielding **5-aminoimidazole-4-(*N*-succinylcarboxamide) ribotide (SAICAR)** that is catalyzed by **SAICAR synthetase (PurC)**. The reaction, which is driven by the hydrolysis of ATP to  $\text{ADP} + \text{P}_i$ , chemically resembles Reaction 3.

**9. Elimination of fumarate.** SAICAR is cleaved with the release of fumarate, yielding **5-aminoimidazole-4-carboxamide ribotide (AICAR)** in a reaction catalyzed by **adenylosuccinate lyase (PurB)**. Reactions 8 and 9 chemically

resemble the reactions in the urea cycle in which citrulline is aminated to form arginine (Sections 26-2C and 26-2D). In both pathways, aspartate's amino group is transferred to an acceptor through an ATP-driven coupling reaction followed by the elimination of the aspartate carbon skeleton as fumarate. In plants and microorganisms, AICAR is also formed in the biosynthesis of histidine (Section 26-5Be) but since in that process the AICAR is derived from ATP, it provides for no net purine biosynthesis.

**10. Acquisition of C2.** The final purine ring atom is acquired through formylation by  $\text{N}^{10}$ -formyltetrahydrofolate, yielding **5-formamidoimidazole-4-carboxamide ribotide (FAICAR)** in a reaction catalyzed by **AICAR transformylase (PurH)**. In bacteria, this reaction and that of Reaction 4 are indirectly inhibited by sulfonamides, which, it will be recalled, prevent the synthesis of folate by competing with its *p*-aminobenzoate component (Section 26-4D). Animals, including humans, must acquire folate through the diet, since they are incapable of synthesizing it. They are therefore unaffected by sulfonamides. The antibiotic properties of sulfonamides are therefore largely a result of their inhibition of nucleic acid biosynthesis in susceptible bacteria.

**11. Cyclization to form IMP.** The final reaction in the pathway, ring closure to form IMP, occurs through the elimination of water as catalyzed by **IMP cyclohydrolase (PurJ)**. In contrast to Reaction 6, the cyclization that forms the imidazole ring, this reaction does not entail ATP hydrolysis.

In animals, the activities catalyzing Reactions 3, 4, and 6, Reactions 7 and 8, and Reactions 10 and 11 occur on single polypeptides. The intermediate products of these multifunctional enzymes are not readily released to the medium but are channeled to the succeeding enzymatic activities of the pathway, thereby increasing the overall rates of these multistep processes and protecting the intermediates from degradation by other cellular enzymes. We have previously seen, for example, that the formation of acetyl-CoA from pyruvate takes place on the pyruvate dehydrogenase multienzyme complex, which contains three enzymes catalyzing five consecutive reactions (Section 21-2A); that all seven enzymatic activities catalyzing fatty acid synthesis in animals occur on a single protein molecule (Section 25-4Ca,b); and that the multifunctional enzymes carbamoyl phosphate synthase I (Section 26-2Aa), glutamate synthase (Section 26-5Aa), tryptophan synthase (Section 26-5Bd), and amidophosphoribosyltransferase (see above) pass reactive intermediate products between their active sites via protein tunnels. It is becoming increasingly apparent that the association of functionally related enzymes is a widespread phenomenon.

## B. Synthesis of Adenine and Guanine Ribonucleotides

IMP does not accumulate in the cell but is rapidly converted to AMP and GMP. AMP, which differs from IMP only in the replacement of its 6-keto group by an amino

**Figure 28-4** IMP is converted to AMP or GMP in separate two-reaction pathways. The X-ray structures for all of the enzymes catalyzing these reactions are shown to the outside of the corresponding reaction arrow. The X-ray structures for these homooligomers are shown as described in the legend to Fig. 28-2. Adenylosuccinate synthetase from *E. coli*, determined by Herbert Fromm and Richard Honzatko, Iowa State University, is a  $C_2$  dimer in complex with IMP (green), GDP (red), and hadacidin (magenta; a competitive inhibitor of aspartate); PDBid

1GIM. Adenylosuccinate lyase, from *Thermatoga maritima*, determined by Todd Yeates, UCLA, is a  $D_2$  tetramer; PDBid 1C3U. IMP dehydrogenase from Chinese hamsters, determined by Keith Wilson, Vertex Pharmaceuticals, Cambridge, Massachusetts, is a  $C_4$  tetramer in complex with oxidized IMP (red) and MPA (purple); PDBid 1JR1. GMP synthetase from *E. coli*, determined by Janet Smith, Purdue University, is a  $D_2$  tetramer in complex with AMP (red), pyrophosphate (blue), and citrate (purple); PDBid 1GPM.

group, is synthesized in a two-reaction pathway (Fig. 28-4, left). In the first reaction, aspartate's amino group is linked to IMP in a reaction driven by the hydrolysis of GTP to GDP +  $P_i$  to yield **adenylosuccinate**. In the second reaction, **adenylosuccinate lyase** eliminates fumarate from adenylosuccinate to form AMP. This enzyme also catalyzes Reaction 9 of the IMP pathway (Fig. 28-2).

GMP is also synthesized from IMP in a two-reaction pathway (Fig. 28-4, right). In the first reaction, **IMP dehydrogenase** catalyzes the  $\text{NAD}^+$ -dependent oxidation of IMP to form **xanthosine monophosphate (XMP; the ribonucleotide of the base xanthine)**. XMP is then converted to GMP by the replacement of its 2-keto group with glutamine's amide nitrogen in a reaction driven by the hydrolysis of ATP to AMP +  $\text{PP}_i$  (and subsequently to 2  $P_i$ ).

IMP dehydrogenase, a homotetramer of 514-residue subunits, was incubated with IMP,  $\text{NAD}^+$ , and the fungally produced inhibitor **mycophenolic acid (MPA)**.

**Mycophenolic acid (MPA)**

The X-ray structure of the resulting complex, determined by Keith Wilson, reveals that the enzyme had bound MPA together with a reaction intermediate in which IMP atom

C2 had become covalently linked to the Cys 331 S atom and then dehydrogenated by  $\text{NAD}^+$  to yield a thioimidate ester:

The mutagenic replacement of Cys 331 by Ala inactivates the enzyme. These observations strongly support a catalytic mechanism in which the Cys 331 thiol group nucleophilically attacks IMP's C2 atom, followed by hydride transfer to  $\text{NAD}^+$  to yield the above covalently bound intermediate, which is subsequently hydrolyzed to yield XMP. The MPA binds to the enzyme with its bicyclic ring stacked on the purine ring (as would be expected for  $\text{NAD}^+$ 's nicotinamide ring) and with its phenolic hydroxyl group in the proposed hydrolytic water site. This blocks the hydrolysis of the thioimidate ester, thereby inactivating the enzyme.

IMP dehydrogenase activity is essential to the immune response (Section 35-2) because it is required by the immune system cells known as B and T lymphocytes to generate the guanosine nucleotides they need to proliferate. Moreover, certain cancer cells have increased IMP dehydrogenase activity. Hence, IMP dehydrogenase is a target for both immunosuppressive therapy and cancer chemotherapy. Indeed, MPA is in clinical use to prevent the rejection of transplanted kidneys.

### a. Nucleoside Diphosphates and Triphosphates Are Synthesized by the Phosphorylation of Nucleoside Monophosphates

In order to participate in nucleic acid synthesis, nucleoside monophosphates must first be converted to the corresponding nucleoside triphosphates. In the first of the two sequential phosphorylation reactions that do so, nucleoside diphosphates are synthesized from the corresponding nucleoside monophosphates by base-specific **nucleoside monophosphate kinases**. For example, adenylate kinase (Section 17-4Fd) catalyzes the phosphorylation of AMP to ADP:

Similarly, GDP is produced by a guanine-specific enzyme:

These nucleoside monophosphate kinases do not discriminate between ribose and deoxyribose in the substrate.

Nucleoside diphosphates are converted to the corresponding triphosphates by **nucleoside diphosphate kinase**; for instance,

Although this reaction is written with ATP as the phosphoryl donor and GDP as the acceptor, nucleoside diphosphate kinase is nonspecific as to the bases on either of its

substrates and as to whether their sugar residues are ribose or deoxyribose. The reaction occurs via a Ping Pong mechanism in which the substrate NTP phosphorylates an enzyme His residue, which in turn, phosphorylates the substrate NDP. The phosphoglycerate mutase reaction of glycolysis also has a phospho-His intermediate (Section 17-2H). The nucleoside diphosphate kinase reaction, as might be expected from the nearly identical structures of its substrates and products, normally operates close to equilibrium ( $\Delta G \approx 0$ ). ADP is, of course, also converted to ATP by a variety of energy-releasing reactions such as those of glycolysis and oxidative phosphorylation. Indeed, it is these reactions that ultimately drive the foregoing kinase reactions.

### C. Regulation of Purine Nucleotide Biosynthesis

The pathways involved in nucleic acid metabolism are tightly regulated, as is evidenced, for example, by the increased rates of nucleotide synthesis during cell proliferation. In fact, the pathways synthesizing IMP, ATP, and GTP are individually regulated in most cells so as not only to control the total amounts of purine nucleotides produced but also to coordinate the relative amounts of ATP and GTP. This control network is diagrammed in Fig. 28-5.

The IMP pathway is regulated at its first two reactions: those catalyzing the synthesis of PRPP and 5-phosphoribo-

**Figure 28-5** Control network for the purine biosynthesis pathway. Red octagons and green dots indicate control points. Feedback inhibition is indicated by dashed red arrows and feedforward activation is represented by dashed green arrows.

 See the Animated Figures

sylamine. We have already seen that ribose phosphate pyrophosphokinase, the enzyme catalyzing Reaction 1 of the IMP pathway, is inhibited by both ADP and GDP (Section 28-1A). Amidophosphoribosyltransferase, the enzyme catalyzing the first committed step of the IMP pathway (Reaction 2), is likewise subject to feedback inhibition. In this case, however, the enzyme binds ATP, ADP, and AMP at one inhibitory site and GTP, GDP, and GMP at another. *The rate of IMP production is consequently independently but synergistically controlled by the levels of adenine nucleotides and guanine nucleotides.* Moreover, amidophosphoribosyltransferase is allosterically stimulated by PRPP (feedforward activation).

A second level of regulation occurs immediately below the branch point leading from IMP to AMP and GMP (Fig. 28-4). AMP and GMP are each competitive inhibitors of IMP in their own synthesis, so that excessive buildup of these products is impeded. In addition, the synthesis rates of adenine and guanine nucleotides are coordinated because GTP powers the synthesis of AMP from IMP, whereas ATP powers the synthesis of GMP from IMP. This reciprocity serves to balance the production of AMP and GMP (which are required in roughly equal amounts in nucleic acid biosynthesis): *The rate of synthesis of GMP increases with [ATP], whereas that of AMP increases with [GTP].*

#### D. Salvage of Purines

Most cells have an active turnover of many of their nucleic acids (particularly some types of RNA) which, through degradative processes described in Section 28-4A, result in the release of adenine, guanine, and hypoxanthine. These free purines are reconverted to their corresponding nucleotides through **salvage pathways**. In contrast to the *de novo* purine nucleotide synthesis pathway, which is virtually identical in all cells, salvage pathways are diverse in character and distribution. In mammals, purines are, for the most part, salvaged by two different enzymes. **Adenine phosphoribosyltransferase (APRT)** mediates AMP formation through the transfer of adenine to PRPP with the release of  $PP_i$ :

**Hypoxanthine–guanine phosphoribosyltransferase (HGPRT)** catalyzes the analogous reaction for both hypoxanthine and guanine:

##### a. Lesch–Nyhan Syndrome Results from HGPRT Deficiency

The symptoms of **Lesch–Nyhan syndrome**, which is caused by a severe HGPRT deficiency, indicate that purine salvage reactions have functions other than conservation of the energy required for *de novo* purine biosynthesis. This sex-linked congenital defect (affects almost only males) results in excessive uric acid production (uric acid is a purine

degradation product; Section 28-4A) and neurological abnormalities such as spasticity, mental retardation, and highly aggressive and destructive behavior, including a bizarre compulsion toward self-mutilation. For example, many children with Lesch–Nyhan syndrome have such an irresistible urge to bite their lips and fingers that they must be restrained. If the restraints are removed, communicative patients will plead that the restraints be replaced even as they attempt to injure themselves.

The excessive uric acid production in patients with Lesch–Nyhan syndrome is readily explained. The lack of HGPRT activity leads to an accumulation of the PRPP that would normally be used in the salvage of hypoxanthine and guanine. The excess PRPP activates amidophosphoribosyltransferase (which catalyzes Reaction 2 of the IMP biosynthesis pathway; Fig. 28-2), thereby greatly increasing the rate of synthesis of purine nucleotides and consequently that of their degradation product, uric acid. Yet the physiological basis of the associated neurological abnormalities remains obscure. That a defect in a single enzyme can cause such profound but well-defined behavioral changes nevertheless has important psychiatric implications.

## 2 SYNTHESIS OF PYRIMIDINE RIBONUCLEOTIDES

The biosynthesis of pyrimidines is a simpler process than that of purines. Isotopic labeling experiments have shown that atoms N1, C4, C5, and C6 of the pyrimidine ring are all derived from aspartic acid, C2 arises from  $\text{HCO}_3^-$ , and N3 is contributed by glutamine (Fig. 28-6). In this section we discuss the pathways for pyrimidine ribonucleotide biosynthesis and how these processes are regulated.

#### A. Synthesis of UMP

The major breakthrough in the determination of the pathway for the *de novo* biosynthesis of pyrimidine ribonucleotides was the observation that mutants of the bread mold *Neurospora crassa*, which are unable to synthesize pyrimidines and therefore require both cytosine and uracil in their growth medium, grow normally when supplied instead with the pyrimidine **orotic acid** (uracil-6-carboxylic acid).

Orotic acid (uracil-6-carboxylic acid)

This observation led to the elucidation of the following six-reaction pathway for the biosynthesis of UMP (Fig. 28-7). Note that, in contrast to the case for purine nucleotides, the pyrimidine ring is coupled to the ribose-5-phosphate moiety *after* the ring has been synthesized.

synthesize arginine via the urea cycle is synthesized by a separate mitochondrial enzyme, **carbamoyl phosphate synthetase I (CPS I)**, which uses ammonia as its nitrogen source. Prokaryotes only have one carbamoyl phosphate synthetase, which supplies both pyrimidine and arginine biosynthesis and utilizes glutamine. This latter enzyme, as we have seen, contains three different active sites that are connected by a remarkable 96-Å-long tunnel through which intermediate products diffuse (Fig. 26-9).

The pyrimidine biosynthetic pathway is a target for antiparasitic drugs. For example, the parasitic protozoan *Toxoplasma gondii*, which infects most mammals, causes **toxoplasmosis**, a disease whose complications include blindness, neurological dysfunction, and death in immunocompromised individuals (e.g., those with AIDS). Most parasites have evolved to take advantage of nutrients supplied by their hosts. However, *T. gondii* is unable to meet its needs exclusively through nucleotide salvage pathways and retains the ability to synthesize uracil *de novo*. Drugs that target the parasite's carbamoyl phosphate synthetase II (an enzyme whose structure and kinetics distinguish it from its mammalian counterpart) could therefore prevent *T. gondii* growth. Moreover, there is evidence that *T. gondii* strains that have been engineered to lack carbamoyl phosphate synthetase II are avirulent and could be useful as vaccines in humans and livestock.

**2. Synthesis of carbamoyl aspartate.** Condensation of carbamoyl phosphate with aspartate to form **carbamoyl aspartate** is catalyzed by **aspartate transcarbamylase (ATCase)**. This reaction, the pathway's flux-generating step, occurs without need of ATP because carbamoyl phosphate is intrinsically activated. The structure and regulation of *E. coli* ATCase is discussed in Section 13-4.

**3. Ring closure to form dihydroorotate.** The third reaction of the pathway was elucidated by Arthur Kornberg following his observation that microorganisms made to utilize orotic acid as a carbon source first reduce it to **dihydroorotate**. The reaction forming the pyrimidine ring yields dihydroorotate in an intramolecular condensation catalyzed by the zinc metalloenzyme **dihydroorotase**.

**4. Oxidation of dihydroorotate.** Dihydroorotate is irreversibly oxidized to orotate by **dihydroorotate dehydrogenase (DHODH)**. The eukaryotic enzyme, which contains FMN, is an integral membrane protein that is located on the outer surface of the inner mitochondrial membrane, where ubiquinone supplies its oxidizing power. The other five enzymes of pyrimidine nucleotide biosynthesis are cytosolic in animal cells. Many bacterial dihydroorotate dehydrogenases are NAD<sup>+</sup>-linked flavoproteins that contain FMN, FAD, and a [2Fe-2S] cluster. These enzymes normally function degradatively, that is, in the direction orotate → dihydroorotate, thereby permitting these bacteria to metabolize orotate and accounting for Kornberg's observation. The reaction mediated by eukaryotic DHODH involves two redox steps, as is indicated in Fig. 28-8. The X-ray structure of human DHODH in complex with orotate, determined by Jon Clardy, reveals that the pyrimidine ring of orotate is stacked over the FMN's flavin ring with

the orotate C6 and FMN N5 separated by 3.6 Å, a distance that is compatible with direct hydride transfer between these two centers. A tunnel leads from the opposite side of the flavin ring to a hydrophobic region on the enzyme surface. The enzyme presumably binds to the mitochondrial membrane surface via this hydrophobic patch, thereby permitting ubiquinone, which readily diffuses within the mitochondrial membrane, to approach and reoxidize the enzyme's bound FMNH<sub>2</sub>. In the X-ray structure, this tunnel contains a tightly bound molecule named **A77 1726**, which is the primary metabolite of **leflunomide** (trade name **Arava**),

A77 1726

Leflunomide

a compound that is in clinical use for the treatment of rheumatoid arthritis. A77 1726 attenuates this autoimmune disease by blocking pyrimidine biosynthesis in T lymphocytes, thereby reducing their inappropriate proliferation. However, A77 1726 does not inhibit bacterial DHODHs.

**5. Acquisition of the ribose phosphate moiety.** Orotate reacts with PRPP to yield **orotidine-5'-monophosphate (OMP)** in a reaction catalyzed by **orotate phosphoribosyltransferase** and driven by hydrolysis of the eliminated PP<sub>i</sub>. This reaction fixes the anomeric form of pyrimidine nucleotides in the β configuration. Orotate phosphoribosyltransferase also acts to salvage other pyrimidine bases, such as uracil and cytosine, by converting them to their corresponding nucleotides. Although the various phosphoribosyltransferases, including HGPRT, exhibit little sequence similarity, their X-ray structures indicate that they contain a common structural core that resembles the dinucleotide binding fold (Section 8-3Bi) but lacks one of its β strands.

**6. Decarboxylation to form UMP.** The final reaction of the pathway is the decarboxylation of OMP by **OMP decarboxylase (ODCase)** to form UMP. ODCase enhances the rate ( $k_{\text{cat}}/K_M$ ) of OMP decarboxylation by a factor of  $2 \times 10^{23}$  over that of the uncatalyzed reaction, making it the most catalytically proficient enzyme known. Yet ODCase has no cofactors to help stabilize the reaction's putative carbanion intermediate. How is it able to do so? The X-ray structure, by Steven Ealick, of ODCase from *B. subtilis* in complex with UMP indicates that a bound OMP's C6

**Figure 28-8** Reactions catalyzed by eukaryotic dihydroorotate dehydrogenase. The reaction is initiated by the enzyme-mediated abstraction of a proton from C5 of dihydroorotate followed by the direct hydride transfer from C6 of dihydroorotate to N5 of FMN to yield orotate and FMNH<sup>-</sup>, which may then be

protonated to yield FMNH<sub>2</sub>. The FMNH<sub>2</sub> (or FMNH<sup>-</sup>) then reacts with coenzyme Q acquired from the inner mitochondrial membrane to regenerate the enzyme in its FMN form and yield coenzyme QH<sub>2</sub>, which then re-enters the inner mitochondrial membrane.

carboxyl group that is coplanar with its pyrimidine ring would be in close proximity to the side chains of both Asp 60 and Lys 62. Ealick has therefore proposed a mechanism (Fig. 28-9) in which the electrostatic interactions between the closely spaced carboxyl groups of OMP and Asp 60 destabilize OMP's ground state. This destabilization would be reduced in the transition state by the shift of OMP's negative charge from its carboxyl group toward C6, where it would be stabilized by the adjacent positively charged side chain of Lys 62. This side chain is also proposed to protonate the fragmenting C—C bond when it becomes sufficiently basic to accept the proton, thus avoiding the formation of a high-energy carbanion intermediate. The

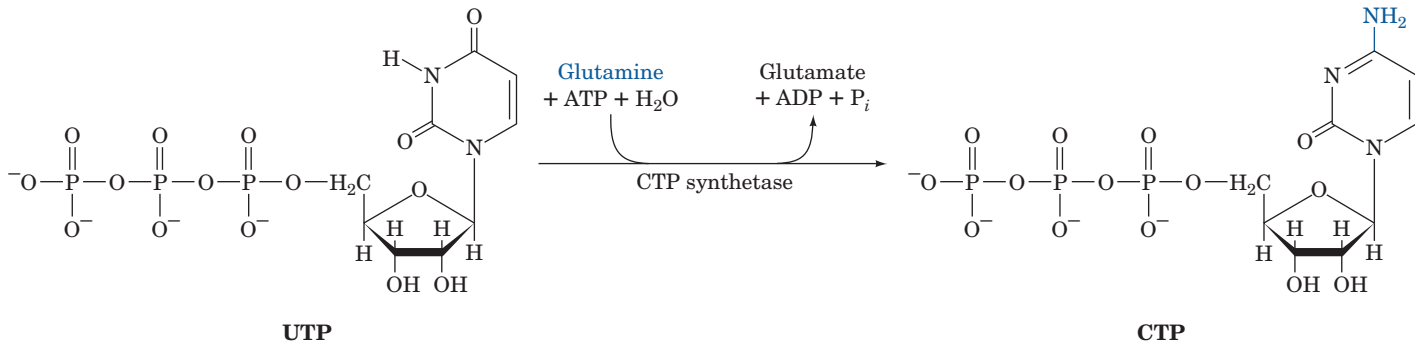

unfavorable electrostatic interaction between OMP and Asp 60 occurs because the enzyme tightly binds OMP through extensive interactions with its other functional groups. Indeed, the removal of OMP's phosphate group, which is quite distant from the C6 carboxyl group, decreases the catalytic reaction's  $k_{\text{cat}}/K_M$  by a factor of  $7 \times 10^7$ , thus providing a striking example of how binding energy can be applied to catalysis (preferential transition state binding).

In bacteria, the six enzyme activities mediating UMP biosynthesis occur on independent proteins (Fig. 28-7). In animals, however, as Mary Ellen Jones demonstrated, the first three enzymatic activities of the pathway, carbamoyl

**Figure 28-9** Proposed catalytic mechanism for OMP decarboxylase. [After Appleby, T.C., Kinsland, C., Begley, T.P., and Ealick, S.E., *Proc. Natl. Acad. Sci.* **97**, 2005 (2000).]

**Figure 28-10** Synthesis of CTP from UTP.

phosphate synthetase II, ATCase, and dihydroorotase, occur on a single 2225-residue polypeptide chain known as **CAD**, which forms 1400-kD homohexamers. Similarly, Reactions 5 and 6 of the animal pyrimidine pathway are catalyzed by a single 480-residue polypeptide named **UMP synthase** that forms 102-kD homodimers.

### B. Synthesis of UTP and CTP

The synthesis of UTP from UMP is analogous to the synthesis of purine nucleotide triphosphates (Section 28-1B). The process occurs by the sequential actions of a nucleoside monophosphate kinase and nucleoside diphosphate kinase:

CTP is formed by amination of UTP by **CTP synthetase** (Fig. 28-10). In animals, the amino group is donated by glutamine, whereas in bacteria it is supplied directly by ammonia.

### C. Regulation of Pyrimidine Nucleotide Biosynthesis

In bacteria, the pyrimidine biosynthesis pathway is primarily regulated at Reaction 2, the ATCase reaction (Fig. 28-11a). In *E. coli*, control is exerted there through the allosteric stimulation of ATCase by ATP and its inhibition by CTP (Section 13-4). In many bacteria, however, UTP is the major ATCase inhibitor.

In animals, ATCase is not a regulatory enzyme. Rather, pyrimidine biosynthesis is controlled by the activity of carbamoyl phosphate synthetase II, which is inhibited by UDP and UTP and activated by ATP and PRPP (Fig. 28-11b). A second level of control in the mammalian pathway occurs at OMP decarboxylase, for which UMP and to a lesser extent CMP are competitive inhibitors. In all organisms, the rate of OMP production varies with the availability of its precursor, PRPP. The PRPP level, it will be recalled, depends on the activity of ribose phosphate pyrophosphokinase, which is inhibited by ADP and GDP (Section 28-1A).

#### a. Orotic Aciduria Results from an Inherited Enzyme Deficiency

**Orotic aciduria**, an inherited human disease, is characterized by the excretion of large amounts of orotic acid in the urine, retarded growth, and severe anemia. It results from a deficiency in the bifunctional enzyme catalyzing

**Figure 28-11** Regulation of pyrimidine biosynthesis. The control networks are shown for (a) *E. coli* and (b) animals. Red octagons and green dots indicate control points. Feedback inhibition is represented by dashed red arrows and activation is indicated by dashed green arrows. See the Animated Figures

Reactions 5 and 6 of pyrimidine nucleotide biosynthesis. Consideration of the biochemistry of this situation led to its effective treatment: the administration of uridine and/or cytidine. The UMP formed through the phosphorylation of these nucleosides, besides replacing that normally synthesized, inhibits carbamoyl phosphate synthetase II so as to attenuate the rate of orotic acid synthesis. Few other genetic deficiencies in pyrimidine nucleotide biosynthesis are known in humans, presumably because most such defects are lethal *in utero*.

### 3 FORMATION OF DEOXYRIBONUCLEOTIDES

DNA differs chemically from RNA in two major respects: (1) its nucleotides contain 2'-deoxyribose residues rather than ribose residues, and (2) it contains the base thymine (5-methyluracil) rather than uracil. In this section we consider the biosynthesis of these DNA components.

#### A. Production of Deoxyribose Residues

Deoxyribonucleotides are synthesized from their corresponding ribonucleotides by the reduction of their C2' position rather than by their *de novo* synthesis from deoxyribose-containing precursors.

This pathway was established through Irwin Rose's study of how rats metabolize cytidine that is  $^{14}\text{C}$ -labeled in both its base and ribose components. The dCMP recovered from the rats' DNA had the same labeling ratio in its cytosine and deoxyribose residues as had the original cytidine, indicating that the DNA's components remained linked during DNA synthesis. If the cytosine and the ribose residues had become separated, dilution of the labeled cytosine and ribose residues with unlabeled residues, which are present in rat tissues in different amounts, would have altered this ratio.

The enzymes that catalyze the formation of deoxyribonucleotides by the reduction of the corresponding ribonucleotides are named **ribonucleotide reductases (RNRs)**. Three classes of RNRs are known that differ in their

substrates (NDP or NTP), the cofactors they employ, and in the way they obtain reducing equivalents (see below). Class I and II RNRs are widely distributed among prokaryotes; some species have a Class I RNR, whereas others, sometimes related species have a Class II RNR. However, all eukaryotes except a few unicellular species have Class I RNRs. Class III RNRs occur in prokaryotes that can grow anaerobically. (Class III RNRs are  $\text{O}_2$ -sensitive whereas Class I RNRs require  $\text{O}_2$  for activation; see below.) In fact, *E. coli*, which can grow both aerobically and anaerobically, expresses a Class I and a Class III RNR. In what follows, we shall mainly discuss the mechanism of Class I RNRs but end with a consideration of the evolutionary relationships among the different classes of RNRs.

#### a. Class I Ribonucleotide Reductase: Structure and Mechanism

The *E. coli* Class I RNR, as Peter Reichard demonstrated, is mainly present *in vitro* as a heterotetramer that can be decomposed to two catalytically inactive homodimers,  $\text{R1}_2$  (761-residue subunits) and  $\text{R2}_2$  (375-residue subunits), which together form the enzyme's two active sites (Fig. 28-12a). Each R1 subunit contains a substrate binding site as well as three independent effector binding sites that control both the enzyme's catalytic activity and its substrate specificity (see below). R1's catalytic residues include several redox-active thiol groups.

The X-ray structure of  $\text{R2}_2$  (Fig. 28-12b), determined by Hans Eklund, reveals that each of its subunits contains a novel binuclear Fe(III) prosthetic group whose two Fe(III) ions are bridged by both an  $\text{O}^{2-}$  ion (a  $\mu$ -oxo bridge) and the carboxyl group of Glu 115 (Fig. 28-12c). Each Fe(III) is further liganded by two carboxyl O atoms from Asp or Glu residues, a His  $\text{N}_\delta$  atom, and a water molecule. The Fe(III) complex interacts with Tyr 122 to form, as EPR measurements indicate, an unusual tyrosyl free radical ( $\text{TyrO}\cdot$ ) that is 5 Å from the closest Fe atom and is buried 10 Å beneath the surface of the protein, where it is out of contact with solvent and any oxidizable side chain [tyrosyl radicals have also been observed in cytochrome *c* oxidase (Section 22-2C5c) and in Photosystem II (Section 24-2Cd)].

The *E. coli* RNR is inhibited by **hydroxyurea**, which specifically quenches (destroys) the tyrosyl radical, and by **8-hydroxyquinoline**, which chelates  $\text{Fe}^{3+}$  ions.

Mammalian RNRs have similar characteristics to the *E. coli* enzyme. Indeed, hydroxyurea is in clinical use as an antitumor agent.

If *E. coli* RNR is incubated with  $[3'\text{-}^3\text{H}]\text{UDP}$ , a small but reproducible fraction of the  $^3\text{H}$  is released as  $^3\text{H}_2\text{O}$ . This observation, together with kinetic, spectroscopic, and site-directed mutagenesis studies, led JoAnne Stubbe to

**Figure 28-12** (Opposite) **Class I ribonucleotide reductase from *E. coli*.** (a) A schematic diagram of its quaternary structure. The enzyme consists of two pairs of identical subunits, R<sub>1</sub><sub>2</sub> and R<sub>2</sub><sub>2</sub>. Each R<sub>2</sub> subunit contains a binuclear Fe(III) complex that generates a phenoxy radical at its Tyr 122. The R<sub>1</sub> subunits each contain three different allosteric effector sites and five catalytically important Cys residues. The enzyme's two active sites are located near the interface between neighboring R<sub>1</sub> and R<sub>2</sub> subunits. (b) The X-ray structure of R<sub>2</sub><sub>2</sub> as viewed perpendicular to its 2-fold axis with the dimer's longest dimension in the horizontal plane. One subunit of the homodimeric protein is shown in blue and the other in yellow. The Fe(III) ions of its binuclear Fe complexes are represented by orange spheres and the radical-harboring Tyr 122 side chains are drawn in space-filling form with their C and O atoms green and red. Note that each subunit consists mainly of a bundle of eight unusually long helices. (c) The binuclear Fe(III) complex of R<sub>2</sub>.

Each Fe(III) ion is octahedrally coordinated by a His N<sub>δ</sub> atom and five O atoms, including those of the O<sup>2-</sup> ion and the Glu carboxyl group that bridges the two Fe(III) ions. (d) The X-ray structure of the R<sub>1</sub> dimer, each subunit of which is in complex with the 20-residue C-terminal peptide of R<sub>2</sub> together with GDP in the active site and dTTP in the specificity site. The ATP analog AMPPNP bound in the activity site of the closely similar complex of R<sub>1</sub> with the 20-residue peptide and AMPPNP has been superimposed on this structure. The structure is viewed along its 2-fold axis with its two subunits lavender and light green, the two R<sub>2</sub> peptides cyan and magenta, and the GDP, dTTP, and ATP shown in space-filling form colored according to atom type (C green, N blue, O red, and P gold). [Parts b and d based on X-ray structures by Hans Eklund, Swedish University of Agricultural Sciences, Uppsala, Sweden. PDBids (b) 1R1B and (d) 3R1R and 4R1R.] See the Animated Figures and Interactive Exercise 28

formulate the following catalytic mechanism for *E. coli* RNR (Fig. 28-13):

**1.** RNR's free radical ( $X\cdot$ ) abstracts an H atom from C3' of the substrate in the reaction's rate-determining step.

**2 and 3.** Acid-catalyzed cleavage of the C2'—OH bond releases  $H_2O$  to yield a radical cation intermediate. The radical mediates the stabilization of the C2' cation by the 3'—OH group's unshared electron pair, thereby accounting for the radical's catalytic role.

**4.** The radical cation intermediate is reduced by the enzyme's redox-active sulfhydryl pair to yield a 3'-deoxynucleotide radical and a protein disulfide group.

**5.** The 3' radical reabstracts an H atom from the protein to yield the product deoxynucleoside diphosphate and restore the enzyme to its radical state. A small fraction of the originally abstracted H atom exchanges with solvent before it can be replaced, thus accounting for the release of  $^3H$  on reduction of [ $3\text{'-}^3H$ ]UDP.

The Tyr 122 radical in R2 is too far away ( $>10 \text{ \AA}$ ) from the enzyme's catalytic site to abstract an electron directly from the substrate. Evidently, the protein mediates electron transfer from this tyrosyl radical to some other group ( $X\cdot$  in Fig. 28-13) that is in close proximity to the substrate C3'—H group. Site-directed mutagenesis studies suggest that Cys 439 of R1, in its thiyl radical form ( $-S\cdot$ ), is the most plausible candidate for  $X\cdot$  (which makes RNR the only enzyme in which a Cys residue is known to reduce a carbohydrate substrate). Similar studies suggest that Cys 225 and Cys 462 of R1 form the redox-active sulfhydryl pair that directly reduces substrate. Moreover, the resulting disulfide bond is subsequently reduced to regenerate active enzyme via disulfide interchange with Cys 754 and Cys 759 on R1, which are apparently positioned to accept electrons from external reducing agents (see below). Thus, each R1 subunit contains at least five Cys residues that chemically participate in nucleotide reduction.

These observations are confirmed by the X-ray structure of R1 in complex with R2's 20-residue C-terminal

**Figure 28-13** Enzymatic mechanism of ribonucleotide reductase. The reaction occurs via a free radical-mediated process in which reducing equivalents are supplied by the

formation of an enzyme disulfide bond. [After Stubbe, J.A., *Biol. Chem.* **265**, 5330 (1990).]

polypeptide (R1 does not crystallize satisfactorily in the absence of this polypeptide), also determined by Eklund (Fig. 28-12*d*). The central domain of the three-domain R1 monomer consists of a novel 10-stranded  $\alpha/\beta$  barrel that is formed by the antiparallel joining of two topologically similar half-barrels, each comprising five parallel  $\beta$  strands connected by four  $\alpha$  helices. As with the similar 8-stranded  $\alpha/\beta$  barrels that form the active sites of numerous enzymes (Section 8-3Bh), R1's active site Cys residues (439, 225, 462) are located in the mouth of the 10-stranded  $\alpha/\beta$  barrel.

The two R1 Cys residues, 754 and 759, that are implicated in the regeneration of the active enzyme are components of R1's C-terminal segment, which is not visible in the X-ray structure of R1 and is presumably disordered. This observation supports the hypothesis that this C-terminal segment acts to flexibly shuttle reducing equivalents from the enzyme surface to its active site.

### b. Radical Generation in Class I RNR Requires the Presence of O<sub>2</sub>

One of the most remarkable aspects of Class I RNR is its ability to stabilize its normally highly reactive TyrO• radical (its half-life is 4 days in the protein vs milliseconds in solution). Yet quenching the radical, say, by hydroxyurea, inactivates the enzyme. How, then, is the radical generated in the first place? The radical may be restored *in vitro* by simply treating the inactive enzyme with Fe(II) and a reducing agent in the presence of O<sub>2</sub>.

This is a four-electron reduction of O<sub>2</sub> in which the reducing agent that supplies the electron represented by e<sup>-</sup> may be ascorbate or even excess Fe<sup>2+</sup>.

### c. The Inability of Oxidized RNR to Bind Substrate Serves an Important Protective Function

Comparison of the X-ray structures of reduced R1 (in which the redox-active Cys 225 and Cys 462 residues are in their SH forms) with that of oxidized R1 (in which Cys 225 and Cys 462 are disulfide linked) reveals that Cys 462 in reduced R1 has rotated away from its position in oxidized R1 to become buried in a hydrophobic pocket, whereas Cys 225 moves into the region formerly occupied by Cys 462. The distance between the formerly disulfide-linked S atoms thereby increases from 2.0 to 5.7 Å. These movements are accompanied by small shifts of the surrounding polypeptide chain. Oxidized RNR does not bind substrate because its R1 Cys

225 would prevent the binding of substrate through steric interference of its S atom with the substrate NDP's O2' atom.

The inability of oxidized RNR to bind substrate has functional significance. In the absence of substrate, the enzyme's free radical is stored in the interior of the R2 protein, close to its dinuclear iron center. When substrate is bound, the radical is presumably transferred to it via a series of protein side chains in both R2 and R1. If the substrate is unable to properly react after accepting this free radical, as would be the case if RNR were in its oxidized state, this could result in the destruction of the substrate and/or the enzyme. Indeed, the mutation of the redox-active Cys 225 to Ser results in an enzyme that permits the formation of the substrate radical (Fig. 28-13); however, since the mutant enzyme is incapable of reducing it, the substrate radical instead decomposes followed by the release of its base and phosphate moieties. More importantly, a transient peptide radical forms, which cleaves and inactivates the R1 polypeptide chain while consuming the radical and thereby inactivating R2. Thus, an important role of the enzyme is to control the release of the radical's powerful oxidizing capability. It does so in part by preventing the binding of substrate while the enzyme is in its oxidized form.

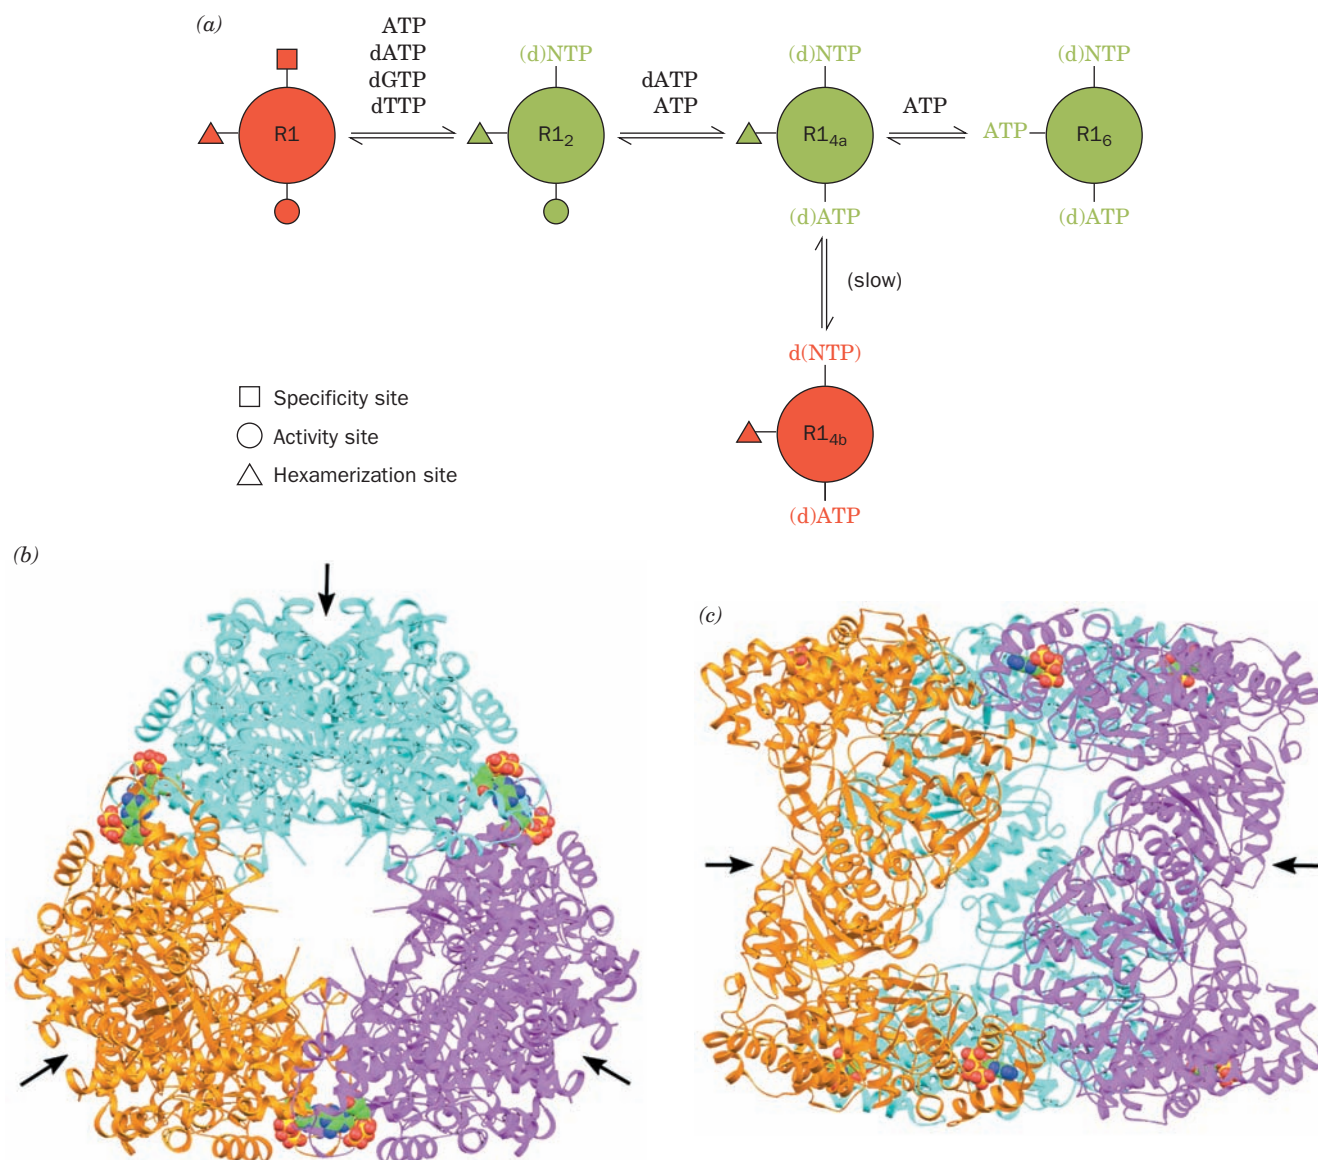

### d. Ribonucleotide Reductase Is Regulated by Effector-Induced Oligomerization

The synthesis of the four dNTPs in the amounts required for DNA synthesis is accomplished through feedback control. The maintenance of the proper intracellular ratios of dNTPs is essential for normal growth. Indeed, *a deficiency of any dNTP is lethal, whereas an excess is mutagenic because the probability that a given dNTP will be erroneously incorporated into a growing DNA strand increases with its concentration relative to those of the other dNTPs.*

The activities of both *E. coli* and mammalian Class I RNRs are allosterically responsive to the concentrations of various (d)NTPs. Thus, as Reichard has shown, ATP induces the reduction of CDP and UDP; dTTP induces the reduction of GDP and inhibits the reduction of CDP and UDP; dGTP induces the reduction of ADP and, in mammals but not *E. coli*, inhibits the reduction of CDP and UDP; and dATP inhibits the reduction of all NDPs.

Barry Cooperman has shown that the catalytic activity of mouse RNR varies with its state of oligomerization (that is, RNR is a morphoein; Section 26-4Ac), which in turn is governed by the binding of nucleotide effectors to three independent allosteric sites on R1: (1) the specificity site, which binds ATP, dATP, dGTP, and dTTP; (2) the activity site, which binds ATP and dATP; and (3) the hexamerization site, which binds only ATP. On the basis of molecular mass, ligand binding, and activity studies on mouse RNR, Cooperman formulated a model that quantitatively accounts for the allosteric regulation of Class I RNR. It has the following features (Fig. 28-14*a*):

1. The binding of ATP, dATP, dGTP, or dTTP to the specificity site induces the catalytically inactive R1 monomers to form a catalytically active dimer, R1<sub>2</sub>.

**Figure 28-14 Ribonucleotide reductase regulation.** (a) A model for the allosteric regulation of Class I RNR via its oligomerization. States shown in green have high activity and those shown in red have little or no activity. R2 has been omitted for simplicity. [After Kashlan, O.B., Scott, C.P., Lear, J.D., and Cooperman, B.S., *Biochemistry* **41**, 461 (2002).] (b) The X-ray structure of the R1 hexamer, which has  $D_3$  symmetry, in complex with AMPPNP as viewed along its 3-fold axis. Each of its three dimers are differently colored (the X-ray structure of a dimer is

shown in Fig. 28-12d). The AMPPNP, which binds to the enzyme's activity sites, is drawn in space-filling form with C green, N blue, O red, and P gold. The black arrows point along the R1 dimers' 2-fold axes and indicate the probable docking sites for the binding of R2 dimers. (c) The R1 · AMPPNP hexamer as viewed along the vertical 2-fold axis in Part b. [Parts b and c based on an X-ray structure by Hans Eklund, Swedish University of Agricultural Sciences, Uppsala, Sweden. PDBid 3R1R.]

2. The binding of dATP or ATP to the activity site causes the dimers to form catalytically active tetramers,  $R1_{4a}$ , that slowly but reversibly change conformation to a catalytically inactive state,  $R1_{4b}$ .

3. The binding of ATP to the hexamerization site induces the tetramers to further aggregate to form catalytically active hexamers,  $R1_6$ , RNR's major active form.

The concentration of ATP in a cell is such that, *in vivo*, R1 is almost entirely in its tetrameric or hexameric forms.

As a consequence, ATP couples the overall rate of DNA synthesis to the cell's energy state.

The specificity and activity sites have been located in X-ray structures of *E. coli* R1 (Fig. 28-12d); the hexamerization site has not yet been identified. The R1 hexamer had, in fact, been previously observed in the X-ray structures of R1 (Fig. 28-14b,c), but the interactions between its contacting dimers are so tenuous that it was assumed that they are merely artifacts of crystallization with no physiological significance. Yet, since the activity site is located at this contact

site, it now seems likely that its binding of (d)ATP induces R1 oligomerization through local conformational changes.

The foregoing model has, for simplicity, neglected the presence of R2 subunits although, of course, R1 and R2 must be present in equimolar amounts in the active enzyme. Presumably, the R1 and R2 dimers bind to one another such that their 2-fold axes coincide. The lack of space on the inside of the R1 hexamer dictates that the R2 dimers must contact the R1 dimers from outside the hexamer (Fig. 28-14b).

dCTP is not an effector of RNR. This is presumably because the intracellular balance between dCTP and dTTP is not controlled by RNR but, rather, is maintained by **deoxycytidine deaminase**, which converts dCTP to dUMP, the precursor of dTTP. This enzyme is activated by dCTP and inhibited by dTTP.

### e. Thioredoxin and Glutaredoxin Are Class I Ribonucleotide Reductase's Physiological Reducing Agents

The final step in the RNR catalytic cycle is the reduction of the enzyme's newly formed disulfide bond to reform its redox-active sulfhydryl pair. Dithiols such as that of 2-mercaptoethanol (Section 7-1B) can serve as the reducing agent for this process *in vitro* through a disulfide interchange reaction. One of the enzyme's physiological reducing agents, however, is **thioredoxin (Trx)**, a ubiquitous monomeric 105-residue protein that has a pair of closely proximal redox-active Cys residues, Cys 32 and Cys 35 (we have previously encountered thioredoxin in our study of the light-induced activation of the Calvin cycle; Section 24-3B). Thioredoxin reduces oxidized RNR via disulfide interchange.

The X-ray structure of reduced *E. coli* Trx (Fig. 28-15) reveals that the side chain of the redox-active Cys 32 is exposed on the protein's surface, where it is available for oxidation. Oxidized thioredoxin is, in turn, reduced by

**Figure 28-15** X-ray structure of human thioredoxin in its reduced (sulfhydryl) state. The 105-residue polypeptide chain is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The side chains of the redox-active residues, Cys 32 and Cys 35, are shown in space-filling form with C green and S yellow. This structure closely resembles those of the homologous  $\alpha$  and  $\alpha'$  domains of protein disulfide isomerase (PDI, Fig. 9-16). [Based on an X-ray structure by William Montfort, University of Arizona. PDBid 1ERT.]

NADPH in a reaction mediated by the flavoprotein **thioredoxin reductase**. NADPH therefore serves as the terminal reducing agent in the RNR-mediated reduction of NDPs to dNDPs (Fig. 28-16).

The existence of a viable *E. coli* mutant devoid of thioredoxin indicates that this protein is not the only substance capable of reducing oxidized RNR *in vivo*. This observation led to the discovery of **glutaredoxin**, a disulfide-containing, monomeric, 85-residue protein that can also reduce RNR (mutants devoid of both thioredoxin and glutaredoxin are nonviable). Oxidized glutaredoxin is reduced, via disulfide interchange, by the Cys-containing tripeptide glutathione which, in turn, is reduced by NADPH as catalyzed by glutathione reductase (GR; Section 21-2Ba). The relative

**Figure 28-16** Electron-transfer pathway for nucleoside diphosphate (NDP) reduction. NADPH provides the reducing

equivalents for this process through the intermediacy of thioredoxin reductase, thioredoxin, and ribonucleotide reductase.

importance of thioredoxin and glutaredoxin in the reduction of RNRs remains to be established.

#### f. Thioredoxin Reductase Alternates Its Conformation with Its Redox State

Thioredoxin reductase (**TrxR**), a homodimer of 316-residue subunits, is a homolog of GR that catalyzes a similar reaction: the reduction of a substrate disulfide bond by NADPH as mediated by an FAD prosthetic group and a redox active sulfhydryl pair (Cys 135 and Cys 138). However, the X-ray structure of the C138S mutant of *E. coli* TrxR in complex with NADP<sup>+</sup> (Fig. 28-17a), determined by Charles Williams and John Kuriyan, reveals that TrxR and GR differ in their active site arrangements such that their redox-active sulfhydryl pairs are on opposite sides of the flavin rings in the two enzymes. Nevertheless, TrxR's redox-active sulfhydryl pair appears properly positioned to reduce the flavin ring. However, the NADP<sup>+</sup>'s nicotinamide ring is >17 Å from the flavin ring and the redox-active sulfhydryl pair is buried such that it could not react with the enzyme's Trx substrate. How then does TrxR manage to transfer an electron pair from its bound NADPH via its flavin ring and redox-active sulfhydryl pair to Trx?

This question was answered by Williams and Martha Ludwig through their X-ray structure determination of the C135S mutant of TrxR, whose Cys 138 is disulfide-linked to Cys 32 of the C35S mutant of *E. coli* Trx (probably the physiologically relevant disulfide bond) and which is in complex with the NADP<sup>+</sup> analog **3-aminopyridine adenine dinucleotide phosphate (AADP<sup>+</sup>)**. In this complex (Fig. 28-17b), TrxR's NADP<sup>+</sup>-binding domain has rotated by 67°

relative to the rest of the protein compared to its position in TrxR alone (Fig. 28-17a). This positions the AADP<sup>+</sup>'s pyridine ring to react with the flavin ring and positions TrxR's redox-active sulfhydryl pair to undergo a disulfide interchange reaction with that of Trx. Moreover, in this latter conformation, the NADP<sup>+</sup>-binding domain appears to provide the recognition site for the substrate Trx. Evidently, TrxR alternates its conformation with each successive step in the process of transferring an electron pair from NADPH to the flavin to its redox-active sulfhydryl pair to its bound Trx substrate. This added mechanistic complication relative to that of GR, which does not undergo a significant conformational change in reducing glutathione disulfide (Section 21-2Ba), has apparently evolved to permit TrxR to reduce its protein substrate: Trx would be too large for its redox-active sulfhydryl pair to properly approach the active site sulfhydryl pair in a GR-like enzyme.

#### g. The Three Classes of Ribonucleotide Reductases Are Evolutionarily Related

We have seen that the active forms of Class I RNRs are R<sub>1</sub>R<sub>2</sub>, R<sub>1</sub>R<sub>4</sub>R<sub>2</sub>, and R<sub>1</sub>R<sub>6</sub>R<sub>2</sub> oligomers that have mechanistically essential tyrosyl radicals that are stabilized by oxo-bridged binuclear Fe(III) complexes, have NDPs for substrates, and obtain their reducing equivalents from thioredoxin and glutaredoxin. In contrast, Class II RNRs, which are α monomers or α<sub>2</sub> dimers, utilize a 5'-deoxyadenosylcobalamin cofactor (coenzyme B<sub>12</sub>; Section 25-2Eb) for radical generation, have NDPs for substrates, and are reduced by thioredoxin and glutaredoxin; whereas Class III RNRs,

**Figure 28-17** X-ray structures of *E. coli* thioredoxin reductase (TrxR). (a) The C138S mutant TrxR in complex with NADP<sup>+</sup>. The protein is shown in ribbon form colored according to its secondary structure. The NADP<sup>+</sup>, the FAD, and the side chains of Cys 135 and Ser 138 are drawn in ball-and-stick form with C yellow, N blue, O red, S green, and P magenta. (b) The C135S mutant TrxR in complex with AADP<sup>+</sup> and covalently linked to the C35S mutant of Trx via a disulfide bond between TrxR Cys 138 and Trx Cys 32. The TrxR is represented as in Part a, the Trx ribbon is blue-gray, and its Cys 32 and Ser 35 side chains are drawn in ball-and-stick form. Comparison of these two structures reveals that TrxR's NADP<sup>+</sup>-binding domain (residues 120–243) undergoes a 67° rotation about the axis drawn in blue relative to the rest of the protein, which is shown in the same orientation in both structures. [Courtesy of Martha Ludwig, University of Michigan. PDBids (a) 1TDF and (b) 1F6M.]

which are  $\alpha_2$  dimers that interact with a radical-generating protein  $\beta_2$  that contains a [4Fe-4S] cluster and requires *S*-adenosylmethionine (SAM; Section 26-3Ea) and NADPH for activity, have NTPs for substrates, and their reducing equivalents are provided by the oxidation of formate to  $\text{CO}_2$ .

Since all known cellular life synthesizes its deoxyribonucleotides from ribonucleotides, the rise of an RNR must have preceded the evolutionary transition from the RNA world (Section 1-5Ca) to DNA-based life-forms. Did the three classes of RNRs arise independently or are they evolutionarily related? Despite the seemingly large differences between these different classes of RNRs, the reactions they catalyze are surprisingly similar. All replace the 2' OH group of ribose with H via a free radical mechanism involving a thiyl radical with the reducing equivalents provided by a Cys sulfhydryl group (Fig. 28-13; the second Cys residue of the redox-active sulfhydryl pair in Class I and II RNRs is replaced by formate in Class III RNRs). They differ mainly in the way they generate the free radical. [In Class II RNRs, the radical is generated by the homolytic cleavage of its 5'-deoxyadenosylcobalamin cofactor's C—Co(III) bond (Section 25-2Ec). In Class III RNRs, it is generated by the NADPH-supplied and [4Fe-4S] cluster-mediated one-electron reductive cleavage of SAM by the  $\beta_2$  protein to yield methionine and the 5'-deoxyadenosyl radical (the same radical generated by the homolytic cleavage of 5'-deoxyadenosylcobalamin), which then abstracts the H atom from a  $\text{C}_\alpha\text{—H}$  group of a specific Gly on the  $\alpha$  subunit to yield 5'-deoxyadenosine and a stable but  $\text{O}_2$ -sensitive glycy radical.] Moreover, the X-ray structures of both Class II and Class III RNRs reveal that their active sites are formed by 10-stranded  $\alpha/\beta$  barrels that have the same connectivity as and are closely superimposable on that of Class I RNRs. It therefore appears that all three classes of RNRs are evolutionarily related. Reichard has proposed that, since life arose under anaerobic conditions and that formate, one of simplest organic reductants, was probably widely available on primitive Earth (Section 1-5B), the primordial RNR was a Class III-like enzyme. The rise of photosynthetic organisms that generated  $\text{O}_2$  then promoted the evolution of Class II RNRs, which can function under both anaerobic and aerobic conditions. Class I RNRs, which require the presence of  $\text{O}_2$  for activation, evolved last, presumably from a Class II RNR.

#### h. dNTPs Are Produced by Phosphorylation of dNDPs

In pathways involving Class I and Class II RNRs, the final step in the production of dNTPs is the phosphorylation of the corresponding dNDPs:

This reaction is catalyzed by nucleoside diphosphate kinase, the same enzyme that phosphorylates NDPs (Section 28-1Ba). As before, the reaction is written with ATP as the phosphoryl donor, although any NTP or dNTP can function in this capacity. In pathways involving Class III RNRs, the production of NTPs from NDPs precedes the reduction of NTPs to dNTPs.

## B. Origin of Thymine

### a. dUTP Diphosphohydrolase

The dTMP component of DNA is synthesized, as we discuss below, by methylation of dUMP. The dUMP is generated through the hydrolysis of dUTP by **dUTP diphosphohydrolase (dUTPase; also called dUTP pyrophosphatase):**

The reason for this apparently energetically wasteful process (dTMP, once formed, is rephosphorylated to dTTP) is that cells must minimize their concentration of dUTP in order to prevent incorporation of uracil into their DNA. This is because, as we discuss in Section 30-5Bd, DNA polymerase does not discriminate between dUTP and dTTP.

The X-ray structure of human dUTPase, determined by John Tainer, reveals the basis for this enzyme's exquisite specificity for dUTP. This homotrimer of 141-residue subunits binds dUTP in a snug-fitting cavity that sterically excludes thymine's C5 methyl group via the side chains of conserved residues (Fig. 28-18a). It differentiates uracil from cytosine via a set of hydrogen bonds from the protein backbone that mimic adenine's base-pairing interaction (Fig. 28-18b), and it differentiates dUTP from UTP by the steric exclusion of ribose's 2' OH group by the side chain of a conserved Tyr.

### b. Thymidylate Synthase

dTMP is synthesized from dUMP by **thymidylate synthase (TS)** with  $N^5, N^{10}$ -methylene tetrahydrofolate ( $N^5, N^{10}$ -methylene-THF) as the methyl donor:

(THF cofactors are discussed in Section 26-4D). Note that the transferred methylene group (in which the carbon has the oxidation state of formaldehyde) is reduced to a methyl group (which has the oxidation state of methanol) at the

expense of the oxidation of the THF cofactor to dihydrofolate (DHF).

The catalytic mechanism of TS, a highly conserved homodimeric protein (with 264-residue subunits in *E. coli*), has been extensively investigated. On incubation of the enzyme with  $N^5,N^{10}$ -methylene-[6- $^3\text{H}$ ]THF and dUMP, the  $^3\text{H}$  is quantitatively transferred to the methyl group of the product dTMP. When [5- $^3\text{H}$ ]dUMP is the substrate, however, the  $^3\text{H}$  is released into the aqueous solvent. Such information, together with the knowledge that uracil C6, which occupies the  $\beta$  position of an  $\alpha,\beta$ -unsaturated ketone, is susceptible to nucleophilic attack, led Daniel Santi to propose the following mechanistic scheme for the TS reaction (Fig. 28-19):

1. An enzyme nucleophile, identified as the thiolate group of Cys 146, attacks C6 of dUMP to form a covalent adduct.
2. C5 of the resulting enolate ion attacks the  $\text{CH}_2$  group of the iminium cation in equilibrium with  $N^5,N^{10}$ -methylene-THF to form an enzyme-dUMP-THF ternary covalent complex.
3. An enzyme base abstracts the acidic proton at the C5 position of the enzyme-bound dUMP, forming an exocyclic methylene group and eliminating the THF cofactor. The abstracted proton subsequently exchanges with solvent.
4. The redox change occurs via the migration of the  $\text{N6-H}$  atom of THF as a hydride ion to the exocyclic methylene group, converting it to a methyl group (thus

accounting for the above described transfer of  $^3\text{H}$ ) and yielding DHF. This reduction promotes displacement of the Cys thiolate group from the intermediate so as to release product, dTMP, and reform active enzyme.

### c. 5-Fluorodeoxyuridylate Is a Potent Antitumor Agent

The above mechanism is supported by the observation that **5-fluorodeoxyuridylate (FdUMP)**

**5-Fluorodeoxyuridylate (FdUMP)**

is an irreversible inhibitor of TS. This substance, like dUMP, binds to the enzyme (an F atom has approximately the same radius as an H atom) and undergoes the first two steps of the normal enzymatic reaction. In Step 3, however, the enzyme cannot abstract the F atom as  $\text{F}^+$  (recall that F is the most electronegative element), so that the enzyme is all but permanently immobilized as the enzyme-FdUMP-THF

(a)

**Figure 28-18** X-ray structure of human dUTPase. (a) The molecular surface at the substrate binding site showing how the enzyme differentiates uracil from thymine. Bound dUTP is drawn in stick form with its N, O, and P atoms represented by blue, red, and yellow spheres.  $\text{Mg}^{2+}$  ions that were modeled into the structure are represented by green spheres. The protein's molecular surface is colored according to its electrostatic potential with positive, negative, and near neutral regions blue, red, and white, respectively. Note how the snug fit of the uracil ring into its binding site would sterically exclude thymine's C5 methyl group. (b) The substrate binding site indicating how the

(b)

enzyme differentiates uracil from cytosine and 2'-deoxyribose from ribose. dUMP bound at the active site is drawn as in Part a. The protein, mainly the backbone of a  $\beta$  hairpin motif, is similarly drawn but with thinner gray bonds. Hydrogen bonds are shown as dotted white lines, and a tightly bound, conserved water molecule is represented by a pink sphere. The pattern of hydrogen bonding donors and acceptors on the protein would prevent cytosine from binding in the active site pocket. The conserved Tyr side chain sterically excludes ribose's 2' OH group. [Courtesy of John Tainer, The Scripps Research Institute, La Jolla, California.]

**Figure 28-19** Catalytic mechanism of thymidylate synthase. The methyl group is supplied by  $N^5,N^{10}$ -methylene-THF, which is concomitantly oxidized to dihydrofolate.

ternary covalent complex analogous to that after Step 2 in Fig. 28-19. Indeed, X-ray structural analysis by William Montfort revealed that crystals of *E. coli* TS that had been soaked in a solution containing FdUMP and  $N^5,N^{10}$ -methylene-THF contain precisely this complex (Fig. 28-20). Enzymatic inhibitors such as FdUMP, which inactivate an enzyme only after undergoing part or all of its normal catalytic reaction, are called **mechanism-based inhibitors** (alternatively, **suicide substrates** because they cause the enzyme to “commit suicide”). *Mechanism-based inhibitors, being targeted for particular enzymes, are among the most powerful, specific, and therefore useful enzyme inactivators.*

The strategic position of thymidylate synthase in DNA biosynthesis has led to the clinical use of FdUMP as an antitumor agent. Rapidly proliferating cells, such as cancer cells, require a steady supply of dTMP in order to survive and are therefore killed by treatment with FdUMP. In contrast, most normal mammalian cells, which grow slowly if at all, have a lesser requirement for dTMP, so that they are

**Figure 28-20** The X-ray structure of the *E. coli* thymidylate synthase in covalent complex with FdUMP and THF. The active site region of one subunit of this dimeric enzyme is shown in ribbon form with its polypeptide chain colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The FdUMP and  $N^5,N^{10}$ -methylene-THF are drawn in stick form with FdUMP C cyan,  $N^5,N^{10}$ -methylene-THF C green, N blue, O red, F purple, and P orange. The C5 and C6 atoms of FdUMP form covalent bonds with the  $\text{CH}_2$  group substituent to N5 of THF and the S atom of Cys 146, whose side chain is drawn in stick form with C green and S yellow. [Based on an X-ray structure by William Montfort, University of Arizona, PDBid 1TSN.]

**Figure 28-21** Regeneration of  $N^5,N^{10}$ -methylenetetrahydrofolate. The DHF product of the thymidylate synthase reaction is converted back to  $N^5,N^{10}$ -methylene-THF by the sequential actions of (1) dihydrofolate reductase and (2) serine hydroxymethyltransferase. Thymidylate synthase is inhibited by FdUMP, whereas dihydrofolate reductase is inhibited by the antifolates methotrexate, aminopterin, and trimethoprim.

relatively insensitive to FdUMP (some exceptions are the bone marrow cells that comprise the blood-forming tissues and much of the immune system, the intestinal mucosa, and hair follicles). **5-Fluorouracil** and **5-fluorodeoxyuridine** are also effective antitumor agents since they are converted to FdUMP through salvage reactions.

#### d. $N^5,N^{10}$ -Methylene-THF Is Regenerated in Two Reactions

The thymidylate synthase reaction is biochemically unique in that it oxidizes THF to DHF; no other enzymatic reaction employing a THF cofactor alters this coenzyme's net oxidation state. The DHF product of the thymidylate synthase reaction is recycled to the enzyme's  $N^5,N^{10}$ -methylene-THF cofactor through two sequential reactions (Fig. 28-21):

1. DHF is reduced to THF by NADPH as catalyzed by **dihydrofolate reductase (DHFR)**; (Section 26-4D). Although, in most organisms, DHFR is a monomeric monofunctional enzyme, in protozoa and at least some plants, DHFR and TS occur on the same polypeptide chain to form a bifunctional enzyme that has been shown to channel DHF from its TS to its DHFR active sites.

2. Serine hydroxymethyltransferase (Section 26-3Bb) transfers the hydroxymethyl group of serine to THF, yielding  $N^5,N^{10}$ -methylene-THF and glycine.

#### e. Antifolates Are Anticancer Agents

Inhibition of DHFR quickly results in all of a cell's limited supply of THF being converted to DHF by the thymidylate synthase reaction. Inhibition of DHFR therefore not only prevents dTMP synthesis (Fig. 28-21), but also blocks all other THF-dependent biological reactions such as the

synthesis of purines (Section 28-1A), methionine (Section 26-5Ba), and, indirectly, histidine (Section 26-5Be). DHFR (Fig. 28-22) therefore offers an attractive target for chemotherapy.

#### Methotrexate (amethopterin), aminopterin, and trimethoprim

are DHF analogs that competitively although all but irreversibly bind to DHFR with an ~1000-fold greater affinity than does DHF. These **antifolates** (substances that interfere with the action of folate cofactors) are effective anticancer agents, particularly against childhood leukemias. In fact, a successful chemotherapeutic strategy is to treat a cancer

**Figure 28-22** X-ray structure of human dihydrofolate reductase in complex with folic acid. The polypeptide is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The folic acid is drawn in space-filling form with C green, N blue, and O red. [Based on an X-ray structure by Joseph Kraut, University of California at San Diego. PDBid 1DHF.]

See Interactive Exercise 29.

victim with a lethal dose of methotrexate and some hours later “rescue” the patient (but hopefully not the cancer) by administering massive doses of 5-formyl-THF and/or thymidine. A low dose of methotrexate is also effective in the treatment of rheumatoid arthritis, inhibiting immune system activity and thus decreasing inflammation. Trimethoprim, which was discovered by George Hitchings and Gertrude Elion, binds much more tightly to bacterial DHFRs than to those of mammals and is therefore a clinically useful antibiotic.

#### 4 NUCLEOTIDE DEGRADATION

Most foodstuffs, being of cellular origin, contain nucleic acids. Dietary nucleic acids survive the acid medium of the stomach; they are degraded to their component nucleotides, mainly in the duodenum, by pancreatic nucleases and intestinal phosphodiesterases. These ionic compounds, which cannot pass through cell membranes, are then hydrolyzed to nucleosides by a variety of group-specific nucleotidases and nonspecific phosphatases. Nucleosides may be directly absorbed by the intestinal mucosa or first undergo further degradation to free bases and ribose or

ribose-1-phosphate through the action of **nucleosidases** and **nucleoside phosphorylases**:

Radioactive labeling experiments have demonstrated that only a small fraction of the bases of ingested nucleic acids are incorporated into tissue nucleic acids. Evidently, the *de novo* pathways of nucleotide biosynthesis largely satisfy an organism’s need for nucleotides. Consequently, ingested bases, for the most part, are degraded and excreted. Cellular nucleic acids are also subject to degradation as part of the continual turnover of nearly all cellular components. In this section we outline these catabolic pathways and discuss the consequences of several of their inherited defects.

##### A. Catabolism of Purines

The major pathways of purine nucleotide and deoxynucleotide catabolism in animals are diagrammed in Fig. 28-23. Other organisms may have somewhat different

**Figure 28-23** Major pathways of purine catabolism in animals. The various purine nucleotides and deoxynucleotides are all degraded to uric acid.

**Figure 28-24** X-ray structure and mechanism of adenosine deaminase. (a) A ribbon diagram of murine adenosine deaminase in complex with its transition state analog 6-hydroxy-1,6-dihydropurine ribonucleoside (HDPR). The polypeptide is drawn in ribbon form colored according to its secondary structure (helices cyan,  $\beta$  strands magenta, and loops salmon) and viewed approximately down the axis of the enzyme's  $\alpha/\beta$  barrel from the N-terminal ends of its  $\beta$  strands. The HDPR is shown in stick form with its C, N, and O atoms green, blue, and red. The enzyme-bound  $Zn^{2+}$  ion, which is coordinated by HDPR's 6-hydroxyl group, is represented by a silver sphere. [Based on an X-ray structure by Florante Quijcho, Baylor College of Medicine. PDBid 1ADA.] (b) The proposed catalytic mechanism of adenosine deaminase. A  $Zn^{2+}$ -polarized  $H_2O$  molecule (Section 15-1Cb) nucleophilically attacks C6 of the enzyme-bound adenosine molecule in a process that is facilitated by His 238 acting as a general base, Glu 217 acting as a general acid, and Asp 295 acting to orient the water molecule via hydrogen bonding. The resulting tetrahedral intermediate decomposes by the elimination of ammonia in a reaction that is aided by the now imidazolium and carboxyl side chains of His 238 and Glu 217 acting as a general acid and a general base, respectively. This yields inosine in its enol tautomeric form, which, on its release from the enzyme, largely assumes its dominant keto form. The  $Zn^{2+}$  is coordinated by three His side chains that are not shown. [After Wilson, D.K. and Quijcho, F.A., *Biochemistry* **32**, 1692 (1993).] See **Interactive Exercise 30**

pathways among these various intermediates (including adenine), but all of these pathways lead to uric acid. Of course, the intermediates in these processes may instead be reused to form nucleotides via salvage reactions. In addition, ribose-1-phosphate, a product of the reaction catalyzed by **purine nucleoside phosphorylase (PNP)**, is isomerized by **phosphoribomutase** to the PRPP precursor ribose-5-phosphate.

Adenosine and deoxyadenosine are not degraded by mammalian PNP. Rather, adenine nucleosides and nucleotides are deaminated by **adenosine deaminase (ADA)** and **AMP deaminase** to their corresponding inosine derivatives, which, in turn, may be further degraded. The X-ray structure of murine ADA that was crystallized in the presence of its inhibitor **purine ribonucleoside** was determined by Florante Quijcho (Fig. 28-24a). The enzyme forms an

eight-stranded  $\alpha/\beta$  barrel with its active site in a pocket at the C-terminal end of the  $\beta$  barrel, as occurs in nearly all known  $\alpha/\beta$  barrel enzymes (Section 8-3Bh). Purine ribonucleoside

binds to ADA in a normally rare hydrated form, **6-hydroxy-1,6-dihydropurine ribonucleoside (HDPR)**,

**Purine ribonucleoside**

**6-Hydroxy-1,6-dihydropurine ribonucleoside (HDPR)**

a nearly ideal transition state analog of the ADA reaction. Although it had been previously reported that ADA does not require a cofactor, its X-ray structure clearly reveals that a zinc ion is bound in the deepest part of the active site pocket, where it is pentacoordinated by three His side chains, a carboxyl oxygen of Asp 295, and the O6 atom of HDPR. ADA's active site complex suggests a catalytic mechanism (Fig. 28-24*b*) reminiscent of that of carbonic anhydrase (Section 15-1Cb): His 238, which is properly positioned to act as a general base, abstracts a proton from a bound  $Zn^{2+}$ -activated water molecule, which nucleophilically attacks the adenine C6 atom to form a tetrahedral intermediate. Products are then formed by the elimination of ammonia.

#### a. Genetic Defects in ADA Result in Severe Combined Immunodeficiency Disease

Abnormalities in purine nucleoside metabolism arising from rare genetic defects in ADA selectively kill **lymphocytes** (a type of white blood cell). Since lymphocytes mediate much of the immune response (Section 35-2A), ADA deficiency results in **severe combined immunodeficiency disease (SCID)** that, without special protective measures, is invariably fatal in infancy due to overwhelming infection. The mutations in all eight known ADA variants obtained from SCID patients appear to structurally perturb the active site of ADA.

Biochemical considerations provide a plausible explanation of SCID's etiology (causes). In the absence of active ADA, deoxyadenosine is phosphorylated to yield levels of dATP that are 50-fold greater than normal. This high concentration of dATP inhibits ribonucleotide reductase (Section 28-3Ad), thereby preventing the synthesis of the other dNTPs, choking off DNA synthesis and thus cell proliferation. The tissue-specific effect of ADA deficiency on the immune system may be explained by the observation that lymphoid tissue is particularly active in deoxyadenosine phosphorylation.

SCID caused by ADA defects does not respond to treatment by the intravenous injection of ADA because the liver clears this enzyme from the bloodstream within minutes. If, however, several molecules of the biologically inert polymer **polyethylene glycol (PEG)**

are covalently linked to surface groups on ADA, the resulting **PEG-ADA** remains in the blood for 1 to 2 weeks, thereby largely resuscitating the SCID victim's immune system. The protein-linked PEG only reduces the catalytic activity of ADA by ~40% but, evidently, masks it from the receptors that filter it out of the blood. SCID can therefore be treated effectively by PEG-ADA. This treatment, however, is expensive and not entirely satisfactory. Consequently, ADA deficiency was selected as one of the first genetic diseases to be treated by gene therapy (Section 5-5Hb): Lymphocytes were extracted from the blood of an ADA-deficient child and grown in the laboratory, had a normal ADA gene inserted into them via genetic engineering techniques (Section 5-5), and were then returned to the child. After 12 years, 20 to 25% of the patient's lymphocytes contained the introduced ADA gene. However, ethical considerations have mandated that the patient continue receiving injections of PEG-ADA so that the efficacy of this gene therapy protocol is unclear.

#### b. The Purine Nucleotide Cycle

The deamination of AMP to IMP, when combined with the synthesis of AMP from IMP (Fig. 28-4, *left*), has the effect of deaminating aspartate to yield fumarate (Fig. 28-25). John Lowenstein demonstrated that this **purine nucleotide cycle** has an important metabolic role in skeletal muscle. An increase in muscle activity requires an increase in the activity of the citric acid cycle. This process usually occurs through the generation of additional citric acid cycle intermediates (Section 21-4). Muscles, however, lack most of the enzymes that catalyze these anaplerotic (filling up) reactions in other tissues. Rather, muscle replenishes its citric acid cycle intermediates as fumarate generated in the purine nucleotide cycle. The importance of the purine nucleotide cycle in muscle metabolism is indicated by the observation that the activities of the three enzymes involved are all severalfold higher in muscle than in other tissues. In fact, individuals with an inherited deficiency in muscle AMP deaminase (**myoadenylate deaminase deficiency**) are easily fatigued and usually suffer from cramps after exercise.

#### c. Xanthine Oxidase Is a Mini-Electron-Transport Protein

**Xanthine oxidase (XO)** converts hypoxanthine to xanthine, and xanthine to uric acid (Fig. 28-23, *bottom*). In mammals, this enzyme occurs mainly in the liver and the small intestinal mucosa. XO is a homodimer of ~1330-residue subunits, each of which binds a variety of electron-transfer agents: an FAD, two spectroscopically distinct [2Fe-2S] clusters, and a **molybdopterin complex (Mo-pt)**

**Molybdopterin complex (Mo-pt)**

Net:  $\text{H}_2\text{O} + \text{Aspartate} + \text{GTP} \rightarrow \text{NH}_4^+ + \text{GDP} + \text{P}_i + \text{fumarate}$

**Figure 28-25** The purine nucleotide cycle. This pathway functions, in muscle, to prime the citric acid cycle by generating fumarate.

in which the Mo atom cycles between its Mo(VI) and Mo(IV) oxidation states. The final electron acceptor is  $\text{O}_2$ , which is converted to  $\text{H}_2\text{O}_2$ , a potentially harmful oxidizing agent that is subsequently disproportionated to  $\text{H}_2\text{O}$  and  $\text{O}_2$  by catalase (Section 1-2Ad). In XO, the polypeptide has been proteolytically cleaved into three segments (the un-cleaved enzyme, which is known as **xanthine dehydrogenase**, preferably uses  $\text{NAD}^+$  as its electron acceptor, whereas XO does not react with  $\text{NAD}^+$ ).

The X-ray structure of XO from cow's milk in complex with the competitive inhibitor salicylic acid (Fig. 25-74), determined by Emil Pai, reveals that the FAD and the molybdopterin complex are interposed by the two  $[\text{2Fe-2S}]$  clusters to form a mini-electron-transport chain (Fig. 28-26). Each of its three peptide segments forms a separate domain with the N-terminal domain binding the two  $[\text{2Fe-2S}]$  clusters, the central domain binding the FAD, and the C-terminal domain binding the Mo-pt complex. Although the salicylic acid does not contact the Mo-pt complex, it binds to XO in a way that blocks the approach of substrates to the metal center.

XO hydroxylates xanthine at its C8 position (and hypoxanthine at its C2 position), yielding uric acid in its enol form that tautomerizes to the more stable keto form:

**Figure 28-26** X-ray structure of xanthine oxidase from cow's milk in complex with salicylic acid.

(a) Ribbon diagram of its 1332-residue subunit in which the N-terminal domain (residues 2–165) is cyan, the central domain (residues 224–528) is gold, and the C-terminal domain (residues 571–1315) is lavender. The enzyme's redox cofactors and bound salicylic acid are shown in space-filling form with C green, N blue, O red, S yellow, P magenta, Fe orange, and Mo light blue. The  $\sim 50$ -residue peptide segments spanning domains are disordered and are apparently highly flexible. (b) The enzyme's redox cofactors and salicylic acid (Sal) drawn in stick form with their S, Fe, and Mo atoms represented by spheres. The atoms are colored as in Part a and viewed from the same direction but with greater magnification. [Based on an X-ray structure by Emil Pai, University of Toronto, Toronto, Ontario, Canada. PDBid 1FIQ.]

**Figure 28-27** Mechanism of xanthine oxidase. The reduced enzyme is subsequently reoxidized by  $O_2$ , yielding  $H_2O_2$ .

(its enol form ionizes with a  $pK$  of 5.4; hence, the name *uric acid*).  $^{18}O$ -labeling experiments have demonstrated that the C8 keto oxygen of uric acid is derived from  $H_2O$ , whereas the oxygen atoms of  $H_2O_2$  come from  $O_2$ . Chemical and spectroscopic studies suggest that the enzyme has the following mechanism (Fig. 28-27):

1. The reaction is initiated by the attack of an enzyme nucleophile, X, on the C8 position of xanthine.
2. The C8—H atom is eliminated as a hydride ion that combines with the Mo(VI) complex, thereby reducing it to the Mo(IV) state.
3. Water displaces the enzyme nucleophile producing uric acid.

In the second stage of the reaction, the now reduced enzyme is reoxidized to its original Mo(VI) state by reaction with  $O_2$ . This complex process, not surprisingly, is but poorly understood. EPR measurements indicate that electrons are funneled from the Mo(IV) through the two [2Fe-2S] clusters to the flavin and ultimately to  $O_2$ , yielding  $H_2O_2$  and regenerated enzyme.

### B. Fate of Uric Acid

In humans and other primates, the final product of purine degradation is uric acid, which is excreted in the urine. The same is true of birds, terrestrial reptiles, and many insects, but these organisms, which do not excrete urea, also catabolize their excess amino acid nitrogen to uric acid via purine biosynthesis. This complicated system of nitrogen excretion has a straightforward function: *It conserves water.*

Uric acid is only sparingly soluble in water, so that its excretion as a paste of uric acid crystals is accompanied by very little water. In contrast, the excretion of an equivalent amount of the much more water-soluble urea osmotically sequesters a significant amount of water.

In all other organisms, uric acid is further processed before excretion (Fig. 28-28). Mammals other than primates oxidize it to their excretory product, **allantoin**, in a reaction catalyzed by the Cu-containing enzyme **urate oxidase**. A further degradation product, **allantoic acid**, is excreted by teleost (bony) fish. Cartilaginous fish and amphibia further degrade allantoin to urea prior to excretion. Finally, marine invertebrates decompose urea to their nitrogen excretory product,  $NH_4^+$ .

#### a. Gout Is Caused by an Excess of Uric Acid

**Gout** is a disease characterized by elevated levels of uric acid in body fluids. Its most common manifestation is excruciatingly painful arthritic joint inflammation of sudden onset, most often in the big toe (Fig. 28-29), caused by deposition of nearly insoluble crystals of sodium urate. Sodium urate and/or uric acid may also precipitate in the kidneys and ureters as stones, resulting in renal damage and urinary tract obstruction. Gout, which affects ~3 per 1000 persons, predominantly males, has been traditionally, although inaccurately, associated with overindulgent eating and drinking. The probable origin of this association is that in previous centuries, when wine was often contaminated with lead during its manufacture and storage, heavy drinking resulted in chronic lead poisoning, which, among other things, decreases the kidney's ability to excrete uric acid.

**Figure 28-28 Degradation of uric acid to ammonia.** The process is arrested at different stages in the indicated species and the resulting nitrogen-containing product is excreted.

The most prevalent cause of gout is impaired uric acid excretion (although usually for other reasons than lead poisoning). Gout may also result from a number of metabolic insufficiencies, most of which are not well characterized. One well-understood cause is HGPRT deficiency (Lesch–Nyhan syndrome in severe cases), which leads to excessive uric acid production through PRPP accumulation (Section 28-1D). Uric acid overproduction is also

**Figure 28-29 The Gout,** a cartoon by James Gillray (1799). [Yale University Medical Historical Library.]

caused by glucose-6-phosphatase deficiency (von Gierke's glycogen storage disease; Section 18-4): The increased availability of glucose-6-phosphate stimulates the pentose phosphate pathway (Section 23-4), increasing the rate of ribose-5-phosphate production and consequently that of PRPP, which in turn stimulates purine biosynthesis.

Gout may be treated by administration of the xanthine oxidase inhibitor **allopurinol**, a hypoxanthine analog with interchanged N7 and C8 positions.

Xanthine oxidase hydroxylates allopurinol, as it does hypoxanthine, yielding **alloxanthine**,

which remains tightly bound to the reduced form of the enzyme, thereby inactivating it. Allopurinol consequently alleviates the symptoms of gout by decreasing the rate of uric acid production while increasing the levels of the more soluble hypoxanthine and xanthine. Although allopurinol controls the gouty symptoms of Lesch–Nyhan syndrome, it has no effect on its neurological symptoms.

**Figure 28-30** Major pathways of pyrimidine catabolism in animals. The amino acid products of these reactions are taken up in other metabolic processes. UMP and dTMP are degraded by the same enzymes; the pathway for dTMP degradation is given in parentheses.

### C. Catabolism of Pyrimidines

Animal cells degrade pyrimidine nucleotides to their component bases (Fig. 28-30, top). These reactions, like those of purine nucleotides, occur through dephosphorylation, deamination, and glycosidic bond cleavages. The resulting uracil and thymine are then broken down in the liver through reduction (Fig. 28-30, middle) rather than by oxidation, as

occurs in purine catabolism. The end products of pyrimidine catabolism,  **$\beta$ -alanine** and  **$\beta$ -aminoisobutyrate**, are amino acids and are metabolized as such. They are converted, through transamination and activation reactions, to malonyl-CoA and methylmalonyl-CoA (Fig. 28-30, bottom left) for further utilization (Sections 25-4A and 25-2Ea).

## 5 BIOSYNTHESIS OF NUCLEOTIDE COENZYMES

In this section we outline the assembly, in animals, of the nucleotide coenzymes  $\text{NAD}^+$  and  $\text{NADP}^+$ , FMN and FAD, and coenzyme A, from their vitamin precursors. These vitamins are synthesized *de novo* only by plants and microorganisms.

### A. Nicotinamide Coenzymes

The nicotinamide moiety of the nicotinamide coenzymes ( $\text{NAD}^+$  and  $\text{NADP}^+$ ) is derived, in humans, from dietary nicotinamide, nicotinic acid, or the essential amino acid tryptophan (Fig. 28-31). **Nicotinate phosphoribosyltransferase**,

**Figure 28-31 Pathways for the biosynthesis of NAD<sup>+</sup> and NADP<sup>+</sup>.** These nicotinamide coenzymes are synthesized from their vitamin precursors, nicotinate and nicotinamide, and from the tryptophan degradation product, quinolinate.

**Figure 28-32** Biosynthesis of FMN and FAD from the vitamin precursor riboflavin.

which occurs in most mammalian tissues, catalyzes the formation of **nicotinate mononucleotide** from nicotinate and PRPP. This intermediate may also be synthesized from **quinolinate**, a degradation product of tryptophan (Section 26-3G), in a reaction mediated by **quinolinate phosphoribosyltransferase**, which occurs mainly in liver and kidney. A poor diet, nevertheless, may result in pellagra (nicotinic acid deficiency; Section 13-3), since, under such conditions, tryptophan will be almost entirely utilized in protein biosynthesis. Nicotinate mononucleotide is joined via a pyrophosphate linkage to an ATP-derived AMP residue by **NAD<sup>+</sup> pyrophosphorylase** to yield **nicotinate adenine dinucleotide (desamido NAD<sup>+</sup>)**. Finally, **NAD<sup>+</sup> synthetase** converts this intermediate to NAD<sup>+</sup> by a transamidation reaction in which glutamine is the NH<sub>2</sub> donor.

NAD<sup>+</sup> may also be synthesized from nicotinamide. This vitamin is converted to **nicotinamide mononucleotide (NMN)** by **nicotinamide phosphoribosyltransferase**, a widely occurring enzyme distinct from nicotinate phosphoribosyltransferase. However, NAD<sup>+</sup> is synthesized from NMN and ATP by NAD pyrophosphorylase, the same enzyme that synthesizes nicotinate adenine dinucleotide.

NADP<sup>+</sup> is formed via the ATP-dependent phosphorylation of the NAD<sup>+</sup> adenosine residue's C2' OH group by **NAD<sup>+</sup> kinase**.

### B. Flavin Coenzymes

FAD is synthesized from riboflavin in a two-reaction pathway (Fig. 28-32). First, the 5'-OH group of riboflavin's ribityl side chain is phosphorylated by **flavokinase**, yielding flavin mononucleotide (FMN; not a true nucleotide since its ribityl residue is not a true sugar). FAD may then be formed by the coupling of FMN and ATP-derived AMP in a pyrophosphate linkage in a reaction catalyzed by **FAD pyrophosphorylase**. Both of these enzymes are widely distributed in nature.

### C. Coenzyme A

Coenzyme A is synthesized in mammalian cells according to the pathway diagrammed in Fig. 28-33. Pantothenate, an essential vitamin, is phosphorylated by **pantothenate kinase** and then coupled to cysteine, the future business end of CoA, by **phosphopantothenoylcysteine synthetase**. After decarboxylation by **phosphopantothenoylcysteine decarboxylase**, the resulting **4'-phosphopantethiene** is coupled to AMP in a pyrophosphate linkage by **dephospho-CoA pyrophosphorylase** and then phosphorylated at its adenosine 3' OH group by **dephospho-CoA kinase** to form CoA. The latter two enzymatic activities occur on a single protein.

**Figure 28-33** Biosynthesis of coenzyme A from pantothenate, its vitamin precursor.

## CHAPTER SUMMARY

**1 Synthesis of Purine Ribonucleotides** Almost all cells synthesize purine nucleotides *de novo* via similar metabolic pathways. The purine ring is constructed in an 11-step reaction sequence that yields IMP. AMP and GMP are then synthesized from IMP in separate pathways. Nucleoside diphosphates and triphosphates are sequentially formed from these products via phosphorylation reactions. The rates of synthesis of these various nucleotides are interrelated through feedback inhibition mechanisms that monitor their concentrations. Purine nucleotides may also be synthesized from free purines salvaged from nucleic acid degradation processes. The importance of these salvage reactions is demonstrated, for example, by the devastating and bizarre consequences of Lesch-Nyhan syndrome.

**2 Synthesis of Pyrimidine Ribonucleotides** Cells also synthesize pyrimidines *de novo* but, in this six-step process, a free base is formed before it is converted to a nucleotide, UMP. UTP is then formed by phosphorylation of UMP, and CTP is synthesized by the amination of UTP. Pyrimidine biosynthesis is regulated by feedback inhibition as well as by the concentrations of purine nucleotides.

**3 Formation of Deoxyribonucleotides** Deoxyribonucleotides are formed by reduction of the corresponding ribonucleotides. Three classes of ribonucleotide reductase (RNR) have been characterized: Class I RNR, which occurs in nearly all eukaryotes and many prokaryotes, contains an Fe(III)—O<sup>2-</sup>—Fe(III) group and a tyrosyl free radical; Class II and III RNRs, which occur only in prokaryotes, contain, respectively, a coenzyme B<sub>12</sub> cofactor, and a [4Fe-4S] cluster together with a glycy radical. All of them catalyze free radical-

based reductions. The substrates for Class I and II RNRs are NDPs, whereas those for Class III RNRs are NTPs. Class I RNR has three independent regulatory sites that control its substrate specificity and its catalytic activity in part via its oligomerization state, thereby generating deoxynucleotides in the amounts required for DNA synthesis. The *E. coli* Class I RNR is reduced to its original state by electron-transport chains involving either thioredoxin, thioredoxin reductase, and NADPH; or glutaredoxin, glutathione, glutathione reductase, and NADPH. Thymine is synthesized by the methylation of dUMP by thymidylate synthase to form dTMP. The reaction's methyl source, N<sup>5</sup>,N<sup>10</sup>-methylene-THF, is oxidized in the reaction to yield dihydrofolate. N<sup>5</sup>,N<sup>10</sup>-Methylene-THF is subsequently regenerated through the sequential actions of dihydrofolate reductase and serine hydroxymethyltransferase. Since this sequence of reactions is required for DNA biosynthesis, it presents an excellent target for chemotherapy. FdUMP, a mechanism-based inhibitor of thymidylate synthase, and methotrexate, an antifolate that essentially irreversibly inhibits dihydrofolate reductase, are both highly effective anticancer agents.

**4 Nucleotide Degradation** Purine nucleotides are catabolized to yield uric acid. Depending on the species, the uric acid is either directly excreted or first degraded to simpler nitrogen-containing substances. Overproduction or underexcretion of uric acid in humans causes gout. Pyrimidines are catabolized in animal cells to amino acids.

**5 Biosynthesis of Nucleotide Coenzymes** The nucleotide coenzymes NAD<sup>+</sup> and NADP<sup>+</sup>, FMN and FAD, and coenzyme A are synthesized in animals from vitamin precursors.

## PROBLEMS

1. Azaserine (*O*-diazaoacetyl-L-serine) and 6-diazo-5-oxo-L-norleucine (DON)

are glutamine analogs. They form covalent bonds to nucleophiles at the active sites of enzymes that bind glutamine, thereby irreversibly inactivating these enzymes. Identify the nucleotide biosynthesis intermediates that accumulate in the presence of either of these glutamine antagonists.

2. Suggest a mechanism for the AIR synthetase reaction (Fig. 28-2, Reaction 6).

\*3. What is the energetic price, in ATPs, of synthesizing the hypoxanthine residue of IMP from  $\text{CO}_2$  and  $\text{NH}_4^+$ ?

4. Why is deoxyadenosine toxic to mammalian cells?

5. Indicate which of the following substances are mechanism-based inhibitors and explain your reasoning. (a) Tosyl-L-phenylalanine chloromethylketone with chymotrypsin (Section 15-3Ab). (b) Trimethoprim with bacterial dihydrofolate reductase. (c) The  $\delta$ -lactone analog of  $(\text{NAG})_4$  with lysozyme (Section 15-2Cb). (d) Allopurinol with xanthine oxidase.

6. Why do individuals who are undergoing chemotherapy with cytotoxic (cell killing) agents such as FdUMP or methotrexate temporarily go bald?

7. Normal cells die in a nutrient medium containing thymidine and methotrexate that supports the growth of mutant cells defective in thymidylate synthase. Explain.

8. FdUMP and methotrexate, when taken together, are less effective chemotherapeutic agents than when either drug is taken alone. Explain.

9. Some microorganisms lack DHFR activity, but their thymidylate synthase has an FAD cofactor. What is the function of the FAD?

10. Why is gout more prevalent in populations that eat relatively large amounts of meat?

11. Gout resulting from the *de novo* overproduction of purines can be distinguished from gout caused by impaired excretion of uric acid by feeding a patient  $^{15}\text{N}$ -labeled glycine and determining the distribution of  $^{15}\text{N}$  in his or her excreted uric acid. What isotopic distributions are expected for each type of defect?

12. 6-Mercaptopurine,

6-Mercaptopurine

after its conversion to the corresponding nucleotide through salvage reactions, is a potent competitive inhibitor of IMP in the pathways for AMP and GMP biosynthesis. It is therefore a clinically useful anticancer agent. The chemotherapeutic effectiveness of 6-mercaptopurine is enhanced when it is administered with allopurinol. Explain the mechanism of this enhancement.

### 3 Supercoiled DNA

- A. Superhelix Topology
- B. Measurements of Supercoiling
- C. Topoisomerases

There are two classes of nucleic acids, **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA)**. DNA is the hereditary molecule in all cellular life-forms, as well as in many viruses. It has but two functions:

1. To direct its own **replication** during cell division.
2. To direct the **transcription** of complementary molecules of RNA.

RNA, in contrast, has more varied biological functions:

1. The RNA transcripts of DNA sequences that specify polypeptides, **messenger RNAs (mRNAs)**, direct the ribosomal synthesis of these polypeptides in a process known as **translation**.
2. The RNAs of ribosomes, which are about two-thirds RNA and one-third protein, have functional as well as structural roles.
3. During protein synthesis, amino acids are delivered to the ribosome by molecules of **transfer RNA (tRNA)**.
4. Certain RNAs are associated with specific proteins to form **ribonucleoproteins** that participate in the post-transcriptional processing of other RNAs.
5. A variety of short RNAs participate in the control of eukaryotic gene expression and in protection against viruses, a phenomenon known as **RNA interference (RNAi)**.
6. In many viruses, RNA, not DNA, is the carrier of hereditary information.

The structure and properties of DNA are introduced in Section 5-3. In this chapter we extend this discussion with emphasis on DNA; the structures of RNAs are detailed in Sections 31-4A and 32-2B. Methods of purifying, sequencing, and chemically synthesizing nucleic acids are discussed in Sections 6-6, 7-2, and 7-6, and recombinant DNA techniques are discussed in Section 5-5. Bioinformatics, as it concerns nucleic acids, is outlined in Section 7-4, and the Nucleic Acid Database is described in Section 8-3Cb.

### 1 DOUBLE HELICAL STRUCTURES

 See **Guided Exploration 23: DNA structures** Double helical DNA has three major helical forms, B-DNA, A-DNA, and Z-DNA, whose structures are depicted in Fig. 29-1. In this section we discuss the major characteristics of each of these helical forms as well as those of double helical RNA and DNA–RNA hybrid helices.

#### A. B-DNA

The structure of **B-DNA** (Fig. 29-1, middle panels), the biologically predominant form of DNA, is described in Section 5-3A. To recapitulate (Table 29-1), B-DNA consists of a right-handed double helix whose two antiparallel sugar–phosphate chains wrap around the periphery of the helix. Its aromatic bases (A, T, G, and C), which occupy the core of the helix, form complementary A · T and G · C Watson–Crick base pairs (Fig. 5-12), whose planes are nearly perpendicular to the axis of the double helix. Neighboring base pairs, whose aromatic rings are 3.4 Å thick, are stacked in van der Waals contact, with the helix axis passing through the middle of each base pair. B-DNA is ~20 Å in diameter and has two deep grooves between its sugar–phosphate chains: the relatively narrow **minor groove**, which exposes that edge of the base pairs from which the glycosidic bonds (the bonds from the base N to the ribose C1') extend (toward the bottom of Fig. 5-12), and the relatively wide **major groove**, which exposes the opposite edge of each base pair (toward the top of Fig. 5-12). Canonical (ideal) DNA has a helical twist of 10 base pairs (bp) per turn and hence a pitch (rise per turn) of 34 Å.

The Watson–Crick base pairs in either orientation are structurally interchangeable, that is, A · T, T · A, G · C, and

**Figure 29-1 Structures of A-, B-, and Z-DNAs.** (a) Ball-and-stick drawings viewed perpendicular to the helix axis. The sugar–phosphate backbones, which wind about the periphery of each molecule, are outlined by green ribbons, and the bases, which occupy its core, are red. Note that the two sugar–phosphate chains in each helix run in opposite directions so as to form right-handed double helices in A- and B-DNAs and a left-handed double helix in Z-DNA. (b) Views along the helix axis. The ribose

ring O atoms are red and the nucleotide pair closest to the viewer is white. Note that the helix axis passes far “above” the major groove of A-DNA, through the base pairs of B-DNA, and through the edge of the minor groove of Z-DNA. Consequently, A-DNA has a hollow core whereas B- and Z-DNAs have solid cores. Also note that the deoxyribose residues in A- and B-DNAs have the same conformation in each helix, but those in Z-DNA have two different conformations so that alternate ribose residues

C · G can replace each other in the double helix without altering the positions of the sugar–phosphate backbones’ C1’ atoms. In contrast, any other combination of bases would require considerable reorientation of the DNA’s sugar–phosphate backbones.

#### a. Real DNA Deviates from the Ideal Watson–Crick Structure

The DNA samples that were available when James Watson and Francis Crick formulated the Watson–Crick structure in 1953 were extracted from cells and hence consisted of molecules of heterogeneous lengths and base sequences.

lie at different radii. (c) Space-filling models viewed perpendicular to the helix axis and colored according to atom type (C white, N blue, O red, and P orange). (d) Space-filling models viewed along the helix axis and colored as in Part c but with the C atoms of the nucleotide pair closest to the viewer green. H atoms in Parts b, c, and d have been omitted for clarity. [Based on X-ray structures by the following: A-DNA, Olga Kennard, Dov Rabinovitch, Zippora Shakked, and Mysore Viswamitra,

Model coordinates for Parts c and d generated by Helen Berman, Rutgers University.]  See Kinemage Exercises 17-1, 17-4, 17-5, and 17-6

Such elongated molecules do not crystallize, but can be drawn into threadlike fibers in which the helix axes of the DNA molecules are all approximately parallel to the fiber axis but are poorly aligned, if at all, in any other way. The X-ray diffraction patterns of such fibers provide only crude, low-resolution images in which the base pair electron den-

sity is the average electron density of all the base pairs in the fiber. The Watson–Crick structure was based, in part, on the X-ray fiber diffraction pattern of B-DNA (Fig. 5-10).

By the late 1970s, advances in nucleic acid chemistry permitted the synthesis and crystallization of ever longer oligonucleotides of defined sequences (Section 7-6A),

**Table 29-1** Structural Features of Ideal A-, B-, and Z-DNA

	A-DNA	B-DNA	Z-DNA
Helical sense	Right-handed	Right-handed	Left-handed
Diameter	~26 Å	~20 Å	~18 Å
Base pairs per helical turn	11.6	10	12 (6 dimers)
Helical twist per base pair	31°	36°	9° for pyrimidine–purine steps; 51° for purine–pyrimidine steps
Helix pitch (rise per turn)	34 Å	34 Å	44 Å
Helix rise per base pair	2.9 Å	3.4 Å	7.4 Å per dimer
Base tilt normal to the helix axis	20°	6°	7°
Major groove	Narrow and deep	Wide and deep	Flat
Minor groove	Wide and shallow	Narrow and deep	Narrow and deep
Sugar pucker	C3'-endo	C2'-endo	C2'-endo for pyrimidines; C3'-endo for purines
Glycosidic bond	Anti	Anti	Anti for pyrimidines; syn for purines

many of which could be crystallized. Consequently, some 25 years after the Watson–Crick structure was formulated, its X-ray crystal structure was clearly visualized for the first time when Richard Dickerson and Horace Drew determined the first X-ray crystal structure of a B-DNA, that of the self-complementary dodecamer d(CGCGAATTCGCG), at near-atomic (1.9 Å) resolution. This molecule, whose structure was subsequently determined at significantly higher (1.4 Å) resolution by Loren Williams, has an average rise per residue of 3.3 Å and has 10.1 bp per turn (a helical twist of 35.5° per bp), values that are nearly equal to those of canonical B-DNA. However, individual residues depart significantly from this average conformation (Fig. 29-1a, middle panel). For example, the helical twist per base pair in this dodecamer ranges from 26° to 43°. Each base pair further deviates from its ideal conformation by such distortions as propeller twisting (the opposite rotation of paired bases about the base pair's long axis; in the 1.4-Å resolution structure, this quantity ranges from –23° to –7°) and base pair roll (the tilting of a base pair as a whole about its long axis; this quantity ranges from –14° to 17°).

X-ray and NMR studies of numerous other double helical DNA oligomers have amply demonstrated that *the conformation of DNA, particularly B-DNA, is irregular in a sequence-specific manner*, although the rules specifying how sequence governs conformation have proved to be surprisingly elusive. This is because *base sequence does not so much confer a fixed conformation on a double helix as it establishes the deformability of the helix*. Thus, 5'-R–Y-3' steps (where R and Y are the abbreviations for purines and pyrimidines, respectively) in B-DNA are easily bent because they exhibit relatively little ring–ring overlap between adjacent base pairs. In contrast, both Y–R steps and R–R steps (the latter, due to base pairing, are equivalent to

Y–Y steps), and most notably A–A steps, are more rigid because the extensive ring–ring overlap between their adjacent base pairs tends to keep these base pairs parallel. *This phenomenon, as we shall see, is important for the sequence-specific binding of DNA to proteins that process genetic information*. This is because many of these proteins wrap their target DNAs around them, in many cases by bending them by well over 90°. DNAs with different sequences than the target DNA would not bind so readily to the protein because they would resist deformation to the required conformation more than the target DNA.

## B. Other Nucleic Acid Helices

X-ray fiber diffraction studies, starting in the mid-1940s, revealed that *nucleic acids are conformationally variable molecules*. Indeed, double helical DNA and RNA can assume several distinct structures that vary with such factors as the humidity and the identities of the cations present, as well as with base sequence. For example, fibers of B-DNA form in the presence of alkali metal ions such as Na<sup>+</sup> when the relative humidity is 92%. In this subsection, we describe the other major conformational states of double-stranded DNA as well as those of double-stranded RNA and RNA–DNA hybrid helices.

### a. A-DNA's Base Pairs Are Inclined to the Helix Axis

When the relative humidity is reduced to 75%, B-DNA undergoes a reversible conformational change to the so-called A form. Fiber X-ray studies indicate that *A-DNA forms a wider and flatter right-handed helix than does B-DNA* (Fig. 29-1, left panels; Table 29-1). A-DNA has 11.6 bp per turn and a pitch of 34 Å, which gives A-DNA an axial hole (Fig. 29-1b, d, left panels). A-DNA's most striking feature, however, is that the planes of its base pairs are

tilted  $20^\circ$  with respect to the helix axis. Since its helix axis passes “above” the major groove side of the base pairs (Fig. 29-1*b, d*, left panels) rather than through them as in B-DNA, A-DNA has a deep major groove and a very shallow minor groove; it can be described as a flat ribbon wound around a 6-Å-diameter cylindrical hole. Most self-complementary oligonucleotides of <10 base pairs, for example, d(GGCCGGCC) and d(GGTATACC), crystallize in the A-DNA conformation. Like B-DNA, these molecules exhibit considerable sequence-specific conformational variation although the degree of variation is less than that in B-DNA.

A-DNA has, so far, been observed in only three biological contexts: at the cleavage center of topoisomerase II (Section 29-3Cd), at the active site of DNA polymerase (Section 30-2Ae), and in certain Gram-positive bacteria that have undergone **sporulation** (the formation, under environmental stress, of resistant although dormant cell types known as **spores**; a sort of biological lifeboat). Such spores contain a high proportion (20%) of **small acid-soluble spore proteins (SASPs)**. Some of these SASPs induce B-DNA to assume the A form, at least *in vitro*. The DNA in bacterial spores exhibits a resistance to UV-induced damage that is abolished in mutants that lack these SASPs. This occurs because the B  $\rightarrow$  A conformation change inhibits the UV-induced covalent cross-linking of pyrimidine bases (Section 30-5Aa), in part by increasing the distance between successive pyrimidines.

### b. Z-DNA Forms a Left-Handed Helix

Occasionally, a seemingly well-understood or at least familiar system exhibits quite unexpected properties. Over 25 years after the discovery of the Watson-Crick structure, the crystal structure determination of the self-complementary hexanucleotide d(CGCGCG) by Andrew Wang and Alexander Rich revealed, quite surprisingly, a *left-handed double helix* (Fig. 29-1, right panels; Table 29-1). A similar helix is formed by d(CGCGATGCG). This helix, which has been dubbed **Z-DNA**, has 12 Watson-Crick base pairs per turn, a pitch of 44 Å, and, in contrast to A-DNA, a deep minor groove and no discernible major groove (its helix axis passes “below” the minor groove side of its base pairs; Fig. 29-1*b, d*, right panels). Z-DNA therefore resembles a left-handed drill bit in appearance. The base pairs in Z-DNA are flipped  $180^\circ$  relative to those in B-DNA (Fig. 29-2) through conformational changes discussed in Section 29-2A. As a consequence, the repeating unit of Z-DNA is a dinucleotide, d(XpYp), rather than a single nucleotide as it is in the other DNA helices. The line joining successive phosphorus atoms on a polynucleotide strand of Z-DNA therefore follows a zigzag path around the helix (Fig. 29-1*a, c*, right panels; hence the name Z-DNA) rather than a smooth curve as it does in A- and B-DNAs (Fig. 29-1*a, c*, left and middle panels).

Fiber diffraction and NMR studies have shown that complementary polynucleotides with alternating purines and pyrimidines, such as poly d(GC) · poly d(GC) and poly

**Figure 29-2 Conversion of B-DNA to Z-DNA.** The conversion, here represented by a 4-bp DNA segment, involves a  $180^\circ$  flip of each base pair (curved arrows) relative to the sugar-phosphate chains (compare the base pair orientations of B- and Z-DNAs in Fig. 29-1*b, d*). Here, the different faces of the base pairs

are colored red and green. Note that if the drawing on the left is taken as looking into the minor groove of unwound A- or B-DNA, then in the drawing on the right, we are looking into the major groove of the unwound Z-DNA segment. [After Rich, A., Nordheim, A., and Wang, A.H.-J., *Annu. Rev. Biochem.* **53**, 799 (1984).]

d(AC) · poly d(GT), take up the Z-DNA conformation at high salt concentrations. Evidently, *the Z-DNA conformation is most readily assumed by DNA segments with alternating purine–pyrimidine base sequences (for structural reasons explained in Section 29-2A)*. A high salt concentration stabilizes Z-DNA relative to B-DNA by reducing the otherwise increased electrostatic repulsions between closest approaching phosphate groups on opposite strands (8 Å in Z-DNA vs 12 Å in B-DNA). The methylation of cytosine residues at C5, a common biological modification (Section 30-7), also promotes Z-DNA formation since a hydrophobic methyl group in this position is less exposed to solvent in Z-DNA than it is in B-DNA.

Does Z-DNA have any biological function? Rich has proposed that the reversible conversion of specific segments of B-DNA to Z-DNA under appropriate circumstances acts as a kind of switch in regulating genetic expression, and there are indications that it transiently forms behind actively transcribing RNA polymerase (Section 31-

4As). It was nevertheless surprisingly difficult to prove the *in vivo* existence of Z-DNA. A major difficulty was demonstrating that a particular probe for detecting Z-DNA, for example, a Z-DNA-specific antibody, does not in itself cause what would otherwise be B-DNA to assume the Z conformation—a kind of biological uncertainty principle (the act of measurement inevitably disturbs the system being measured). However, Rich has discovered several proteins that specifically bind Z-DNA, including a family of Z-DNA-binding protein domains named  $Z\alpha$ . The existence of these proteins strongly suggests that Z-DNA does, in fact, exist *in vivo*.

The X-ray structure of the 81-residue  $Z\alpha$  domain from the RNA editing enzyme **ADAR1** (Section 31-4As) in complex with d(TCGCGCG) has been determined (Fig. 29-3a). The CGCGCG segment of this heptanucleotide is self-complementary, and therefore forms a 2-fold symmetric, 6-bp segment of Z-DNA with an overhanging dT at the 5' end of each strand (although these dT's are disordered in the

**Figure 29-3 Structures of DNA in complex with ADAR1  $Z\alpha$ .** (a) X-ray structure of the complex of two  $Z\alpha$  domains with Z-DNA consisting of a duplex of the self-complementary hexamer d(CGCGCG) as viewed along its 2-fold axis of symmetry. The Z-DNA is shown in stick form with its backbones red and its remaining portions pink. The  $Z\alpha$  domains are drawn in ribbon form with helices blue and sheets light green. Note that each  $Z\alpha$  domain contacts only one strand of the Z-DNA. (b) X-ray structure of a junction between Z-DNA and B-DNA. The complex consists of d(GTCGCGCGCCATAAACC) and d(ACGGTTTATGGCGCGCG) in complex with four  $Z\alpha$  domains (not shown here for the sake of clarity). The DNA forms a duplex with a 2-nucleotide overhang at each end in which the lower 8 nucleotide pairs form Z-DNA, the upper 6 nucleotide pairs form B-DNA, and the A and T nucleotides at the interface between these two DNA segments have been extruded from the double helix. The DNA is drawn in space-filling form with C gray, N blue, O red, and P yellow. The white lines connect adjacent P atoms in the same polynucleotide, thereby showing the zigzag pattern of the left-handed Z-DNA and the smoother pattern of the right-handed B-DNA. [Courtesy of Alexander Rich, MIT. PDBids 1QBJ and 2ACJ.]

X-ray structure). A monomeric unit of  $Z\alpha$  binds to each strand of the Z-DNA, out of contact with the  $Z\alpha$  that binds to the opposite strand. The protein primarily interacts with Z-DNA via hydrogen bonds and salt bridges between polar and basic protein side chains and the Z-DNA's sugar-phosphate backbone. Note that none of the DNA's bases participate in these associations. The protein's DNA-binding surface, which is complementary in shape to the Z-DNA, is positively charged, as is expected for a protein that interacts with several closely spaced, anionic phosphate groups. It is postulated that ADAR1's  $Z\alpha$  domain targets it to the Z-DNA upstream of actively transcribing genes (for reasons discussed in Section 31-4As).

In an effort to visualize the structure of the junction between B-DNA and Z-DNA, Rich and Kyeong Kyu Kim cocrystallized  $Z\alpha$  with a duplex DNA that has two overhanging nucleotides at each end and whose two 17-nucleotide strands have the sequences d(GTCGCGGC-CATAAACC) and d(ACGGTTTATGGCGCGCG). The X-ray structure of this complex reveals that 8 nucleotide pairs at one end of the double helix are Z-DNA, 6 nucleotide pairs at the other end of the helix are B-DNA, and the nucleotides that would otherwise form an A · T base pair at the junction between these segments have been expelled from the double helix (Fig. 29-3b). The base pairs of the B- and Z-DNA segments form a continuous stack, which stabilizes the structure (Section 29-2C). Four  $Z\alpha$ 's are bound to the Z-DNA segment, two per polynucleotide strand, in a manner closely similar to that in the foregoing  $Z\alpha$ -d(TCGCGCG) complex (for clarity, the  $Z\alpha$ 's are not shown in Fig. 29-3b) and the B- and Z-DNA segments adopt their standard conformations. Evidently, under the proper conditions, the handedness of duplex DNA can be reversed by breaking one base pair and ejecting its nucleotides from the duplex.

### c. RNA-11 and RNA-DNA Hybrids Have an A-DNA-Like Conformation

Double helical RNA is unable to assume a B-DNA-like conformation because of steric clashes involving its 2'-OH groups. Rather, it usually assumes a conformation resembling A-DNA (Fig. 29-1, left panels) known as **A-RNA** or **RNA-11**, which ideally has 11.0 bp per helical turn, a pitch of 30.9 Å, and its base pairs inclined to the helix axis by 16.7°. Many RNAs, for example, transfer and ribosomal RNAs (whose structures are detailed in Sections 32-2B and 32-3A), contain complementary sequences that form double helical stems.

Hybrid double helices, which consist of one strand each of DNA and RNA, are also predicted to have A-RNA-like conformations. In fact, the X-ray structure, by Nancy Horton and Barry Finzel, of a 10-bp complex of the DNA oligonucleotide d(GGCGCCGAA) with the complementary RNA oligonucleotide r(UUCGGGCGCC) reveals (Fig. 29-4) that it forms a double helix with A-RNA-like character (Table 29-1) in that it has 10.9 bp per turn, a pitch of 31.3 Å, and its base pairs are, on average, inclined to the helix axis by 13.9°. Nevertheless, this hybrid helix also has B-DNA-like qualities in that the width of its minor groove

**Figure 29-4** X-ray structure of a 10-bp RNA-DNA hybrid helix consisting of d(GGCGCCGAA) in complex with r(UUCGGGCGCC). The structure is shown in stick form with RNA C atoms cyan, DNA C atoms green, N blue, O red except for RNA O2' atoms, which are magenta, and P yellow. [Based on an X-ray structure by Nancy Horton and Barry Finzel, Pharmacia & Upjohn, Inc., Kalamazoo, Michigan. PDBid 1FIX.]

See Interactive Exercise 31

(9.5 Å) is intermediate between those for canonical B-DNA (7.4 Å) and A-DNA (11 Å) and in that some of the ribose rings of its DNA strand have conformations characteristic of B-DNA (Section 29-2A), whereas others have conformations characteristic of A-RNA. Note that this structure is of biological significance because short segments of RNA · DNA hybrid helices occur in both the transcription of RNA on DNA templates (Section 31-2Ba) and in the initiation of DNA replication by short lengths of RNA (Section 30-1D). The RNA component of this helix is a substrate for **RNase H**, which specifically hydrolyzes the RNA strands of RNA · DNA hybrid helices *in vivo* (Section 30-4C).

## 2 FORCES STABILIZING NUCLEIC ACID STRUCTURES

Double-stranded DNA does not exhibit the structural complexity of proteins because it has only a limited repertoire of secondary structures and no comparable tertiary or

quaternary structures (although see Section 29-3). This is perhaps to be expected since there is a far greater range of chemical and physical properties among the 20 amino acid residues of proteins than there is among the four DNA bases. However, many RNAs have well-defined tertiary structures (Sections 31-4A, 32-4Ca, 32-2B, and 32-3A).

In this section we examine the forces that give rise to the structures of nucleic acids. These forces are, of course, much the same as those that are responsible for the structures of proteins (Section 8-4) but, as we shall see, the way they combine gives nucleic acids properties that are quite different from those of proteins.

### A. Sugar-Phosphate Chain Conformations

The conformation of a nucleotide unit, as Fig. 29-5 indicates, is specified by the six torsion angles of the sugar-phosphate backbone and the torsion angle describing the orientation of the base about the glycosidic bond. It would seem that these seven degrees of freedom per nucleotide would render polynucleotides highly flexible. Yet, as we shall see, these torsion angles are subject to a variety of internal constraints that greatly restrict their conformational freedom.

#### a. Torsion Angles About Glycosidic Bonds Have Only One or Two Stable Positions

The rotation of a base about its glycosidic bond is greatly hindered, as is best seen by the manipulation of a space-filling molecular model. Purine residues have two sterically permissible orientations relative to the sugar known as the **syn** (Greek: with) and **anti** (Greek: against) conformations (Fig. 29-6). For pyrimidines, only the anti conformation is easily formed because, in the syn conformation, the sugar residue sterically interferes with the pyrimidine's C2 substituent. In most double helical nucleic acids, all bases are in the anti conformation (Fig. 29-1a,c, left and middle panels). The exception is Z-DNA (Section 29-1Bb), in which the alternating pyrimidine and purine residues are anti and syn (Fig. 29-1a,c, right panels). *This explains Z-DNA's pyrimidine-purine alternation.* Indeed, the base pair flips that convert B-DNA to Z-DNA (Fig. 29-2) are brought about by rotating each purine base about its gly-

**Figure 29-5** The conformation of a nucleotide unit is determined by the seven indicated torsion angles.

cosidic bond from the anti to syn conformation, whereas it is the sugars that rotate in the pyrimidine nucleotides, thereby maintaining them in their anti conformations.

#### b. Sugar Ring Pucker Is Largely Limited to Only a Few of Its Possible Arrangements

The ribose ring has a certain amount of flexibility that significantly affects the conformation of the sugar-phosphate backbone. The vertex angles of a regular pentagon are  $108^\circ$ , a value quite close to the tetrahedral angle ( $109.5^\circ$ ), so that one might expect the ribofuranose ring to be nearly flat. However, the ring substituents are eclipsed when the ring is planar. To relieve the resultant crowding, which even occurs between hydrogen atoms, the ring **puckers**; that is, it becomes slightly nonplanar, so as to reorient the ring substituents (Fig. 29-7; this is readily observed by the manipulation of a skeletal molecular model).

**Figure 29-6** The sterically allowed orientations of purine and pyrimidine bases with respect to their attached ribose units.

**Figure 29-7 Ribose ring pucker.** The substituents to (a) a planar ribose ring (here viewed down the C3'—C4' bond) are all eclipsed. The resulting steric strain is partially relieved by ring puckering such as in (b), a half-chair conformation in which C3' is the out-of-plane atom.

One would, in general, expect only three of a ribose ring's five atoms to be coplanar since three points define a plane. Nevertheless, in the great majority of the >50 nucleoside and nucleotide crystal structures that have been reported, four of the ring atoms are coplanar to within a few hundredths of an angstrom and the remaining atom is out of this plane by several tenths of an angstrom (the **half-**

**chair** conformation). If the out-of-plane atom is displaced to the same side of the ring as atom C5', it is said to have the **endo** conformation (Greek: *endon*, within), whereas displacement to the opposite side of the ring from C5' is known as the **exo** conformation (Greek: *exo*, out of). In the great majority of known nucleoside and nucleotide structures (molecules that are subject to few of the conformational constraints of double helices), the out-of-plane atom is either C2' or C3' (Fig. 29-8). C2'-endo is the most frequently occurring ribose pucker with C3'-endo and C3'-exo also being common. Other ribose conformations are rare.

The ribose pucker is conformationally important in nucleic acids because it governs the relative orientations of the phosphate substituents to each ribose residue (Fig. 29-8). For instance, it is difficult to build a regularly repeating model of a double helical nucleic acid unless the sugars are either C2'-endo or C3'-endo. In fact, canonical B-DNA has the C2'-endo conformation, whereas canonical A-DNA and RNA-11 are C3'-endo. In canonical Z-DNA, the purine nucleotides are all C3'-endo and the pyrimidine nucleotides are C2'-endo, which is another reason that the repeating unit of Z-DNA is a dinucleotide. The sugar puckers observed in the X-ray structures of A-DNA are, in fact, almost entirely C3'-endo. However, those of B-DNAs, although predominantly C2'-endo, exhibit significant variation including C4'-exo, O4'-endo, C1'-exo, and C3'-exo. This variation in B-DNA's sugar pucker is probably indicative of its greater flexibility relative to other types of DNA helices.

### c. The Sugar-Phosphate Backbone Is Conformationally Constrained

If the torsion angles of the sugar-phosphate chain (Fig. 29-5) were completely free to rotate, there could probably be no stable nucleic acid structure. However, the comparison, by Muttaiya Sundaralingam, of some 40 nucleoside and nucleotide crystal structures has revealed that these angles are really quite restricted. For example, the torsion angle about the C4'—C5' bond ( $\gamma$  in Fig. 29-5) is rather narrowly distributed such that O4' usually has a gauche

**Figure 29-8 Nucleotide sugar conformations.** (a) The C3'-endo conformation (on the same side of the sugar ring as C5'), which occurs in A-DNA and RNA-11. (b) The C2'-endo conformation, which occurs in B-DNA. The distances between adjacent P atoms

in the sugar-phosphate backbone are indicated. [After Saenger, W., *Principles of Nucleic Acid Structure*, p. 237, Springer-Verlag (1983).]  See Kinemage Exercise 17-3

**Figure 29-9** Conformational wheel showing the distribution of the torsion angle about the C4'—C5' bond. The torsion angle ( $\gamma$  in Fig. 29-5) was measured in 33 X-ray structures of nucleosides, nucleotides, and polynucleotides. Each radial line represents the position of the C4'—O4' bond in a single structure relative to the substituents of C5' as viewed from C5' to C4'. Note that most of the observed torsion angles fall within a relatively narrow range. [After Sundaralingam, M., *Biopolymers* **7**, 838 (1969).]

conformation (having a torsion angle of  $\sim 60^\circ$ ) with respect to O5' (Fig. 29-9). This is because the presence of the ribose ring together with certain noncovalent interactions of the phosphate group stiffens the sugar–phosphate chain by restricting its range of torsion angles. These restrictions are even greater in polynucleotides because of steric interference between residues.

The sugar–phosphate conformational angles of the various double helices are all reasonably strain free. *Double helices are therefore conformationally relaxed arrange-*

*ments of the sugar–phosphate backbone.* Nevertheless, the sugar–phosphate backbone is by no means a rigid structure, so, on strand separation, it assumes a random coil conformation.

## B. Base Pairing

Base pairing is apparently a “glue” that holds together double-stranded nucleic acids. Only Watson–Crick pairs occur in the crystal structures of self-complementary oligonucleotides. It is therefore important to understand how Watson–Crick base pairs differ from other doubly hydrogen bonded arrangements of the bases that have reasonable geometries (e.g., Fig. 29-10).

### a. Unconstrained A · T Base Pairs Assume Hoogsteen Geometry

When monomeric adenine and thymine derivatives are cocrystallized, the A · T base pairs that form invariably have adenine N7 as the hydrogen bonding acceptor (**Hoogsteen geometry**; Fig. 29-10b) rather than N1 (Watson–Crick geometry; Fig. 5-12). This suggests that Hoogsteen geometry is inherently more stable for A · T pairs than is Watson–Crick geometry. Apparently steric and other environmental influences make Watson–Crick geometry the preferred mode of base pairing in double helices. A · T pairs with Hoogsteen geometry are nevertheless of biological importance; for example, they help stabilize the tertiary structures of tRNAs (Section 32-2Ba). In contrast, monomeric G · C pairs always cocrystallize with Watson–Crick geometry as a consequence of their triply hydrogen bonded structures.

### b. Non-Watson–Crick Base Pairs Are of Low Stability

The bases of a double helix, as we have seen (Section 5-3A), associate such that any base pair position may interchangeably be A · T, T · A, G · C, or C · G without affecting the conformations of the sugar–phosphate chains. One might reasonably suppose that this requirement of **geometric complementarity** of the Watson–Crick base pairs, A with T and G with C, is the only reason that other

**Figure 29-10** Some non-Watson–Crick base pairs. (a) The pairing of adenine residues in the crystal structure of 9-methyladenine. (b) Hoogsteen pairing between adenine and thymine residues in the crystal structure of 9-methyladenine ·

1-methylthymine. (c) A hypothetical pairing between cytosine and thymine residues. Compare these base pairs with the Watson–Crick base pairs in Fig. 5-12.

**Figure 29-11** The infrared spectra, in the N—H stretch region, of guanine, cytosine, and adenine derivatives. The derivatives were analyzed both separately and in the indicated mixtures. The solvent,  $\text{CDCl}_3$ , does not hydrogen bond with the bases and is relatively transparent in the frequency range of interest. (a) G + C. The brown curve in the lower panel, which is the sum of the spectra in the two upper panels, is the calculated spectrum of

G + C for noninteracting molecules. The band near  $3500\text{ cm}^{-1}$  in the observed G + C spectrum (purple) is indicative of a specific hydrogen bonding association between G and C. (b) G + A. The close match between the calculated and observed spectra of the G + A mixture indicates that G and A do not significantly interact. [After Kyogoku, Y., Lord, R.C., and Rich, A., *Science* **154**, 5109 (1966).]

base pairs do not occur in a double helical environment. In fact, this was precisely what was believed for many years after the DNA double helix was discovered.

Eventually, the failure to detect pairs of different bases in nonhelical environments other than A with T (or U) and G with C led Richard Lord and Rich to demonstrate, through spectroscopic studies, that *only the bases of Watson–Crick pairs have a high mutual affinity*. Figure 29-11a shows the infrared (IR) spectrum in the N—H stretch region of guanine and cytosine derivatives, both separately and in a mixture. The band in the spectrum of the G + C mixture that is not present in the spectra of either of its components is indicative of a specific hydrogen bonding interaction between G and C. Such an association, which can occur between like as well as unlike molecules, may be described by ordinary mass action equations.

From analyses of IR spectra such as Fig. 29-11, the values of  $K$  for the various base pairs have been determined. The self-association constants of the Watson–Crick bases are given in the top of Table 29-2 (the hydrogen bonded association of like molecules is indicated by the appearance of new IR bands as the concentration of the molecule is increased). The bottom of Table 29-2 lists the association constants of the Watson–Crick pairs. Note that each of these latter quantities is larger than the self-association constants of either of their component bases, so that Watson–Crick

base pairs preferentially form from their constituents. In contrast, the non-Watson–Crick base pairs, A · C, A · G, C · U, and G · U, whatever their geometries, have association constants that are negligible compared with the self-pairing association constants of their constituents (e.g., Fig. 29-11b). Evidently, a second reason that non-Watson–Crick base pairs do not occur in DNA double helices is that they have relatively little stability. Conversely, the exclusive presence of Watson–Crick base pairs in DNA results, in part, from an **electronic complementarity** matching A to T and G to C. The theoretical basis of this electronic complementarity, which is an experimental observation, is obscure.

**Table 29-2** Association Constants for Base Pair Formation

Base Pair	$K (M^{-1})^a$
<b>Self-Association</b>	
A · A	3.1
U · U	6.1
C · C	28
G · G	$10^3$ – $10^4$
<b>Watson–Crick Base Pairs</b>	
A · U	100
G · C	$10^4$ – $10^5$

<sup>a</sup>Data measured in deuteriochloroform at  $25^\circ\text{C}$ .

Source: Kyogoku, Y., Lord, R.C., and Rich, A., *Biochim. Biophys. Acta* **179**, 10 (1969).

This is because the approximations inherent in theoretical treatments make them unable to accurately account for the minor (few  $\text{kJ} \cdot \text{mol}^{-1}$ ) energy differences between specific and nonspecific hydrogen bonding associations. The double helical segments of many RNAs, however, contain occasional non-Watson–Crick base pairs, most often  $\text{G} \cdot \text{U}$ , which have functional as well as structural significance (e.g., Sections 32-2Ba and 32-2Db).

### c. Hydrogen Bonds Only Weakly Stabilize DNA

It is clear that hydrogen bonding is required for the specificity of base pairing in DNA that is ultimately responsible for the enormous fidelity required to replicate DNA with almost no error (Section 30-3D). Yet, as is also true for proteins (Section 8-4Ba), *hydrogen bonding contributes little to the stability of the double helix*. For instance, adding the relatively nonpolar ethanol to an aqueous DNA solution, which strengthens hydrogen bonds, destabilizes the double helix, as is indicated by its decreased melting temperature ( $T_m$ ; Section 5-3Ca). This is because hydrophobic forces, which are largely responsible for DNA's stability (Section 29-2C), are disrupted by nonpolar solvents. In contrast, *the hydrogen bonds between the base pairs of native DNA are replaced in denatured DNA by energetically nearly equivalent hydrogen bonds between the bases and water*. This accounts for the thermodynamic observation that hydrogen bonding contributes only 2 to 8 kJ/mol to base pairing stability.

### C. Base Stacking and Hydrophobic Interactions

*Purines and pyrimidines tend to form extended stacks of planar parallel molecules*. This has been observed in the structures of nucleic acids (e.g., Fig. 29-1) and in the several hundred reported X-ray crystal structures that contain nucleic acid bases. The bases in these structures are usually partially overlapped (e.g., Fig. 29-12). In fact, crystal structures of chemically related bases often exhibit similar stacking patterns. Apparently stacking interactions, which in the solid state are a form of van der Waals interaction (Section 8-4Ab), have some specificity, although certainly not as much as base pairing.

#### a. Nucleic Acid Bases Stack in Aqueous Solution

*Bases aggregate in aqueous solution*, as has been demonstrated by the variation of osmotic pressure with concentration. The van't Hoff law of osmotic pressure is

$$\pi = RTm \quad [29.2]$$

where  $\pi$  is the osmotic pressure,  $m$  is the molality of the solute (mol solute/kg solvent),  $R$  is the gas constant, and  $T$  is the temperature. The molecular mass,  $M$ , of an ideal solute can be determined from its osmotic pressure since  $M = c/m$ , where  $c = g \text{ solute/kg solvent}$ .

If the species under investigation is of known molecular mass but aggregates in solution, Eq. [29.2] must be rewritten:

$$\pi = \phi RTm \quad [29.3]$$

**Figure 29-12** Stacking of adenine rings in the crystal structure of 9-methyladenine. The partial overlap of the rings is typical of the association between bases in crystal structures and in double helical nucleic acids. [After Stewart, R.F. and Jensen, L.H., *J. Chem. Phys.* **40**, 2071 (1964).]

where  $\phi$ , the **osmotic coefficient**, indicates the solute's degree of association.  $\phi$  varies from 1 (no association) to 0 (infinite association). The variation of  $\phi$  with  $m$  for nucleic acid bases in aqueous solution (e.g., Fig. 29-13) is consistent with a model in which the bases aggregate in successive steps:

where  $n$  is at least 5 (if the reaction goes to completion,  $\phi = 1/n$ ). This association cannot be a result of hydrogen bonding since  **$N^6, N^6$ -dimethyladenosine**,

**$N^6, N^6$ -Dimethyladenosine**

which cannot form interbase hydrogen bonds, has a greater degree of association than does adenosine (Fig. 29-13). Apparently *the aggregation arises from the formation of stacks of planar molecules*. This model is corroborated by proton NMR studies: The directions of the aggregates' chemical shifts are compatible with a stacked but not a hydrogen bonded model. The stacking associations of monomeric bases are not observed in nonaqueous solutions.

Single-stranded polynucleotides also exhibit stacking interactions. For example, poly(A) shows a broad increase of

**Figure 29-13** Variation of the osmotic coefficient  $\phi$  with the molal concentrations  $m$  of adenosine derivatives in  $\text{H}_2\text{O}$ . The decrease of  $\phi$  with increasing  $m$  indicates that these derivatives aggregate in solution. [After Broom, A.D., Schweizer, M.P., and Ts'o, P.O.P., *J. Am. Chem. Soc.* **89**, 3613 (1967).]

UV absorbance with temperature (Fig. 29-14a). This hyperchromism (which is indicative of nucleic acid denaturation; Section 5-3Ca) is independent of poly(A) concentration, so that it cannot be a consequence of intermolecular disaggregation. Likewise, it is not due to a reduction in intramolecular hydrogen bonding because poly( $N^6, N^6$ -dimethyladenosine) exhibits a greater degree of hyperchromism than does poly(A). The hyperchromism must therefore arise from some sort of stacking associations within a single strand that melt out with increasing temperature. This is not a very cooperative process, as is indicated by the broadness of the melting curve and the observation that short polynucleotides, including dinucleoside phosphates such as ApA, exhibit similar melting curves (Fig. 29-14b).

### b. Nucleic Acid Structures Are Stabilized by Hydrophobic Forces

Stacking associations in aqueous solutions are largely stabilized by hydrophobic forces. One might reasonably suppose that hydrophobic interactions in nucleic acids are similar in character to those that stabilize protein structures. However, closer examination reveals that these two types of interactions are qualitatively different in character. Thermodynamic analysis of dinucleoside phosphate melting curves in terms of the reaction

(Table 29-3) indicates that *base stacking is enthalpically*

**Figure 29-14** Melting curves for poly(A) and ApA. The broad temperature range of hyperchromic shifts at 258 nm of (a) poly(A) and (b) ApA is indicative of noncooperative conformational changes in these substances. Compare this figure with Fig. 5-16. [After Leng, M. and Felsenfeld, G., *J. Mol. Biol.* **15**, 457 (1966).]

*driven and entropically opposed. Thus the hydrophobic interactions responsible for the stability of base stacking associations in nucleic acids are diametrically opposite in character to those that stabilize protein structures (which are enthalpically opposed and entropically driven; Section 8-4C). This is reflected in the differing structural properties of these interactions. For example, the aromatic side chains of proteins are almost never stacked and the crystal structures of aromatic hydrocarbons such as benzene, which resemble these side chains, are characteristically devoid of stacking interactions.*

*Hydrophobic forces in nucleic acids are poorly understood. The observation that they are different in character from the hydrophobic forces that stabilize proteins is nevertheless not surprising because the nitrogenous bases are considerably more polar than the hydrocarbon residues of proteins that participate in hydrophobic interactions. There is, however, no theory available that adequately explains the nature of hydrophobic forces in nucleic acids (our understanding of hydrophobic forces in proteins, it will be recalled, is similarly incomplete). They are complex interactions of which base stacking is probably a significant component. Whatever their origins, hydrophobic forces are of central importance in determining nucleic acid structures.*

**Table 29-3** Thermodynamic Parameters for the Reaction

Dinucleoside Phosphate	$\Delta H_{\text{stacking}}$ ( $\text{kJ} \cdot \text{mol}^{-1}$ )	$-T \Delta S_{\text{stacking}}$ ( $\text{kJ} \cdot \text{mol}^{-1}$ at $25^\circ\text{C}$ )

### D. Ionic Interactions

Any theory of the stability of nucleic acid structures must take into account the electrostatic interactions of their charged phosphate groups. Polyelectrolyte theory approximates the electrostatic interactions of DNA by considering the anionic double helix to be a homogeneously charged line or cylinder. We shall not discuss the details of this theory here, but note that it is often in reasonable agreement with experimental observations.

The melting temperature of duplex DNA increases with the cation concentration because these ions bind more tightly to duplex DNA than to single-stranded DNA due to the duplex DNA's higher anionic charge density. An increased salt concentration therefore shifts the equilibrium toward the duplex form, thus increasing the DNA's  $T_m$ . The observed relationship for  $\text{Na}^+$  is

$$T_m = 41.1X_{G+C} + 16.6 \log[\text{Na}^+] + 81.5 \quad [29.4]$$

where  $X_{G+C}$  is the mole fraction of G · C base pairs (recall that  $T_m$  increases with the G + C content; Fig. 5-17); the equation is valid in the ranges  $0.3 < X_{G+C} < 0.7$  and  $10^{-3} M < [\text{Na}^+] < 1.0M$ . Other monovalent cations such as  $\text{Li}^+$  and  $\text{K}^+$  have similar nonspecific interactions with phosphate groups. Divalent cations, such as  $\text{Mg}^{2+}$ ,  $\text{Mn}^{2+}$ , and  $\text{Co}^{2+}$ , in contrast, specifically bind to phosphate groups, so that *divalent cations are far more effective shielding agents for nucleic acids than are monovalent cations*. For example, an  $\text{Mg}^{2+}$  ion has an influence on the DNA double helix comparable to that of 100 to 1000  $\text{Na}^+$  ions. Indeed, enzymes that mediate reactions with nucleic acids or just nucleotides (e.g., ATP) usually require  $\text{Mg}^{2+}$  for activity. Moreover,  $\text{Mg}^{2+}$  ions play an essential role in stabilizing the complex structures assumed by many RNAs such as transfer RNAs (tRNAs; Section 32-2B) and ribosomal RNAs (rRNAs; Section 32-3A).

## 3 SUPERCOILED DNA

 See Guided Exploration 24: DNA supercoiling Genetic analyses indicate that numerous viruses and bacteria have circular genetic maps, which implies that their chromosomes are

likewise circular. This conclusion has been confirmed by electron micrographs in which circular DNAs are seen (Fig. 29-15). Some of these circular DNAs have a peculiar twisted appearance, a phenomenon that is known equivalently as **supercoiling**, **supertwisting**, and **superhelicity**. Supercoiling arises from a biologically important topological property of covalently closed circular duplex DNA that is the subject of this section. It is occasionally referred to as DNA's tertiary structure.

### A. Superhelix Topology

Consider a double helical DNA molecule in which both strands are covalently joined to form a circular duplex molecule as is diagrammed in Fig. 29-16 (each strand can be joined only to itself because the strands are antiparallel). A *geometric property of such an assembly is that the number of times one strand wraps about the other cannot be altered without first cleaving at least one of its polynucleotide strands*. You can easily demonstrate this to yourself with a buckled belt in which each edge of the belt represents a strand of DNA. The number of times the belt is twisted before it is buckled cannot be changed without unbuckling or cutting the belt (cutting a polynucleotide strand).

This phenomenon, as James White proved mathematically in 1969, is expressed

$$L = T + W \quad [29.5]$$

in which:

1.  $L$ , the **linking number** (also symbolized  $Lk$ ), is the number of times that one DNA strand winds about the other. This integer quantity is most easily counted when the molecule's duplex axis is constrained to lie in a plane (see below). However, *the linking number is invariant no matter how the circular molecule is twisted or distorted so long as both its polynucleotide strands remain covalently intact; the linking number is therefore a topological property of the molecule*.

2.  $T$ , the **twist** (also symbolized  $Tw$ ), is the number of complete revolutions that one polynucleotide strand makes about the duplex axis in the particular conformation

**Figure 29-15** Electron micrographs of circular duplex DNAs. Their conformations vary from no supercoiling (left) to tightly supercoiled (right). [Electron micrographs by Laurien Polder.]

From Kornberg, A. and Baker, T.A., *DNA Replication* (2nd ed.), p. 36, W.H. Freeman (1992). Used with permission.]

**Figure 29-16** Schematic diagram of covalently closed circular duplex DNA that has 26 double helical turns. Its two polynucleotide strands are said to be **topologically bonded** to each other because, although they are not covalently linked, they cannot be separated without breaking covalent bonds.

under consideration. By convention,  $T$  is positive for right-handed duplex turns, so that, for B-DNA in solution, the twist is normally the number of base pairs divided by 10.5 (the number of base pairs per turn of the B-DNA double helix under physiological conditions; see Section 29-3Bc).

3.  $W$ , the **writhing number** (also symbolized  $Wr$ ), is the number of turns that the duplex axis makes about the su-

perhelix axis in the conformation of interest. Its value is readily determined by projecting the DNA onto a plane and counting the number of times the duplex axis crosses itself (Fig. 29-17). The **writhing number** is a measure of the DNA's **superhelicity**. The difference between writhing and twisting is illustrated by the familiar example in Fig. 29-18.  $W = 0$  when the DNA's duplex axis is constrained to lie in a plane (e.g., Fig. 29-16); then  $L = T$ , so  $L$  may be evaluated by counting the DNA's duplex turns.

The two DNA conformations diagrammed on the right of Fig. 29-19 are topologically equivalent; that is, they have the same linking number,  $L$ , but differ in their twists and writhing numbers. Note that  $T$  and  $W$  need not be integers (at least mathematically), only  $L$ . Although, strictly speaking, superhelicity is only defined for covalently closed circular duplex DNA, a linear segment of duplex DNA that is mechanically constrained from rotating at both ends (e.g., by protein anchors) has identical topological properties.

**Figure 29-17** Topological relationships in covalently closed duplex DNA. (a) DNA molecules are represented by circular ribbons. DNA with no torsional strain is said to be relaxed. Underwinding or overwinding produces negative (-1) or positive (+1) supercoils. (b) A negative writhe has a crossover in which a clockwise rotation of the front segment of  $<180^\circ$  aligns it over the back segment, whereas a positive writhe has the corresponding counterclockwise rotation. [After Dewees, J.E., Osheroff, M.A., and Osheroff, N., *Biochem. Mol. Biol. Educ.* **37**, 2 (2009).]

**Figure 29-18** The difference between writhing and twist as demonstrated by a coiled telephone cord. Here the cord represents a double helical DNA molecule. In its relaxed state (*left*), the cord is in a helical form that has a large writhing number and a small twist. As the coil is pulled out (*middle*) until it is nearly straight (*right*), its writhing number becomes small as its twist becomes large.

**Figure 29-19** Two ways of introducing one supercoil into a DNA with 10 duplex turns.

The two closed circular forms shown (right) are topologically equivalent; that is, they are interconvertible without breaking any covalent bonds. The linking number  $L$ , twist  $T$ , and writhing number  $W$  are indicated for each form. Strictly speaking, the linking number is only defined for a covalently closed circle.

Since  $L$  is constant in an intact duplex DNA circle, for every new double helical twist,  $\Delta T$ , there must be an equal and opposite superhelical twist, that is,  $\Delta W = -\Delta T$ . For example, a closed circular DNA without supercoils (Fig. 29-19, upper right) can be converted to a negatively supercoiled conformation (Fig. 29-18, lower right) by winding the duplex helix the same number of positive (right-handed) turns.

#### a. Supercoils May Be Toroidal or Interwound

A supercoiled duplex may assume two topologically equivalent forms:

1. A **toroidal helix** in which the duplex axis is wound as if about a cylinder (Fig. 29-20a).
2. An **interwound helix** in which the duplex axis is twisted around itself (Fig. 29-20b).

Note that these two interconvertible superhelical forms have opposite handedness. Since left-handed toroidal turns may be converted to left-handed duplex turns (e.g., Fig. 29-19), left-handed toroidal turns and right-handed interwound turns both have negative writhing numbers. Thus an underwound duplex ( $T < \text{number of bp}/10.5$ ), for example, will tend to develop right-handed interwound or left-handed toroidal superhelical turns when the constraints causing it to be underwound are released (the molecular forces in a DNA double helix promote its winding to its normal number of helical turns).

#### b. Supercoiled DNA Is Relaxed by Nicking One Strand

Supercoiled DNA may be converted to **relaxed circles** (as appears in the leftmost panel of Fig. 29-15) by treatment with **pancreatic DNase I**, an **endonuclease** (an enzyme that cleaves phosphodiester bonds within a polynucleotide strand) that cleaves only one strand of a duplex DNA. *One single-strand nick is sufficient to relax a supercoiled DNA.* This is because the sugar-phosphate chain opposite the nick is free to swivel about its backbone bonds (Fig. 29-5) so as to change the molecule's linking number and thereby alter its superhelicity. Supercoiling builds up elastic strain in a

DNA circle, much as it does in a rubber band. This is why the relaxed state of a DNA circle is not supercoiled.

### B. Measurements of Supercoiling

Supercoiled DNA, far from being just a mathematical curiosity, has been widely observed in nature. In fact, its discovery in polyomavirus DNA by Jerome Vinograd stimulated the elucidation of the topological properties of superhelices rather than *vice versa*.

#### a. Intercalating Agents Control Supercoiling by Unwinding DNA

*All naturally occurring DNA circles are underwound;* that is, their linking numbers are less than those of their

**Figure 29-20** Toroidal and interwound supercoils. A rubber tube that has been (a) toroidally coiled in a left-handed helix around a cylinder with its ends joined such that it has no twist jumps to (b) an interwound helix with the opposite handedness when the cylinder is removed. Neither the linking number, the twist, nor the writhing number are changed in this transformation.

**Figure 29-21** Sedimentation rate of underwound closed circular duplex DNA as a function of ethidium bromide concentration. The intercalation of ethidium between the base pairs locally untwists the double helix (Fig. 29-22), which, since the linking number of the circle is constant, is accompanied by an equivalent increase in the writhing number. As the negatively coiled superhelix untwists, it becomes less compact and hence sediments more slowly. At the low point on the curve, the DNA

circles have bound sufficient ethidium to become fully relaxed. As the ethidium concentration is further increased, the DNA supercoils in the opposite direction, yielding a positively coiled superhelix. The supertwisted appearances of the depicted DNAs have been verified by electron microscopy. [After Bauer, W.R., Crick, F.H.C., and White, J.H., *Sci. Am.* **243**(1), 129 (1980). Copyright © 1981 by Scientific American, Inc.]

corresponding relaxed circles. This phenomenon has been established by observing the effect of ethidium ion binding on the sedimentation rate of circular DNA (Fig. 29-21). Intercalating agents such as ethidium (a planar aromatic cation; Section 6-6Ca) alter a circular DNA's degree

of superhelicity because they cause the DNA double helix to unwind (untwist) by  $\sim 26^\circ$  at the site of the intercalated molecule (Fig. 29-22).  $W < 0$  in an unconstrained underwound circle because of the tendency of a duplex DNA to maintain its normal twist of 1 turn per 10.5 bp. The titra-

**Figure 29-22** X-ray structure of a complex of ethidium with 5-iodo-UpA. Ethidium (red) intercalates between the base pairs (green with 1 purple) of the double helically paired dinucleoside phosphate and thereby provides a model for the binding of ethidium to duplex DNA. [After Tsai, C.-C., Jain, S.C., and Sobell, H.M., *Proc. Natl. Acad. Sci.* **72**, 629 (1975).]

**2. Type II topoisomerases**, the first of which was discovered by Martin Gellert in 1976, act by making transient double-strand breaks in DNA with the accompanying hydrolysis of ATP to ADP + P<sub>i</sub>. Type II enzymes are subclassified into **types IIA** and **IIB topoisomerases** on the basis of their amino acid sequences. Type II topoisomerases are denoted by even Roman numerals (e.g., topoisomerase II, IV, etc.).

**a. Type I Topoisomerases Incrementally Relax Supercoiled DNA**

*Type I topoisomerases catalyze the relaxation of supercoils in DNA by changing their linking number in increments of one turn until the supercoil is entirely relaxed.* In most organisms, type IA enzymes, which are present in all cells, relax only negatively supercoiled DNA, whereas type IB enzymes, which are present in all eukaryotes and many prokaryotes (but not *E. coli*), relax both negatively and positively coiled DNA. However, many hyperthermophiles, both eubacteria and archaea, have a type IA

topoisomerase known as **reverse gyrase** that induces positive supercoiling in DNA through the ATP-driven action of a **helicase** domain that is fused to the N-terminus of the topoisomerase domain (helicases are discussed in Section 30-2C). This suggests that positive supercoiling, which tightens the DNA double helix, protects DNA from thermal denaturation. Although types IA and IB topoisomerases are both monomeric, ~100-kD enzymes, they share no apparent sequence or structural similarities and function, as we shall see, via different enzymatic mechanisms.

A clue to the mechanism of type IA topoisomerase was provided by the observation that it reversibly **catenates** (interlinks) single-stranded circles (Fig. 29-24a). Apparently the enzyme operates by cutting a single strand, passing a single-strand loop through the resulting gap, and then resealing the break (Fig. 29-24b), thereby twisting double helical DNA by one turn. In support of this **strand passage** mechanism, the denaturation of type IA enzyme that has been incubated with single-stranded circular DNA yields a linear DNA that has its 5'-terminal phosphoryl group linked to the enzyme via a phosphoTyr diester linkage.

**Figure 29-24** Type IA topoisomerase action. By cutting a single-stranded DNA, passing a loop of a second strand through the break, and then resealing the break, a type IA topoisomerase can (a) catenate two single-stranded circles or (b) unwind duplex DNA by one turn.

In contrast, denatured type IB enzyme is linked to the 3' end of DNA via a phosphoTyr linkage. By forming such covalent enzyme–DNA intermediates, the free energy of the cleaved phosphodiester bond is preserved, so that no energy input is required to reseal the nick.

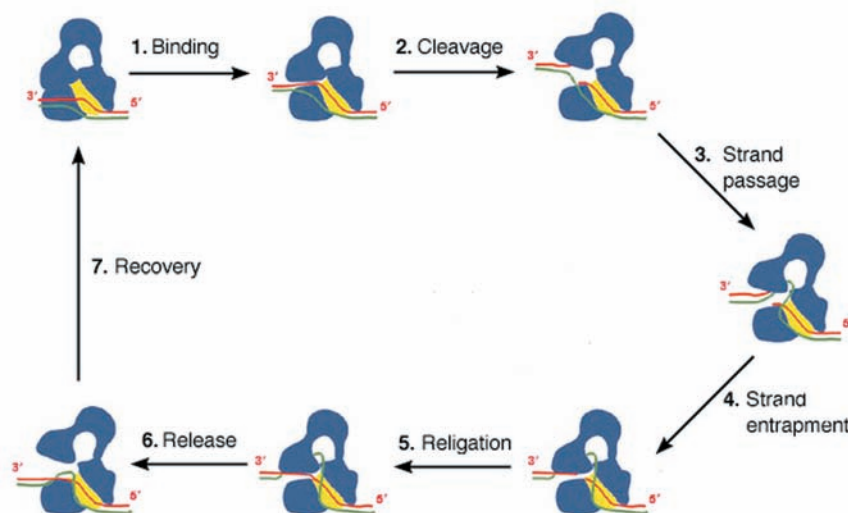

**b. Type IA Topoisomerase Functions via a Strand Passage Mechanism**

Cells of *E. coli* contain two type IA topoisomerases named **topoisomerase I** (also called  **$\omega$  protein**) and **topoisomerase III**. Topoisomerase III's Tyr 328 is the active site residue that forms a 5'-phosphoTyr linkage with the cleaved DNA. The X-ray structure of the inactive Y328F mutant of topoisomerase III in complex with the single-stranded octanucleotide d(CGCAACTT), determined by Alfonso

**Figure 29-25** X-ray structure of the Y328F mutant of *E. coli* topoisomerase III, a type IA topoisomerase, in complex with the single-stranded octanucleotide d(CGCAACTT). The two views shown are related by a 90° rotation about a vertical axis. The protein's four domains are drawn in different colors. The DNA is

drawn in space-filling form with C white, N blue, O red, and P yellow. The enzyme's active site is marked by the side chain of Phe 328, which is shown in space-filling form in yellow-green. [Based on an X-ray structure by Alfonso Mondragón, Northwestern University. PDBid 117D.]

**Figure 29-26** Proposed mechanism for the strand passage reaction catalyzed by type IA topoisomerases. The enzyme is shown in blue with the yellow patch representing the binding groove for single-stranded (ss) DNA. The two DNA strands, which are drawn in red and green, could represent the two strands of a covalently closed circular duplex or two ss circles. (1) The protein recognizes a ss region of the DNA, here the red strand, and binds it in its binding groove. This is followed by or occurs simultaneously with the opening of a gap between domains I and III. (2) The DNA is cleaved with the newly formed 5' end becoming covalently linked to the active site Tyr and the segment with the newly formed 3' end remaining tightly but noncovalently bound in the binding groove. (3) The unbroken (green) strand is passed through the opening or gate formed by

the cleaved (red) strand to enter the protein's central hole. (4) The unbroken strand is trapped by the partial closing of the gap. (5) The two cleaved ends of the red strand are rejoined in what is probably a reversal of the cleavage reaction. (6) The gap between domains I and III reopens to permit the escape of the red strand, yielding the reaction product in which the green strand has been passed through a transient break in the red strand. (7) The enzyme returns to its initial state. If the two strands form a negatively supercoiled duplex DNA, its linking number,  $L$ , has increased by 1; if they are separate ss circles, they have been catenated or decatenated. For duplex DNA, this process can be repeated until all of its supercoils have been removed ( $W = 0$ ). [After a drawing by Alfonso Mondragón, Northwestern University.]

Mondragón (Fig. 29-25), reveals that this 659-residue monomer folds into four domains which enclose an  $\sim 20$  by  $28$  Å hole that is large enough to contain a duplex DNA and which is lined with numerous Arg and Lys side chains. The octanucleotide binds in a groove that is also lined with Arg and Lys side chains with its sugar–phosphate backbone in contact with the protein and with most of its bases exposed for possible base pairing. Curiously, this single-stranded DNA assumes a B-DNA-like conformation even though its complementary strand would be sterically excluded from the groove. The DNA strand is oriented with its 3' end near the active site, where, if the mutant Phe 328 were the wild-type Tyr, its side chain would be properly positioned to nucleophilically attack the phosphate group bridging the DNA's C6 and T7 to form a 5'-phosphoTyr linkage with T7 and release C6 with a free 3'-OH. This structure and that of the homologous and structurally similar *E. coli* topoisomerase I suggest the mechanism for the type IA topoisomerase-catalyzed strand passage reaction that is diagrammed in Fig. 29-26.

### c. Type IB Topoisomerase Functions via a Controlled Rotation Mechanism

Human **topoisomerase I** is a 765-residue type IB topoisomerase (and hence is unrelated to *E. coli* topoisomerase I). It mediates the transient cleavage of one strand of a duplex DNA through the nucleophilic attack of Tyr 723 on a DNA P atom to yield a 3'-linked phosphoTyr diester bond and a free 5'-OH group on the succeeding nucleotide. Limited proteolysis studies revealed that topoisomerase I consists of four major regions: its N-terminal, core, linker, and C-terminal domains. The  $\sim 210$ -residue, highly polar, N-terminal domain, which is poorly conserved, contains several nuclear targeting signals and is dispensable for enzymatic activity.

The X-ray structure of the catalytically inactive Y723F mutant of topoisomerase I lacking its N-terminal 214

residues and in complex with a 22-bp palindromic duplex DNA was determined by Wim Hol (Fig. 29-27). The core domain of this bilobal protein is wrapped around the DNA in a tight embrace. If the mutant Phe 723 were the wild-type Tyr, its OH group would be colinear with the scissile P—O5' bond and hence ideally positioned to nucleophilically attack this P atom so as to form a covalent linkage with the 3' end of the cleaved strand. As expected, the protein interacts with the DNA in a largely sequence independent manner: Of the 41 direct contacts that the protein makes to the DNA, 37 are protein–phosphate interactions and only one is base-specific. The protein interacts to a much greater extent with the five base pairs of the DNA's upstream segment (which would contain the cleaved strand's newly formed 5' end; 29 of the 41 contacts) than it does with the base pairs of the DNA's downstream segment (to which Tyr 723 would be covalently linked; 12 of the 41 contacts).

Topoisomerase I does not seem sterically capable of unwinding supercoiled DNA via the strand passage mechanism that type IA topoisomerases appear to follow (Fig. 29-26). Rather, as is diagrammed in Fig. 29-28, it is likely that topoisomerase I relaxes DNA supercoils by permitting the cleaved duplex DNA's loosely held downstream segment to rotate relative to the tightly held upstream segment. This rotation can only occur about the sugar–phosphate bonds in the uncleaved strand ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\epsilon$ , and  $\zeta$  in Fig. 29-5) that are opposite the cleavage site because the cleavage frees these bonds to rotate. In support of this mechanism, the protein region surrounding the downstream segment contains 16 conserved, positively charged residues that form a ring about this duplex DNA, which would presumably hold the DNA in the ring but not in any specific orientation. Nevertheless, the downstream segment is unlikely to rotate freely because the cavity containing it is shaped so as to interact with the downstream segment during some portions of its rotation. Hence,

**Figure 29-27** X-ray structure of the N-terminally truncated, Y723F mutant of human topoisomerase I in complex with a 22-bp duplex DNA. The protein's various domains and subdomains are drawn in different colors. The DNA's uncleaved

strand is cyan, and the upstream and downstream portions of the scissile strand are purple and pink, respectively. [Courtesy of Wim Hol, University of Washington. PDBid 1A36.]

**Figure 29-28** **Controlled rotation mechanism for type IB topoisomerases.** A highly negatively supercoiled DNA (red, with a right-handed writhe) is converted, via stages (a) through (g), to a less supercoiled form (green). Topoisomerase I is drawn as a bilobal space-filling structure, in which the cyan lobe is formed by core subdomains I and II (Fig. 29-27) and the purple lobe is formed by core subdomain III, the linker domain, and the C-terminal domain. The structure shown in (d), which is expanded by a factor of 2, shows the downstream portion of the rotating DNA (that containing the cleaved strand's new 5' end) at 30° intervals, all differently colored. Since the enzyme is not always in direct contact with the rotating DNA, small rocking motions of the protein (small curved arrows) may accompany the controlled rotation. [Courtesy of Wim Hol, University of Washington.]

type IB topoisomerases are said to mediate a **controlled rotation** mechanism in relaxing supercoiled DNA. This unwinding is driven by the superhelical tension in the DNA and hence requires no other energy input. Eventually, the DNA is religated by a reversal of the cleavage reaction and the now less supercoiled DNA is released.

Type IC topoisomerase, whose only known family member, **topoisomerase V**, occurs exclusively in archaea, resembles type IB topoisomerases (which do not occur in archaea) in that it forms 3'-phosphoTyr intermediates and appears to function via a controlled rotation mechanism. However, it has no sequence or structural resemblance to type IB topoisomerases.

#### d. Type II Topoisomerases Function via a Strand Passage Mechanism

Bacteria have two types of type IIA topoisomerases: **DNA gyrase** (or just **gyrase**) and **topoisomerase IV**, both of which are  $A_2B_2$  heterotetramers. Eukaryotic type IIA topoisomerases, which are named **topoisomerase II**, are homologous to bacterial type IIA topoisomerases but with

their A and B subunits fused so that they are homodimers. The type IIB topoisomerase family has only one member, **topoisomerase VI**, an  $A_2B_2$  heterotetramer that occurs mainly in archaea (although some archaea express both type IIA and IIB topoisomerases). The A subunits of types IIA and IIB topoisomerases share a common ATPase module, but their B subunits are unrelated.

*Gyrase is unique among topoisomerases in that it generates negative supercoils in DNA.* All other topoisomerases but reverse gyrase only relax supercoils (DNA supercoiling in eukaryotes is generated differently from that in prokaryotes; Section 34-1Ba). Its A and B subunits are named **GyrA** and **GyrB**.

Type II topoisomerases can also catenate and decatenate double-stranded circles as well as tie and untie knots in them. The importance of this function can be seen as follows. The  $\sim 6.1$  billion base pairs of DNA in a diploid human cell have an aggregate length of  $\sim 2$  m and are confined to a nucleus that is 5 to 10  $\mu\text{m}$  in diameter. Imagine that the  $\sim 20$ -Å-wide DNA was expanded by a factor of 5 million to the width of a 1-cm-diameter rope. It would

then be ~10,000 km long (the distance from San Francisco to Rome) and confined to an expanded nucleus that is 25 to 50 m in diameter. Then imagine trying to manipulate the ropes in this system without generating tangles or knots. Yet such difficulties normally occur in cells during DNA replication, repair, and recombination (Chapter 30), as well as the segregation of the daughter chromosomes in dividing cells (Section 1-4B). It is the function of type II topoisomerases to untangle the DNA during these processes.

Bacterial but not eukaryotic type IIA topoisomerases are inhibited by a variety of substances including **novobiocin**, a member of the *Streptomyces*-derived **coumarin** family of antibiotics, and **ciprofloxacin** (trade name **Cipro**), a member of the synthetically generated **quinolone** family of antibiotics (their coumarin and quinolone groups are drawn in red):

These agents profoundly inhibit bacterial DNA replication and RNA transcription, thereby demonstrating the importance of properly supercoiled DNA in these processes. Studies using *E. coli* gyrase mutants resistant to these substances have demonstrated that ciprofloxacin associates with GyrA and novobiocin binds to GyrB.

The gel electrophoretic pattern of duplex circles that have been exposed to gyrase shows a band pattern in which the linking numbers differ by increments of 2 rather than 1, as occurs with type I topoisomerases. Evidently, gyrase acts by cutting both strands of a duplex, passing the duplex through the break, and resealing it (Fig. 29-29). This hypothesis is corroborated by the observation that when gyrase is incubated with DNA and ciprofloxacin, and subsequently denatured with guanidinium chloride, a GyrA subunit remains covalently linked to the 5' end of each of the two cut strands through a phosphoTyr linkage. These cleavage sites are staggered by 4 bp, thereby yielding sticky ends.

*Saccharomyces cerevisiae* (baker's yeast) topoisomerase II is a homodimer of 1428-residue subunits whose N- and C-terminal segments are homologous to *E. coli*'s GyrB (804 residues) and GyrA (878 residues) subunits, respectively. The breakage/reunion domain, which encompasses residues 410 to 1202, can, by itself, cleave duplex DNA but cannot transport it through the break without the action of the enzyme's ATPase domain (residues 1–409). However, the C-terminal segment (residues 1203–1428), which is poorly conserved, appears to be dispensable.

Although the structure of a full length type IIA topoisomerase is as yet unknown, those of its ATPase and breakage/reunion domains from both *E. coli* gyrase and yeast topoisomerase II have been determined. The X-ray structure of the homodimeric topoisomerase II ATPase in complex with the nonhydrolyzable ATP analog AMPPNP, determined by James Berger, consists of two domains (Fig.

**Figure 29-29** A demonstration, in which DNA is represented by a ribbon, that cutting a duplex circle, passing the double helix through the resulting gap, and then resealing the break changes

the linking number by 2. Separating the resulting single strands (slitting the ribbon along its length; right) indicates that one single strand makes two complete revolutions about the other.

**Figure 29-30** X-ray structures of *S. cerevisiae* topoisomerase II. (a) Structure of a homodimer of the N-terminal ATPase domain (residues 7–406) in complex with AMPPNP as viewed with its 2-fold axis vertical. The protein is displayed in ribbon form with one subunit gray and the other colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The bound AMPPNP molecules are shown in space-filling form with C green, N blue, O red, and P orange. (b) Structure of a homodimer of the DNA breakage/reunion domain (residues 419–1177) in complex with a doubly nicked 34-bp DNA. The structure is viewed with its 2-fold axis vertical. The DNA, which describes a 150° arc, is drawn in stick form with C green, N blue, O red, and P orange embedded in its semitransparent molecular surface (*orange*). The protein is displayed in ribbon form with one subunit gray and the other colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The side chains of the two active site Tyr residues (Y782) are shown in space-filling form with C magenta and O red. The polypeptides in Parts *a* and *b*, which in the intact protein are joined by an 11-residue linker (represented by the dotted lines), presumably share the same 2-fold axis as drawn, although their relative orientation about this axis is unknown. (c) Same as Part *b* but viewed from below. Note that the Y782 side chain O atoms are positioned to link to opposite DNA strands at sites separated by 4 base pairs. [Based on X-ray structures by James Berger, University of California at Berkeley. PDBids 1PVC and 2RGR.] See Interactive Exercise 32

29-30a). The N-terminal domain binds AMPPNP and the C-terminal domains form the walls of a large hole through the dimer, which in the X-ray structure of the structurally similar *E. coli* GyrB is 20 Å across, the same width as the B-DNA double helix.

Berger also determined the X-ray structure of the yeast topoisomerase breakage/reunion domain in complex a 15-bp DNA that has a self-complementary 4-nucleotide overhang on the 5' end of one of its strands. The DNA thereby forms a 2-fold symmetric 34-bp duplex with nicks on opposite strands separated by 4 bp (Fig. 29-30b,c). These are precisely the sites at which the enzyme would cleave an intact DNA by linking its newly formed 5'-ending strands to the

active site Tyr 782 residues. The protein binds the DNA in a positively charged groove that spans the width of the dimer and, in doing so, bends it through an arc of 150° (we shall see in later chapters that DNA-binding proteins often deform their bound DNA, although such an extreme deformation is unusual). Interestingly, the DNA between the two cleavage sites is essentially in the A form. There are almost no direct contacts between the protein and the DNA bases, as is expected for a protein with little sequence specificity. Note also that the C-terminal portions of the protein come together to enclose a large centrally located empty space.

Consideration of the foregoing two structures and those of the corresponding portions of *E. coli* gyrase suggests a

type of strand passage model for the mechanism of type IIA topoisomerases (Fig. 29-31) in which the DNA duplex to be cleaved, the so-called G-segment (G for gate), binds to the above-described groove across the top of the cleavage/reunion domain. ATP binding to the ATP-binding domain then induces a sequence of conformational changes in which the G-segment is cleaved and the resulting two fragments are spread apart by at least 20 Å through the action of the protein. This permits the passage of the DNA's so-called T-segment (T for transported) through the break in the DNA and breakage/reunion domain's upper gate (which may also contain portions of the ATPase domain) into its central hole, thereby incrementing the DNA's linking number by 2. Then, in a process that is accompanied by ATP hydrolysis, the upper gate closes to reseal the cleaved DNA, and the T-segment passes through the breakage/reunion domain's bottom gate. Finally, the resulting ADP and  $P_i$  are released and the bottom gate closes to yield recycled enzyme. Many of these enzymatic states have been observed in the several known X-ray structures of type IIA topoisomerase components.

#### e. Topoisomerase Inhibitors Are Effective Antibiotics and Cancer Chemotherapy Agents

Coumarin derivatives such as novobiocin, and quinolone derivatives such as ciprofloxacin, specifically inhibit gyrase and are therefore antibiotics. In fact, ciprofloxacin is the most efficacious oral antibiotic against gram-negative bacteria presently in clinical use (novobiocin's adverse side effects and the rapid generation of bacterial resistance to it have resulted in the discontinuation of its use in the treatment of human infections). A number of substances, including **doxorubicin** (also called **adriamycin**; a product of *Streptomyces peucetius*) and **etoposide** (a synthetic derivative),

**Doxorubicin (Adriamycin)**

**Etoposide**

**Figure 29-31 Model for the enzymatic mechanism of type II topoisomerases.** The protein's ATPase domain and the upper and lower portions of the breakage/reunion domain are colored yellow, red, and purple, respectively, and the DNA's G- and T-segments are colored gray and green, respectively. In **1**, the G-segment binds to the enzyme, thereby inducing the conformational change drawn in **2**. The binding of ATP (represented by asterisks) and a T-segment (**3**) induces a series of conformational changes in which the G-segment is cleaved as the upper gate opens. The ATPase domains dimerize, and the T-segment is transported through the break into the central hole (**4**). The DNA transport step is shown as proceeding through the hypothetical intermediate in square brackets. The G-segments are then resealed and the T-segment is released through the lower gate (**5**). This gate then closes as the ATP is hydrolyzed and the resulting ADP and  $P_i$  released to yield the enzyme in its starting state (**2**). [Courtesy of James Wang, Harvard University.]

inhibit eukaryotic type IIA topoisomerases and are therefore widely used in cancer chemotherapy. Indeed, ~50% of cancer chemotherapy regimens contain at least one drug targeted to type IIA topoisomerases.

Type IIA topoisomerase inhibitors act in either of two ways. Many of them, including novobiocin, inhibit their target enzyme's ATPase activity (novobiocin is a competitive inhibitor of ATP because it tightly binds to GyrB in a way that prevents the binding of ATP's adenine ring). They therefore kill cells by blocking topoisomerase activity, which results in the arrest of DNA replication and RNA transcription. However, other substances, including ciprofloxacin, doxorubicin, and etoposide, enhance the rate at which their target type IIA topoisomerases cleave double-stranded DNA and/or reduce the rate at which these enzymes reseal these breaks. Consequently, these agents induce higher than normal levels of transient protein-bridged breaks in the DNA of treated cells. These protein bridges are easily ruptured by the passage of the replication and transcription machinery, thereby rendering the breaks permanent. Although all cells have elaborate enzymatic systems to repair damaged DNA (Section 30-5), a sufficiently high level of DNA damage overwhelms these

systems and hence results in cell death. Consequently, since rapidly replicating cells such as cancer cells have elevated levels of type IIA topoisomerases, they are far more likely to incur lethal DNA damage through the poisoning of their type IIA topoisomerases than are slow-growing or quiescent cells.

Type IB topoisomerases are specifically inhibited by the quinoline-based alkaloid **camptothecin**

(a product of the Chinese yew tree, *Camptotheca acuminata*) and its derivatives, which act by stabilizing the covalent topoisomerase I–DNA complex. These compounds, the only known naturally occurring topoisomerase IB inhibitors, are potent anticancer agents.

## CHAPTER SUMMARY

**1 Double Helical Structures** B-DNA consists of a right-handed double helix of antiparallel sugar–phosphate chains with ~10 bp per turn of 34 Å and with its bases nearly perpendicular to the helix axis. Bases on opposite strands hydrogen-bond in a geometrically complementary manner to form A · T and G · C Watson–Crick base pairs. At low humidity, B-DNA undergoes a reversible transformation to a wider, flatter right-handed double helix known as A-DNA. Z-DNA, which is formed at high salt concentrations by polynucleotides of alternating purine and pyrimidine base sequences, is a left-handed double helix. Double helical RNA and RNA · DNA hybrids have A-DNA-like structures. The conformation of DNA, particularly that of B-DNA, varies with its base sequence largely because DNA's flexibility varies with its base sequence.

**2 Forces Stabilizing Nucleic Acid Structures** The orientations about the glycosidic bond and the various torsion angles in the sugar–phosphate chain are sterically constrained in nucleic acids. Likewise, only a few of the possible sugar pucker conformations are commonly observed. Watson–Crick base pairing is both geometrically and electronically complementary. Yet hydrogen bonding interactions do not greatly stabilize nucleic acid structures. Rather, the structures are largely stabilized by hydrophobic interactions. Nevertheless, the hydrophobic forces in nucleic acids are qualitatively different in character from those that stabilize proteins. Electrostatic interactions between charged phosphate groups are also important structural determinants of nucleic acids.

**3 Supercoiled DNA** The linking number ( $L$ ) of a covalently closed circular DNA is topologically invariant. Consequently, any change in the twist ( $T$ ) of a circular duplex must be balanced by an equal and opposite change in its writhing number ( $W$ ), which indicates its degree of supercoiling. Supercoiling can be induced by intercalation agents. The gel electrophoretic mobility of DNA increases with its degree of superhelicity. Naturally occurring DNAs are all negatively supercoiled and must be so in order to participate in DNA replication and RNA transcription.

Type IA topoisomerases relax negatively supercoiled DNAs via a strand passage mechanism in which they cleave a single strand of DNA to form a 5'-phosphoTyr bond, pass a single-strand DNA segment through the gap, and then reseal the gap. Type IB topoisomerases relax both negatively and positively supercoiled DNAs via a controlled rotation mechanism involving a single-strand cleavage in which a transient phosphoTyr bond is formed with the newly generated 3' end. Type II topoisomerases relax duplex DNA in increments of two supertwists at the expense of ATP hydrolysis by making a double-strand scission in the DNA so as to form two transient 5'-phosphoTyr linkages, passing the duplex through the break, and resealing it. DNA gyrase also generates negative supertwists in an ATP-dependent manner. Topoisomerases are the targets of several antibiotics and chemotherapeutic agents.

## PROBLEMS

**1.** A · T base pairs in DNA exhibit greater variability in their propeller twisting than do G · C base pairs. Suggest the structural basis of this phenomenon.

**\*2.** At Na<sup>+</sup> concentrations >5M, the  $T_m$  of DNA decreases with increasing [Na<sup>+</sup>]. Explain this behavior. (*Hint*: Consider the solvation requirements of Na<sup>+</sup>.)

**\*3.** Why are the most commonly observed conformations of the ribose ring those in which either atom C2' or atom C3' is out of the plane of the other four ring atoms? (*Hint:* In puckering a planar ring such that one atom is out of the plane of the other four, the substituents about the bond opposite the out-of-plane atom remain eclipsed. This is best observed with a ball-and-stick model.)

**4.** Polyomavirus DNA can be separated by sedimentation at neutral pH into three components that have sedimentation coefficients of 20, 16, and 14.5S and that are known as Types I, II, and III DNAs, respectively. These DNAs all have identical base sequences and molecular masses. In 0.15M NaCl, both Types II and III DNA have melting curves of normal cooperativity and a  $T_m$  of 88°C. Type I DNA, however, exhibits a very broad melting curve and a  $T_m$  of 107°C. At pH 13, Types I and III DNAs have sedimentation coefficients of 53 and 16S, respectively, and Type II separates into two components with sedimentation coefficients of 16 and 18S. How do Types I, II, and III DNAs differ from one another? Explain their different physical properties.

**5.** When the helix axis of a closed circular duplex DNA of 2310 bp is constrained to lie in a plane, the DNA has a twist ( $T$ ) of 207. When released, the DNA takes up its normal twist of 10.5 bp per turn. Indicate the values of the linking number ( $L$ ), writhing number ( $W$ ), and twist for both the constrained and unconstrained conformational states of this DNA circle. What is the superhelix density,  $\sigma$ , of both the constrained and unconstrained DNA circles?

**6.** A covalently closed circular duplex DNA has a 100-bp segment of alternating C and G residues. On transfer to a solution containing a high salt concentration, this segment undergoes a transition from the B conformation to the Z conformation. What is the accompanying change in its linking number, writhing number, and twist?

**7.** You have discovered an enzyme secreted by a particularly virulent bacterium that cleaves the C2'—C3' bond in the deoxyribose residues of duplex DNA. What is the effect of this enzyme on supercoiled DNA?

**8.** A bacterial chromosome consists of a protein–DNA complex in which its single DNA molecule appears to be supercoiled, as demonstrated by ethidium bromide titration. However, in contrast to the case with naked circular duplex DNA, the light single-strand nicking of chromosomal DNA does not abolish this supercoiling. What does this indicate about the structure of the bacterial chromosome, that is, how do its proteins constrain its DNA?

**9.** Although types IA and IIA topoisomerases exhibit no significant sequence similarity, it has been suggested that they are distantly related based on the similarities of certain aspects of their enzymatic mechanisms. What are these similarities?

**10.** Draw the mechanism of DNA strand cleavage and rejoining mediated by topoisomerase IA.

### 1 DNA REPLICATION: AN OVERVIEW

Watson and Crick's seminal paper describing the DNA double helix ended with the statement: "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material." In a succeeding paper they expanded on this rather cryptic remark by pointing out that a DNA strand could act as a template to direct the synthesis of its complementary strand. Although Meselson and Stahl demonstrated, in 1958, that DNA is, in fact, semiconservatively replicated (Section 5-3B), it was not until some 20 years later that the mechanism of DNA replication in prokaryotes was understood in reasonable detail. This is because, as we shall see in this chapter, the DNA replication process rivals translation in its complexity but is mediated by often loosely associated protein assemblies that are present in only a few copies per cell. *The surprising intricacy of DNA replication compared to the chemically similar transcription process (Section 31-2) arises from the need for extreme accuracy in DNA replication so as to preserve the integrity of the genome from generation to generation.*

#### A. Replication Forks

*DNA is replicated by enzymes known as **DNA-directed DNA polymerases** or simply **DNA polymerases**. These enzymes utilize single-stranded DNA as templates on which to catalyze the synthesis of the complementary strand from the appropriate deoxynucleoside triphosphates (Fig. 30-1). The incoming nucleotides are selected by their ability to form Watson-Crick base pairs with the template DNA so that the newly synthesized DNA strand forms a double helix with the template strand. *Nearly all known DNA polymerases can only add a nucleotide donated by a nucleoside triphosphate to the free 3'-OH group of a base paired polynucleotide so that DNA chains are extended only in the 5' → 3' direction.* DNA polymerases are discussed further in Sections 30-2A, 30-2B, and 30-4B.*

#### a. Duplex DNA Replicates Semiconservatively at Replication Forks

John Cairns obtained the earliest indications of how chromosomes replicate through the autoradiography of replicating DNA. Autoradiograms of circular chromosomes grown in a medium containing [ $^3$ H]thymidine show

Here we begin a three-chapter series on the basic processes of gene expression: DNA replication (this chapter), transcription (Chapter 31), and translation (Chapter 32). These processes have been outlined in Section 5-4. We shall now discuss them in greater depth with an emphasis on how we have come to know what we know.

**Figure 30-1** Action of DNA polymerase. DNA polymerases assemble incoming deoxynucleoside triphosphates on

single-stranded DNA templates such that the growing strand is elongated in its 5' → 3' direction.

the presence of replication “eyes” or “bubbles” (Fig. 30-2). These so-called **θ structures** (after their resemblance to the Greek letter theta) indicate that *double-stranded DNA (dsDNA) replicates by the progressive separation of its two parental strands accompanied by the synthesis of their complementary strands to yield two semiconservatively replicated duplex daughter strands* (Fig. 30-3). DNA replication involving θ structures is known as **θ replication**.

A branch point in a replication eye at which DNA synthesis occurs is called a **replication fork**. A replication bubble may contain one or two replication forks (**unidirectional** or **bidirectional replication**). Autoradiographic studies have demonstrated that θ replication is almost always bidirectional (Fig. 30-4). Moreover, such experiments, together with genetic evidence, have established that prokaryotic and bacteriophage DNAs have but one **replication origin** (point where DNA synthesis is initiated).

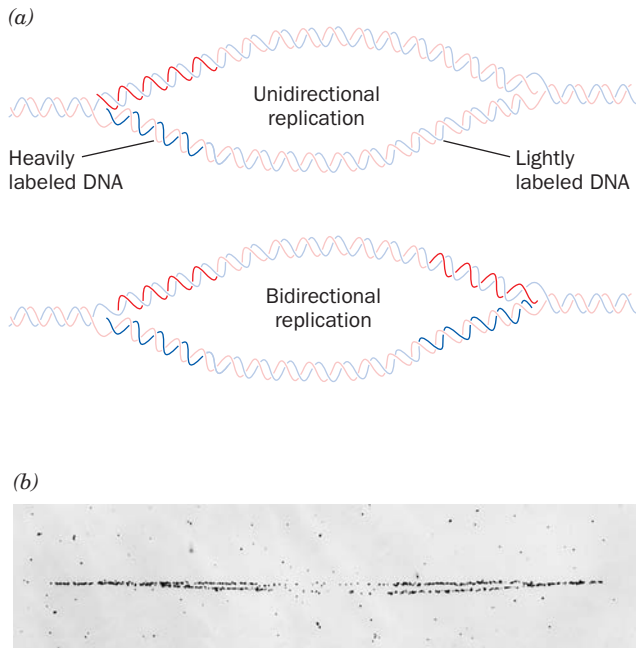

**Figure 30-2** Autoradiogram and its interpretive drawing of a replicating *E. coli* chromosome. The bacterium had been grown for somewhat more than one generation in a medium containing [<sup>3</sup>H]thymidine, thereby labeling the subsequently synthesized DNA so that it appears as a line of dark grains in the photographic emulsion (red lines in the interpretive drawing). The size of the replication eye indicates that the circular chromosome is about one-sixth duplicated in the present round of replication. [Courtesy of John Cairns, Cold Spring Harbor Laboratory, New York.]

### B. Role of DNA Gyrase

The requirement that the parent DNA unwind at the replication fork (Fig. 30-3) presents a formidable topological obstacle. For instance, *E. coli* DNA is replicated at a rate of ~1000 nucleotides/s. If its 1300-μm-long chromosome were linear, it would have to flail around within the confines of a 3-μm-long *E. coli* cell at ~100 revolutions/s

**Figure 30-3** Replication of DNA.

**Figure 30-4** Autoradiographic differentiation of unidirectional and bidirectional DNA replication. (a) An organism is grown for several generations in a medium that is lightly labeled with  $^3\text{H}$ thymidine so that all of its DNA will be visible in an autoradiogram. A large amount of  $^3\text{H}$ thymidine is then added to the medium for a few seconds before the DNA is isolated (**pulse labeling**) in order to label only those bases near the replication fork(s). Unidirectional DNA replication will exhibit only one heavily labeled branch point (*above*), whereas bidirectional DNA replication will exhibit two such branch points (*below*). (b) An autoradiogram of *E. coli* DNA so treated, demonstrating that it is bidirectionally replicated. [Courtesy of David M. Prescott, University of Colorado.]

(recall that B-DNA has  $\sim 10$  bp per turn). But since the *E. coli* chromosome is, in fact, circular, even this could not occur. Rather, the DNA molecule would accumulate +100 supercoils/s (see Section 29-3A for a discussion of supercoiling) until it became too tightly coiled to permit further unwinding. Naturally occurring DNA's negative supercoiling promotes DNA unwinding but only to the extent of  $\sim 5\%$  of its duplex turns (recall that naturally occurring DNAs are typically underwound by one supercoil per  $\sim 19$  duplex turns; Section 29-3Bb). In prokaryotes, however, negative supercoils may be introduced into DNA through the action of a type IIA topoisomerase (DNA gyrase; Section 29-3Cd) at the expense of ATP hydrolysis. This process is essential for prokaryotic DNA replication as is demonstrated by the observation that DNA gyrase inhibitors, such as novobiocin, arrest DNA replication except in mutants whose DNA gyrase does not bind these antibiotics.

### C. Semidiscontinuous Replication

The low-resolution images provided by autoradiograms such as Figs. 30-2 and 30-4b suggest that dsDNA's two antiparallel strands are simultaneously replicated at an advancing replication fork. Yet, all known DNA polymerases can only extend DNA strands in the  $5' \rightarrow 3'$  direction. How, then, does DNA polymerase copy the parent strand that extends in the  $5' \rightarrow 3'$  direction past the replication fork? This question was answered in 1968 by Reiji Okazaki through the following experiments. If a growing *E. coli* culture is pulse-labeled for 30 s with  $^3\text{H}$ thymidine, much of the radioactive and hence newly synthesized DNA has a sedimentation coefficient in alkali of 7S to 11S. These so-called **Okazaki fragments** evidently consist of only 1000 to 2000 nucleotides (**nt**; 100–200 nt in eukaryotes). If, however, following the 30 s  $^3\text{H}$ thymidine pulse, the *E. coli* are transferred to an unlabeled medium (a **pulse-chase** experiment), the resulting radioactively labeled DNA sediments at a rate that increases with the time that the cells had grown in the unlabeled medium. The Okazaki fragments must therefore become covalently incorporated into larger DNA molecules.

Okazaki interpreted his experimental results in terms of the **semidiscontinuous replication** model (Fig. 30-5). The two parent strands are replicated in different ways. *The newly synthesized DNA strand that extends  $5' \rightarrow 3'$  in the direction of replication fork movement, the so-called leading strand, is essentially continuously synthesized in its  $5' \rightarrow 3'$  direction as the replication fork advances. The other newly synthesized strand, the lagging strand, is also synthesized in its  $5' \rightarrow 3'$  direction but discontinuously as Okazaki fragments. The Okazaki fragments are only covalently joined together sometime after their synthesis in a reaction catalyzed by the enzyme **DNA ligase** (Section 30-2D).*

The semidiscontinuous model of DNA replication is corroborated by electron micrographs of replicating DNA showing single-stranded regions on one side of the

**Figure 30-5** Semidiscontinuous DNA replication. In DNA replication, both daughter strands (*leading strand red, lagging strand blue*) are synthesized in their  $5' \rightarrow 3'$  directions. The leading strand is synthesized continuously, whereas the lagging strand is synthesized discontinuously.

**Figure 30-6** Electron micrograph of a replication eye in *Drosophila melanogaster* DNA. Note that the single-stranded regions (arrows) near the replication forks have the trans configuration consistent with the semidiscontinuous model of DNA replication. [From Kreigstein, H.J. and Hogness, D.S., *Proc. Natl. Acad. Sci.* **71**, 173 (1974).]

replication fork (Fig. 30-6). In bidirectionally replicating DNA, moreover, the two single-stranded regions occur, as expected, on diagonally opposite sides of the replication bubble.

#### D. RNA Primers

DNA polymerases' all but universal requirement for a free 3'-OH group to extend a DNA chain poses a question that was emphasized by the establishment of the semidiscontinuous model of DNA replication: How is DNA synthesis initiated? Careful analysis of Okazaki fragments revealed

**Figure 30-7** Priming of DNA synthesis by short RNA segments.

that their 5' ends consist of RNA segments of 1 to 60 nt (a length that is species dependent) that are complementary to the template DNA chain (Fig. 30-7). *E. coli* has two enzymes that can catalyze the formation of these **RNA primers**: **RNA polymerase**, the ~459-kD multisubunit enzyme that mediates transcription (Section 31-2), and the much smaller primase (60 kD), the monomeric product of the *dnaG* gene.

Primase is insensitive to the RNA polymerase inhibitor **rifampicin** (Section 31-2Bb). The observation that rifampicin inhibits only leading strand synthesis therefore indicates that *primase initiates the Okazaki fragment primers*. The initiation of leading strand synthesis in *E. coli*, a much rarer event than that of Okazaki fragments, can be mediated *in vitro* by either RNA polymerase or primase alone but is greatly stimulated when both enzymes are present. It is therefore thought that these enzymes act synergistically *in vivo* to prime leading strand synthesis.

Mature DNA does not contain RNA. The RNA primers are eventually removed and the resulting single-strand gaps are filled in with DNA by a mechanism described in Section 30-2Aj.

## 2 ENZYMES OF REPLICATION

DNA replication is a complex process involving a great variety of enzymes. It requires, to list only its major actors in their order of appearance: (1) DNA topoisomerases, (2) enzymes known as helicases that separate the DNA strands at the replication fork, (3) proteins that prevent them from reannealing before they are replicated, (4) enzymes that synthesize RNA primers, (5) a DNA polymerase, (6) an enzyme to remove the RNA primers, and (7) an enzyme to covalently link successive Okazaki fragments. In this section, we describe the properties and functions of many of these proteins.

### A. DNA Polymerase I

In 1957, Arthur Kornberg reported that he had discovered an enzyme that catalyzes the synthesis of DNA in extracts of *E. coli* through its ability to incorporate the radioactive label from [<sup>14</sup>C]thymidine triphosphate into DNA. This enzyme, which has since become known as **DNA polymerase I** or **Pol I**, consists of a monomeric 928-residue polypeptide.

*Pol I* couples deoxynucleoside triphosphates on DNA templates (Fig. 30-1) in a reaction that occurs through the nucleophilic attack of the growing DNA chain's 3'-OH group on the  $\alpha$ -phosphoryl of an incoming nucleoside triphosphate. The reaction is driven by the resulting elimination of PP<sub>i</sub> and its subsequent hydrolysis by inorganic pyrophosphatase. The overall reaction resembles that catalyzed by RNA polymerase (Fig. 5-23) but differs from it by the strict requirement that the incoming nucleoside be linked to a free 3'-OH group of a polynucleoside that is base paired to the template (RNA polymerase initiates

transcription by linking together two ribonucleoside triphosphates on a DNA template; Section 31-2C). The complementarity between the product DNA and the template was at first inferred through base composition and hybridization studies but was eventually directly established by base sequence determinations. The error rate of Pol I in copying the template is extremely low, as was first demonstrated by its *in vitro* replication of the 5386-nt DNA from bacteriophage  $\phi$ X174 to yield fully infective phage DNA. In fact, its measured error rate is around one wrong base per 10 million.

Pol I is said to be **processive** in that it catalyzes a series of successive polymerization steps, typically 20 or more, without releasing the template (the opposite of “processive” is “**distributive**”). Pol I can, of course, work in reverse by degrading DNA through pyrophosphorolysis. This reverse reaction, however, probably has no physiological significance because of the low *in vivo* concentration of  $PP_i$ , resulting from the action of inorganic pyrophosphatase.

#### a. Pol I Recognizes the Incoming dNTP According to the Shape of the Base Pair It Forms with the Template DNA

The specificity of Pol I for an incoming base arises from the requirement that it form a Watson–Crick base pair with the template rather than direct recognition of the incoming base (recall that the four base pairs, A · T, T · A, G · C, and C · G, have nearly identical shapes; Fig. 5-12). Thus, as Eric Kool demonstrated, when the “base” **2,4-difluorotoluene (F)**,

2,4-Difluorotoluene base (F)

Thymine (T)

which is isosteric with (has the same shape as) thymine but does not accept hydrogen bonds, is synthetically inserted into a template DNA, Pol I incorporates A opposite the F with a similar rate of mismatches as it incorporates A opposite T. Likewise, dFTP is incorporated opposite template A with a similar fidelity as is dTTP. Yet the incorporation of F opposite an A in DNA destabilizes the double helix by 15 kJ/mol relative to T opposite this A. Evidently, *Pol I selects an incoming dNTP largely according to its ability to form a Watson–Crick-shaped pair with the template base but with little regard for its hydrogen bonding properties*. Indeed, the NMR structure of a 12-bp DNA containing a centrally located F opposite an A reveals that it assumes a B-DNA conformation in which the F–A pair closely resembles a T · A base pair in the same position of an otherwise identical DNA.

#### b. Pol I Can Edit Its Mistakes

In addition to its polymerase activity, Pol I has two independent hydrolytic activities:

1. It can act as a 3' → 5' exonuclease.
2. It can act as a 5' → 3' exonuclease.

The 3' → 5' exonuclease reaction differs chemically from the pyrophosphorolysis reaction (the reverse of the polymerase reaction) only in that  $H_2O$  rather than  $PP_i$  is the nucleotide acceptor. Kinetic and crystallographic studies, however, indicate that these two catalytic activities occupy separate active sites (see below). The 3' → 5' exonuclease function is activated by an unpaired 3'-terminal nucleotide with a free OH group. If Pol I erroneously incorporates a wrong (unpaired) nucleotide at the end of a growing DNA chain, the polymerase activity is inhibited and the 3' → 5' exonuclease excises the offending nucleotide (Fig. 5-36). The polymerase activity then resumes DNA replication. *Pol I therefore has the ability to proofread or edit a DNA chain as it is synthesized so as to correct its mistakes*. This explains the great fidelity of DNA replication by Pol I: The overall fraction of bases that the enzyme misincorporates,  $\sim 10^{-7}$ , is the product of the fraction of bases that its polymerase activity misincorporates and the fraction of misincorporated bases that its 3' → 5' exonuclease activity fails to excise. The price of this high fidelity is that  $\sim 3\%$  of correctly incorporated nucleotides are also excised.

The Pol I 5' → 3' exonuclease binds to dsDNA at single-strand nicks with little regard to the character of the 5' nucleotide (5'-OH or phosphate group; base paired or not). It cleaves the DNA in a base paired region beyond the nick such that the DNA is excised as either mononucleotides or oligonucleotides of up to 10 residues (Fig. 5-33). In contrast, the 3' → 5' exonuclease removes only unpaired mononucleotides with 3'-OH groups.

#### c. Pol I's Polymerase and Two Exonuclease Functions Each Occupy Separate Active Sites

The 5' → 3' exonuclease activity of Pol I is independent of both its 3' → 5' exonuclease and its polymerase activities. In fact, as we saw in Section 7-2A, proteases such as subtilisin or trypsin cleave Pol I into two fragments: a larger C-terminal or **Klenow fragment** (residues 324–928), which contains both the polymerase and the 3' → 5' exonuclease activities; and a smaller, N-terminal fragment (residues 1–323), which contains the 5' → 3' exonuclease activity. Thus Pol I contains three active sites on a single polypeptide chain.

#### d. The X-Ray Structure of Klenow Fragment Indicates How It Binds DNA

The X-ray structure of Klenow fragment in complex with dsDNA, determined by Thomas Steitz, reveals that

**Figure 30-8** X-ray structure of *E. coli* DNA polymerase I Klenow fragment in complex with a dsDNA. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red) and embedded in its semitransparent molecular surface. The DNA is shown in stick form with the C atoms of its 10-nt template strand cyan, the C atoms of its 13-nt primer strand magenta, N blue, O red, and P orange, and with successive P atoms in each polynucleotide strand connected by orange rods. A  $Zn^{2+}$  ion (purple sphere) marks the  $3' \rightarrow 5'$ -exonuclease active site. [Based on an X-ray structure by Thomas Steitz, Yale University. PDBid 1KLN.]

 See Interactive Exercise 33

the enzyme consists of two domains (Fig. 30-8). The smaller domain (residues 324–517) contains the  $3' \rightarrow 5'$  exonuclease site, as was demonstrated by the absence of this function but not polymerase activity in a genetically engineered Klenow fragment mutant that lacks the divalent metal ion-binding sites known to be essential for  $3' \rightarrow 5'$  exonuclease activity but which otherwise has a normal structure. The larger domain (residues 521–928) contains the polymerase active site at the bottom of a prominent cleft, a surprisingly large distance ( $\sim 25$  Å) from the  $3' \rightarrow 5'$  exonuclease site. The cleft, which is lined with positively charged residues, has the appropriate size ( $\sim 22$  Å wide by  $\sim 30$  Å deep) and shape to bind a B-DNA molecule in a manner resembling a right hand grasping a rod. Consequently, Klenow fragment's polymerase domains are known as its “fingers,” “thumb,” and “palm” (Fig. 30-8). Indeed, all DNA polymerases of known structure have similar shapes with a fingers domain that binds the incoming nucleotide and the

templating base, a thumb domain that guides the newly formed dsDNA as it leaves the active site, and a palm domain that contains the active site at the bottom of the cleft between the fingers and thumb domains (Sections 30-2Ba, 30-4Ba, and 30-4Ca).

#### e. DNA Polymerase Distinguishes Watson–Crick Base Pairs via Sequence-Independent Interactions That Induce Domain Movements

DNA polymerase I from the thermophile *Thermus aquaticus* (Taq), which is 51% identical to its *E. coli* homolog, lacks a functional  $3' \rightarrow 5'$  exonuclease. Its X-ray structure (Fig. 30-9a), also determined by Steitz, reveals that its C-terminal domain closely resembles Klenow fragment (Fig. 30-8), although the metal ion-binding carboxylate residues that are essential for the  $3' \rightarrow 5'$  exonuclease function of Klenow fragment are absent in Taq polymerase. Its N-terminal  $5' \rightarrow 3'$  exonuclease domain, which appears to be only loosely tethered to the C-terminal polymerase domain, contains a conserved cluster of metal ions at the bottom of a cleft that is  $\sim 70$  Å from the polymerase active site. It is therefore unclear how the polymerase and  $5' \rightarrow 3'$  exonuclease functions work in concert, as we shall see (Section 30-2Ai), to produce dsDNA with a single nick.

Gabriel Waksman crystallized the C-terminal domain of Taq DNA polymerase I [**Klentaq1**; which is often used in PCR experiments (Section 5-5F)] in complex with an 11-bp dsDNA that has a GGAAA-5' overhang at the 5' end of its template strand, and the crystals were incubated with 2',3'-dideoxy-CTP (ddCTP; which lacks a 3'-OH group). The X-ray structure of these crystals (Fig. 30-9b) reveals that a ddC residue had been covalently linked to the 3' end of the primer and formed a Watson–Crick pair with the template overhang's 3' G. Moreover, a second ddCTP molecule (to which the primer's new 3'-terminal ddC residue is incapable of forming a covalent bond) occupies the enzyme's active site where it forms a Watson–Crick pair with the template's next G that is largely out of contact with the surrounding aqueous solution. Clearly, Klentaq1 retains its catalytic activity in this crystal.

A DNA polymerase must distinguish correctly paired bases from mismatches and yet do so via sequence-independent interactions with the incoming dNTP. The foregoing X-ray structure reveals that this occurs through an active site pocket that is complementary in shape to Watson–Crick base pairs. The pocket is formed by the stacking of a conserved Tyr side chain on the template base, as well as by van der Waals interactions with the protein and with the preceding base pair. In addition, although the dsDNA is mainly in the B conformation, the 3 base pairs nearest the active site assume the A conformation, as has also been observed in the X-ray structures of several other DNA polymerases in their complexes with DNA. The resulting wider and shallower minor groove (Section 29-1Ba) permits protein side chains to form hydrogen bonds with the otherwise inaccessible N3 atoms of the purine bases and O2 atoms of the pyrimidine bases. The positions of these hydrogen bond acceptors are sequence-

**Figure 30-9** X-ray structures of *T. thermophilus* DNA polymerase I. (a) X-ray structure of the entire protein drawn in ribbon form. The N-terminal 5' → 3' exonuclease domain is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The Zn<sup>2+</sup> ion at its active site is represented by a purple sphere. The C-terminal KlenTaq1 domain, which is oriented similarly to the Klenow fragment in Fig. 30-8, is light green. (b) The X-ray structures of KlenTaq1 in its closed conformation (with bound ddCTP) and (c) in its open conformation (ddCTP depleted). The protein, which is viewed similarly to Fig. 30-8, is drawn in worm form with its N-terminal, palm, fingers, and thumb domains colored yellow, magenta, green, and blue, respectively. The DNA is shown in stick form, whereas the primer strand's 3'-terminal ddC residue is drawn in space-filling form as is the ddCTP in Part b that is base paired with a template G residue in the enzyme's active site pocket. The atoms are colored according to type with template strand C cyan, primer strand C green, ddCTP C yellow, N blue, O red, and P orange. [Part a based on an X-ray structure by Thomas Steitz, Yale University. PDBid 1TAQ. Parts b and c based on X-ray structures by Gabriel Waksman, Washington University School of Medicine. PDBids 3KTQ and 2KTQ.]

independent as can be seen from an inspection of Fig. 5-12 [in contrast, the positions of the hydrogen bonding acceptors in the major groove vary with both the identity (A · T vs G · C) and the orientation (e.g., A · T vs T · A) of the base pair]. However, with a non-Watson-Crick pairing, these hydrogen bonds would be greatly distorted if not completely disrupted. The protein also makes extensive sequence-independent hydrogen bonding and van der Waals interactions with the DNA's sugar-phosphate backbone.

The above KlenTaq1 · DNA · ddCTP crystals were partially depleted of ddCTP by soaking them in a stabilizing solution that lacks ddCTP. The X-ray structure of the ddCTP-depleted crystals (Fig. 30-9c) reveals that KlenTaq1

assumes a so-called open conformation, which differs significantly from that in the so-called closed conformation described above by a  $46^\circ$  hingelike motion of the fingers domain away from the polymerase active site (Fig. 30-9c). Evidently, the formation of a Watson–Crick base pair at the polymerase active site triggers the formation of a productive ternary complex that buries the incoming nucleotide. In particular, the foregoing Tyr side chain, which extends from the rightmost helix of the fingers domain (Fig. 30-9b), stacks on the incoming base, an interaction that is absent in the open conformation. Moreover, a Lys and an Arg side chain, that also extend from the rightmost helix of the fingers domain, form salt bridges with the  $\alpha$ - and  $\beta$ -phosphate groups of the incoming dNTP. These observations are consistent with kinetic measurements on Pol I indicating that the binding of the correct dNTP to the enzyme induces a rate-limiting conformational change that yields a tight ternary complex. It therefore appears that the enzyme rapidly samples the available dNTPs in its open conformation but only when it binds the correct dNTP in a Watson–Crick pairing with the template base does it form the catalytically competent closed conformation. The subsequent reaction steps then rapidly yield the product complex which, following a second conformational change, releases the product  $PP_i$ . Finally, the DNA is translocated in the active site, probably via a linear diffusion mechanism, so as to position it for the next reaction cycle.

The comparison of the above X-ray structures with that of Klenotaq1 alone indicates that on binding DNA, the thumb domain moves to wrap around the DNA. It is likely that this conformational change is largely responsible for Pol I's processivity. In both Klenotaq1 · DNA structures, neither the dsDNA nor the single-stranded DNA (ssDNA) passes through the cleft between the thumb and fingers domain as the shape and position of the cleft suggest. Rather, the template strand makes a sharp bend at the first unpaired base, thereby unstacking this base and positioning this ssDNA on the same side of the cleft as the dsDNA. Similar arrangements have been observed in X-ray structures of other DNA polymerases in their complexes with DNA.

#### f. The DNA Polymerase Catalytic Mechanism Involves Two Metal Ions

The X-ray structures of a variety of DNA polymerases suggest that they share a common catalytic mechanism for nucleotidyl transfer (Fig. 30-10). Their active sites all contain two metal ions, usually  $Mg^{2+}$ , that are liganded by two invariant Asp side chains in the palm domain. Metal ion B in Fig. 30-10 is liganded by all three phosphate groups of the bound dNTP, whereas metal ion A bridges the  $\alpha$ -phosphate group of this dNTP and the primer's 3'-OH group. Metal ion A presumably activates the primer's 3'-OH group for an in-line nucleophilic attack on the  $\alpha$ -phosphate group (Fig. 16-6b), whereas metal ion B functions to orient its bound triphosphate group and to electrostatically shield their negative charges as well as the additional negative charge on the transition state leading to the release of the  $PP_i$  ion (Section 16-2B).

**Figure 30-10** Schematic diagram for the nucleotidyl transfer mechanism of DNA polymerases. A and B represent enzyme-bound metal ions that usually are  $Mg^{2+}$ . Atoms are colored according to type (C gray, N blue, O red, and P yellow) and metal ion coordination is represented by dotted lines. Metal ion A activates the primer's 3'-OH group for in-line nucleophilic attack on the incoming dNTP's  $\alpha$ -phosphate group (arrow), whereas metal ion B acts to orient and electrostatically stabilize the negatively charged triphosphate group. [Courtesy of Tom Ellenberger, Harvard Medical School.]

#### g. Editing Complexes Contain the Primer Strand in the 3' → 5' Exonuclease Site

The complex of Klenow fragment with DNA shown in Fig. 30-8 contains a 13-nt primer strand [d(GCCTCGCG-GCGGC)] and a 10-nt template strand [d(GCCGC-GAGGC)] that is complementary to the 10-nt segment at the 5' end of the primer strand. The 3'-terminal nucleotide of the primer strand (the last one that an active polymerase would have added) is bound at the 3' → 5' exonuclease active site. This arrangement is made possible by the opening up of the G · C base pair that would otherwise be formed by the 5' nucleotide of the template strand, which remains bound near the entrance of the polymerase active site. Evidently, the Klenow fragment has bound the primer strand in an "editing" complex rather than in the polymerase cleft.

In *E. coli* Pol I, how does the 3' end of the primer strand transfer between the polymerase active site and the 3' → 5' exonuclease active site? This appears to occur through the competition of these sites for the 3' end of the primer strand, which base pairs to form dsDNA in the polymerase

site and binds as a single strand to the exonuclease site. Thus, the formation of a Watson–Crick base pair facilitates the binding of the primer strand to the polymerase site preparatory for the next round of chain extension, whereas a mismatched base pair greatly slows the polymerase reaction while promoting the binding of the primer strand to the exonuclease site. Comparison of the editing complex with those of the KlenTaq1 · DNA complexes suggests that the transfer of the primer strand from the polymerase to the editing sites of Klenow fragment requires that the dsDNA translocate backward (toward the 3' end of the template strand) by several angstroms along the helix axis.

#### h. Pol I Functions Physiologically to Repair DNA

For some 13 years after Pol I's discovery, it was generally assumed that this enzyme was *E. coli*'s DNA replicase because no other DNA polymerase activity had been detected in *E. coli*. This assumption was made untenable by Cairns and Paula De Lucia's isolation, in 1969, of a mutant *E. coli* whose extracts exhibit <1% of the normal Pol I activity (although it has nearly normal levels of the 5' → 3' exonuclease activity) but which nevertheless reproduce at the normal rate. This mutant strain, however, is highly susceptible to the damaging effects of UV radiation and **chemical mutagens** (substances that chemically induce mutations; Section 32-1A). *Pol I evidently plays a central role in the repair of damaged (chemically altered) DNA.*

Damaged DNA, as we discuss in Section 30-5, is detected by a variety of DNA repair systems. Many of them endonucleolytically cleave the damaged DNA on the 5' side of the lesion, thereby activating Pol I's 5' → 3' exonuclease. While excising this damaged DNA, Pol I simultaneously fills in the resulting single-strand gap through its polymerase activity. In fact, its 5' → 3' exonuclease activity increases 10-fold when the polymerase function is active. Perhaps the simultaneous excision and polymerization activities of Pol I protect DNA from the action of cellular nucleases that would further damage the otherwise gapped DNA.

#### i. Pol I Catalyzes Nick Translation

Pol I's combined 5' → 3' exonuclease and polymerase activities can replace the nucleotides on the 5' side of a single-strand nick on otherwise undamaged DNA. These reactions, in effect, translate (move) the nick toward the DNA strand's 3' end without otherwise changing the molecule (Fig. 30-11). This **nick translation** process, in the presence of labeled deoxynucleoside triphosphates, is synthetically employed to prepare highly radioactive DNA (the required nicks may be generated by treating the DNA with a small amount of pancreatic **Dnase I**).

#### j. Pol I's 5' → 3' Exonuclease Functions Physiologically to Excise RNA Primers

*Pol I's 5' → 3' exonuclease also removes the RNA primers at the 5' ends of newly synthesized DNA while its DNA polymerase activity fills in the resulting gaps (Fig. 5-34).* The importance of this function was demonstrated by the isolation

**Figure 30-11** Nick translation as catalyzed by Pol I.

of temperature-sensitive *E. coli* mutants that are neither viable nor exhibit any 5' → 3' exonuclease activity at the restrictive temperature of ~43°C (the low level of polymerase activity in the Pol I mutant isolated by Cairns and De Lucia is apparently sufficient to carry out this essential gap-filling process during chromosome replication). Thus Pol I has an indispensable role in *E. coli* DNA replication although a different one than was first supposed.

#### B. DNA Polymerase III

The discovery of normally growing *E. coli* mutants that have very little Pol I activity stimulated the search for an additional DNA polymerizing activity. This effort was rewarded by the discovery of two more enzymes, designated, in the order they were discovered, **DNA polymerase II (Pol II)** and **DNA polymerase III (Pol III)**. The properties of these enzymes are compared with that of Pol I in Table 30-1. Pol II and Pol III had not previously been detected because their combined activities in the assays used are normally <5% that of Pol I.

A mutant *E. coli* lacking measurable Pol II activity grows normally. However, Pol II has been implicated as a participant in repairing DNA damage via the **SOS response** (Section 30-5D), as have two additional *E. coli* enzymes that

were more recently discovered: **DNA polymerase IV (Pol IV)** and **DNA polymerase V (Pol V)** (Section 30-5Db).

### a. Pol III Is *E. coli*'s DNA Replicase

The cessation of DNA replication in temperature-sensitive *polC* mutants above the restrictive (high) temperature demonstrates that *Pol III is E. coli's DNA replicase*. Its **Pol III core** has the subunit composition  $\alpha\epsilon\theta$  where  $\alpha$ , the *polC* gene product (Table 30-2), contains the polymerase function. The catalytic properties of Pol III core resemble those of Pol I (Table 30-1) except for Pol III core's inability to replicate primed ssDNA or nicked dsDNA. Rather, Pol III core acts *in vitro* at single-strand gaps of <100 nucleotides, a situation that probably resembles the state of DNA at the replication fork. The Pol III 3'  $\rightarrow$  5' exonuclease function, which resides on the enzyme's  $\epsilon$  subunit, is DNA's primary editor during replication; it enhances the enzyme's replication fidelity by up to 200-fold. However, the Pol III 5'  $\rightarrow$  3' exonuclease acts only on single-stranded DNA, so it cannot catalyze nick translation.  $\theta$  is an accessory protein that stimulates the editing function of  $\epsilon$ .

The X-ray structure of residues 1 to 917 of the 1160-residue *E. coli* Pol III  $\alpha$  subunit, determined Mike O'Donnell and John Kuriyan, reveals that this protein has the expected thumb, fingers, and palm domains (Fig. 30-12). Nevertheless, it exhibits no significant sequence similarity and a different fold from all but two other DNA polymerases of known structure (both from gram-positive bacteria). In addition, Pol III  $\alpha$  has an N-terminal PHP (for polymerases and histidinol phosphatase) domain that buttresses both the palm and thumb domains.

*Pol III core ( $\alpha\epsilon\theta$ ) functions in vivo as part of a complicated and labile multisubunit enzyme, the Pol III holoenzyme, which consists of at least 10 types of subunits (Table*

**Figure 30-12** X-ray structure of the *E. coli* Pol III  $\alpha$  subunit.

The protein is drawn in ribbon form with its thumb, PHP, palm, and finger domains green, blue, magenta, and orange, respectively. Note the handlike shape of the protein but its entirely different fold from that of KlenTaq1 (Fig. 30-9). 30-2). The latter 7 subunits in Table 30-2 act to modulate Pol III core's activity. For example, Pol III core has a processivity of 10 to 15 residues; it can only fill in short single-stranded regions of DNA. However, Pol III core is rendered processive by association with the  **$\beta$  subunit** in the presence of the 7-subunit  **$\gamma$  complex** ( $\gamma\tau_2\delta\delta'\chi\Psi$ ). Assembly of the processive enzyme is a two-stage process in which the  $\gamma$  complex transfers the  $\beta$  subunit to the primed template in an ATP-dependent reaction followed by the assembly of Pol III core with the  $\beta$  subunit on the DNA (Section 30-3Cc). The  $\beta$  subunit confers essentially unlimited processivity (>5000 residues) on the core enzyme even if the  $\gamma$  complex is subsequently removed. In fact, the  $\beta$  subunit is very strongly bound to the DNA, although it can freely slide along it.

### b. The $\beta$ Subunit Forms a Ringlike Sliding Clamp

The observation that a  $\beta$  subunit clamped to a cut circular DNA slides to the break and falls off suggests that the  $\beta$  subunit forms a closed ring around the DNA, thereby preventing its escape. Kuriyan and O'Donnell determined the X-ray structure of the  $\beta$  subunit in complex with a primer-template DNA (dsDNA with a single-stranded extension on the 5' end of one of its strands, the template strand). The protein forms a homodimer of C-shaped, 366-residue monomer units that associate to form an  $\sim$ 80-Å-diameter doughnut-shaped structure (Fig. 30-13a) that is equivalently known as the **sliding clamp** and the  **$\beta$  clamp**. The sliding clamp's central hole is  $\sim$ 35 Å in diameter, which is larger than the 20- and 26-Å diameters of B- and A-DNAs (recall that the hybrid helices which RNA

**Figure 30-13** X-ray structure of the  $\beta$  subunit of *E. coli* Pol III holoenzyme in complex with DNA. (a) The homodimeric sliding clamp is drawn in ribbon form embedded in its semitransparent surface diagram and viewed along its 2-fold axis with one subunit magenta and the other colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The DNA, which consists of a 10-bp double-stranded segment with a 4-nt single-stranded extension at the 5' end of one of the strands, is drawn in stick form with the C atoms of the template strand cyan, those of the primer strand green, N blue, O red, and P orange, and with an

orange rod connecting successive P atoms in each strand. (b) Cutaway diagram of the structure in Part a rotated 90° about the horizontal axis. The DNA, which is shown in space-filling form, is inclined by ~22° to the protein's 2-fold axis, which is vertical in this diagram. Note that in a replicating system, the primer strand would be extended toward the top of the diagram. [Based on an X-ray structure by John Kuriyan, University of California at Berkeley, and Mike O'Donnell, The Rockefeller University. PDBid 3BEP.]

primers make with DNA have A-DNA-like conformations; Section 29-1Bc). Each  $\beta$  subunit consists of six tandem  $\beta\alpha\beta\beta$  motifs of identical topology, which associate in pairs to form three pseudo-2-fold symmetric domains of very similar structures (although with <20% sequence identity). The dimeric ring therefore has the shape of a 6-pointed star in which the 12 helices line the central hole and the  $\beta$  strands associate in six  $\beta$  sheets that form the protein's outer surface. Electrostatic calculations indicate that the interior surface of the ring is positively charged, whereas its outer surface is negatively charged.

The  $\alpha$  helices lining the protein's central hole are all approximately perpendicular to their radially adjacent segments of the sugar-phosphate backbone. These helices therefore span the major and minor grooves of the DNA rather than entering into them as do many helices that make sequence-specific interactions with dsDNA (e.g., Section 31-3Da). Since A- and B-DNAs have 11 and 10.5 bp per turn, whereas the sliding clamp has a pseudo-12-fold symmetry, it appears that the sliding clamp largely minimizes its associations with its threaded DNA, which facilitates the unencumbered passage of the DNA through the

sliding clamp. Nevertheless, the primer-template DNA's helix axis is inclined to the homodimeric protein's 2-fold axis by ~22° such that its ssDNA segment is in van der Waals contact with a specific portion of the  $\beta$  clamp's inner wall (Fig. 30-13b; in previous model building studies based on the structure of the sliding clamp alone, these axes were assumed to be coincident). In fact, primer-template DNA binds to the sliding clamp ~4-fold more tightly than does dsDNA and the mutation of the residues that interact with the ssDNA segment significantly reduces the efficiency of DNA replication. Indeed, as is explained in Section 30-3Cc, the interaction between the ssDNA and the sliding clamp is physiologically significant.

### C. Unwinding DNA: Helicases and Single-Strand Binding Protein

Pol III holoenzyme, unlike Pol I, cannot unwind dsDNA. Rather, *three proteins*, DnaB protein (the product of the *dnaB* gene; proteins may be assigned the name of the gene specifying them but in roman letters with the first letter capitalized), Rep helicase, and single-strand binding protein

**Table 30-3 Unwinding and Binding Proteins of *E. coli* DNA Replication**

Protein	Subunit Structure	Subunit Mass (kD)
DnaB protein	Hexamer	50
SSB	Tetramer	19
Rep protein	Monomer	68
PriA protein	Monomer	76

(SSB) (Table 30-3), work in concert to unwind the DNA before an advancing replication fork (Fig. 30-14) in a process that is driven by ATP hydrolysis.

#### a. Hexameric Helicases Mechanically Separate the Strands of dsDNA by Climbing Up One Strand

Access to the genetic information encoded in a double helical nucleic acid requires that its base-paired strands be separated. The proteins that do so, which are known as **helicases**, form a diverse group of enzymes that facilitate a variety of functions including DNA replication, recombination, and repair, as well as transcription termination (Section 31-2Da), RNA splicing, and RNA editing (Section 31-4A). Indeed, all forms of life contain helicases, 12 varieties of which occur in *E. coli*. A helicase functions by translocating along one strand of a double helical nucleic acid so as to separate the strands in its path. This, of course, requires free energy, and hence helicases are driven by NTP hydrolysis. Helicases have been classified into six superfamilies that vary in their characteristics, including their direction of translocation along their bound single strand ( $5' \rightarrow 3'$  or  $3' \rightarrow 5'$ ) and whether they function as hexameric rings or dimers.

*E. coli* **DnaB** protein, a **hexameric helicase** of identical 471-residue subunits, separates the strands of dsDNA by translocating along the lagging strand template in the  $5' \rightarrow 3'$  direction while hydrolyzing ATP (it can also use GTP and CTP but not UTP). Electron microscopy and X-ray studies reveal that DnaB forms a hexameric ring that, depending on conditions, exhibits  $C_3$  or  $C_6$  symmetry and which encloses an  $\sim 30$ -Å-diameter central channel. Hexameric DnaB binds three primase molecules via the latter's helicase binding domain (Section 30-2E). Similarly, the bacteriophage **T7 gene 4 helicase/primase** (bacteriophage T7 infects *E. coli*) forms a two-tiered hexagonal ring (Fig. 30-15) whose N-terminal domains (residues 1–271) contain its primase activity and whose C-terminal domains (residues 272–566) carry out its helicase function. T7 gene 4 helicase/primase (also called **T7 gp4**; gp for gene product) translocates along ssDNA in the  $5' \rightarrow 3'$  direction while preferentially hydrolyzing dTTP (but also hydrolyzes dATP and ATP).

Leemor Joshua-Tor determined the only known X-ray structure of a hexameric helicase in complex with DNA, that of the **E1 protein** of bovine papillomavirus, which translocates along ssDNA in the  $3' \rightarrow 5'$  direction (the

**Figure 30-14 Unwinding of DNA by the combined action of DnaB and SSB proteins.** The hexameric DnaB protein moves along the lagging strand template in the  $5' \rightarrow 3'$  direction. The resulting separated DNA strands are prevented from reannealing by SSB binding.

opposite direction of DnaB and T7 gp4). The protein in the structure, which contains the C-terminal 274 residues of the 605-residue E1 protein, consists of two domains: a 74-residue N-terminal oligomerization domain and a 200-residue C-terminal **AAA+ domain** (AAA+ for ATPases associated with cellular activities; a functionally diverse protein family). There are two families of hexameric helicases, the RecA family and the AAA+ family. RecA-family hexameric helicases (RecA catalyzes homologous recombination; Section 30-6Ab), such as DnaB and T7 gp4,

**Figure 30-15 Electron microscopy-based image reconstruction of T7 gene 4 helicase/primase.** In this two-tiered hexameric ring (yellow), the smaller lobe of each subunit forms the N-terminal primase domain and the larger lobe forms the C-terminal helicase domain. The protein is postulated to interact with DNA as is depicted by this model of a DNA fork consisting of a 30-bp duplex segment and two 25-nt single-stranded segments with the  $5'$  tail threaded through the hexameric ring. The way in which the  $3'$  tail interacts with the protein, if at all, is unknown. [Courtesy of S.S. Patel and K.M. Picha, University of Medicine and Dentistry of New Jersey.]

**Figure 30-16** X-ray structure of bovine papillomavirus E1 helicase in complex with poly(dT) and ADP. (a) The protein is drawn in ribbon form viewed along the homohexamer's pseudo-6-fold axis with each protein subunit differently colored and with the oligomerization domain of each subunit more lightly shaded than its AAA+ domain. The protein loops extending radially inward from each subunit to interact with the DNA's phosphate groups are purple. The poly(dT), 6 nt of which are visible, is drawn in stick form with C gray, N blue, O red, and P orange and

with successive P atoms joined by orange rods. Its 5' end is closest to the viewer. The ADP is shown in space-filling form with C green, N blue, O red, and P orange. (b) Side view of the protein related to that in Part a by a 90° rotation about the horizontal axis. The blue and green AAA+ domains in Part a, except for their DNA-interacting loops, have been deleted to expose the DNA, which is drawn in space-filling form. [Based on an X-ray structure by Leemor Joshua-Tor, Cold Spring Harbor Laboratory, New York. PDBid 2GXA.]

translocate in the 5' → 3' direction and occur mainly in eubacteria and their phages, whereas AAA+ hexameric helicases, such as the E1 protein, translocate in the 3' → 5' direction and occur mainly in archaea, eukaryotes, and their viruses.

The E1 structure reveals that this helicase, which was crystallized with ADP and a 13-nt poly(dT) (although only 6 nt are visible in the X-ray structure), forms a two-layered hexagonal ring in which the oligomerization domains form a rigid collar with nearly perfect 6-fold symmetry. In contrast, the AAA+ domains deviate significantly from this symmetry (Fig. 30-16a). An ADP is bound at a radially peripheral site between each neighboring pair of AAA+ domains. The poly(dT) forms a right-handed helix that binds in the minimally ~13-Å-diameter central channel of the AAA+ domain hexamer (which is too narrow to admit dsDNA) with its 5' end toward the top of the hexamer in Fig. 30-16. The DNA's phosphate groups each interact with a positively charged loop (residues 505–508) that extends radially inward from each AAA+ domain and hence these loops form an arrangement that resembles a right-handed spiral staircase that tracks the ssDNA's sugar–phosphate backbone. Apparently, the protein steps through a series of ATP-driven conformational changes that, via interactions with the loops, pushes the ssDNA through the channel from bottom to top in Fig. 30-16b. During this process, each loop maintains its grip on the same phosphate group. ATP

hydrolysis occurs toward the bottom of the spiral staircase and ADP release occurs between subunits located toward its top. A new ATP then binds to this site, which causes the topmost loop to drop to the bottom of the staircase, where it binds the next available phosphate group and repeats the catalytic cycle. Thus the E1 helicase mechanically separates the strands of dsDNA by pulling itself along the groove of one strand in its 3' → 5' direction but without turning relative to the DNA.

#### b. Rep Helicase Dimers Separate the Strands of dsDNA via an “Active, Rolling” Mechanism

Two other helicases, **Rep helicase** and **PriA protein**, have been implicated in the replication of various *E. coli* phage DNAs (Section 30-3B) and also participate in certain aspects of *E. coli* DNA replication (Section 30-3C). Both proteins translocate along DNA in the 3' → 5' direction (and hence along the opposite strand from DnaB) while hydrolyzing ATP. Rep helicase is not essential for *E. coli* DNA replication but the rate at which *E. coli* replication forks propagate is reduced ~2-fold in *rep*<sup>-</sup> mutants.

Rep helicase is a 673-residue monomer in solution but dimerizes on binding to DNA. Both subunits of the Rep dimer bind to ssDNA or dsDNA such that DNA binding to one subunit strongly inhibits DNA binding to the other (negative cooperativity). This observation led Timothy Lohman to propose the “active, rolling” mechanism for

**Figure 30-17** Active, rolling mechanism for DNA unwinding by Rep helicase. (1) The subunit of dimeric Rep helicase that is not bound to ssDNA binds to dsDNA accompanied by ATP binding. (2) The subunit bound to dsDNA unwinds the double strand and remains bound to the 3'-ending strand. (3) In a

process that is accompanied by the release of the ATP hydrolysis products, the subunit closer to the 3' end of the bound ssDNA releases it preparatory for a new cycle of dsDNA unwinding. [Courtesy of Gabriel Waksman, Washington University School of Medicine.]

Rep-mediated DNA unwinding in which the two subunits of the dimer alternate in binding dsDNA and the 3' end of the ssDNA at the ssDNA/dsDNA junction (Fig. 30-17). The two subunits then “walk” up the DNA while unwinding it in an ATP-dependent manner via a subunit switching mechanism in which the helicase subunit that is bound to the dsDNA displaces its 5'-starting strand while remaining bound to its 3'-starting strand. Release of the other subunit from the 3'-starting ssDNA then permits this subunit to bind to and unwind the new end of the dsDNA, thereby continuing the cycle.

The X-ray structure of *E. coli* Rep helicase in complex with the short ssDNA dT(pT)<sub>15</sub> and ADP (Fig. 30-18), determined by Lohman and Waksman, reveals that the relatively straight ssDNA molecule binds two contacting Rep monomers. A Rep monomer consists of two domains, 1 and 2, each of which is formed by two subdomains, A and B, with the two N-terminal subdomains (1A and 2A) homologous to each other. In the two Rep monomers that are bound to the same ssDNA, subdomain 2B exhibits strikingly different orientations with respect to the other three subdomains (Fig. 30-18). The Rep monomer that is bound to the 5' end of the ssDNA (which it contacts between bases 1 and 8) assumes the “open” conformation in which the four subdomains form an assembly that is reminiscent of a crab claw with one pincer (subdomain 2B) larger than the other (subdomain 1B). The DNA is bound at the bottom of the resulting cleft, whose floor is formed by subdomains 1A and 2A. In the Rep monomer that binds to the 3' end of the ssDNA (which it contacts between bases 9 and 16), subdomain 2B has reoriented relative to the other subdomains via a 130° rotation about a hinge region between subdomains 2A and 2B, thereby closing the cleft about the DNA to form the “closed” conformation. This conformation change is consistent with the active, rolling mechanism even though the way in which two Rep monomers form the dimer observed in solution remains unknown. The ADP binds to Rep between its subdomains 1A and 2A in close proximity to the DNA, suggesting that conformation changes at the ATP-binding site arising from ATP hydroly-

sis are transmitted to the DNA-binding site via the secondary structural elements that contact both sites. The way in which Rep separates the two strands of dsDNA is, as yet, unknown.

**Figure 30-18** Superposition of the X-ray structures of Rep helicase in its open and closed forms in complex with dT(pT)<sub>15</sub> and ADP. The monomer in the open conformation is drawn in ribbon form colored according to secondary structure (helices magenta,  $\beta$  sheets yellow, and coil cyan) with its bound ssDNA segment and ADP drawn in stick form in blue and in red. In the closed conformation, subdomain 2B (transparent green ribbon) has rotated via a 130° hinge motion relative to subdomains 1A, 1B, and 2A so as to close over the ssDNA. ### c. Single-Strand Binding Protein Prevents ssDNA from Reannealing

If left to their own devices, the separated DNA strands behind an advancing helicase would rapidly reanneal to reform dsDNA. What prevents them from doing so is the binding of **single-strand binding protein (SSB)**. It also prevents ssDNA from forming fortuitous intramolecular secondary structures (helical stems) and protects it from nucleases. Numerous copies of SSB cooperatively coat ssDNA, thereby maintaining it in an unpaired state. Note, however, that ssDNA must be stripped of SSB before it can be replicated by Pol III holoenzyme.

*E. coli* SSB is a homotetramer of 177-residue subunits. SSB binds ssDNA in several distinct modes referred to as  $(SSB)_n$ , which differ by the number of nucleotides ( $n$ )

**Figure 30-19** X-ray structure of *E. coli* SSB in complex with  $dC(pC)_{34}$ . The homotetramer, which has  $D_2$  symmetry, is viewed along one of its 2-fold axes with its other 2-fold axes horizontal and vertical. Each of its subunits (which include the N-terminal 134 residues of the 177-residue polypeptide) are differently colored. Its two bound ssDNA molecules are drawn in space-filling form colored according to atom type with the upper strand C cyan, lower strand C green, N blue, O red, and P orange. (The lower strand is partially disordered and hence appears to consist of two fragments.) [Based on an X-ray structure by Timothy Lohman and Gabriel Waksman, Washington University School of Medicine. PDBid 1EYG.]

bound to each tetramer. The two major modes are  $(SSB)_{35}$ , in which only two of the tetramer's subunits strongly interact with the ssDNA, and  $(SSB)_{65}$ , in which all four subunits interact with the ssDNA. The  $(SSB)_{35}$  mode displays unlimited cooperativity in that it forms extended strings of contacting tetramers along the length of a bound ssDNA, whereas the  $(SSB)_{65}$  mode has limited cooperativity in that it forms beaded clusters on ssDNA that consist of only a few contacting tetramers.

Proteolysis studies have shown that SSB's ssDNA-binding site is contained within its 115 N-terminal residues. The X-ray structure of *E. coli* SSB's chymotryptic fragment (residues 1–135) in complex with  $dC(pC)_{34}$ , determined by Lohman and Waksman, reveals that the tetrameric protein has  $D_2$  symmetry and binds two molecules of  $dC(pC)_{34}$  (Fig. 30-19). For one of these 35-mers, 28 nucleotides (residues 3–30) were visible and these assumed the shape of an elongated horseshoe that wrapped around two SSB subunits with approximate 2-fold symmetry and with its apex contacting a third subunit. The other bound ssDNA was partially disordered such that only two segments were visible, one with 14 nt (residues 3–16) and the other with 9 nt (residues 19–27). The paths of the ssDNA segments along the surface of the SSB suggested models that rationalize the different properties of  $(SSB)_{35}$  and  $(SSB)_{65}$ . In the  $(SSB)_{65}$  model, the two ends of a 65-nt segment emerge from the same side of the tetramer, which would limit the number of SSB tetramers that can bind to contiguous 65-nt segments of ssDNA. However, in the  $(SSB)_{35}$  model, the two ends of a 35-nt segment emerge from opposite ends of the tetramer, thereby permitting an unlimited series of SSB tetramers to interact end-to-end along the length of a ssDNA.

### D. DNA Ligase

Pol I, as we saw in Section 30-2A, replaces the Okazaki fragments' RNA primers with DNA through nick translation. *The resulting single-strand nicks between adjacent Okazaki fragments, as well as the nick on circular DNA after leading strand synthesis, are sealed in a reaction catalyzed by DNA ligase.* The free energy required by this reaction is obtained, in a species-dependent manner, through the coupled hydrolysis of either  $NAD^+$  to  $NMN^+ + AMP$  or  $ATP$  to  $PP_i + AMP$ . The *E. coli* enzyme, which is also known as **LigA**, is a 671-residue monomer that utilizes  $NAD^+$  and catalyzes a three-step reaction (Fig. 30-20):

1. The adenylyl group of  $NAD^+$  is transferred to the  $\epsilon$ -amino group of an enzyme Lys residue to form an unusual phosphoamide adduct that is, nevertheless, readily isolated.

2. The adenylyl group of this activated enzyme is transferred to the 5'-phosphoryl terminus of the nick to form an adenylylated DNA. Here, AMP is linked to the 5'-nucleotide via a pyrophosphate rather than the usual phosphodiester bond.

**Figure 30-20** The reactions catalyzed by *E. coli* DNA ligase. In eukaryotic and T4 DNA ligases, NAD<sup>+</sup> is replaced by ATP so that PP<sub>i</sub>, rather than NMN<sup>+</sup> is eliminated in the first reaction step. The numbered steps are described in the text.

**3.** DNA ligase catalyzes the formation of a phosphodiester bond by attack of the 3'-OH on the 5'-phosphoryl group, thereby sealing the nick and releasing AMP.

ATP-requiring DNA ligases, such as those of all eukaryotes and bacteriophage T4, release PP<sub>i</sub> in the first step of the reaction rather than NMN<sup>+</sup>. T4 ligase is also noteworthy in that, at high DNA concentrations, it can link together two duplex DNAs (**blunt end ligation**) in a reaction that is a boon to genetic engineering (Section 5-5C).

The X-ray structure of *E. coli* DNA ligase in complex with a singly nicked 26-bp dsDNA and AMP was determined by Stewart Shuman. The complex was formed by reacting the protein with NAD<sup>+</sup> in the presence of Mg<sup>2+</sup> (thus forming the phosphoamide product of step 1 of the DNA ligase reaction; Fig. 30-20), removing the Mg<sup>2+</sup>, and then adding the nicked dsDNA. The X-ray structure of

crystals of this complex revealed that the protein forms a C-shaped clamp that encircles a 19-bp segment of the DNA centered on the nick (Fig. 30-21). Moreover, the complex had progressed through step 2 of the reaction, that is, the adenylyl group had formed a pyrophosphate linkage with the 5'-phosphate group at the nick. The reason that the enzyme did not complete its catalytic cycle by sealing the nick is presumably due to the absence of Mg<sup>2+</sup>.

Residues 587 to 671 form a domain that is not visible in this X-ray structure although it is poorly resolved in the X-ray structure of DNA ligase from *Thermus filiformis*. Apparently, this domain has high mobility, which suggests that it folds out to allow the enzyme's nicked dsDNA substrate to bind to the active site and then folds back to help immobilize the DNA.

### E. Primase

The primases from bacteria and several bacteriophages track the moving replication fork in close association with its DNA helicase. Thus, the N-terminal domain of T7 gene 4 helicase/primase forms its primase function (Fig. 30-15), whereas *E. coli* primase (**DnaG**) forms a noncovalent complex with DnaB. Since these DNA helicases translocate along the lagging strand template DNA in its 5' → 3' direction (Fig. 30-14), the primase must reverse its direction of travel in order to synthesize an RNA primer in its 5' → 3' direction. DnaG, which is held to the RNA primed site by its association with SSB, can synthesize up to 60-nt primers *in vitro*, although *in vivo*, primers have the length of 11 ± 1 nt. Since a replication fork in *E. coli* moves at ~1000 nt per second and Okazaki fragments are ~1000 nt in length, about one RNA primer must be synthesized per second at each replication fork. Primases tend to initiate synthesis at specific 3-nt sequences on the template. In *E. coli* this sequence is GTA, which is overrepresented in templates for lagging strand synthesis.

DnaG is a 581-residue monomeric protein. Proteolysis studies have shown that it consists of three domains: an N-terminal Zn<sup>2+</sup>-binding domain (residues 1–110), which tetrahedrally ligands a Zn<sup>2+</sup> ion via three Cys residues and a His residue and is implicated in recognizing ssDNA; a central RNA polymerase domain (residues 111–433) that carries out primer synthesis; and a C-terminal helicase binding domain (residues 434–581) that interacts with DnaB. Isolated DnaG is only weakly active *in vitro*; it synthesizes primers at a maximum rate of three per hour. However, in the presence of DnaB, it synthesizes primers at the rate observed *in vivo*. Since *E. coli* have 50 to 100 DnaG molecules per cell, this presumably limits primer synthesis to the replication fork. The importance of this function is underscored by T7 gp4, whose helicase and primase functions reside on the same polypeptide (Fig. 30-15).

The X-ray structure of the DnaG catalytic domain in complex with a 15-nt ssDNA (Fig. 30-22), determined by James Berger, reveals a cashew-shaped protein whose fold is unrelated to those of any other DNA or RNA polymerases. It contains an ~100-residue segment that is similar in both sequence and structure to segments in types IA

**Figure 30-21** X-ray structure of *E. coli* DNA ligase in complex with a singly nicked 26-bp dsDNA and AMP. (a) The enzyme is drawn in ribbon form with its four domains colored, from N- to C-terminus, blue, aquamarine, yellow, and red. The dsDNA is shown in ladder form with the sugar–phosphate backbone of its 26-nt strand orange and those of its complementary two 13-nt strands magenta and purple. The AMP, which is covalently bound in pyrophosphate linkage to the phosphate group at the 5'-end of the purple strand, is drawn in space-filling form with C green, N blue, O red, and P orange. The side chain of Lys 115, which forms a phosphamide adduct in step 1

of the DNA ligase reaction (Fig. 30-20) is shown in stick form with C magenta and N blue. A  $Zn^{2+}$  ion, represented by a cyan sphere, is tetrahedrally liganded by four Cys residues. It is distant from the active site and therefore appears to have structural rather than catalytic function. (b) The 4 bp of nicked DNA in the boxed area of Part a in pyrophosphate linkage with the AMP together with the side chain of Lys 115 are all shown in stick form. The structure is viewed and colored as in Part a but with DNA C gray. The arrow points to the DNA's single-strand nick. [Based on an X-ray structure by Stewart Shuman, Sloan-Kettering Institute, New York, New York. PDBid 2OWO.]

**Figure 30-22** X-ray structure of *E. coli* primase in complex with ssDNA. The protein is represented by its molecular surface colored according to its electrostatic potential with red negative, white nearly neutral, and blue positive. The DNA is drawn in stick form with C and P yellow, N blue, and O red. Note the strongly basic character of the DNA binding groove and the highly acidic nature of the active site region. [Courtesy of James Berger, University of California at Berkeley. PDBid 3B39.]

and IIA topoisomerases (Section 29-3C) and has therefore been named the **Toprim fold** (for *topoisomerase* and *primase*). The Toprim fold consists of a 4-stranded parallel  $\beta$  sheet flanked by three helices that resembles the nucleotide-binding (Rossmann) fold (Section 8-3Bi). The active site is marked by several residues that are highly conserved in DnaG-type primases, and in particular, a Glu and two Asp residues, which are invariant in all known Toprim folds and which, in the X-ray structure of a type IIA topoisomerase, coordinate an  $Mg^{2+}$  ion.

The ssDNA in the structure, only 5 nt of which are visible, occupies a positively charged groove on the surface of the catalytic subunit that feeds into its active site. The protein makes only a few hydrogen bonding and van der Waals interactions with the DNA's sugar–phosphate backbone and no specific interactions with its bases. Apparently, this DNA binding groove functions to nonspecifically capture a DNA template strand and direct it to the enzyme's active site.

### 3 PROKARYOTIC REPLICATION

Bacteriophages are among the simplest biological entities and their DNA replication mechanisms reflect this fact. Much of what we know about how DNA is replicated therefore stems from the study of this process in various phages. In this section we examine DNA replication in the **coliphages** (bacteriophages that infect *E. coli*) **M13** and  $\phi$ X174 and then consider DNA replication in *E. coli* itself. Eukaryotic DNA replication is discussed in Section 30-4.

#### A. Bacteriophage M13

**Bacteriophage M13** carries a 6408-nt single-stranded circular DNA known as its **viral** or (+) strand. On infecting an *E. coli* cell, this strand directs the synthesis of its complementary or (–) strand to form the circular duplex **replicative form (RF)**, which may be either nicked (**RF II**) or supercoiled (**RF I**). This replication process (Fig. 30-23)

**Figure 30-23** The synthesis of the M13 (–) strand DNA on a (+) strand template to form M13 RF I DNA.

may be taken as a paradigm for leading strand synthesis in duplex DNA.

As the M13 (+) strand enters the *E. coli* cell, it becomes coated with SSB except at a palindromic 57-nt segment that forms a hairpin. RNA polymerase commences primer synthesis 6 nt before the start of the hairpin and extends the RNA 20 to 30 residues to form a segment of RNA–DNA hybrid duplex. The DNA that is displaced from the hairpin becomes coated with SSB so that when RNA polymerase reaches it, primer synthesis stops. Pol III holoenzyme then extends the RNA primer around the circle to form the (–) strand. The primer is removed by Pol I-catalyzed nick translation, thereby forming RF II, which is converted to RF I by the sequential actions of DNA ligase and DNA gyrase.

#### B. Bacteriophage $\phi$ X174

Bacteriophage  $\phi$ X174, as does M13, carries a small (5386 nt) single-stranded circular DNA. Curiously, the *in vivo* conversion of the  $\phi$ X174 viral DNA to its replicative form is a much more complex process than that for M13 DNA in that  $\phi$ X174 replication requires the participation of a nearly 600-kD protein assembly known as a **primosome** (Table 30-4).

##### a. $\phi$ X174 (–) Strand Replication Is a Paradigm for Lagging Strand Synthesis

$\phi$ X174 (–) strand synthesis occurs in a six-step process (Fig. 30-24):

**1.** The reaction sequence begins in the same way as that for M13: The (+) strand is coated with SSB except for a 44-nt hairpin. A 70-nt sequence containing this hairpin, known as *pas* (for *primosome assembly site*), is then recognized and bound by the PriA, PriB, and PriC proteins.

**2.** DnaB and DnaC proteins in the form of a DnaB<sub>6</sub> · DnaC<sub>6</sub> complex add to the DNA with the help of DnaT protein in an ATP-requiring process. DnaC protein is then released yielding the **preprimosome**. The preprimosome, in turn, binds primase yielding the primosome.

**Table 30-4** Proteins of the Primosome<sup>a</sup>

Protein	Subunit Structure	Subunit Mass (kD)
PriA	Monomer	76
PriB	Dimer	11.5
PriC	Monomer	23
DnaT	Trimer	22
DnaB	Hexamer	50
DnaC <sup>b</sup>	Monomer	29
Primase (DnaG)	Monomer	60

<sup>a</sup>The complex of all primosome proteins but primase is known as the preprimosome.

<sup>b</sup>Not part of the preprimosome or the primosome.

**Figure 30-24** The synthesis of the  $\phi$ X174 (-) strand on a (+) strand template to form  $\phi$ X174 RF I DNA. [After Arai, K., Low, R., Kobori, J., Schlomai, J., and Kornberg, A., *J. Biol. Chem.* **256**, 5280 (1981).]

3. The primosome is propelled in the  $5' \rightarrow 3'$  direction along the (+) strand by the PriA and DnaB helicases at the

**Figure 30-25** Electron micrograph of a primosome bound to a  $\phi$ X174 RF I DNA. Such complexes always contain a single primosome with one or two associated small DNA loops. [Courtesy of Jack Griffith, Lineberger Cancer Research Center, University of North Carolina.]

expense of ATP hydrolysis. This motion, which displaces the SSB in its path, is opposite in direction to that of template reading during DNA chain propagation.

4. At randomly selected sites, the primosome reverses its migration while primase synthesizes an RNA primer. The initiation of primer synthesis requires the participation of DnaB protein which, through concomitant ATP hydrolysis, is thought to alter template DNA conformation in a manner required by primase.

5. Pol III holoenzyme extends the primers to form Okazaki fragments.

6. Pol I excises the primers and replaces them by DNA. The fragments are then joined by DNA ligase and supercoiled by DNA gyrase to form the  $\phi$ X174 RF I.

The primosome remains complexed with the DNA (Fig. 30-25) where it participates in (+) strand synthesis (see below).

#### b. $\phi$ X174 (+) Strand Replication Serves as a Model for Leading Strand Synthesis

One strand of a circular duplex DNA may be synthesized via the **rolling circle** or  **$\sigma$ -replication** mode (so called because of the resemblance of the replicating structure to the Greek letter sigma; Fig. 30-26). The  $\phi$ X174 (+) strand is synthesized on an RF I template by a variation on this process, the **looped rolling circle mode** (Fig. 30-27):

1. (+) strand synthesis begins with the primosome-aided binding of the phage-encoded 513-residue enzyme **gene A protein** to its  $\sim 30$ -bp recognition site. There, gene A protein cleaves a specific phosphodiester bond on the (+) strand nucleotide (near the beginning of gene A) by forming a covalent bond between a Tyr residue and the DNA's 5'-phosphoryl group, thereby conserving the cleaved bond's energy.

2. Rep helicase (Section 30-2Cb) subsequently attaches to the (-) strand at the gene A protein and, with the aid of

**Figure 30-26** The rolling circle mode of DNA replication. The (+) strand being synthesized is extended from a specific cut made at the replication origin (1) so as to strip away the old (+) strand (2 and 3). The continuous synthesis of the (+) strand on a circular (-) strand template produces a series of tandemly linked (+) strands (4), which may later be separated by a specific endonuclease.

the primosome still associated with the (+) strand, commences unwinding the duplex DNA from the (+) strand's

**Figure 30-27** The synthesis of the  $\phi$ X174 (+) strand by the looped rolling circle mode. The numbered steps are described in the text.

5' end. The displaced (+) strand is coated with SSB, which prevents it from reannealing to the (-) strand. Rep helicase is essential for the replication of  $\phi$ X174 DNA, but not for the *E. coli* chromosome, as is demonstrated by the inability of  $\phi$ X174 to multiply in *rep*<sup>-</sup> *E. coli*. Pol III holoenzyme extends the (+) strand from its free 3'-OH group.

3. The extension process generates a **looped rolling circle** structure in which the 5' end of the old (+) strand remains linked to the gene A protein at the replication fork. It is thought that as the old (+) strand is peeled off the RF, the primosome synthesizes the primers required for the later generation of a new (-) strand.

4. When it has come full circle around the (-) strand, the gene A protein again makes a specific cut at the replication origin so as to form a covalent linkage with the new (+) strand's 5' end. Simultaneously, the newly formed 3'-terminal OH group of the old, looped-out (+) strand nucleophilically attacks its 5'-phosphoryl attachment to the gene A protein, thereby liberating a covalently closed (+) strand. This is possible because the gene A protein has two closely spaced Tyr residues that alternate in their attachment to the 5' ends of successively synthesized (+) strands.

The replication fork continues its progress about the duplex circle, producing new (+) strands in a manner reminiscent of linked sausages being pulled off a reel.

In the intermediate stages of a  $\phi$ X174 infection, each newly synthesized (+) strand directs the synthesis of the (-) strand to form RF I as described above. In the later stages of infection, however, the newly formed (+) strands are packaged into phage particles.

### C. *Escherichia coli*

 See Guided Exploration 25. The replication of DNA in *E. coli* The *E. coli* chromosome replicates by the bidirectional  $\theta$  mode from a single replication origin (Section 30-1Aa). The most plausible model for events at the *E. coli* replication fork (Fig. 30-28) is largely derived from studies on the simpler and more experimentally accessible DNA replication mechanisms of coliphages such as M13 and  $\phi$ X174. Duplex DNA is unwound by DnaB helicase on the lagging strand template,

**Figure 30-28** The replication of *E. coli* DNA. (a) The *E. coli* DNA replisome, which contains two DNA polymerase III holoenzyme complexes, synthesizes both the leading and the lagging strands. The lagging strand template must loop around to permit the holoenzyme to extend the primosome-primed lagging strand. Although not shown here, the DnaB helicase binds to  $\tau_2$  and hence moves with the replisome. (b) The holoenzyme releases the lagging strand template when it encounters the previously synthesized Okazaki fragment. This possibly signals the primosome to initiate the

synthesis of lagging strand RNA primer. (c) The holoenzyme rebinds the lagging strand template and extends the RNA primer to form a new Okazaki fragment. Note that in this model, leading strand synthesis is always ahead of lagging strand synthesis.

where it is joined by the primosome. The separated single strands are immediately coated by SSB. Leading strand synthesis is catalyzed by Pol III holoenzyme, as is that of the lagging strand after priming by primosome-associated primase. Both leading and lagging strand syntheses occur on a single ~900-kD multisubunit particle, the **replisome**, which contains two Pol III cores ( $\alpha\epsilon\theta$ ) that are joined together by a dimer of  $\tau$  subunits that bridges the  $\alpha$  subunits. Hence, the lagging strand template must be looped around (Fig. 30-28). The  $\tau_2$  dimer also binds the DnaB helicase (an interaction that is not indicated in Fig. 30-28), thereby stimulating its helicase action while holding it to the replication fork. After completing the synthesis of an Okazaki fragment, the lagging strand holoenzyme relocates to a new primer near the replication fork, the primer heading the previously synthesized Okazaki fragment is excised by Pol I-catalyzed nick translation, and the nick is sealed by DNA ligase. Since lagging strand synthesis is more complex and hence more time-consuming than leading strand synthesis, the replisome functions to coordinate these two processes.

### a. *E. coli* DNA Replication Is Initiated at *oriC* in a Process Mediated by DnaA Protein

The replication origin of the *E. coli* chromosome consists of a unique 250-bp segment known as the *oriC* locus. This sequence, segments of which are highly conserved among gram-negative bacteria, supports the bidirectional replication of the various plasmids into which it has been inserted. The *oriC* locus contains five highly conserved 9-bp segments with consensus sequence 5'-TTATCCACA-3' known as **DnaA boxes** because they are specifically bound by **DnaA protein** (Fig. 30-29a). These are interspersed with several so-called **I-sites** that deviate from this consensus sequence and are bound by DnaA with lesser affinity. In addition, the “left” boundary region of *oriC* contains three tandemly repeated, 13-bp, AT-rich segments (consensus sequence 5'-GATCTNTTNTTTT-3' where N marks nonspecific positions) that are known as **DNA unwinding elements (DUEs)**.

DnaA (467 residues in *E. coli*) consists of four domains that are, from N- to C-terminus, a helicase interaction domain that mediates interactions with DnaB helicase (see below), a

**Figure 30-29** DNA replication initiation at *oriC*. (a) Diagram of *oriC* showing the relative positions of its DnaA boxes (green) and its DNA unwinding elements (DUEs; yellow). (b) X-ray structure of the right-handed helical filament formed by the two C-terminal domains of *A. aeolicus* DnaA. It has eight subunits per turn and a pitch of 178 Å. Twelve subunits are shown, from right to left, in the alternating colors red, green, yellow, and blue. The right subunits are drawn as surface diagrams and the left subunits are represented by their polypeptide back bones with helices in tube form. (c) Model for initiation at *oriC*. The green ovals represent the N-terminal three domains of DnaA and the yellow ovals represent the associated C-terminal DNA-binding domains. See the text for an explanation. [Parts b and c courtesy of James Berger, University of California at Berkeley. PDBid 2HCB.]

flexible and poorly conserved linker, an ATPase domain that is a member of the AAA+ family (Section 30-2Ca), and a DNA binding domain. The X-ray structure of the C-terminal two domains of DnaA from *Aquifex aeolicus* (a thermophilic bacterium), determined by Berger, unexpectedly revealed that it forms a multisubunit right-handed helix (Fig. 30-29b).

Experiments with *oriC*-containing plasmids, pioneered by Kornberg, together with the X-ray structure of DnaA, indicate that replication initiation in *E. coli* occurs via the following process (Fig. 30-29c):

1. In the presence of ATP, DnaA, which is normally bound to three of *oriC*'s five DnaA boxes throughout *E. coli*'s lifetime, recruits additional DnaA subunits to the remaining DnaA boxes and to the I-sites so as to form a right-handed helix of DnaA subunits that is bound to the DNA. This generates local positive supercoils in the DNA. The superhelical strain resulting from the compensating negative supercoils (recall that the linking number of a covalently closed circular DNA such as an *E. coli* chromosome is invariant; Section 29-3A) melts the DUE-containing segment [Fig. 30-29c, *middle left*; recall that bacterial chromosomes are normally already negatively supercoiled (Section 29-2Bb)]. Alternatively, or in addition, the DnaA's ATPase domains may actively unwind the DNA (Fig. 30-29c, *middle right*). This process is facilitated by two homologous DNA-binding proteins, **HU** and **integration host factor (IHF)**, that induce DNA bending (IHF is discussed in Section 33-3Ca).

2. The *oriC*-DnaA complex recruits two DnaB<sub>6</sub> · DnaC<sub>6</sub> complexes to opposite ends of the melted region to form the **prepriming complex**. DnaC, an ATPase that is a homolog of DnaA, functions to facilitate the loading of the DnaB hexamers onto the DNA. Its X-ray structure, also determined by Berger, shows that it forms a helical assembly similar to that

of DnaA. The AAA+ domains of DnaA and DnaC interact in an ATP-dependent manner to recruit and properly position the DnaB helicases, following which the DnaC is released.

In the presence of SSB and gyrase, DnaB helicase further unwinds the DNA in the prepriming complex in both directions so as to permit the entry of primase and RNA polymerase. The participation of both these enzymes in leading strand primer synthesis (Section 30-1D), together with the limitation of this process to the *oriC* site, suggests that the RNA polymerase activates primase to synthesize the primer. This perhaps explains the similarity of *oriC*'s DUEs to RNA polymerase's transcriptional promoters (Section 31-2Ba). The stage is thereby set for bidirectional DNA replication by Pol III holoenzyme as described above.

### b. The Initiation of *E. coli* DNA Replication Is Strictly Regulated

*Chromosome replication in E. coli occurs only once per cell division, so this process must be tightly controlled.* The doubling (cell generation) time of *E. coli* at 37°C varies with growth conditions from <20 min to ~10 h. Yet the constant ~1000 nt/s rate of movement of each replication fork fixes the  $4.6 \times 10^6$ -bp *E. coli* chromosome's replication time, *C*, at ~40 min. Moreover, the segregation of cellular components and the formation of a septum between them, which must precede cell division, requires a constant time, *D* = 20 min, after the completion of the corresponding round of chromosome replication. *Cells with doubling times less than C + D = 60 min must consequently initiate chromosome replication before the end of the preceding cell division cycle.* This results in the formation of **multiforked chromosomes** as is diagrammed in Fig. 30-30 for a cell division time of 35 min.

Even in cells that contain multiple *oriC* sites, DNA replication is initiated at each such site once and only once per cell generation. However, after initiation has occurred, chain elongation proceeds at a uniform, largely uncontrolled rate. This suggests that a post-initiation *oriC* site is somehow sequestered from (prevented from interacting with) the replication initiation machinery, a phenomenon called **sequestration**. There is extensive morphological evidence, such as shown in Fig. 30-31, that the *E. coli* chromosome is associated with the cell membrane. This attachment

**Figure 30-30 Multiforked chromosomes in *E. coli*.** In cells that are dividing every 35 min, the fixed 60-min interval between the initiation of replication and cell division results in the production of multiforked chromosomes. [After Lewin, B., *Genes VII*, p. 370, Oxford University Press (2000).]

**Figure 30-31 Electron micrograph of an intact and supercoiled *E. coli* chromosome attached to two fragments of the cell membrane.** [From Delius, H. and Worcel, A., *J. Mol. Biol.* **82**, 108 (1974).]

would help explain how replicated chromosomes are segregated into different cells during cell division. But what is the mechanism of sequestration?

The sequence most commonly methylated in *E. coli* is the palindrome GATC, which is methylated at N6 of both its A bases by **Dam methyltransferase** (Section 30-7). GATC occurs 11 times in *oriC*, including at the beginning of all four of its 13-bp DUEs (see above). Newly replicated GATC segments are hemimethylated, that is, the GATC sequences on the newly synthesized strand are unmethylated. Although Dam methyltransferase begins methylating most hemimethylated GATC segments immediately after their synthesis (within  $\sim 1.5$  min), those on *oriC* remain hemimethylated for around one-third of a cell generation. Consequently, the observation that membranes bind hemimethylated *oriC*, but not unmethylated or fully methylated *oriC*, suggests that hemimethylated *oriC* is bound to the membrane in a way that makes it inaccessible to both the initiation machinery and Dam methyltransferase.

The association of hemimethylated *oriC* with membrane requires the presence of the 181-residue **SeqA** protein, the product of *seqA* gene. Thus in *seqA*<sup>-</sup> cells: (1) the time to fully methylate hemimethylated GATC sites in *oriC* is reduced to 5 min, whereas the time to do so for other GATC sites is unaffected; (2) the synchrony of initiation of multiple *oriC* sites is lost; and (3) in the absence of functional Dam methyltransferase, fully methylated *oriC*-containing plasmids are replicated numerous times per cell generation, whereas in the presence of SeqA they are replicated only once. Evidently, sequestration occurs via the SeqA-mediated binding of hemimethylated *oriC* to the membrane. The hemimethylated promoter of the *dnaA* gene is similarly sequestered so as to repress its transcription, thereby providing an additional mechanism for preventing promiscuous initiation of DNA replication.

### c. The Clamp Loader Loads the Sliding Clamp onto the DNA

Extensive investigations in many laboratories have led to the model of the *E. coli* replisome drawn in Fig. 30-32. The sliding clamp, which is responsible for Pol III's high processivity, is a ring-shaped dimer of  $\beta$  subunits through which the DNA strand being replicated is threaded (Section 30-2Bb). The two tightly associated  $\beta$  subunits ( $K_D < 50$  nM) that form the sliding clamp dissociate with a half-life of  $\sim 100$  min at 37°C. Yet, since each replisome synthesizes around one Okazaki fragment per second, a sliding clamp must be loaded onto the lagging strand template at this frequency. This loading function is carried out in an ATP-dependent process by the  $\gamma$  complex ( $\gamma\tau_2\delta\delta'\chi\Psi$ ). The  $\tau$  and  $\gamma$  subunits are both encoded by the *dnaX* gene with  $\tau$  (643 residues) the full-length product and  $\gamma$  (431 residues) its C-terminally truncated form; the C-terminal 122 residues of  $\tau$  are known as  $\tau_c$ . The  $\gamma$  complex, of which only  $\tau_2$  is diagrammed in Fig. 30-28, bridges the replisome's two Pol III cores via its  $\tau_c$  segments, which also bind the DnaB helicase (Fig. 30-32). The  $\chi$  and  $\Psi$  subunits form a heterodimer in which  $\chi$  competes with primase for its binding site on SSB and hence functions to accelerate the dissociation of primase from the RNA primer it synthesized as well as link the  $\gamma$  complex to SSB. However,  $\chi$  and  $\Psi$  are not essential participants in the clamp loading process and, therefore, we shall refer to the  $\gamma\tau_2\delta\delta'$  complex as the **clamp loader**. How does the clamp loader do its job?

Of the clamp loader's five subunits, only  $\delta$  is capable of binding to and opening up the sliding clamp on its own. Kuriyan and O'Donnell determined the X-ray structure of the  $\delta$  subunit in 1:1 complex with a  $\beta$  subunit that had two residues in its dimerization interface mutated so as to prevent its dimerization. The structure reveals (Fig. 30-33) that  $\delta$ , which consists of three domains, inserts its  $\beta$  interaction element, a hydropho-

**Figure 30-32** Architecture of the *E. coli* replisome. See the text for details. Compare this to Fig. 30-28. [Courtesy of Charles Richardson, Harvard Medical School.]

**Figure 30-33** X-ray structure of the  $\beta$ - $\delta$  complex. A second  $\beta$  subunit taken from the X-ray structure of the sliding clamp (Fig. 30-13), the “Reference  $\beta$  monomer,” is drawn in gray. The view is along the edge of the  $\beta$  ring. The  $\delta$  subunit’s  $\beta$  interaction element (yellow) consists largely of the  $\alpha 4$  helix and two hydrophobic residues, Leu 73 and Phe 74, whose side chains are drawn in stick form. [Courtesy of John Kuriyan, University of California at Berkeley. PDB 1JQJ.]

bic plug that forms the tip of its N-terminal domain, into a hydrophobic pocket on one face of  $\beta$ . Comparison of  $\delta$  in this structure with that in the  $\gamma_3\delta\delta'$  complex (see below) reveals that the  $\beta$  interaction element undergoes a dramatic conformational change on binding to  $\beta$  in which its  $\alpha 4$  helix rotates by  $45^\circ$  and translates by  $5.5 \text{ \AA}$ . Moreover, in forming the  $\beta$ - $\delta$

complex, the  $\beta$  subunit increases its radius of curvature relative to that in the  $\beta$  dimer (Fig. 30-13) such that the  $\beta$ - $\delta$  interaction would induce the opening of one of the sliding clamp’s  $\beta$ - $\beta$  interfaces by  $\sim 15 \text{ \AA}$ . Such a gap is large enough to permit the passage of ssDNA but not dsDNA. Apparently, the clamp loader functions by trapping one  $\beta$  subunit of the sliding clamp in a conformation that prevents ring closure rather than actively pulling apart the two halves of the ring. This is corroborated by molecular dynamics simulations (Section 9-4a) suggesting that a  $\beta_2$  dimer has a stable conformation but that an isolated  $\beta$  subunit with the conformation it has in the  $\beta_2$  dimer rapidly (in  $\sim 1.5 \text{ ns}$ ) converts to a conformation resembling that in the  $\beta$ - $\delta$  complex. Thus, the conformational change of the  $\delta$  subunit’s  $\beta$  interaction element on binding to a  $\beta$  subunit is reminiscent of the action of a plumber’s wrench in unlatching the nearby  $\beta$ - $\beta$  interface so as to allow the sliding clamp to spring open.

The X-ray structure of the  $\gamma_3\delta\delta'$  complex (the clamp loader with both its  $\tau$  subunits lacking  $\tau_c$ ;  $\gamma$  and  $\tau$  are interchangeable in terms of their clamp loading functions) in complex with a primer-*template* DNA and  $\text{ADP} \cdot \text{BeF}_3$  (an ATP analog), also determined by Kuriyan and O’Donnell, suggests how the clamp loader functions. The  $\gamma$ ,  $\delta$ , and  $\delta'$  subunits all have similar folds; their N-terminal domains are all members of the widely distributed AAA+ family (DnaA and DnaC proteins are also members of this family) even though only the  $\gamma$  (and  $\tau$ ) subunits bind and hydrolyze ATP. The conserved regions of AAA+ proteins consist of two domains, an N-terminal ATP-binding domain and a smaller domain composed of a 3-helix bundle, whose relative orientations vary with ATP binding. The  $\gamma_3\delta\delta'$  pentamer’s C-terminal domains form a ring-shaped collar (Fig. 30-34a) in which the subunits are arranged in clockwise order  $\delta'$ - $\gamma 1$ - $\gamma 2$ - $\gamma 3$ - $\delta$  (Fig. 30-34b). The AAA+ domains are arranged in a right-handed spiral that tracks the minor groove of the dsDNA. Nevertheless, the clamp

**Figure 30-34** X-ray structure of the  $\gamma_3\delta\delta'$  clamp loader in complex with a primer-*template* DNA and  $\text{ADP} \cdot \text{BeF}_3$ . (a) View between the  $\delta'$  and  $\delta$  subunits approximately perpendicular to the dsDNA’s helical axis. The protein is drawn in tube-and-arrow form with its subunits colored as indicated and with the C-terminal domain of each subunit a lighter shade. The DNA consists of 10 bp with a 5’ overhang of 5 nt and, together with the  $\text{ADP} \cdot \text{BeF}_3$ , is drawn in space-filling form with primer C cyan, template C green, ADP C magenta, N blue, O red, and P orange,

Be light green, and F light blue. (b) View rotated  $90^\circ$  about the horizontal axis relative to Part a. The C-terminal domain of each subunit has been deleted for clarity. Note how the single-stranded portion of the template strand turns by  $\sim 90^\circ$  to avoid colliding with the collar formed by the clamp loader’s C-terminal domains. The stiffness of dsDNA makes it unlikely that it could make such a turn. [Based on an X-ray structure by Mike O’Donnell, The Rockefeller University, and John Kuriyan, University of California at Berkeley. PDBid 3GLF.]

loader associates with the DNA almost entirely through contacts with the phosphate groups of the template strand alone. Thus, this structure is reminiscent of that of the E1 helicase in complex with ssDNA (Section 30-2Ca) with one of its six subunits missing.

The clamp loader must tightly bind the sliding clamp prior to its loading on the template DNA but must subsequently release the clamp to avoid interfering with its binding to the Pol III core ( $\alpha\epsilon\theta$ ). The structures of the clamp loader and the  $\beta$ - $\delta$  complex, together with a variety of biochemical evidence, suggest a model of how this might occur (Fig. 30-35): The binding of ATP to  $\gamma 1$  (the  $\gamma$  subunit that contacts  $\delta'$ ) results in a conformational change that exposes the otherwise occluded ATP-binding site of  $\gamma 2$ ; ATP binding to  $\gamma 2$  likewise exposes  $\gamma 3$ ; and ATP binding to  $\gamma 3$  exposes the  $\delta$  subunit's  $\beta$  interaction element, thereby permitting it to bind to a  $\beta$  subunit so as to spring open the sliding clamp. Primer-template DNA then inserts itself through the resulting gap in the sliding clamp. This process is facilitated by the gap between the AAA+ domains of  $\delta$  and  $\delta'$  subunits, which permits the clamp loader to track the template strand while avoiding contact with the primer strand. Eventually,  $\beta$ - and DNA-stimulated hydrolysis of the bound ATPs releases the  $\beta$  subunit from the clamp loader, whereon the sliding clamp closes around the DNA.

The departure of the clamp loader permits the Pol III core to bind to the sliding clamp. However, when the synthesis of an Okazaki fragment has been completed, the Pol III core must dissociate from the sliding clamp so that it can initiate the synthesis of the next Okazaki fragment. How does this occur?

Pol III's  $\alpha$  subunit binds to the same hydrophobic pocket on the  $\beta_2$  sliding clamp as does the  $\delta$  subunit. This was shown by the observations that the phosphorylation of a kinase recognition sequence that had been engineered into the C-terminal segment of  $\beta$  is inhibited by both  $\alpha$  and  $\delta$ . The  $\beta$  subunit has an  $\sim 30$ -fold greater affinity for the  $\gamma$  complex in the presence of ATP than it has for the Pol III core. However, when primer-template DNA is also present, this order of affinity is reversed with  $\beta$  preferring to bind to the Pol III core (possibly due to the additional con-

tacts between the core and the DNA). Thus once the sliding clamp has been loaded onto the primer-template, the clamp loader is replaced by the Pol III core, which thereby blocks the clamp loader from unloading the clamp. Instead, the clamp loader loads a new clamp onto the lagging strand template in association with the primer that the primosome had synthesized in preparation for the next round of Okazaki fragment synthesis (Fig. 30-28b).

The X-ray structure of the sliding clamp in complex with primer-template DNA (Fig. 30-13) indicates that its ssDNA segment binds to the same site as do the  $\alpha$  and  $\delta$  subunits. This may serve to attract the primer-template DNA to the inside of the open clamp, which in turn may facilitate the release of the clamp loader and hence the closure of the sliding clamp. The binding of ssDNA to the sliding clamp may also prevent it from sliding away before it can be bound by the  $\alpha$  subunit.

When the Pol III core has completed its synthesis of the Okazaki fragment, that is, when the gap between the two successively synthesized Okazaki fragments has been reduced to a nick, it releases the DNA and the sliding clamp. The Pol III core then binds to the newly primed template and its associated clamp (displacing the clamp loader), where it commences the synthesis of the next Okazaki fragment. Thus, a series of switches that are activated by ATP and DNA structure ensure the vectorial progression of lagging strand replication. Throughout this process, the Pol III holoenzyme is held at the replication fork by the leading strand Pol III core, which remains tethered to the DNA by its associated sliding clamp.

The sliding clamp that remains around the completed Okazaki fragment probably functions to recruit Pol I and DNA ligase so as to replace the RNA primer on the previously synthesized Okazaki fragment with DNA and seal the remaining nick. However, the sliding clamp must eventually be recycled. It was initially assumed that this was the job of the clamp loader. However, it is now clear that the release of the sliding clamp from its associated DNA is largely carried out by free  $\delta$  subunit (the "wrench" in the clamp loader that cracks apart the  $\beta$  subunits forming the sliding clamp), which is synthesized in 5-fold excess over that required to populate the cell's few clamp loaders.

**Figure 30-35** Schematic diagram of the clamp loader cycle.

This speculative model is based on a combination of structural and biochemical information. The "arginine finger," an Arg side chain that interacts with the  $\gamma$ -phosphate group of an ATP bound

to a neighboring subunit, is a common feature of AAA+ ATPases that form ringlike structures. [Modified from a drawing by Mike O'Donnell, The Rockefeller University, and John Kuriyan, University of California at Berkeley.]

#### d. Replication Termination Is Facilitated by Tus Protein

The *E. coli* replication terminus is a large (350 kb) region flanked by ten nearly identical nonpalindromic ~23-bp terminator sites, *TerH*, *TerI*, *TerE*, *TerD*, and *TerA* on one side and *TerJ*, *TerG*, *TerF*, *TerB*, and *TerC* on the other (Fig. 30-36; note that *oriC* is directly opposite the terminus region on the *E. coli* chromosome). A replication fork traveling counterclockwise as drawn in Fig. 30-36 passes through *TerJ*, *TerG*, *TerF*, *TerB*, and *TerC* but stops on encountering either *TerA*, *TerD*, *TerE*, *TerI*, or *TerH* (*TerD*, *TerE*, *TerI*, and *TerH* are presumably backup sites for *TerA*). Similarly, a clockwise-traveling replication fork transits *TerH*, *TerI*, *TerE*, *TerD*, and *TerA* but halts at *TerC* or, failing that, *TerB* or *TerF* or *TerG* or *TerI*. Thus, these termination sites act as one-way valves that allow replication forks to enter the termination region but not to leave it. This arrangement guarantees that the two replication forks generated by bidirectional initiation at *oriC* will meet in the replication terminus even if one of them arrives there well ahead of its counterpart.

The arrest of replication fork motion at *Ter* sites requires the action of **Tus** protein, a 309-residue monomer that is the product of the *tus* gene (for terminator utilization substance). Tus specifically binds to a *Ter* site, where it prevents strand displacement by DnaB helicase, thereby arresting replication fork motion. The X-ray structure of Tus in complex with a 15-bp *Ter* sequence-containing DNA with a single T overhang at each 5' end, determined by Kosuke Morikawa, reveals that Tus consists of two domains that

form a deep positively charged cleft that largely envelops the bound DNA (Fig. 30-37). A 5-bp segment of the DNA near the side of Tus that permits the passage of the replication fork (the lower side of Fig. 30-37) is deformed and underwound relative to canonical (ideal) B-DNA such that its major groove becomes deeper and its minor groove is significantly expanded. The protein makes polar contacts with more than two-thirds of the phosphate groups in a 13-bp region and its interdomain  $\beta$  sheet penetrates the deepened major groove to make sequence-specific contacts with the exposed bases. The importance of this interdomain region for Tus function is demonstrated by the observation that most single residue mutations that reduce the ability of Tus to arrest replication occur in this interdomain region.

When Tus is fused to another DNA-binding protein, replication is inhibited at the other protein's binding site. This suggests that Tus does not act as a simple DNA-binding clamp, but interacts with DnaB helicase, the leading component of a replication fork (Fig. 30-32), to inhibit its helicase action. Apparently, Tus prevents the progress of DnaB in unwinding DNA from one side of Tus but not the other. Indeed, the encounter of DnaB with a Tus–*Ter* complex in the permissive direction causes Tus to rapidly dissociate from the DNA, whereas such an encounter from the nonpermissive direction generates a so-called locked Tus–*Ter* complex. Nevertheless, the way Tus and DnaB interact is unknown. Curiously, however, this termination system is not essential for termination. When the replication

**Figure 30-36** Map of the *E. coli* chromosome showing the positions of the *Ter* sites and the *oriC* site. The *TerJ*, *TerG*, *TerF*, *TerB*, and *TerC* sites, in combination with Tus protein, allow a counterclockwise-moving replisome to pass but not a clockwise-moving replisome. The opposite is true of the *TerH*, *TerI*, *TerE*, *TerD*, and *TerA* sites. Consequently, two replication forks that initiate bidirectional DNA replication at *oriC* will meet between the oppositely facing *Ter* sites.

**Figure 30-37** X-ray structure of *E. coli* Tus protein in complex with a 15-bp *Ter*-containing DNA. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The DNA is shown in stick form with C gray, N blue, O red, and P orange and with successive P atoms in the same strand joined by orange rods. **Figure 30-38** The formation and separation of catenated dsDNAs at the replication termination site. The parental strands are red and black and the daughter strands are green and blue.

For clarity, the double helical character of the newly formed dsDNA molecules is not shown.

terminus is deleted, replication simply stops, apparently through the collision of opposing replication forks. Nevertheless, this termination system is highly conserved in gram-negative bacteria.

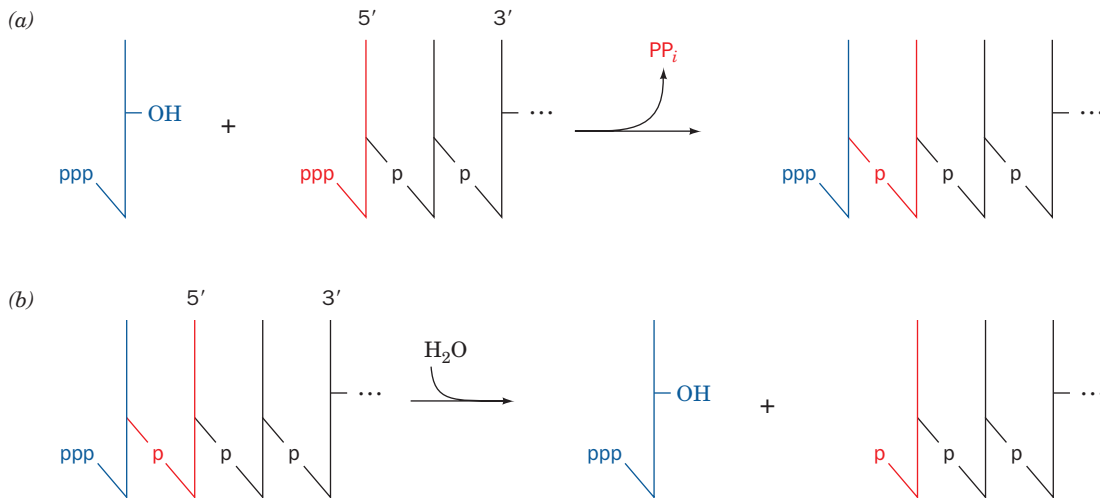

As two oppositely moving replication forks collide at the termination site, the newly synthesized strands become covalently linked to yield two covalently closed double-stranded chromosomes. However, since the parental DNA strands remain wound about each other by several turns (presumably, DNA gyrase cannot gain access to the DNA when the colliding replication forks closely approach each other), the product dsDNA strands must be wound about each other by the same number of turns (Fig. 30-38). The resulting catenated circular dsDNAs must be separated so that each can be passed to a different daughter cell. This is the job of the type II topoisomerase named topoisomerase IV (Section 29-3Cd).

#### D. Fidelity of Replication

Since a single polypeptide as small as the Pol I Klenow fragment can replicate DNA by itself, why does *E. coli* maintain a battery of >20 intricately coordinated proteins to replicate its chromosome? The answer apparently is to ensure the nearly perfect fidelity of DNA replication required to preserve the genetic message's integrity from generation to generation.

The rates of reversion of mutant *E. coli* or T4 phage to the wild type indicates that only one mispairing occurs per  $10^8$  to  $10^{10}$  base pairs replicated. This corresponds to  $\sim 1$  error per 1000 bacteria per generation. Such high replication accuracy arises from four sources:

1. Cells maintain balanced levels of dNTPs through the mechanism discussed in Section 28-3Ad. This is an important aspect of replication fidelity because a dNTP present

**Figure 30-39** Chemical consequences if a DNA polymerase could synthesize DNA in its 3' → 5' direction. (a) The coupling of each nucleoside triphosphate to the growing chain would be driven by the hydrolysis of the previously appended nucleoside

triphosphate. (b) The editorial removal of an incorrect 5'-terminal nucleoside triphosphate would render the DNA chain incapable of further extension.

at aberrantly high levels is more likely to be misincorporated and, conversely, one present at low levels is more likely to be replaced by the dNTPs present at higher levels.

2. The polymerase reaction itself has extraordinary fidelity. This is because, as we have seen (Section 30-2Ae), the polymerase reaction occurs in two stages: (1) a binding step in which the incoming dNTP base-pairs with the template while the enzyme is in an open conformation that cannot catalyze the polymerase reaction; and (2) a catalysis step in which the polymerase forms a closed conformation about the newly formed base pair, which properly positions its catalytic residues (induced fit). Since the formation of the closed conformation requires that the incoming dNTP form a Watson-Crick-shaped base pair with the template, the conformation change constitutes a double check for correct base pairing.

3. The 3' → 5' exonuclease functions of Pol I and Pol III detect and eliminate the occasional errors made by their polymerase functions. In fact, mutations that increase a DNA polymerase's proofreading exonuclease activity decrease the rates of mutation of other genes.

4. A remarkable battery of enzyme systems, contained in all cells, function to repair residual errors in the newly synthesized DNA as well as any damage that it may incur after its synthesis through chemical and/or physical insults. We discuss these DNA repair systems in Section 30-5.

In addition, *the inability of a DNA polymerase to initiate chain elongation without a primer is a feature that increases DNA replication fidelity.* The first few nucleotides of a chain to be coupled together are those most likely to be mispaired because of the cooperative nature of base pairing interactions (Section 29-2). The editing of a short duplex oligonucleotide is similarly an error-prone process. The use of RNA primers eliminates this source of error since the

RNA is eventually replaced by DNA under conditions that permit accurate base pairing to be achieved.

One might wonder why cells have evolved the complex system of discontinuous lagging strand synthesis rather than a DNA polymerase that could simply extend DNA chains in their 3' → 5' direction. Consideration of the chemistry of DNA chain extension also leads to the conclusion that this system promotes high-fidelity replication. The linking of 5'-deoxynucleotide triphosphates in the 3' → 5' direction would require the retention of the growing chain's 5'-terminal triphosphate group to drive the next coupling step (Fig. 30-39a). On editing a mispaired 5'-terminal nucleotide (Fig. 30-39b), this putative polymerase would—in analogy with Pol I, for example—excise the offending nucleotide, leaving either a 5'-OH or a 5'-phosphate group. Neither of these terminal groups is capable of energizing further chain extension. A proofreading 3' → 5' DNA polymerase would therefore have to be capable of reactivating its edited product. The inherent complexity of such a system has presumably selected against its evolution.

## 4 EUKARYOTIC REPLICATION

*There is a remarkable degree of similarity between eukaryotic and prokaryotic DNA replication mechanisms.* Nevertheless, there are important differences between these two replication systems as a consequence of the vastly greater complexity of eukaryotes in comparison to prokaryotes. For example, eukaryotic chromosomes are structurally complicated and dynamic complexes of DNA and protein (Section 34-1) with which the replication machinery must interact in carrying out its function. Consequently, as is true of most aspects of biochemistry, our knowledge of how DNA is replicated in eukaryotes has lagged well behind that for prokaryotes, although in recent years there has

been significant progress in our understanding of this essential process. In this section, we outline what is known about DNA replication in eukaryotes. We also discuss two DNA polymerases that are peculiar to eukaryotic systems: reverse transcriptase and telomerase.

### A. The Cell Cycle

The **cell cycle**, the general sequence of events that occur during the lifetime of a eukaryotic cell, is divided into four distinct phases (Fig. 30-40):

1. Mitosis and cell division occur during the relatively brief **M phase** (for *mitosis*).
2. This is followed by the **G<sub>1</sub> phase** (for *gap*), which covers the longest part of the cell cycle. This is the main period of cell growth.
3. G<sub>1</sub> gives way to the **S phase** (for *synthesis*), which in contrast to events in prokaryotes, *is the only period in the cell cycle when DNA is synthesized*.
4. During the relatively short **G<sub>2</sub> phase**, the now tetraploid cell prepares for mitosis. It then enters M phase once again and thereby commences a new round of the cell cycle.

The cell cycle for cells in culture typically occupies a 16- to 24-h period. In contrast, cell cycle times for the different types of cells of a multicellular organism may vary from as little as 8 h to >100 days. Most of this variation occurs in the G<sub>1</sub> phase. Moreover, many terminally differentiated cells, such as neurons or muscle cells, never divide; they assume a quiescent state known as the **G<sub>0</sub> phase**.

A cell's irreversible "decision" to proliferate is made during G<sub>1</sub>. Quiescence is maintained if, for example, nutrients are in short supply or the cell is in contact with other cells (**contact inhibition**). Conversely, DNA synthesis may be induced by various agents such as carcinogens or tumor viruses, which trigger uncontrolled cell proliferation (can-

**Figure 30-40** The eukaryotic cell cycle. Cells in G<sub>1</sub> may enter a quiescent phase (G<sub>0</sub>) rather than continuing about the cycle.

cer; Sections 19-3B and 34-4C); by the surgical removal of a tissue, which results in its rapid regeneration; or by proteins known as **mitogens**, which bind to cell-surface receptors and induce cell division (Section 34-4D).

#### a. The Cell Cycle Is Controlled by Cyclins and Cyclin-Dependent Protein Kinases

The progression of a cell through the cell cycle is regulated by proteins known as **cyclins** and **cyclin-dependent protein kinases (Cdks)**. Cyclins are so named because they are synthesized during one phase of the cell cycle and completely degraded during a succeeding phase (protein degradation is discussed in Section 32-6). A particular cyclin specifically binds to and thereby activates its corresponding Cdk(s) to phosphorylate its target proteins, thus activating these proteins to carry out the processes comprising that phase of the cell cycle. In order to enter a new phase in the cell cycle, a cell must satisfy a corresponding **checkpoint**, which monitors whether the cell has satisfactorily completed the preceding phase [e.g., the attachment of all chromosomes to the mitotic spindle must precede mitosis (Section 1-4Aa); if this were not the case for even one chromosome, one daughter cell would lack this chromosome and the other would have two, both deleterious if not lethal conditions]. If the cell has not met the criteria of the checkpoint, the cell cycle is slowed or even arrested until it does so. We further discuss cell cycle control in Section 34-4C.

### B. Eukaryotic Replication Mechanisms

Much of what we know about eukaryotic DNA replication has been learned from studies on budding yeast (*Saccharomyces cerevisiae*) and fission yeast (*Schizosaccharomyces pombe*), the simplest eukaryotes, and on simian virus 40 (SV40), which has a 5243-bp circular DNA chromosome that has only one replication origin. However, studies of DNA replication in the cells of **metazoa** (multicellular animals), particularly *Drosophila*, *Xenopus laevis* (an African clawed toad, whose eggs are easily studied), and humans, have also led to important advances in our knowledge.

#### a. Eukaryotic Cells Contain Numerous DNA Polymerases

The many known DNA polymerases can be classified into six families based on phylogenetic relationships. Members of families A (e.g., *E. coli* Pol I), B (e.g., *E. coli* Pol II), and C (e.g., *E. coli* Pol III) encompass all replicative polymerases as well as some repair polymerases, family D occurs only in archaea where its functions are poorly understood, and families X and Y participate in DNA repair. The fingers and thumb domains have structures that are unique to each family, whereas the catalytic residue-containing palm domains are similar in families A, B, and Y. Animal cells express at least four distinct types of DNA polymerases that are implicated in DNA replication (Table 30-5). They are designated, in the order of their discovery, DNA polymerases (pols)  $\alpha$ ,  $\gamma$ ,  $\delta$ , and  $\epsilon$  (alternatively, POLA, POLG, POLD1, and POLE), of which pol  $\gamma$  is a member of family A and the others are members of family B.

**Table 30-5** Properties of Eukaryotic DNA Polymerases That Participate in DNA Replication

	$\alpha$	$\gamma$	$\delta$	$\epsilon$
Location	Nucleus	Mitochondrion	Nucleus	Nucleus
Subunit masses (kD) <sup>a</sup>	167, 79, 62, 48 (166, 66, 59, 50)	144 (140, 55)	125, 55, 40 (124, 51, 51)	256, 78, 23, 22 (262, 60, 17, 12)
Family	B	A	B	B

<sup>a</sup>Yeast *S. cerevisiae* (human cells).

Source: Mainly Johnson, A. and O'Donnell, M., *Annu. Rev. Biochem.* **74**, 283 (2005).

**Pol  $\alpha$**  occurs only in the cell nucleus where it participates in the replication of chromosomal DNA. This function was largely established through the use of its specific inhibitor **aphidicolin**

and by the observation that pol  $\alpha$  activity varies with the rate of cellular proliferation. Pol  $\alpha$ , as do all DNA polymerases, replicates DNA by extending a primer 5'  $\rightarrow$  3' under the direction of a single-stranded DNA template. This heterotetramer, which lacks exonuclease activity, consists of a 167-kD polymerase subunit, a 48-kD primase subunit, a 62-kD subunit that is required for full primase activity, and a 79-kD subunit that is implicated in the regulation of initiation, all of which are collectively known as **pol  $\alpha$ /primase**.

**Pol  $\delta$**  is a heterotrimer whose 125-kD catalytic subunit lacks an associated primase but contains a proofreading 3'  $\rightarrow$  5' exonuclease domain. The X-ray structure of the yeast pol  $\delta$  catalytic subunit (also called pol  $\delta$ ), determined by Aneel Aggarwal, reveals that this enzyme consists of five domains arranged around a central hole that is near its polymerase active site (Fig. 30-41). It has the right-hand-like architecture first seen in A-family DNA polymerases (Figs. 30-8 and 30-9), and its palm domain has a structurally similar core that contains the two invariant Asp residues implicated in the nucleotidyl transfer mechanism (Fig. 30-10). However, there are major differences between A-family polymerases (e.g., Fig. 30-8) and pol  $\delta$ , which is representative of B-family polymerases. Most notably, in pol  $\delta$ :

1. The fingers domain, which consists of only a pair of antiparallel helices, is rotated by  $\sim 60^\circ$  relative to that in A-family polymerases.

2. The exonuclease domain projects from the top of the fingers domain rather than from the bottom of the palm domain, as it does in A-family polymerases.

3. There is a large N-terminal domain that A-family polymerases lack.

4. The template strand enters the active site from a cleft between the N-terminal and exonuclease domains, whereas in A-family polymerases, it does so from the fingers domain.

5. The newly formed dsDNA nearest the active site has a B-DNA-like conformation instead of the A-DNA-like conformation observed in A-family polymerases (Section 30-2Ae).

**Figure 30-41** X-ray structure of yeast DNA polymerase  $\delta$  (pol  $\delta$ ) in complex with primer-template DNA and dCTP. The protein is drawn in ribbon form with its five domains differently colored as indicated. The DNA, whose primer and template strands consist of 12 and 16 nt, together with the incoming dCTP, is drawn in stick form with template C green, primer C cyan, dCTP C magenta, N blue, O red, and P orange and with successive P atoms in each DNA strand connected by orange rods. The  $\text{Ca}^{2+}$  ions at the polymerase (Pol) active site are represented by dark green spheres as is the  $\text{Ca}^{2+}$  ion at the exonuclease (Exo) active site. [Based on an X-ray structure by Aneel Aggarwal, Mount Sinai School of Medicine, New York, New York. PDBid 3IAY.]

In contrast to pol  $\alpha$ , which exhibits only moderate processivity ( $\sim 100$  nucleotides), that of pol  $\delta$  is essentially unlimited (replicates the entire length of a template), but only when it is in complex with a protein named **proliferating cell nuclear antigen (PCNA)**; so named because it occurs only in the nuclei of proliferating cells and reacts with antibodies produced by a subset of patients with the autoimmune disease systemic lupus erythematosus). The X-ray structure of PCNA (Fig. 30-42), determined by Kuriyan, reveals that it forms a trimeric ring with almost identical structure (and presumably function) as the *E. coli*  $\beta_2$  sliding clamp (Fig. 30-13). Thus, each PCNA subunit consists of four rather than six of the structurally similar  $\beta\alpha\beta\beta$  motifs from which the *E. coli*  $\beta$  subunit is constructed. Intriguingly, PCNA and the  $\beta$  subunit exhibit no significant sequence identity, even when their structurally similar portions are aligned. Archaea also have sliding clamps with pseudo-hexagonal symmetry.

Pol  $\delta$  in complex with PCNA is required for lagging strand synthesis. In contrast, pol  $\alpha$ /primase functions to synthesize  $\sim 12$ -nt RNA primers, which it extends by an additional  $\sim 20$  nt of DNA. Then, in a process called **polymerase switching**, the eukaryotic counterpart of the *E. coli* clamp loader (Section 30-3Cc), **replication factor C (RFC)**, displaces the pol  $\alpha$  and loads PCNA on the template DNA

**Figure 30-42** X-ray structure of human PCNA. Its three subunits, which form a 3-fold symmetric ring, are drawn in ribbon form embedded in their semitransparent surface diagram. One of these subunits is colored in rainbow order from its N-terminus (blue) to its C-terminus (red), another is pink, and the third is light green. A space-filling model of B-DNA viewed along its helix axis has been drawn in the center of the PCNA ring. Compare this structure with that of the  $\beta_2$  sliding clamp of the *E. coli* Pol III holoenzyme (Fig. 30-13). [Based on an X-structure by John Kuriyan, University of California at Berkeley. PDBid 1AXC.]  See Interactive Exercise 35

near the primer strand, following which pol  $\delta$  binds to the PCNA and processively extends the DNA strand.

RFC, like the *E. coli* clamp loader, is a heteropentamer of AAA+ family subunits, but whereas the clamp loader contains three identical subunits ( $\gamma_3\delta\delta'$ ), RFC consists of five different subunits, RFC-A through RFC-E (alternatively, RFC1–RFC5). The X-ray structure of yeast RFC in complex with PCNA (Fig. 30-43), determined by O'Donnell and Kuriyan, reveals that RFC's A, B, and C subunits bind in conserved hydrophobic grooves on the face of PCNA on which its C-terminal residues are located (since PCNA's three identical subunits are linked head-to-tail, its two faces are different). In fact, this so-called C side of PCNA, which faces away from the direction of polymerase motion, binds many of the proteins that participate in replicative processes, including most DNA polymerases, and hence PCNA plays a major role in

**Figure 30-43** X-ray structure of yeast RFC in complex with PCNA, ADP, and ATP $\gamma$ S. Both proteins are drawn in tube-and-arrow form with the RFC subunits colored as their homologs in Fig. 30-34a (with the RFC-A, B, C, D, and E subunits corresponding to the *E. coli* clamp loader's  $\delta$ ,  $\gamma_3$ ,  $\gamma_2$ ,  $\gamma_1$ , and  $\delta'$  subunits, respectively) and the PCNA colored as in Fig. 30-42. The view is similar to that of the *E. coli* clamp loader in Fig. 30-34a. ADP, which binds to only RFC-E, and ATP $\gamma$ S, which binds to the other four subunits, are shown in space-filling form with ATP $\gamma$ S C green, ADP C magenta, N blue, O red, P orange, and S yellow. Note that all five RFC subunits have a nucleotide binding site, whereas the *E. coli*  $\delta$  and  $\delta'$  subunits do not. [Based on an X-ray structure by Mike O'Donnell, The Rockefeller University, and John Kuriyan, University of California at Berkeley. PDBid 1SXJ.]

recruiting the components of the various types of replication forks. The C-terminal domains of each RFC subunit associate to form a ring-shaped collar, as do the C-terminal domains of the *E. coli* clamp loader (Fig. 30-34). Likewise, RFC's AAA+ domains are arranged in a right-handed spiral that matches the helical path of the sugar-phosphate backbone of B-DNA. Presumably, prokaryotic and eukaryotic clamp loaders interact with primer-template DNA and their corresponding sliding clamps in similar ways.

**Pol  $\epsilon$** , a heterotetrameric nuclear enzyme, is the most enigmatic participant in DNA replication. Pol  $\epsilon$  is highly processive in the absence of PCNA and has a 3'  $\rightarrow$  5' exonuclease activity that degrades single-stranded DNA to 6- or 7-residue oligonucleotides rather than to mononucleotides, as does that of pol  $\delta$ . Although pol  $\epsilon$  is necessary for the viability of yeast, its essential function can be carried out by only the noncatalytic C-terminal half of its 256-kD catalytic subunit, which is unique among B-family DNA polymerases. This suggests that the C-terminal half of the pol  $\epsilon$  catalytic subunit is required for the assembly of the replication complex. Nevertheless, Thomas Kunkel has shown that pol  $\epsilon$  is probably the leading strand replicase, although it may also contribute to lagging strand synthesis. Moreover, pol  $\delta$  may also participate in leading strand synthesis.

**Pol  $\gamma$** , a monomer, occurs exclusively in the mitochondrion, where it presumably replicates the mitochondrial DNA. Chloroplasts contain a similar enzyme.

Eukaryotic cells contain batteries of DNA polymerases. These include the DNA polymerases that participate in chromosomal DNA replication (pols  $\alpha$ ,  $\delta$ , and  $\epsilon$ ) and several that take part in DNA repair processes (Section 30-5) including **pols  $\beta$ ,  $\eta$ ,  $\iota$ ,  $\kappa$ , and  $\zeta$**  (alternatively, POLB, POLH, POLI, POLK, and POLZ). Pol  $\beta$ , an X-family enzyme, is remarkable for its small size (a 335-residue monomer in humans).

### b. Eukaryotic Chromosomes Consist of Numerous Replicons

*Eukaryotic and prokaryotic DNA replication systems differ most obviously in that eukaryotic chromosomes have multiple replication origins in contrast to the single replication origin of prokaryotic chromosomes.* Eukaryotic cells replicate DNA at the rate of  $\sim 50$  nt/s ( $\sim 20$  times slower than does *E. coli*) as was determined by autoradiographically measuring the lengths of pulse-labeled sections of eukaryotic chromosomes. Since a eukaryotic chromosome typically contains 60 times more DNA than those of prokaryotes, its bidirectional replication from a single origin would require  $\sim 1$  month to complete. Electron micrographs such as Fig. 30-44, however, reveal that eukaryotic chromosomes contain multiple origins, one every 3 to 300 kb depending on both the species and the tissue, so that S phase usually occupies only a few hours.

Cytological observations indicate that the various chromosomal regions are not all replicated simultaneously; rather, clusters of 20 to 80 adjacent **replicons**

**Figure 30-44** Electron micrograph of a fragment of replicating *Drosophila* DNA. The arrows indicate its multiple replication eyes. [From Kreigstein, H.J. and Hogness, D.S., *Proc. Natl. Acad. Sci.* **71**, 136 (1974).]

(replication units; DNA segments that are each served by a replication origin) are activated simultaneously. New replicons are activated throughout S phase until the entire chromosome has been replicated. During this process, replicons that have already been replicated are distinguished from those that have not; that is, *a cell's chromosomal DNA is replicated once and only once per cell cycle.*

### c. The Assembly of the Eukaryotic Initiation Complex Occurs in Two Stages

The once-and-only-once replication of eukaryotic DNA per cell cycle is conferred by a type of binary switch. A **pre-replicative complex (pre-RC)** is assembled at each replication origin during the G<sub>1</sub> phase of the cell cycle. This is the only period of the cell cycle during which the pre-RC can form and hence this process is known as **licensing**. However, a licensed pre-RC cannot initiate DNA replication. Rather, it must be activated to do so, a process that occurs only during S phase. *This temporal separation of pre-RC assembly and origin activation ensures that a new pre-RC cannot assemble on an origin that has already "fired" (commenced replication) so that an origin can only fire once per cell cycle.* How does this occur?

The licensing process and how the pre-RC is activated to form an initiation complex are still incompletely understood. Thus, although it appears that most of the proteins forming these complexes have been identified, their structures, interactions, and, in many cases, their functions are largely unknown. Keeping this in mind, let us consider what is known about these processes.

Replication origins are surprisingly variable among species, often within the same organism, and even vary with a given organism's developmental stage. Thus, whereas *S. cerevisiae* origins, which are known as **autonomously replicating sequences (ARS)**, contain a highly conserved 11-bp AT-rich sequence within a less well defined  $\sim 125$ -bp region, some metazoan origins are dispersed over 10 to 50 kb "initiation zones" that contain multiple origins and, in some cases, require no specific DNA sequence at all. Despite this disparity, the proteins that participate in eukaryotic DNA replication are highly conserved from yeast to humans.

**Figure 30-45** Schematic diagram for the assembly of the eukaryotic pre-replicative complex (pre-RC). The actual stoichiometries, positions, and interactions of its various components are largely unknown. The pre-RC only forms during the  $G_1$  phase of the cell cycle.

The assembly of the pre-RC (Fig. 30-45) begins late in M phase or early in  $G_1$  phase with the binding of the **origin recognition complex (ORC)**, a hexamer of related proteins (**Orc1** through **Orc6**), to the origin, where it remains bound during most or all of the cell cycle. ORC, the functional analog of DnaA protein in *E. coli* replication initiation (Section 30-3Ca), then recruits two proteins, **Cdc6** in *S. cerevisiae* (**Cdc18** in *S. pombe*; Cdc for cell division cycle) and **Cdt1**. These proteins then cooperate with the ORC to load the **MCM complex** [named for its *minichromosome* (plasmid) *maintenance* functions], a hexamer of related subunits (**Mcm2** through **Mcm7**), onto the DNA to yield the licensed pre-RC. The MCM complex, a ring-shaped ATP-driven helicase, is the analog of *E. coli* DnaB helicase, whereas Cdc6/Cdc18 together with Cdt1 appears to be an analog of *E. coli* DnaC (which facilitates DnaB loading). With the exception of Cdt1, all of these proteins, Orc1 through Orc6, Cdc6/Cdc18, Mcm2 through Mcm7, as well as *E. coli* DnaA, DnaB, and DnaC, are AAA+ ATPases.

The conversion of a licensed pre-RC to an active initiation complex requires the addition of pol  $\alpha$ /primase, pol  $\epsilon$ , and several accessory proteins, which only occurs at the onset of S phase. This process begins with addition of **Mcm10** protein (which shares no sequence similarity with any of the subunits of the MCM complex) to the pre-RC, which probably displaces Cdt1. This is followed by the addition of at least two protein kinases, a Cdk and **Ddk**, the latter being a heterodimer of the protein kinase **Cdc7** with its activating subunit **Dbf4** (Ddk stands for *Dbf4-dependent kinase*). Ddk acts to phosphorylate five of the six MCM subunits (all but Mcm2) so as to activate the MCM complex as a helicase. In contrast, the way in which Cdks activate the pre-RC is poorly understood, although several ORC and MCM proteins as well as Cdc6/Cdc18 are phosphorylated by Cdks. Ddk together with a Cdk also recruits **Cdc45** to the growing initiation complex. Cdc45, in turn, is required for the assembly of the initiating synthetic machinery at the replication fork, including pol  $\alpha$ /primase, pol  $\epsilon$ , PCNA, and **replication protein A (RPA)**, the heterotrimeric eukaryotic counterpart of SSB, thereby forming an active initiation complex.

#### d. Re-Replication Is Prevented through the Actions of Cdks and Geminin

Once initiation (priming) has occurred, the initiation complex is joined by RFC and pol  $\delta$  and, as is described above, is converted to an active replicative complex by polymerase switching. DNA replication then proceeds bidirectionally until each replication fork has collided with an oppositely traveling replication fork, thereby completing the replication of the replicon. An active replication fork will destroy any licensed pre-RCs and unfired initiation complexes in its path, thereby preventing the DNA at such sites from being replicated twice. Eukaryotes appear to lack termination sequences and proteins analogous to the *Ter* sites and Tus protein in *E. coli*.

Several redundant mechanisms ensure that a pre-RC can initiate DNA synthesis only once. Cdks are active from late  $G_1$  phase through late M phase. These elevated Cdk levels, which are required to activate initiation, also prevent reinitiation. The Cdk-mediated phosphorylation of Cdc6/Cdc18, which occurs late in  $G_1$  after the pre-RCs have formed, causes Cdc6/Cdc18 to be proteolytically degraded in yeast and exported from the nucleus in mammalian cells. Evidently, Cdc6/Cdc18 is only required for the assembly of the pre-RC, not its activation. The helicase activity of the MCM complex is inhibited by phosphorylation, at least *in vitro*. Moreover, MCM proteins are exported from the nucleus in  $G_2$  and M phases, a process that is interrupted by Cdk inactivation. However, the function of Cdk-mediated phosphorylation of ORC proteins is unclear.

Metazoan cells have yet another mechanism to prevent the assembly of a licensed pre-RC on already replicated DNA. High levels of a protein named **geminin** appear in S phase and continue to accumulate until late M phase, when geminin is degraded. Geminin associates with Cdt1 (which together with Cdc6/Cdc18 loads the MCM complex onto

the ORC) so as to inhibit the assembly of the pre-RC. This inhibition can be reversed by the addition of excess Cdt1. It therefore seems likely that the presence of geminin provides protection against DNA re-replication under conditions when Cdks are inhibited by checkpoint activation. In addition, re-replication is also prevented by the degradation of Cdt1 after the origin with which it is associated has fired. The requirement for DNA replication in this process is indicated by its blockage by the DNA polymerase inhibitor aphidicolin.

Finally, cells that have shifted to the  $G_0$  (quiescent) phase of the cell cycle (Fig. 30-40)—the majority of cells in the human body—cease making DNA. Such cells are characterized by the absence of Cdk activity. In proliferating cells, this would permit the re-replication of DNA. However, cells in  $G_0$  also lack the proteins of the MCM complex and are therefore incapable of assembling licensed pre-RCs. Since cancerous cells are characterized by being in a state of rapid proliferation (Section 19-3B), the presence of MCM complex proteins in what should be quiescent cells is a promising diagnostic marker for cancer.

#### e. Primers Are Removed by RNase H1 and Flap Endonuclease-1

In lagging strand synthesis, when pol  $\delta$  reaches the previously synthesized Okazaki fragment, it partially displaces its RNA primer through DNA synthesis, thereby generating an RNA flap. The primer is then removed through the actions of two enzymes: **RNase H1** removes most of the RNA leaving only a 5' ribonucleotide adjacent to the DNA, which is then removed by **flap endonuclease-1 (FEN1)**. However, as we have seen, pol  $\alpha$ /primase extends the RNA primers it has made by  $\sim 20$  nt of DNA before it is displaced by pol  $\delta$ . Since pol  $\alpha$  lacks proofreading ability, this primer extension is more likely to contain errors than the DNA synthesized by pol  $\delta$ . However, FEN1, which is recruited to the replication fork by its binding to the C side of PCNA, provides what is, in effect, pol  $\alpha$ 's proofreading function: It is also an endonuclease that excises mismatch-containing oligonucleotides up to 15 nt long from the 5' end of an annealed DNA strand. Moreover, FEN1 can make several such excisions in succession to remove more distant mismatches. The excised segment is later replaced by pol  $\delta$  as it synthesizes the succeeding Okazaki fragment.

#### f. Mitochondrial DNA Is Replicated via RNA Okazaki Fragments

Mammalian mitochondria contain two to ten copies of their  $\sim 16$ -kb circular chromosome. The pol  $\gamma$ -mediated replication of this chromosome occurs unidirectionally from a single origin. In this process, as Ian Holt showed, the lagging strand Okazaki fragments are entirely synthesized as RNA (Fig. 30-46). The RNA is then replaced by DNA, although the way this occurs is poorly understood. One possibility is that this RNA is excised in much the same way as the primers in the nucleus, that is, through the actions of RNase H1 and FEN1, followed by the synthesis of lagging strand DNA by pol  $\gamma$ .

**Figure 30-46** Replication of the mammalian mitochondrial chromosome. This circular chromosome is unidirectionally replicated from a single origin by a process in which the Okazaki fragments are entirely RNA.

### C. Reverse Transcriptase

The **retroviruses**, which are RNA-containing eukaryotic viruses such as certain tumor viruses and human immunodeficiency virus (HIV), contain an **RNA-directed DNA polymerase (reverse transcriptase)**. This enzyme, which was independently discovered in 1970 by Howard Temin and David Baltimore, acts much like Pol I in that it synthesizes DNA in the 5'  $\rightarrow$  3' direction from primed templates. In the case of reverse transcriptase, however, RNA is the template. The discovery of reverse transcriptase caused a mild sensation in the biochemical community because it was perceived by some as being heretical to the central dogma of molecular biology (Section 5-4). There is, however, no thermodynamic prohibition to the reverse transcriptase reaction; in fact, under certain conditions, Pol I can likewise copy RNA templates.

Reverse transcriptase transcribes the retrovirus's single-stranded RNA genome to a double-stranded DNA as follows (Fig. 30-47):

1. The retroviral RNA acts as a template for the synthesis of its complementary DNA (RNA-directed DNA polymerase activity), yielding an RNA–DNA hybrid helix. The DNA synthesis is primed by a host cell tRNA whose 3' end partially unfolds to base pair with a complementary segment of the viral RNA.

2. The RNA strand is then nucleolytically degraded (**RNase H** activity; H for hybrid).

3. The DNA strand acts as a template for the synthesis of its complementary DNA (DNA-directed DNA polymerase activity), yielding double-stranded DNA.

The DNA is then integrated into a host cell chromosome.

Reverse transcriptase has been a particularly useful tool in genetic engineering because of its ability to transcribe mRNAs to complementary strands of DNA (cDNA). In transcribing eukaryotic mRNAs, which have poly(A) tails (Section 31-4Ab), the primer can be oligo(dT). cDNAs have been used, for example, as probes in Southern blotting (Section 5-5D) to identify the genes coding for their

**Figure 30-47** The reactions catalyzed by reverse transcriptase.

corresponding mRNAs. An RNA's base sequence can be easily determined by sequencing its cDNA (Section 7-2A).

#### a. X-Ray Structure of HIV-1 Reverse Transcriptase

**HIV-1 reverse transcriptase (RT)** is a dimeric protein whose subunits are synthesized as identical 66-kD polypeptides, known as **p66** (p for *protein*), that each contain a polymerase domain and an RNase H domain. However, the RNase H domain of one of the two subunits is proteolytically excised, thereby yielding a 51-kD polypeptide named **p51**. Thus, RT is dimer of p66 and p51.

The first drugs to be clinically approved to treat AIDS, **3'-azido-3'-deoxythymidine (AZT; zidovudine)**, **2',3'-dideoxyinosine (ddI; didanosine)**, **2',3'-dideoxycytidine (ddC; zalcitabine)**, and **2',3'-dideohydro-3'-deoxythymidine (stavudine)**,

are RT inhibitors. Unfortunately, resistant strains of HIV-1 arise quite rapidly because RT lacks a proofreading exonuclease function and hence is highly error prone. Thus, as we have seen (Section 15-4Cd), effective long-term anti-HIV therapy requires the concurrent administration of at least one RT inhibitor and an HIV protease inhibitor.

Edward Arnold determined the X-ray structure of RT complexed to a 21-bp primer-template DNA with a 5-nt overhang at the 5' end of its template strand, a dideoxy-dG (ddG) residue at the 3' end of its primer strand (which prevents its further extension), and in complex with dATP (Fig. 30-48). The polymerase domains of p66 and p51 each contain four subdomains, which, because of their collective resemblance in p66 to DNA polymerases, are named, from N- to C-terminus, fingers, palm, thumb, and connection. Indeed, reverse transcriptases form a separate family of DNA polymerases, family RT. In p66, the RNase H domain follows the connection.

p51 has undergone a remarkable conformational change relative to p66: The connection has rotated by  $155^\circ$  and translated by  $17 \text{ \AA}$  to bring it from a position in p66 in which it contacts only the RNase H domain (Fig. 30-48a) to one in p51 in which it contacts all three other polymerase subdomains (Fig. 30-48b). This permits p66 and p51 to bring different surfaces of their connections into juxtaposition to form, in part, RT's DNA-binding groove. Thus, the chemically identical polymerase domains of p66 and p51 are not related by 2-fold molecular symmetry (a rare but not unprecedented phenomenon), but instead, associate in a sort of head-to-head and tail-to-tail arrangement (Fig. 30-48c). Consequently, RT has only one polymerase active site and one RNase H active site. This is an example of viral genetic economy: HIV-1, with its limited genome size, has

**Figure 30-48** X-ray structure of HIV-1 reverse transcriptase in complex with primer–template DNA and dATP. (a) A ribbon diagram of the p66 subunit in which the N-terminal fingers domain is blue, the palm is red, the thumb is green, the connection is yellow, and the RNase H domain is magenta. (b) The p51 subunit with its palm subunit oriented similarly to that of p66. Note the different orientations of its four domains relative to p66. (c) A ribbon diagram of the HIV-1 RT p66/p51 heterodimer in complex with DNA and dATP. The domains of p66 and p51 are colored as in Parts a and b (the labels indicate subunit and domain; e.g., 51F and 66R denote the p51 finger domain and the p66 RNase H domain). The DNA is drawn in ladder form. The complex is oriented with its p66 polymerase domain toward the top of the figure and viewed toward the protein’s template–primer binding cleft (whose floor is largely composed of the connection domains of p66 and p51). [Based on an X-ray structure by Edward Arnold, Rutgers University. PDBid 3JYT.] See Interactive Exercise 36

succeeded in using a single polypeptide for what are essentially two different functions.

The dATP binds at the 3' end of the primer strand, near p66's three catalytically essential Asp side chains, where it pairs with a template dT base. The DNA assumes a conformation that, near the polymerase active site, resembles A-DNA (note the A-DNA-like tilt of the bases with respect to the helix axis below the dATP in Fig. 30-48c), but elsewhere more closely resembles B-DNA (in which the bases are nearly perpendicular to the helix axis), a phenomenon that also has been observed in several structures of A-family DNA polymerases in their complexes with DNA (Section 30-2Ae). Most of the protein–DNA interactions involve the DNA's sugar–phosphate backbone.

The RT active site region contains the few sequence motifs that are conserved among the various polymerases. Indeed, this region of p66 has a striking structural resemblance to DNA polymerases of known structure (Sections 30-2A and 30-4Ba). This suggests that other DNA polymerases are likely to bind DNA in a similar manner.

#### D. Telomeres and Telomerase

The ends of linear chromosomes cannot be replicated by any of the mechanisms we have yet considered. This is because the RNA primer at the 5' end of a completed lagging strand cannot be replaced with DNA; the primer required to do this would have no place to bind. How, then, are the DNA sequences at the ends of eukaryotic chromosomes, the **telomeres** (Greek: *telos*, end), replicated?

Telomeric DNA has an unusual sequence: It consists of up to several thousand tandem repeats of a simple, species-dependent, G-rich sequence concluding the 3'-ending strand of each chromosomal terminus. For example, the ciliated protozoan *Tetrahymena* has the repeating telomeric sequence TTGGGG, whereas in all vertebrates it is

**Figure 30-49** Proposed mechanism for the synthesis of telomeric DNA by *Tetrahymena* telomerase. The telomere's 5'-ending strand is later extended by normal lagging strand synthesis. [After Greider, C.W. and Blackburn, E.H., *Nature* **337**, 336 (1989).]

TTAGGG. Moreover, this strand ends with an overhang that varies from ~20 nt in yeast to ~200 bp in humans.

Elizabeth Blackburn, Carol Greider, and Jack Szostak have shown that telomeric DNA is synthesized by a novel mechanism. The enzyme that synthesizes the G-rich strand of telomeric DNA is named **telomerase**. *Tetrahymena* telomerase, for example, adds tandem repeats of the telomeric sequence TTGGGG to the 3' end of any G-rich telomeric oligonucleotide independently of any exogenously added template. A clue as to how this occurs came from the discovery that telomerases are ribonucleoproteins whose RNA components contain a segment that is complementary to the repeating telomeric sequence. This sequence apparently acts as a template in a kind of reverse transcriptase reaction that synthesizes the telomeric sequence, translocates to the DNA's new 3' end, and repeats the process (Fig. 30-49). This hypothesis is confirmed by the observation that mutationally altering the telomerase RNA gene segment complementary to telomere DNA results in telomere DNA with the corresponding altered sequence. In fact, telomerase's highly conserved protein component, which is named **TERT**, is homologous to known reverse transcriptases (its RNA component is called **TER**). The DNA strand complementary to the telomere's G-rich

strand is apparently synthesized by the normal cellular machinery for lagging strand synthesis, thereby accounting for the 3' overhang of the G-rich strand.

#### a. TERT Resembles Other DNA Polymerases

The X-ray structure of the 596-residue TERT from the red flour beetle *Tribolium castaneum*, determined by Emanuel Skordalakes, reveals that this subunit contains the familiar fingers–palm–thumb domain organization of other DNA polymerases (Fig. 30-50) and, in particular, resembles the corresponding domains of the HIV-1 reverse transcriptase p66 subunit (Fig. 30-48). In addition, TERT has an N-terminal RNA-binding domain named TRBD (for *telomere repeat binding domain*). TRBD closes the gap between the thumb and fingers, thereby yielding a ringlike protein with a hole that is ~26 Å wide and ~21 Å deep. This is sufficient to accommodate an ~8-bp segment of double-stranded nucleic acid.

#### b. Telomeres Must Be Capped

Without the action of telomerase, a chromosome would be shortened at both ends by 50 to 100 nt with every cycle of DNA replication and cell division. It was therefore initially assumed that, in the absence of active telomerase, essential genes located near the ends of chromosomes would eventually be lost, thereby killing the descendants of the originally affected cells. However, it is now evident that telomeres serve a vital chromosomal function that is compromised before this can happen. Free DNA ends, which are subject to nuclease degradation, trigger DNA damage repair systems that normally function to rejoin the ends of broken chromosomes (as well as cell cycle arrest until this has happened). Thus exposed telomeric DNA would result in the end-to-end fusion of chromosomes, a process that leads to chromosomal instability and eventual cell death [fused chromosomes often break in mitosis (their two centromeres may cause them to be pulled in opposite directions), activating DNA damage checkpoints]. However, in a process known as **capping**, telomeric DNA is specifically bound by proteins that sequester the DNA ends. There is mounting evidence that capping is a dynamic process in which the probability of a telomere spontaneously upcapping increases as telomere length decreases. Since most somatic cells in multicellular organisms have very low levels of telomerase activity, this explains why such cells in culture can only undergo a limited number of doublings (20–60) before they reach senescence (a stage in which they cease dividing) and eventually die (Section 19-3B). Indeed, otherwise immortal *Tetrahymena* cultures with mutationally impaired telomerases exhibit characteristics reminiscent of senescent mammalian cells before dying off. Apparently, *the loss of telomerase function in somatic cells is a basis for aging in multicellular organisms*.

#### c. Telomere Length Correlates with Aging

There is strong experimental evidence in support of this theory of aging. The analysis of cultured human fibroblasts

**Figure 30-50** X-ray structure of TERT from *Tribolium castaneum*. The protein is shown ribbon form with its TRBD, fingers, palm, and thumb colored orange, blue, red, and green, respectively, and embedded in its like-colored semitransparent

surface diagram. Compare this structure with that of p66 subunit of HIV-1 reverse transcriptase (Fig. 30-48a). [Based on an X-ray structure by Emmanuel Skordalakes, The Wistar Institute, Philadelphia, Pennsylvania. PDBid 3DU5.]

from a number of donors between 0 and 93 years old indicates that there is only a weak correlation between the proliferative capacity of a cell culture and the age of its donor. There is, however, a strong correlation, valid over the entire donor age range, between the initial telomere length in a cell culture and its proliferative capacity. Thus, cells that initially have relatively short telomeres undergo significantly fewer doublings than cells with longer telomeres. Moreover, fibroblasts from individuals with **progeria** (a rare disease characterized by rapid and premature aging resulting in childhood death) have short telomeres, an observation that is consistent with their known reduced proliferative capacity in culture. In contrast, sperm (which, being germ cells, are in effect immortal) from donors ranging in age from 19 to 68 years had telomeres that did not vary in length with donor age, which indicates that telomerase is active at some stage of germ cell growth. Likewise, those few cells in a culture that become immortal (capable of unlimited proliferation) exhibit an active telomerase and a telomere of stable length, as do the cells of unicellular eukaryotes (which are also immortal). It therefore appears that telomere erosion is a significant cause of cellular senescence and hence aging. Indeed transgenic mice that constitutively (at a constant rate) express telomerase have increased lifespans (although, in contrast to humans, mice in which telomerase has been knocked out survive without significant problems for several generations before they become infertile).

#### d. Cancer Cells Have Active Telomerases

What advantage might multicellular organisms gain by eliminating telomerase activity in their somatic cells? An intriguing possibility is that cellular senescence is a mechanism that protects multicellular organisms from cancer. The two defining characteristics of cancer cells are that they are immortal and grow uncontrollably (Sections 19-3B and 34-4C). If mammalian cells were normally immortal, the incidence of cancer would probably be far greater than it is since immortalization, which requires an active telomerase, is a major step toward **malignant transformation** (cancer formation), which requires several independent genetic changes (Section 19-3B). Indeed, nearly all human cancers exhibit high telomerase activity. Moreover, as Robert Weinberg demonstrated, human fibroblasts in culture can be malignantly transformed by the acquisition of only three genes, those encoding: (1) TERT (its TER subunit is normally expressed in somatic cells), (2) an oncogenic variant of H-Ras (an essential participant in intracellular signal transduction pathways; Section 19-3C), and (3) the SV40 **large-T antigen** [SV40 is a tumor virus whose large-T antigen binds and functionally inactivates the tumor suppressor proteins known as **Rb** and **p53** (Section 34-4C; it also functions as a helicase in viral DNA replication)]. The age-related decline in telomere length in humans does not occur in mice, which suggests that telomere loss evolved to suppress tumor formation in long-lived animals, such as humans, but not in short-lived animals,

such as mice. Thus, telomerase inhibitors may be effective antitumor agents.

#### e. Telomeric DNA Can Dimerize via G-Quartets

It has long been known that guanine forms strong Hoogsteen-type base pairs (Table 29-2) that can further associate to form cyclic tetramers known as **G-quartets** (Fig. 30-51a). Indeed, G-rich polynucleotides are notoriously difficult to work with because of their propensity to aggregate. The G-rich overhanging strands of telomeres dimerize to form stable complexes in solution, presumably via the formation of G-quartet-containing structures.

**Figure 30-51** NMR structure of the telomeric oligonucleotide **d(GGGGTTTGGGG)**. (a) The base-pairing interactions in the G-quartet at the end of the quadruplex in solution. (b) Schematic diagram of the NMR solution structure, in which the strand directions are indicated by arrows. The nucleotides are numbered 1 to 12 in one strand and 1\* to 12\* in the symmetry-related strand. Guanine residues G1 to G4 are represented by dark blue rectangles, G8 to G12 are light blue, G1\* to G4\* are red, and G9\* to G12\* are pink. [After Schultze, P., Smith, F.W., and Feigon, J., *Structure* 2, 227 (1994). PDBid 156D.]

The 3'-terminal telomeric overhang of the ciliated protozoan *Oxytricha nova* has the sequence  $d(T_4G_4)_2$ , which resembles the repeating telomeric sequences of other organisms. The NMR structure of the dodecamer  $d(G_4T_4G_4)$ , determined by Juli Feigon (Fig. 30-51b), reveals that each oligonucleotide folds back on itself to form a hairpin, two of which associate in an antiparallel fashion to form a structure that contains four stacked G-quartets, with the  $T_4$  sequences forming the loops at the ends of each stack.

The **telomere end binding protein (TEBP)** of *O. nova* is a heterodimeric capping protein that binds to and protects the foregoing 3' overhang. The X-ray structure of TEBP in complex with  $d(G_4T_4G_4)$ , determined by Steve Schultz, reveals that the DNA binds in a deep cleft between the protein's  $\alpha$  and  $\beta$  subunits, where it adopts an irregular nonhelical conformation (Fig. 30-52). In addition, two other  $d(G_4T_4G_4)$  molecules form a G-quartet-linked dimer with the same conformation they adopt in solution (Fig. 30-51). The G-quartet assembly fits snugly into a small positively

**Figure 30-52** X-ray structure of *Oxytricha nova* telomere end binding protein (TEBP) in complex with  $d(G_4T_4G_4)$ . The TEBP is drawn in ribbon form with its  $\alpha$  and  $\beta$  subunits magenta and cyan. The DNA is drawn in stick form with its bases yellow, the sugar-phosphate backbone of the single strand that binds in a cleft between the protein's  $\alpha$  and  $\beta$  subunits blue, and the backbones of two strands that form a G-quartet-linked dimer red and green. The G-quartet-linked dimer binds in a cavity formed by the N-terminal domains of three symmetry-related  $\alpha$  chains, although only one of them is shown here. [Based on an X-ray structure by Steve Schultz, University of Colorado. PDBid 1JB7.]

charged cavity formed by the N-terminal domains of three symmetry-related (in the crystal)  $\alpha$  subunits at sites distinct from their ssDNA binding sites. The  $\alpha$  subunit (TEBP $\alpha$ ) contains three so-called **OB folds** (OB for oligomer binding), common oligonucleotide/oligosaccharide binding motifs that each contain a characteristic 5-stranded  $\beta$  barrel. Two of these OB folds participate in DNA binding and a third interacts with TEBP $\beta$ , which also contains an OB fold. The presence of both the ssDNA and the G-quartet assembly in the X-ray structure supports the hypothesis that multiple DNA structures and, in particular, G-quartets, play a role in telomere biology.

Although TEBP is not present in yeast or vertebrates, both humans and fission yeast express a telomere end-binding protein named **POT1** (for *protection of telomeres-1*) and its binding partner **TPP1** (so named because it had been previously called *TINT1*, *PTOP*, and *PIP1*), which bind to the single-stranded overhang at the ends of telomeres. POT1 consists mainly of two OB folds in which the N-terminal OB fold is homologous to that of TEBP $\alpha$ . The deletion of POT1 causes rapid loss of telomeric DNA and chromosomal end-joining. TPP1 is structurally similar to TEBP $\beta$ , despite their only 11% sequence identity, and hence the POT1–TPP1 complex appears to be a homolog of TEBP.

#### f. Telomeres Form T-Loops

Mammalian telomeric DNA is also capped by two related proteins, **TRF1** and **TRF2** (TRF for telomere repeat-binding factor). Jack Griffith and Titia de Lange have shown through electron microscopy (EM) studies that, in the presence of TRF2, otherwise linear telomeric DNA forms large duplex end loops named **T-loops** (T for telomere);

Fig. 30-53a). Moreover, the EM of DNA from mammalian telomeres, whose strands had been chemically cross-linked to preserve their structural relationships on deproteination, likewise revealed the presence of abundant T-loops of varying sizes. These observations suggest that T-loops are formed by the TRF2-induced invasion of the 3' telomeric overhang into the repeating telomeric dsDNA (Fig. 30-53b) to form a **D-loop** (D for displacement; a segment of dsDNA whose two strands are separated). T-loops have also been observed in protozoa, suggesting that T-loops are a conserved feature of eukaryotic telomeres. TRF1 is implicated in controlling telomeric length, presumably by somehow limiting the number of TRF1 molecules that can bind to a telomere.

POT1, which binds to the single-stranded 3' extension at chromosome ends, and TRF1 and TRF2, which bind double-stranded telomere DNA, are bridged by TPP1 and **TIN2** (for TRF1 interacting protein 2). A sixth protein, **RAP1** (for repressor activator protein 1), binds mainly to TRF2. The complex formed by these six proteins, which is known as **shelterin**, apparently functions both to protect the mammalian telomere from being mistaken for a broken chromosome and hence being subject to DNA repair, and to limit telomere length by preventing the extension of its bound telomere by telomerase.

## 5 REPAIR OF DNA

DNA is by no means the inert substance that might be supposed from naive consideration of genome stability. Rather, the reactive environment of the cell, the presence

(a)

(b)

**Figure 30-53 The telomeric T-loop.** (a) An electron micrograph of a dsDNA consisting of a 3-kb unique sequence followed by  $\sim 2$  kb of the repeating sequence TTAGGG on the strand that ends with a 150- to 200-nt 3' overhang. This model telomeric DNA was then incubated with human TRF2. [Courtesy of Jack Griffith, University of North Carolina at Chapel Hill.] (b) The proposed structure of a T-loop. In a process that is mediated by TRF2, the repeating TTAGGG sequence in the DNA's 3' overhang displaces a portion of the same strand (blue) in the double-stranded region of the DNA to form a duplex segment with the complementary strand (red), thereby generating a D-loop. The telomere end-binding protein POT1 specifically binds to the end of the 3' overhang.

**Figure 30-54** The types and sites of chemical damage to which DNA is normally susceptible *in vivo*. Red arrows indicate sites subject to oxidative attack, blue arrows indicate sites subject to spontaneous hydrolysis, and green arrows indicate sites subject

to nonenzymatic methylation by *S*-adenosylmethionine. The width of an arrow is indicative of the relative frequency of the reaction. [After Lindahl, T., *Nature* **362**, 709 (1993).]

of a variety of toxic substances, and exposure to UV or ionizing radiation subjects it to numerous chemical insults that excise or modify bases and alter sugar–phosphate groups (Fig. 30-54). Indeed, some of these reactions occur at surprisingly high rates. For example, under normal physiological conditions, the glycosidic bonds of ~10,000 of the 3 billion purine nucleotides in each human cell hydrolyze spontaneously each day.

Any DNA damage must be repaired if the genetic message is to maintain its integrity. Such repair is possible because of duplex DNA's inherent information redundancy. The biological importance of DNA repair is indicated by the identification of at least 130 genes in the human genome that participate in DNA repair and by the great variety of DNA repair pathways possessed by even relatively simple organisms such as *E. coli*. In fact, the major DNA repair processes in eukaryotic cells and *E. coli* are chemically quite similar. These processes are outlined in this section.

The two redundant copies of genetic information carried by dsDNA ideally suit it for the repair of damage to one of its strands: The damaged strand can be repaired under the direction of the undamaged strand. The importance of dsDNA to the storage of genetic information is indicated by the fact that only a few small viruses carry single-stranded DNA or RNA as their genetic material (e.g.,  $\phi$ X174 and HIV). The DNA repair systems discussed below do not operate on single-stranded nucleic acids and hence these viruses have very high rates of mutation. Thus it appears that only organisms with very small genomes can afford the economy of not encoding their genomes on dsDNA.

## A. Direct Reversal of Damage

### a. Pyrimidine Dimers Are Split by DNA Photolyase

UV radiation of 200 to 300 nm promotes the formation of a cyclobutyl ring between adjacent thymine residues on the same DNA strand to form an intrastrand **thymine**

**dimer** (Fig. 30-55). Similar cytosine and thymine–cytosine dimers are likewise formed but at lesser rates. Such **cyclobutane pyrimidine dimers (CPDs)** locally distort DNA's base-paired structure such that it can be neither transcribed nor replicated. Indeed, a single thymine dimer, if unrepaired, is sufficient to kill an *E. coli*.

Pyrimidine dimers may be restored to their monomeric forms through the action of light-absorbing enzymes named **photoreactivating enzymes** or **DNA photolyases** that are present in many prokaryotes and eukaryotes (including goldfish, rattlesnakes, and marsupials, but not placental mammals). These enzymes are 55- to 65-kD monomers that bind to a pyrimidine dimer in DNA, a process that can occur in the dark. A noncovalently bound chromophore, in

**Figure 30-55** The cyclobutylthymine dimer that forms on UV irradiation of two adjacent thymine residues on a DNA strand. The ~1.6-Å-long covalent bonds joining the thymine rings (red) are much shorter than the normal 3.4-Å spacing between stacked rings in B-DNA, thereby locally distorting the DNA.

some species an  $N^5, N^{10}$ -methenyltetrahydrofolate (MTHF; Fig. 26-49) and in others a **5-deazaflavin**,

**8-Hydroxy-7,8-didemethyl-5-deazariboflavin**

then absorbs 300- to 500-nm light and transfers the excitation energy to a noncovalently bound  $FADH^-$ , which in turn transfers an electron to the pyrimidine dimer, thereby splitting it. Finally, the resulting pyrimidine anion re-reduces the  $FADH\cdot$  and the now unblemished DNA is released, thereby completing the catalytic cycle. DNA photolyases bind either dsDNA or ssDNA with high affinity but without regard to base sequence.

Thomas Carell and Lars-Oliver Essen determined the X-ray structure of the 474-residue DNA photolyase from the cyanobacterium *Anacystis nidulans* in complex with a 9-bp dsDNA containing a synthetic thymine dimer whose bridging phosphate group was replaced by a  $-O-CH_2-O-$  group (which does not affect the enzyme's ability to split the dimer). The DNA binds to a highly positively charged surface on the protein with its thymine dimer flipped out of the double helix and bound in a deep cavity (Fig. 30-56). This flip-out is probably facilitated by the relatively weak base pairing interactions of the thymine dimer and the distortions it imposes on the double helix. In the following discussions we shall see that this so-called **base flipping** (really nucleotide flipping since entire nucleotides flip out of the double helix) is by no means an unusual process for enzymes that perform chemistry on the bases of dsDNA. The DNA outside of the thymine dimer assumes the B conformation but at the thymine dimer is bent by  $50^\circ$  away from the protein, thereby unstacking the adenine bases complementary to the dimerized thymine bases. The "hole" in the DNA helix left by the flipped-out thymine dimer is partially occupied by an irregular protein ridge.

In the X-ray structure, the thymine dimer's C5—C5 and C6—C6 bonds are broken. Yet, in the crystal, the enzyme-bound thymine dimer is stable in the dark for at least a year. Apparently, the X-rays used to generate the diffraction data mimic the effects of the light that normally ruptures these bonds. Moreover, the FAD's isoalloxazine ring exhibits a  $9^\circ$  "butterfly" bend about its N5—N10 axis (the isoalloxazine ring's atomic numbering scheme is given in Fig. 16-8), which is indicative that it is in the fully reduced  $FADH^-$  form. The isoalloxazine ring and adenine ring of the  $FAD^-$ , which has a folded conformation, are in van der Waals contact with one or the other bases of the thymine dimer and the isoalloxazine ring is  $\sim 10 \text{ \AA}$  distant from the

**Figure 30-56** X-ray structure of *A. nidulans* DNA photolyase in complex with dsDNA containing a synthetic thymine dimer.

The protein is drawn in worm form embedded in its semitransparent surface diagram. The DNA, in which the phosphate group bridging the nucleotides of the thymine dimer is replaced by a  $-O-CH_2-O-$  group, is drawn mainly in stick form but with the bases of the thymine dimer in space-filling form, all colored according atom type (C green, N blue, O red, and P orange) and with successive P atoms in each polynucleotide chain connected by orange rods. The FAD and MTHF are drawn in stick form with their flavin and flavinlike rings in space-filling form and with FAD C magenta and MTHF C yellow. [Based on an X-ray structure by Thomas Carell, Ludwig Maximilians University, Munich, Germany, and Lars-Oliver Essen, Philipps University, Marburg, Germany. PDBid 1TEZ.]

flavin-like ring of the MTHF. This permits the observed efficient energy transfer in the photolyase reaction (which has a quantum yield of  $\sim 0.9$ ).

#### b. Alkyltransferases Dealkylate Alkylated Nucleotides

The exposure of DNA to alkylating agents such as *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG)

***N*-Methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG)**

***O*<sup>6</sup>-Methylguanine residue**

yields, among other products, ***O*<sup>6</sup>-alkylguanine** residues. The formation of these derivatives is highly mutagenic because on replication, they frequently cause the incorporation of thymine instead of cytosine.

**O<sup>6</sup>-Methylguanine** and **O<sup>6</sup>-ethylguanine** lesions of DNA in all species tested are repaired by **O<sup>6</sup>-alkylguanine–DNA alkyltransferase**, which directly transfers the offending alkyl group to one of its own Cys residues. The reaction inactivates this protein, which therefore cannot be strictly classified as an enzyme. The alkyltransferase reaction has elicited considerable attention because carcinogenesis induced by methylating and ethylating agents is correlated with deficient repair of O<sup>6</sup>-alkylguanine lesions.

The *E. coli* O<sup>6</sup>-alkylguanine–DNA alkyltransferase activity occurs on the 178-residue C-terminal segment of the 354-residue **Ada protein** (the product of the *ada* gene). Its X-ray structure (Fig. 30-57a), determined by Eleanor Dodson and Peter Moody, reveals, unexpectedly, that its active site Cys residue, Cys 321, is buried inside the protein. Apparently, the protein must undergo a significant conformational change on DNA binding in order to effect the methyl transfer reaction.

Ada protein's 92-residue N-terminal segment has an independent function: It repairs methyl phosphotriesters in DNA (methylated phosphate groups) by irreversibly transferring the offending methyl group to its Cys 69. The NMR structure of Ada's N-terminal domain (Fig. 30-57b), determined by Gregory Verdine and Gerhard Wagner, reveals

that Cys 69, together with three other Cys residues, tetrahedrally coordinates a Zn<sup>2+</sup> ion. This presumably stabilizes the thiolate form of Cys 69 over its thiol form, thereby facilitating its nucleophilic attack on the methyl group.

Intact Ada protein that is methylated at its Cys 69 binds to a specific DNA sequence, which is located upstream of the *ada* gene and several other genes encoding DNA repair proteins, thereby inducing their transcription. Evidently, Ada also functions as a chemosensor of methylation damage.

## B. Excision Repair

Cells employ two types of excision repair mechanisms: (1) **nucleotide excision repair (NER)**, which functions to repair relatively bulky DNA lesions; and (2) **base excision repair (BER)**, which repairs nonbulky lesions involving a single base.

### a. Nucleotide Excision Repair

*NER is a DNA repair mechanism found in all cells that eliminates damage to dsDNA by excising an oligonucleotide containing the lesion and filling in the resulting single-strand*

**Figure 30-57 Structure of the *E. coli* Ada protein.** (a) The X-ray structure of Ada's 178-residue C-terminal segment, which contains its O<sup>6</sup>-alkylguanine–DNA alkyltransferase function. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The side chain of Cys 146 (Cys 321 in the intact protein), to which the methyl group is irreversibly transferred, is shown in space-filling form with C green and S yellow. Note that this residue is almost entirely buried within the protein. [Based on an X-ray structure by Eleanor Dodson and Peter Moody, University of York, U.K. PDBid 1SFE.] (b) The NMR structure of Ada's 92-residue,

N-terminal segment, which mediates its methyl phosphotriester repair function. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). Its bound Zn<sup>2+</sup> ion is represented by a purple sphere and its four tetrahedrally coordinating Cys side chains are shown in ball-and-stick form, with C green and S yellow except for the orange S atom of Cys 69, which becomes irreversibly methylated when the protein encounters a methylated phosphate group on DNA. The coordinate bonds to the Zn<sup>2+</sup> ion are represented by gray sticks. [Based on an NMR structure by Gregory Verdine and Gerhard Wagner, Harvard University. PDBid 1ADN.]

gap. NER repairs lesions that are characterized by the displacement of bases from their normal positions, such as pyrimidine dimers, or by the addition of a bulky substituent to a base. This system appears to be activated by a helix distortion rather than by the recognition of any particular group. In humans, NER is the major defense against two important carcinogens, sunlight and cigarette smoke. The mechanism of NER in prokaryotes is similar to that in eukaryotes. However, prokaryotic NER employs 3 subunits, whereas eukaryotic NER involves the actions of 16 subunits. The eukaryotic proteins are conserved from yeast to humans but none of them exhibit any sequence similarity to the prokaryotic proteins, suggesting that the two NER systems arose by convergent evolution.

In *E. coli*, NER is carried out in an ATP-dependent process through the actions of the **UvrA**, **UvrB**, and **UvrC** proteins (the products of the *uvrA*, *uvrB*, and *uvrC* genes). This system, which is often referred to as the **UvrABC endonuclease** (although, as we shall see, there is no complex that contains all three subunits), cleaves the damaged DNA strand at the seventh and at the third or fourth phosphodiester bonds from the lesion's 5' and 3' sides, respectively (Fig. 30-58; this system is also known as an **excinuclease** to indicate that it *excises* a DNA segment rather than cleaving it in only one place as do most endonucleases). The excised 11- or 12-nt oligonucleotide is displaced by the binding of **UvrD** (also called **helicase II**) and replaced through the actions of Pol I and DNA ligase.

The mechanism of prokaryotic NER was elucidated mainly by Aziz Sançar. It begins with the damage recognition step in which a (UvrA)<sub>2</sub>UvrB heterotrimer binds

**Figure 30-58** The mechanism of nucleotide excision repair (NER) of pyrimidine photodimers.

tightly although nonspecifically to dsDNA, which it probes for damage according to its local propensity for bending and unwinding. The presence of a lesion activates the helicase function of UvrB to unwind 5 bp around the lesion in an ATP-driven process. This conformational change induces the dissociation of the UvrA from the complex, which allows the binding of UvrC. UvrB then makes the incision on the 3' side of the lesion following which UvrC makes the incision on its 5' side. UvrD binds to the resulting nicks in the DNA, which displaces UvrC and the lesion-containing oligomer. This makes the 5' incision site accessible to Pol I, which fills in the gap and displaces UvrB. Finally, DNA ligase seals the remaining nick yielding refurbished DNA.

#### b. Xeroderma Pigmentosum and Cockayne Syndrome Are Caused by Genetically Defective NER

In humans, the rare inherited disease **xeroderma pigmentosum (XP)**; Greek: *xeros*, dry + *derma*, skin) is mainly characterized by the inability of skin cells to repair UV-induced DNA lesions. Individuals suffering from this autosomal recessive condition are extremely sensitive to sunlight. During infancy they develop marked skin changes such as dryness, excessive freckling, and keratoses (a type of skin tumor; the skin of these children is described as resembling that of farmers with many years of sun exposure), together with eye damage, such as opacification and ulceration of the cornea. Moreover, they develop often fatal skin cancers at a 10 to 20-fold greater rate than normal and internal cancers at a 10 to 20-fold increased rate. Curiously, many individuals with XP also have a bewildering variety of seemingly unrelated symptoms including progressive neurological degeneration and developmental deficits.

*Cultured skin fibroblasts from individuals with xeroderma pigmentosum are defective in the NER of pyrimidine dimers.* Cell-fusion experiments with cultured cells taken from various patients have demonstrated that this disease results from defects in any of 8 complementation groups (Section 1-4Cc), indicating that there must be at least 8 gene products, **XPA** through **XPG** and **XPV**, involved in this clearly important UV damage repair pathway.

What is the biochemical basis for the diverse group of symptoms associated with impaired NER? The reactive oxygen species (ROS; Section 22-4Cg) produced by oxidative metabolism readily damages DNA. Some of these oxidative lesions are repaired via NER. Since neurons have high rates of respiration and are long-lived nondividing cells, it seems likely that they would be particularly susceptible to oxidative damage in the absence of NER. This explains the progressive neurological deterioration in XP.

The need to repair a DNA lesion is particularly urgent if the damaged gene is being transcribed because RNA polymerase cannot transcribe through damaged DNA. Cells therefore recruit their DNA repair machinery to such genes in a process known as **transcription-coupled repair (TCR)**, which operates only on the DNA strand that is being transcribed (lesions on the complementary strand are repaired at normal rates). For example, pyrimidine dimers are more rapidly removed from transcribed portions of DNA than from unexpressed sequences.

**Cockayne syndrome (CS)** is an inherited disease caused by defective TCR. Individuals with CS are hypersensitive to UV radiation (although they have a normal incidence of skin cancer) and exhibit stunted growth as well as neurological dysfunction due to neuron demyelination leading to death in childhood. CS is most often caused by mutations in two complementation groups, **CSA** and **CSB**, although certain defects in **XPB**, **XPD**, and **XPG** can also cause CS in addition to XP.

The retarded development typical of **XPB** and **XPD** defects and perhaps the demyelination that occurs in CS appear to be due more to impaired transcription than to defective NER. This is explained by the fact that the DNA helicases **XPB** and **XPD** are subunits of the ten-subunit eukaryotic transcription factor **TFIIH**, whose proper functioning is required for transcription initiation by RNA polymerase II (Section 34-3Bb) as well as NER and TCR. A eukaryotic RNA polymerase that is stalled at a DNA lesion is recognized by **CSB**, which then recruits the other TCR components. **CSA** interacts with both **CSB** and the **p44** subunit of **TFIIH**. Once the damage has been repaired, the RNA polymerase resumes transcription. Thus, in CS, RNA polymerase molecules become permanently stalled on DNA lesions.

TCR also occurs in bacteria. For example, in *E. coli*, the protein **TCRF** (for transcription repair coupling factor; also known as **Mfd** protein, for *mutation frequency decline*) is an ATP-powered DNA translocase that displaces stalled RNA polymerase from the damaged template strand, following which **TCRF** recruits the proteins of the **UvrABC** system to the damage site. The repaired gene is then transcribed from its beginning. Since prokaryotic genes are much shorter than eukaryotic genes (most of which contain several long noncoding segments known as introns; Section 31-4Ac), this is a more efficient use of resources than generating the complex machinery necessary to restart transcription as occurs in eukaryotes.

### c. Base Excision Repair

DNA bases are modified by reactions that occur under normal physiological conditions as well as through the action of environmental agents. For example, adenine and cytosine residues spontaneously deaminate at finite rates to yield hypoxanthine and uracil residues, respectively. *S*-Adenosylmethionine (SAM), a common metabolic methylating agent (Section 26-3Ea), occasionally nonenzymatically methylates a base to form derivatives such as 3-methyladenine and 7-methylguanine residues (Fig. 30-54). Ionizing radiation can promote ring opening reactions in bases. Such changes modify or eliminate base pairing properties.

DNA containing a damaged base may be restored to its native state through base excision repair (BER). Cells contain a variety of **DNA glycosylases** that each cleave the glycosidic bond of a corresponding specific type of altered nucleotide (Fig. 30-59), thereby leaving a deoxyribose residue in the backbone. Such **apurinic** or **apyrimidinic (AP) sites** (also called **abasic sites**) are also generated under normal physiological conditions by the spontaneous hydrolysis of a glycosidic bond. The deoxyribose residue is then cleaved on one side by an **AP endonuclease**, the deoxyribose and several adjacent residues are removed by the action of a

**Figure 30-59 Action of DNA glycosylases.** These enzymes hydrolyze the glycosidic bond of their corresponding altered base (red) to yield an AP site.

cellular exonuclease (possibly associated with a DNA polymerase), and the gap is filled in and sealed by a DNA polymerase and DNA ligase.

### d. Uracil in DNA Would Be Highly Mutagenic

For some time after the essential functions of nucleic acids had been elucidated, there seemed no apparent reason for nature to go to the considerable metabolic effort of using thymine in DNA and uracil in RNA when these substances have virtually identical base pairing properties. This enigma was solved by the discovery of cytosine's penchant for conversion to uracil by deamination, either via spontaneous hydrolysis (Fig. 30-54), which is estimated to occur ~120 times per day in each human cell, or by reaction with nitrites (Section 32-1Aa). If U were the normal DNA base, the deamination of C would be highly mutagenic because there would be no indication of whether the resulting mismatched **G · U** base pair had originally been **G · C** or **A · U**. Since **T** is DNA's normal base, however, any **U** in DNA is almost certainly a deaminated **C**. U's that occur in DNA are efficiently excised by **uracil-DNA glycosylase [UDG; also called uracil N-glycosylase (UNG)]** and then replaced by **C** through BER.

UDG also has an important function in DNA replication. dUTP, an intermediate in dTTP synthesis, is present in all cells in small amounts (Section 28-3Ba). DNA polymerases do not discriminate well between dUTP and dTTP (recall that DNA polymerases select a base for incorporation into DNA according to its ability to form a Watson-Crick-shaped base pair with the template; Section 30-2Aa) so that, despite the low dUTP level that cells maintain, newly synthesized DNA contains an occasional **U**. These **U**'s are rapidly replaced by **T** through BER. However, since excision occurs more rapidly than repair, all

newly synthesized DNA is fragmented. When Okazaki fragments were first discovered (Section 30-1C), it therefore seemed that all DNA was synthesized discontinuously. This ambiguity was resolved with the discovery of *E. coli* defective in UDG. In these *ung*<sup>-</sup> mutants, only about half of the newly synthesized DNA is fragmented, strongly suggesting that DNA's leading strand is synthesized continuously.

#### e. Uracil–DNA Glycosylase Induces Uridine Nucleotides to Flip Out

The X-ray structure of human UDG in complex with a 10-bp DNA containing a U · G mismatch (which can form a doubly hydrogen-bonded base pair whose shape differs from that of Watson–Crick base pairs; Section 32-2Db), determined by John Tainer, reveals that the UDG has bound the DNA with its uridine nucleotide flipped out of the ds-DNA (Fig. 30-60). Moreover, the enzyme has hydrolyzed uridine's glycosidic bond yielding the free uracil base and an AP site on the DNA, although both remain bound to the enzyme. The cavity in the DNA's base stack that would otherwise be occupied by the flipped-out uracil is filled by the side chain of Arg 272, which intercalates into the DNA from its minor groove side. The X-ray structure of a similar complex in which the U · G mismatch was replaced by a U · A base pair contained essentially identical features. However, when the U in the U · A-containing complex was replaced by **pseudouridine** (in which the “glycosidic” bond is made to uracil's C5 atom rather than to N1),

**Pseudouridine**

the uracil remained covalently linked to the DNA because the UDG could not hydrolyze its now C—C “glycosidic” bond.

How does UDG detect a base-paired uracil in the center of DNA and how does it discriminate so acutely between uracil and other bases, particularly the closely similar thymine? The above X-ray structures indicate that the phosphate groups flanking the flipped-out nucleotide are 4 Å closer together than they are in B-DNA (8 Å vs 12 Å), which causes the DNA to kink by ~45° in the direction parallel to the view in Fig. 30-60. These distortions arise from the binding of three rigid protein loops to the DNA, which would be unable to simultaneously bind to undistorted B-DNA. This led Tainer to formulate the “pinch–push–pull” mechanism for uracil detection in which he postulated that UDG rapidly scans a DNA for uracil by periodically binding to it so as to compress and thereby slightly bend the DNA's backbone (pinch). The DNA's presumed low resistance to bending at a uracil-containing site (a U · G base pair is smaller than C · G and hence leaves a space in the base stack, whereas a U · A base pair is even weaker than T · A) permits the enzyme to flip out the uracil by intercalating Arg 272 into the minor groove (push), thereby fully bending and kinking the DNA.

**Figure 30-60** X-ray structure of human uracil–DNA glycosylase (UDG) in complex with a 10-bp DNA containing a U · G base pair. The protein (the C-terminal 223 residues of the 304-residue monomer) is represented by its ribbon diagram embedded in its transparent molecular surface. The DNA, viewed looking into its major groove, is drawn in stick form colored according to atom type (C green, N blue, O red, P orange). The U · G base pair's uridine nucleotide has flipped out of the double helix (to the right of the DNA) and has been hydrolyzed to yield an AP nucleotide (stick form with C cyan) and uracil (space-filling form with C cyan), which remains bound in the enzyme's binding pocket. The side chain of Arg 272 (space-filling form with C yellow) has intercalated into the DNA base stack to fill the space vacated by the flipped-out uracil base. [Based on an X-ray structure by John Tainer, The Scripps Research Institute, La Jolla, California. PDBId 4SKN.]

This process is aided by the tight binding of the flipped-out uracil to the enzyme (pull). The exquisite specificity of this binding pocket for uracil prevents the binding and hence hydrolysis of any other base that the enzyme may have induced to flip out. Thus the overall shapes of adenine and guanine exclude them from this pocket, whereas thymine's 5-methyl group is sterically blocked by the rigidly held side chain of Tyr 147. Cytosine, which has approximately the same shape as uracil, is excluded through a set of hydrogen bonds emanating from the protein that mimic those made by adenine in a Watson–Crick A · U base pair.

AP sites in DNA are highly cytotoxic because they irreversibly trap mammalian topoisomerase I in its covalent complex with DNA (Section 29-3Ca). Moreover, since the ribose at the AP site lacks a glycosidic bond, it can readily convert to its linear form (Section 11-1B), whose reactive aldehyde group can cross-link to other cell components. This rationalizes why AP sites remain tightly bound to UDG in solution as well as in crystals. UDG activity is enhanced by AP endonuclease, the next enzyme in the BER pathway, but the two enzymes do not interact in the absence of DNA. This suggests that UDG remains bound to an AP site it generated until it is displaced by the more tightly binding AP endonuclease, thereby protecting the cell from the AP site's cytotoxic effects. It seems likely that other damage-specific DNA glycosylases function similarly.

### C. Mismatch Repair

Any replicational mispairing that has eluded the editing functions of the various participating DNA polymerases may still be corrected by a process known as **mismatch repair (MMR)**. For example, *E. coli* Pol I and Pol III have error rates of  $10^{-6}$  to  $10^{-7}$  per base pair replicated but the observed mutational rates in *E. coli* are  $10^{-9}$  to  $10^{-10}$  per base pair replicated. In addition, the MMR system can correct insertions or deletions of up to 4 nt (which arise from the slippage of one strand relative to the other in the active site of DNA polymerase). The importance of MMR is indicated by the fact that defects in the human MMR system result in a high incidence of cancer, most notably **hereditary nonpolyposis colorectal cancer (HNPCC)**; which affects several organs and may be the most common inherited predisposition to cancer).

If an MMR system is to correct errors in replication rather than perpetuate them, it must distinguish the parental DNA, which has the correct base, from the daughter strand, which has an incorrect although normal base. In *E. coli*, as we have seen (Section 30-3C), this is possible because newly replicated GATC palindromes remain hemimethylated until the Dam methyltransferase has had sufficient time to methylate the daughter strand.

*E. coli* mismatch repair, which was elucidated in large part by Paul Modrich, requires the participation of three proteins and occurs as follows (Fig. 30-61):

1. **MutS** (853 residues) binds to a mismatched base pair or unpaired bases as a homodimer.
2. The MutS–DNA complex binds **MutL** (615 residues), also as a homodimer.
3. The MutS–MutL complex translocates along the DNA in both directions, thereby forming a loop in the DNA. The translocation appears to be driven by the ATPase function of MutS.
4. On encountering a hemimethylated GATC palindrome, the MutS–MutL complex recruits **MutH** (228 residues) and activates this single-strand endonuclease to make a nick on the 5' side of the unmethylated GATC. This GATC may be located on either side of the mismatch and over 1000 bp distant from it, although repair efficiency decreases with the distance between the nick and the mismatch.
5. MutS–MutL recruits UvrD helicase, which in concert with an exonuclease separates the strands and degrades the nicked strand from the nick to beyond the mismatch. If the nick is on the 3' side of the mismatch as shown, the exonuclease is **exonuclease I** (a  $3' \rightarrow 5'$  exonuclease), whereas if the nick is on the 5' side of the mismatch, the exonuclease can be either **RecJ** or **exonuclease VII** (both  $5' \rightarrow 3'$  exonucleases).

The resulting gap is filled in by Pol III and sealed by DNA ligase, thereby correcting the mismatch. MutL is also an ATPase, which, it is postulated, functions to coordinate the various steps of mismatch repair.

Eukaryotic MMR systems are, not surprisingly, more complicated than those of *E. coli*. Eukaryotes express six homologs of MutS and five homologs of MutL that form

**Figure 30-61** The mechanism of mismatch repair in *E. coli*.

heterodimers on mismatched DNA. However, homologs of MutH only occur in gram-negative bacteria. Eukaryotes must have some other way of differentiating the parental and daughter DNA strands. Perhaps a newly synthesized daughter strand is identified by its as-yet unsealed nicks. DNA resynthesis is probably mediated by pol  $\delta$ .

### D. The SOS Response

Agents that damage DNA, such as UV radiation, alkylating agents, and cross-linking agents, induce a complex system of cellular changes in *E. coli* known as the **SOS response**. *E. coli* so treated cease dividing and increase their capacity to repair damaged DNA.

#### a. LexA Protein Represses the SOS Response

Clues as to the nature of the SOS response were provided by the observations that *E. coli* with mutant *recA* or *lexA* genes have their SOS response permanently switched on. **RecA**, a 353-residue protein that coats DNA as a multimeric helical filament, plays a central role, as we shall see, in homologous recombination (Section 30-6Ab). When *E. coli* are exposed to agents that damage DNA or inhibit DNA replication, their RecA specifically mediates the proteolytic cleavage

of **LexA** (202 residues) between its Asp 84 and Gly 85. RecA is activated to do so on binding to ssDNA (it was initially assumed that RecA catalyzes the proteolysis of LexA but subsequent experiments by John Little indicate that activated RecA stimulates LexA to cleave itself). Further investigations indicated that LexA functions as a repressor of 43 genes that participate in DNA repair and the control of cell division, including *recA*, *lexA*, *uvrA*, and *uvrB*. DNA sequence analyses of the LexA-repressible genes revealed that they are all preceded by a homologous 20-nt sequence, the so-called **SOS box**, that has the palindromic symmetry characteristic of operators (control sites to which repressors bind so as to interfere with transcriptional initiation by RNA polymerase; Section 5-4A). Indeed, LexA has been shown to specifically bind the SOS boxes of *recA* and *lexA*.

The preceding observations suggest a model for the regulation of the SOS response (Fig. 30-62). During normal

**Figure 30-62** Regulation of the SOS response in *E. coli*. In a cell with undamaged DNA (above), LexA largely represses the synthesis of LexA, RecA, UvrA, UvrB, and other proteins involved in the SOS response. When there has been extensive

DNA damage (below), RecA is activated by binding to the resulting single-stranded DNA to stimulate LexA self-cleavage. The consequent synthesis of the SOS proteins results in the repair of the DNA damage.

growth, LexA largely represses the expression of the SOS genes, including the *lexA* gene, by binding to their SOS boxes so as to inhibit RNA polymerase from initiating the transcription of these genes. When DNA damage has been sufficient to produce postreplication gaps, however, this ssDNA binds to RecA so as to stimulate LexA cleavage. The LexA-repressible genes are consequently released from repression and direct the synthesis of SOS proteins including that of LexA (although this repressor continues to be cleaved through the influence of RecA). When the DNA lesions have been eliminated, RecA ceases stimulating LexA's autoproteolysis. The newly synthesized LexA can then function as a repressor, which permits the cell to return to normality.

### b. SOS Repair Is Error Prone

The *E. coli* Pol III holoenzyme is unable to replicate through a variety of lesions such as AP sites and thymine dimers. On encountering such lesions, the replisome stalls and disassembles by releasing its Pol III cores, a process that is called replication fork “collapse.” Cells have two general modes for restoring collapsed replication forks, **recombination repair** and **SOS repair**. Recombination repair circumvents the damaged template by using a homologous chromosome as its template DNA in a process known as **homologous recombination**, which also functions to generate genetic diversity. Hence we shall postpone our discussion of recombination repair until after our consideration of homologous recombination in Section 30-6A. In the following paragraphs we discuss SOS repair.

In SOS repair, the Pol III core lost from the collapsed replication fork is replaced by one of two so-called **bypass DNA polymerases**, whose synthesis is induced by the SOS response: **DNA polymerase IV (Pol IV)**, the 336-residue product of the *dinB* gene) or **DNA polymerase V [Pol V]**; the heterotrimeric product of the *umuD* and *umuC* genes, **UmuD'<sub>2</sub>C** (umu for *UV mutagenesis*), where UmuD' is produced by the RecA-assisted self-cleavage of the 139-residue **UmuD** to remove its N-terminal 24 residues, and UmuC consists of 422 residues]. Both of these enzymes are Y-family DNA polymerases, all of whose members lack 3' → 5' proofreading exonuclease activity and replicate undamaged DNA with poor fidelity and low processivity and hence are also known as **error-prone DNA polymerases**.

**Translesion synthesis (TLS)** by Pol V, which was characterized in large part by O'Donnell and Myron Goodman, requires the simultaneous presence of the β<sub>2</sub> sliding clamp, the γ complex (clamp loader), and SSB, together with a RecA filament in complex with the ssDNA arising from the action of helicase on the dsDNA ahead of the stalled replication fork. This so-called **Pol V mutasome** tends to incorporate G about half as often as A opposite thymine dimers and AP sites, with pyrimidines being installed infrequently. This process is, of course, highly mutagenic. But even in replicating undamaged DNA, Pol V is at least 1000-fold more error prone than is Pol I or Pol III holoenzyme. However, after synthesizing ~7 nt, the Pol V mutasome is replaced by Pol III holoenzyme, which commences normal

DNA replication after the now bypassed lesion. Pol II, a TLS participant that accurately replicates DNA, is also induced by the SOS response but it is synthesized well before Pol V appears (see below). The role of Pol II appears to be the mediation of error-free TLS, and only if this process fails is it replaced by Pol V to carry out error-prone TLS.

There are numerous types of DNA lesions besides AP sites and thymine dimers that interfere with normal DNA replication. Depending on the type of lesion, Pol IV, which is also error prone, may instead be recruited to carry out TLS. With many lesions, TLS may skip over the altered nucleotide, resulting in deletion of one or two bases in the daughter strand opposite the lesion (yielding a **frameshift mutation**, so called because it would change a structural gene's reading frame from that point onward; Section 5-4Bd). Moreover, Pol IV is prone to generating frameshift mutations even when replicating undamaged DNA.

The Y-family DNA polymerase **Dpo4** from the archaeobacterium *Sulfolobus solfataricus* P2, a homolog of *E. coli* Pol IV and Pol V, misincorporates ~1 base per 500 replicated nucleotides. The X-ray structure of a complex of Dpo4 with a primer–template DNA that had been incubated with ddATP (which is complementary to the template base), determined by Wei Yang, reveals the structural basis for this low fidelity (Fig. 30-63). The 352-residue protein contains the fingers, palm, and thumb domains

**Figure 30-63** X-ray structure of the bypass DNA polymerase **Dpo4** from *Sulfolobus solfataricus* P2 in complex with a primer–template DNA and ddADP. The protein is drawn in ribbon form with its fingers, palm, thumb, and little finger domains blue, red, green, and purple, respectively. The DNA is gold with its backbones drawn as ribbons and its bases represented by rods. The ddADP, which is base-paired to a template T in the enzyme's active site, is shown in ball-and-stick form colored according to atom type (C pink, N blue, O red, and P magenta). [Courtesy of Wei Yang, NIH, Bethesda, Maryland. PDBid 1JX4.]

common to all known DNA polymerases (although their orders differ in the sequences of the different families of DNA polymerases) and, in addition, has a C-terminal domain unique to Y-family DNA polymerases that has been dubbed the “little finger” domain. The enzyme, as expected, has incorporated a ddA residue at the 3' end of the primer and, in addition, binds a ddADP in base-paired complex to the new template T. The little finger domain binds in the major groove of the DNA. However, the fingers and thumb domains are small and stubby compared to those of replicative DNA polymerases such as KlenTaq1 (Fig. 30-9) and pol  $\delta$  (Fig. 30-41), and the residues that contact the base pair in the active site are all Gly and Ala rather than the Phe, Tyr, and Arg that mainly do so in the replicative DNA polymerases. Moreover, the bound DNA is entirely in the B form rather than in the A form at the active site as occurs in many replicative DNA polymerases. Since the minor groove is more accessible in A-DNA than in B-DNA (Section 29-1B), this suggests that error-prone DNA polymerases have relatively little facility to monitor the base-pairing fidelity of the incoming nucleotide. This accounts for the ability of error-prone DNA polymerases to accommodate distorted template DNA as well as non-Watson–Crick base pairs at their active sites.

*SOS repair is an error-prone and hence mutagenic process.* It is therefore a process of last resort that is only initiated ~50 min after SOS induction if the DNA has not already been repaired by other means. Yet, DNA damage that normally activates the SOS response is nonmutagenic in the *recA*<sup>-</sup> *E. coli* that survive. This is, as we saw, because bypass DNA polymerases will replicate over a DNA lesion even when there is no information as to which bases were originally present. Indeed, *most mutations in E. coli arise from the actions of the SOS repair system*, which is therefore a testimonial to the proposition that survival with a chance of loss of function (and the possible gain of new ones) is advantageous, in the Darwinian sense, over death, although only a small fraction of cells actually survive this process. It has therefore been suggested that, under conditions of environmental stress, the SOS system functions to increase the rate of mutation so as to increase the rate at which the *E. coli* adapt to the new conditions. Finally, it should be noted that the eukaryotic pols  $\eta$ ,  $\iota$ , and  $\kappa$ , all Y-family members, and pol  $\zeta$ , an X-family member, are implicated in TLS and that pol  $\eta$ , the product of the *XPV* gene, is defective in the XPV form of xeroderma pigmentosum (Section 30-5Bb).

### E. Double-Strand Break Repair

Double-strand breaks (**DSBs**) in DNA are produced when a replication fork encounters a nick and by the reactive oxygen species (ROS) by-products of oxidative metabolism and ionizing radiation (which also produces ROS). In fact, around 5 to 10% of dividing cells in culture exhibit at least one chromosome break at any given time. Moreover, DSBs are normal intermediates in certain specialized cellular processes such as recombination during meiosis (Sec-

tion 1-4Ab) and **V(D)J recombination** in lymphoid cells, which helps generate the vast diversity of antigen-binding sites in antibodies and T-cell receptors (Section 35-2C). Unrepaired or misrepaired DSBs can be lethal to cells or cause chromosomal aberrations that may lead to cancer. Hence, the efficient repair of DSBs is essential for cell viability and genomic integrity.

Cells have two general modes to repair DSBs: recombination repair, which only occurs during the late S and G<sub>2</sub> phases of the cell cycle (when sister chromatids are present to serve as templates), and **nonhomologous end-joining (NHEJ)**, which functions throughout the cell cycle. Here we discuss NHEJ, a process which, as its name implies, directly rejoins DSBs. The recombination repair of DSBs is discussed in Section 30-6Ag.

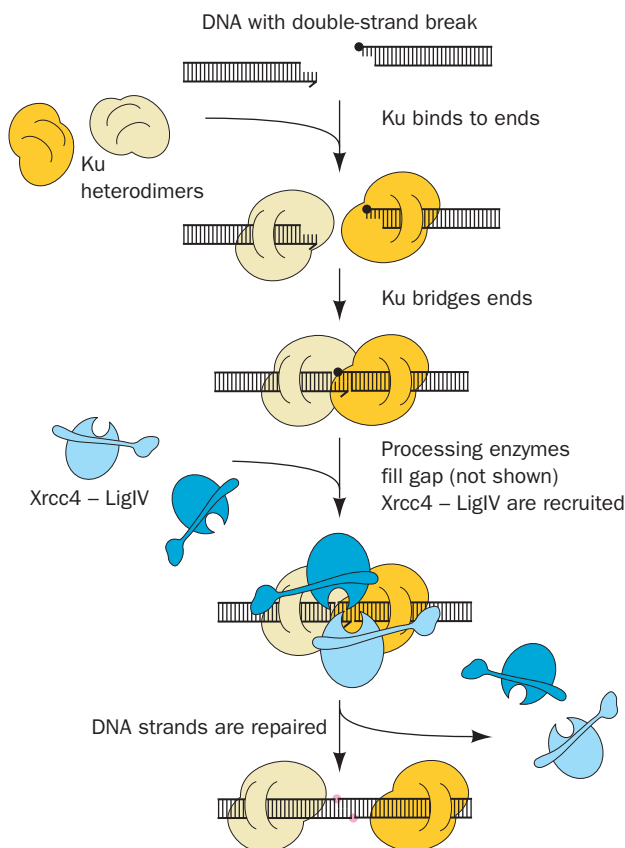

In NHEJ, the broken ends of the DSB must be aligned, its frayed ends trimmed and/or filled in, and their strands ligated. The core NHEJ machinery in eukaryotes includes the DNA end-binding protein **Ku** (a heterodimer of homologous 70- and 83-kD subunits, **Ku70** and **Ku80**), **DNA ligase IV**, and the accessory protein **Xrcc4**. Ku, an abundant nuclear protein, binds to a DSB, whether blunt or with an overhang, and hence appears to be the cell's primary DSB sensor. The X-ray structure of Ku in complex with a 14-bp DNA, determined by Jonathan Goldberg, reveals that the protein cradles the dsDNA segment along its entire length and encircles its central ~3 bp segment (Fig. 30-64). The protein ring is also present in the closely

**Figure 30-64** X-ray structure of human Ku protein in complex with DNA containing 14 bp. The subunits of Ku70 (red helices and yellow strands) and Ku80 (blue helices and green strands) are viewed along the pseudo-2-fold axis relating them. The DNA, viewed with its DSB pointing upward, is drawn in space-filling form with its sugar–phosphate backbone dark gray and its base pairs light gray. Note that the DNA is surrounded by a ring of protein. [Courtesy of John Tainer, The Scripps Research Institute, La Jolla, California. Based on an X-ray structure by Jonathan Goldberg, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1JEY.]

similar X-ray structure of Ku alone, thereby explaining why Ku that is bound to a dsDNA, which is then circularized, becomes permanently associated with it. Ku makes no specific contacts with the DNA's bases and few with its sugar-phosphate backbone, but instead fits snugly into the DNA's major and minor grooves so as to precisely orient it.

Ku-DNA complexes have been shown to dimerize so as to align the members of a DSB, both blunt ended and with short (1–4 bp) complementary single strands, for ligation as is diagrammed in Fig. 30-65. The DNA ends are exposed along one face of each Ku-DNA complex, presumably making them accessible to polymerases that fill in gaps and to nucleases that trim excess and inappropriate ends preparatory for ligation by DNA ligase IV in complex with Xrcc4. Nucleotide trimming, which of course generates mutations, appears to be carried out in

**Figure 30-65** Schematic diagram of nonhomologous end-joining (NHEJ). The left dsDNA fragment is missing a base and the right fragment is blocked by a nonligatable group (filled black circle). The two Ku heterodimers are drawn in two shades of yellow and the Xrcc4–DNA ligase IV complexes are drawn in two shades of blue. The newly repaired links in the DNA are represented by pink circles. [After Jones, J.M., Gellert, M., and Yang, W., *Structure* **9**, 881 (2001).]

an ATP-dependent manner by the evolutionarily conserved **Mre11 complex**, which consists of two **Mre11** nuclease subunits and two **Rad50** ATPase subunits. Ku is eventually released from the rejoined DNA, perhaps by proteolytic cleavage.

The reason that the mutations generated by NHEJ are usually not unacceptably deleterious is that only a small fraction of the mammalian genome is expressed (Section 34-2A). In fact, the genome in a somatic cell of a 70-year-old human typically contains ~2000 “scars” caused by NHEJ.

## F. Identification of Carcinogens

Many forms of cancer are known to be caused by exposure to certain chemical agents that are therefore known as **carcinogens**. It has been estimated that as much as 80% of human cancer arises in this fashion. There is considerable evidence that the primary event in carcinogenesis is often damage to DNA (carcinogenesis is discussed in Section 34-4C). Carcinogens are consequently also likely to induce the SOS response in bacteria and thus act as indirect mutagenic agents. In fact, there is a high correlation between carcinogenesis and mutagenesis (recall, e.g., the progress of xeroderma pigmentosum; Section 30-5Bb).

There are presently over 80,000 man-made chemicals of commercial importance and ~1000 new ones are introduced each year. The standard animal tests for carcinogenesis, exposing rats or mice to high levels of the suspected carcinogen and checking for cancer, are expensive and require ~3 years to complete. Thus, relatively few substances have been tested in this manner.

### a. The Ames Test Assays for Probable Carcinogenicity

Bruce Ames devised a rapid and effective bacterial assay for carcinogenicity that is based on the high correlation between carcinogenesis and mutagenesis. He constructed special tester strains of *Salmonella typhimurium* that are *his*<sup>−</sup> (cannot synthesize histidine so that they are unable to grow in its absence), have cell envelopes that lack the lipopolysaccharide coating that renders normal *Salmonella* impermeable to many substances (Section 11-3Bc), and have inactivated excision repair systems. Mutagenesis in these tester strains is indicated by their reversion to the *his*<sup>+</sup> phenotype.

In the **Ames test**, ~10<sup>9</sup> tester strain bacteria are spread on a culture plate that contains only a small amount of histidine to permit the bacteria to initially grow and mutate. Usually a mixture of several *his*<sup>−</sup> strains is used so that mutations due to both base changes and nucleotide insertions or deletions can be detected. A mutagen placed in the culture medium causes some of these *his*<sup>−</sup> bacteria to revert to the *his*<sup>+</sup> phenotype, which is detected by their growth into visible colonies after 2 days at 37°C (Fig. 30-66). The mutagenicity of a substance is scored as the number of such colonies less the few spontaneously revertant colonies that occur in the absence of the mutagen.

**Figure 30-66 The Ames test for mutagenesis.** A filter paper disk containing a mutagen, in this case the alkylating agent ethyl methanesulfonate, is centered on a culture plate containing *his*<sup>-</sup> tester strains of *Salmonella typhimurium* in a medium that initially contained only a small amount histidine. A dense halo of revertant bacterial colonies appears around the disk from which the mutagen diffused. The larger colonies distributed about the culture plate are spontaneous revertants. The bacteria near the disk have been killed by the toxic mutagen's high concentration. [Courtesy of Raymond Devoret, Institut Curie, Orsay, France.]

Many noncarcinogens are converted to carcinogens in the liver or in other tissues via a variety of detoxification reactions (e.g., those catalyzed by the cytochromes P450; Section 15-4Bc). A small amount of rat liver homogenate is therefore included in the Ames test medium in an effort to approximate the effects of mammalian metabolism.

#### **b. Both Man-Made and Naturally Occurring Substances Can Be Carcinogenic**

There is an ~80% correspondence between the compounds determined to be carcinogenic by animal tests and those found to be mutagenic by the Ames test. Dose-response curves, which are generated by testing a given compound at a number of concentrations, are almost always linear and extrapolate back to zero, indicating that *there is no threshold concentration for mutagenesis*. Several compounds to which humans have been extensively exposed that were found to be mutagenic by the Ames test were later found to be carcinogenic in animal tests. These include tris(2,3-dibromopropyl)phosphate, which was used as a flame retardant on children's sleepwear in the mid-1970s and can be absorbed through the skin; and furylfuramide, which was used in Japan in the 1960s and 1970s as an antibacterial additive in many prepared foods (and had passed two animal tests before it was found to be mutagenic). Carcinogens are not confined to man-made compounds but also occur in nature. For example, carcinogens are contained in many plants that are

common in the human diet, including alfalfa sprouts. **Aflatoxin B<sub>1</sub>**,

one of the most potent carcinogens known, is produced by fungi that grow on peanuts and corn. Charred or browned food, such as occurs on broiled meats and toasted bread, contains a variety of DNA-damaging agents. Thus, with respect to carcinogenesis, as Ames has written, "Nature is not benign."

## **6 RECOMBINATION AND MOBILE GENETIC ELEMENTS**

The chromosome is not just a simple repository of genetic information. If this were so, the unit of mutation would have to be an entire chromosome rather than a gene because there would be no means of separating a mutated gene from the other genes of the same chromosome. Chromosomes would therefore accumulate deleterious mutations until they became nonviable.

It has been known from some of the earliest genetic studies that pairs of allelic genes may exchange chromosomal locations by a process known as **genetic recombination** (Section 1-4Cb). Mutated genes can thereby be individually tested, since their propagation is then not absolutely dependent on the propagation of the genes with which they had been previously associated. In this section, we consider the mechanisms by which genetic elements can move, both between chromosomes and within them.

### **A. Homologous Recombination**

**Homologous recombination** (also called **general recombination**) is defined as the exchange of homologous segments between two DNA molecules. Both genetic and cytological studies have long indicated that such a crossing-over process occurs in higher organisms during meiosis (Fig. 1-27). Bacteria, which are normally haploid, likewise have elaborate mechanisms for the interchange of genetic information. They can acquire foreign DNA through transformation (Section 5-2A), through a process called **conjugation** (mating) in which DNA is directly transferred from one cell to another via a cytoplasmic bridge (Section 31-1Ac), and via **transduction** in which a defective bacteriophage that has erroneously acquired a segment of bacterial DNA rather than the viral chromosome transfers this DNA to another bacterial cell. In all of these processes, the foreign DNA is installed in the recipient's chromosome or plasmid

through homologous recombination (to be propagated, a DNA segment must be part of a replicon; that is, be associated with a replication origin such as occurs in a chromosome, a plasmid, or a virus).

### a. Recombination Occurs via a Crossed-Over Intermediate

The prototypical model for homologous recombination (Fig. 30-67) was proposed by Robin Holliday in 1964 on the basis of genetic studies on fungi. The corresponding strands of two aligned homologous DNA duplexes are nicked, and the nicked strands cross over to pair with the nearly complementary strands of the homologous duplex after which the nicks are sealed (Fig. 30-67a–e), thereby yielding a four-way junction known as a **Holliday junction** (Fig. 30-67e). A Holliday junction has, in fact, been observed in the X-ray structure of d(CCGGTACCGG), determined Shing Ho (Fig. 30-68), in which, perhaps unexpectedly, all the bases

form normal Watson–Crick base pairs without any apparent strain. The crossover point can move in either direction, often thousands of nucleotides, in a process known as **branch migration** (Fig. 30-67e, f) in which the four strands exchange base-pairing partners.

A Holliday junction can be resolved into two duplex DNAs in two equally probable ways (Fig. 30-67g–l):

1. The cleavage of the strands that did not cross over (right branch of Fig. 30-67j–l) exchanges the ends of the original duplexes to form, after nick sealing, the traditional recombinant DNA (Fig. 1-27b).

2. The cleavage of the strands that crossed over (left branch of Fig. 30-67j–l) exchanges a pair of homologous single-stranded segments.

The recombination of circular duplex DNAs results in the types of structures diagrammed in Fig. 30-69. Electron microscopic evidence for the existence of the postulated

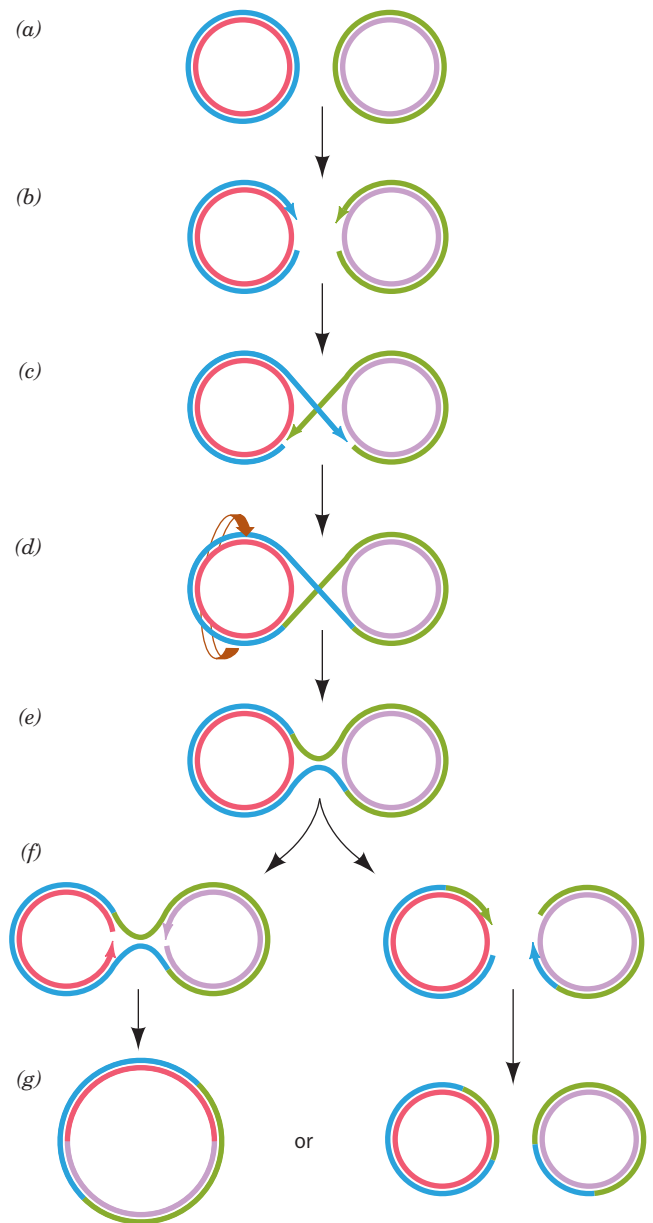

**Figure 30-67** The Holliday model of homologous recombination between homologous DNA duplexes.

 See the Animated Figures

**Figure 30-68** X-ray structure of the self-complementary decameric DNA d(CCGGTACCGG). (a) The secondary structure of the four-stranded Holliday junction formed by this sequence in which the four strands, A, B, C, and D, are differently colored, their nucleotides are numbered 1 to 10 from their 5' to 3' termini, and Watson–Crick base-pairing interactions are represented by black dashes. The 2-fold axis relating the two helices of this so-called **stacked-X conformation** is represented by the black lenticular symbol. (b) The observed three-dimensional structure of the Holliday junction, as viewed along its 2-fold axis, in which the oligonucleotides are represented in stick form with their backbones traced by ribbons, all colored as in Part a. With the exception of the backbones of strands B and D at the crossovers, the two arms of this structure each form an undistorted B-DNA helix, including the stacking of the base pairs flanking the crossovers. The two helices are inclined to each other by 41°. Note that Fig. 30-67g is a schematic representation of the stacked-X conformation as viewed perpendicular to both helices (from the side in this drawing and hence having the projected appearance of the letter X). A Holliday junction can also assume a so-called **open-X conformation**, which is represented by Fig. 30-67i. [Courtesy of Shing Ho, Oregon State University. PDBid 1DCW.]

**Figure 30-69** Homologous recombination between two circular DNA duplexes. This process can result either in two circles of the original sizes or in a single composite circle.

(a)

(b)

**Figure 30-70** Electron micrographs of intermediates in the homologous recombination of two plasmids. (a) A figure-8 structure. This corresponds to Fig. 30-69d. (b) A chi structure that results from the treatment of a figure-8 structure with a restriction endonuclease. Note the thinner single-stranded connections in the crossover region. “figure-8” structures is shown in Fig. 30-70a. These figure-8 structures were shown not to be just twisted circles by cutting them with a restriction endonuclease to yield **chi structures** (after their resemblance to the Greek letter  $\chi$ ) such as that pictured in Fig. 30-70b.

### b. Homologous Recombination in *E. coli* Is Catalyzed by RecA

The observation that *recA*<sup>-</sup> *E. coli* have a 10<sup>4</sup>-fold lower recombination rate than the wild-type indicates that *RecA* protein has an important function in recombination. Indeed, RecA greatly increases the rate at which complementary strands renature *in vitro*. This versatile protein (recall it also stimulates the autoproteolysis of LexA to trigger the SOS response and is an essential participant in the translesion synthesis of DNA; Section 30-5D) polymerizes cooperatively without regard to base sequence on ssDNA or on dsDNA that has a single-stranded gap. The resulting filaments, which may contain up to several thousand RecA monomers, specifically bind the homologous dsDNA, and, in an ATP-dependent reaction, catalyze strand exchange.

EM studies by Edward Egelman revealed that RecA filaments bound to ssDNA or dsDNA form a right-handed helix with ~6.2 RecA monomers per turn and a pitch (rise per turn) of 95 Å. The DNA in these filaments binds to the protein with 3 nt (or bp) per RecA monomer and hence is underwound with ~18.5 nt (or bp) per turn (vs 10 bp per turn for canonical B-DNA).

The formation of RecA–DNA filaments is highly cooperative; it requires five or six RecA protomers to form a stable assembly. Consequently, attempts to crystallize RecA–DNA filaments over many years were unsuccessful. Nikola Pavletich ingeniously solved this conundrum by linking five or six *E. coli* RecA genes (each corresponding to residues 1–335 of this 353-residue protein) in tandem via 14-residue linkers and mutating the first and last RecA so as to prevent them from forming longer filaments. These fusion proteins, which had DNA-dependent ATPase and strand-exchange activities comparable to that of monomeric RecA, formed crystals containing both ssDNA and dsDNA.

The X-ray structure of the RecA<sub>5</sub>–(ADP–AlF<sub>4</sub><sup>-</sup>)<sub>5</sub>–(dT)<sub>15</sub>–(dA)<sub>12</sub> complex (Fig. 30-71; ADP–AlF<sub>4</sub><sup>-</sup> is a nonhy-

**Figure 30-71** X-ray structure of the RecA<sub>5</sub>–(ADP–AlF<sub>4</sub><sup>-</sup>)<sub>5</sub>–(dT)<sub>15</sub>–(dA)<sub>12</sub> complex viewed with its filament axis vertical. The RecA units RecA<sup>1</sup> (the N-terminal unit) through RecA<sup>4</sup> are colored green, cyan, magenta, and gray, respectively, with the C-terminal unit, RecA<sup>5</sup>, colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The DNA and ADP–AlF<sub>4</sub><sup>-</sup> are drawn in space-filling form with DNA C gray, ADP C green, N blue, O red, P orange, F light blue, and Al purple. [Based on an X-ray structure by Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 3CMX.]

droyzable ATP analog) exhibits a straight filament axis with overall helical parameters that are closely similar to those derived from EM studies. Each RecA unit consists of a largely helical 30-residue N-terminal segment, a 240-residue  $\alpha/\beta$  ATPase core, and a 64-residue C-terminal globular domain. The linkers connecting adjacent RecA units are disordered. Each RecA unit makes extensive contacts with its nearest neighbors so as to form a filament with a deep helical groove that exposes the DNA bound in its interior (Fig. 30-71 is viewed looking into this groove).

The two DNA strands, which lie close to the filament axis, form a complete set of Watson–Crick base pairs. However, rather than being smoothly stretched out, as had been expected, the dsDNA assumes an irregular conformation in which each 3-bp segment that is bound to a RecA unit closely resembles B-DNA with the steps between successive base pairs in this triplet having an axial rise of  $\sim 3.4$  Å and a helical twist of  $\sim 30^\circ$  (vs 3.4 Å and  $36^\circ$  for canonical B-DNA; Table 29-1). In contrast, the step between successive base pair triplets has an axial rise of 8.4 Å and a helical twist of  $-4^\circ$ , thereby forming a 5-Å-high gap between successive triplets that is partially filled by the side chain of the conserved Ile 199. The sugar–phosphate backbone of the DNA strand furthest from the viewer in Fig. 30-71 [the (dT)<sub>15</sub>]

makes extensive contacts with RecA. In contrast, the other strand [the (dA)<sub>12</sub>] makes few contacts with the protein; it is held in place almost entirely by base pairing with the first strand. The ADP–AlF<sub>4</sub><sup>-</sup> is sandwiched between adjacent  $\alpha/\beta$  ATPase cores, where it is completely buried.

The X-ray structure of the ssDNA-containing RecA<sub>6</sub>–(ADP–AlF<sub>4</sub><sup>-</sup>)<sub>6</sub>–(dT)<sub>18</sub> complex closely resembles that of the foregoing dsDNA-containing complex but with the absence of the DNA strand closest to the viewer in Fig. 30-71. Thus, each RecA unit binds a (dT)<sub>3</sub> segment that is held in a B-DNA-like conformation with successive (dT)<sub>3</sub> segments separated by a 7.8-Å axial rise.

How does RecA mediate DNA strand exchange between single-stranded and duplex DNAs? On encountering a dsDNA with a strand that is complementary to its bound ssDNA, RecA partially unwinds the duplex and, in a reaction driven by RecA-catalyzed ATP hydrolysis, exchanges the ssDNA with the corresponding strand on the duplex. *This process tolerates only a limited degree of mispairing and requires that one of the participating DNA strands have a free end.* The assimilation (exchange) of a single-stranded circle with a strand on a linear duplex (Fig. 30-72) cannot proceed past the 3' end of a highly mismatched segment in the complementary strand. *The invasion of the single strand must*

#### Assimilation of 3' end of homologous DNA

#### No assimilation of noncomplementary DNA

**Figure 30-72** The RecA-catalyzed assimilation of a single-stranded circle by a dsDNA can occur only if the dsDNA has a 3' end that can base-pair with the circle (red strand).

Strand assimilation cannot proceed through a noncomplementary segment (purple and orange strands).

**Figure 30-73** Hypothetical model for the RecA-mediated strand exchange reaction. Homologous DNA molecules are paired in advance of strand exchange in a three-stranded helix. The ATP-driven rotation of the RecA filament about its helix

axis would cause duplex DNA to be “spooled in” to the filament, right to left as drawn. [After West, S.C., *Annu. Rev. Biochem.* **61**, 617 (1992).]

therefore begin at its 5' end. A model for the consequent branch migration process is diagrammed in Fig. 30-73. Of course, two such strand exchange processes must occur simultaneously in a Holliday junction (Figs. 30-67 and 30-69).

The above structures suggest that the fidelity of homologous recombination arises from the B-DNA-like conformation that RecA imposes on the otherwise flexible bound ssDNA strand, which would exclude non-Watson–Crick base pairs. Strand exchange, of course, requires the separation of the two strands of the incoming dsDNA to permit one of its strands to sample base pairing with the ssDNA substrate. The above structures suggest that this is facilitated by the disruption of base stacking between base pair triplets in the RecA–DNA complex. However, the structure of the triple helical DNA intermediate in the strand exchange reaction is, as yet, unknown.

### c. Eukaryotes Have RecA-Like Proteins

Yeast **RAD51** (339 residues) functions in the ATP-dependent repair and recombination of DNA in much the same way as does the 30% homologous *E. coli* RecA protein. The electron micrograph–based image reconstruction of RAD51 in complex with double-stranded DNA is nearly identical to that of RecA at low resolution: Both complexes form helical filaments in which the DNA has an  $\sim 5.1\text{-}\text{\AA}$  rise per base pair and 18.6 bp per turn. Since RAD51 homologs occur in chickens, mice, and humans, it is very likely that such filaments universally mediate DNA repair and recombination.

### d. RecBCD Initiates Recombination by Making Single-Strand Nicks

The single-strand nicks to which RecA binds are made by the **RecBCD** protein, the 330-kD heterotrimeric product of the SOS genes *recB*, *recC*, and *recD*. RecB is both a  $3' \rightarrow 5'$  helicase and a nuclease, whereas RecD is a  $5' \rightarrow 3'$  helicase. The formation of a RecA binding site begins with RecBCD binding to the end of a dsDNA and then unwinding it via its two ATP-driven helicase functions (Fig. 30-74). As it does so, RecB nucleolytically degrades the unwound single strands behind it, with the  $3'$ -ending strand being

cleaved more often and hence broken down to smaller fragments than the  $5'$ -ending strand. However, on RecC encountering the sequence GCTGGTGG from its  $3'$  end (the so-called **Chi** sequence, which occurs about every  $\sim 5$  kb in the *E. coli* genome), the enzyme pauses and ceases its cleavage of the  $3'$ -ending strand but increases the rate at which it cleaves the  $5'$ -ending strand. RecBCD then helps load RecA onto the  $3'$ -ending strand before dissociating from the DNA.

**Figure 30-74** The generation of a  $3'$ -ending single-strand DNA segment by RecBCD to initiate recombination. (1) RecBCD binds to a free end of a dsDNA and, in an ATP-driven process, advances along the helix, unwinding the DNA and degrading the resulting single strands behind it, with the  $3'$ -ending strand cleaved more often than the  $5'$ -ending strand. (2) When RecBCD encounters a properly oriented Chi sequence, it binds it and thus stops cleaving the  $3'$ -ending strand but increases the frequency at which it cleaves the  $5'$ -ending strand. This generates the potentially invasive  $3'$ -ending strand segment to which RecA binds.

**Figure 30-75** X-ray structure of *E. coli* RecBCD in complex with a 51-nt DNA capable of forming a 21-bp hairpin loop. The protein is drawn in semitransparent ribbon form with RecB yellow, RecC cyan, and RecD magenta. Note how the RecB nuclease domain is linked to the rest of the subunit by an extended polypeptide tether. The DNA is shown in space-filling form with C gray, N blue, O red, and P orange. A loop from RecC, which is drawn in space-filling form in green, is situated so as to wedge apart the two strands of the incoming dsDNA with the 3'-ending strand binding to the 3' → 5' helicase of RecB and the 5'-ending strand passing through RecC to bind to the 5' → 3' helicase of RecD. [Based on an X-ray structure by Dale Wigley, The London Research Institute, Herts, U.K. PDBid 3K70.]

Dale Wigley determined the X-ray structure of *E. coli* RecBCD in complex with a 51-nt DNA that could form a hairpin loop containing an up to 21-bp dsDNA stem (Fig. 30-75). The structure shows that RecB (1180 residues) and RecC (1122 residues) are intimately intertwined with RecB's C-terminal nuclease domain connected to the rest of the subunit by an extended 21-residue polypeptide tether. A 15-bp segment of dsDNA enters the protein through a tunnel between RecB and RecC. There it encounters a loop from RecC that appears to wedge the two strands apart, with the 6-nt 3'-ending single strand of the DNA binding to RecB and the 10-nt 5'-ending single strand binding to RecD (608 residues; the 5-nt loop connecting the two strands of the dsDNA at the top of Fig. 30-75 is disordered). The structure explains the different rates of cleavage of the two DNA strands. The 3'-ending strand emerges from a tunnel through RecC in the vicinity of the RecB nuclease domain, which is positioned to processively cleave it. The 5'-ending strand competes with the 3'-ending strand for the nuclease site, but since the 5'-ending strand is less favorably located, it is cleaved less frequently. However, after RecD has bound a Chi sequence,

the 3'-ending strand is no longer available for cleavage, which permits the nuclease to cleave the 5'-ending strand more frequently.

RecBCD can only commence unwinding DNA at a free duplex end. Such ends are not normally present in *E. coli*, which has a circular genome, but become available during such recombinational processes as bacterial transformation, conjugation, and viral transduction, as well as at collapsed replication forks.

#### e. RuvABC Mediates the Branch Migration and the Resolution of the Holliday Junction

The branch migration of the RecA-generated Holliday junction (Fig. 30-67e,f) requires the breaking and reforming of base pairs as the bases exchange partners in passing from one double helical stem to the other. Since  $\Delta G = 0$  for this process, it was initially assumed that it occurs spontaneously. However, such a process would move forward and backward at random and, moreover, would be blocked by as little as a single mismatched base pair. In *E. coli*, and most other bacteria, branch migration is an ATP-driven unidirectional process that is mediated by two proteins whose synthesis is induced by the SOS response (Section 30-5D): **RuvB** (336 residues; Ruv for repair of UV damage), an ATP-powered pump that drives branch migration but binds only weakly to DNA; and **RuvA** (203 residues), which binds to both a Holliday junction and to RuvB, thereby targeting **RuvB** to the DNA.

The X-ray structure of *Mycobacterium leprae* (the cause of leprosy) RuvA in complex with a synthetic and immobile Holliday junction (Fig. 30-76a), determined by Morikawa, reveals that RuvA forms a homotetramer to which the Holliday junction binds in its open-X conformation (Fig. 30-76b). The RuvA tetramer, which has the appearance of a four-petaled flower (it has  $C_4$  symmetry rather than the  $D_2$  symmetry of the vast majority of homotetramers), is relatively flat ( $80 \times 80 \times 45 \text{ \AA}$ ) with one square face concave and the other convex. The concave face (that facing the viewer in Fig. 30-76b), which is highly positively charged and is studded with numerous conserved residues, has four symmetry-related grooves that bind the Holliday junction's four arms. This face's centrally located projection or "pin" is formed by the side chains of Glu 55 and Asp 56 from each subunit, and hence the repulsive forces between them and the Holliday junction's anionic phosphate groups probably facilitate the separation of the single-stranded DNA segments and guide them from one double helix to another.

RuvB is a member of the AAA+ family of ATPases (Section 30-2Ca). The X-ray structure of *Thermus thermophilus* RuvB crystallized in the presence of both ADP and AMPPNP, determined by Morikawa, reveals two molecules of RuvB with somewhat different conformations: one binding ADP and the other binding AMPPNP. Each RuvB molecule consists of three consecutive domains arranged in a crescentlike configuration with the adenine nucleotides binding at the interface between its N-terminal and middle domains. EM studies indicate that, in the presence of dsDNA, RuvB oligomerizes to form a hexamer (Fig. 30-77a),

(a)

**Figure 30-76 X-ray structure of a RuvA tetramer in complex with a Holliday junction.** (a) A schematic drawing of the synthetic and immobile Holliday junction in this structure showing its base sequence. The two A · T base pairs that are disrupted at the crossover (and which, if the Holliday junction consisted of two homologous dsDNAs, as it normally does, would exchange base pairing partners) are magenta. as do most other AAA+ family members, including the D2 domain of NSF (Fig. 12-78). A hexameric model of RuvB (Fig. 30-77b), constructed by superimposing the N-terminal

domain of the RuvB monomer on the ATPase domains of the NSF D2 hexamer, agrees well with the EM-based image and contains no serious steric clashes. This 130-Å-diameter

the homologous ATPase domains of the NSF D2 homohexamer (Fig. 12-78). The N-terminal, middle, and C-terminal domains are blue, yellow, and green, respectively, and its bound AMPPNP is drawn in stick form in red. [Courtesy of Kosuke Morikawa, Biomolecular Engineering Research Institute, Osaka, Japan. PDBid 1HQJ.]

hexameric model contains a 30-Å-diameter hole through which a single dsDNA can readily be threaded (see below). Moreover the six  $\beta$  hairpins, one per monomer, that have been implicated in binding to RuvA are located on the top face of the hexamer (as pictured in Fig. 30-77b).

The EM images of the RuvAB–Holliday junction complex indicate that RuvA binds two oppositely located RuvB hexamers. This has led to the model of their interaction depicted in Fig. 30-78 in which RuvA binds the Holliday junction and helps load the RuvB hexameric rings onto two opposing arms of the Holliday junction. The two hexameric rings are postulated to counter-rotate, each in the anticlockwise direction looking toward the center of the junction, so as to screw the horizontal DNA strands through the center of the junction and into the top and bottom double helices, thereby effecting branch migration (although rather than actually rotating relative to RuvA, a RuvB hexamer might pull the dsDNA through its central hole by “walking” up its grooves in a manner resembling that postulated for hexagonal helicases; Section 30-2Ca). The direction of branch migration depends on which pair of arms the RuvB hexamers are loaded.

The final stage of homologous recombination is the resolution of the Holliday junction into its two homologous dsDNAs. This process is carried out by **RuvC**, a homodimeric endonuclease of 173-residue subunits whose X-ray structure indicates that its active sites are located  $\sim 30$  Å apart on the same face of the protein. This suggests that RuvC sits down on the open face of the RuvAB–Holliday junction complex, that facing the viewer in Fig. 30-78, to

**Figure 30-78 Model of the RuvAB–Holliday junction complex.** The model is based on electron micrographs such as that in the inset. The proteins are represented by their surface diagrams with the RuvA tetramer, as seen in its X-ray structure, green and the two oppositely oriented RuvB hexamers white. The DNA of the Holliday junction is drawn in space-filling form with its homologous blue and pink strands complementary to its light blue and red strands. The complex is postulated to drive branch migration via the ATP-driven counter-rotation of the RuvB hexamers relative to the RuvA tetramer. This pumps (screws) the horizontal dsDNAs through the RuvB hexamers to the center of the Holliday junction, where their strands separate and then base-pair with their homologs to form new dsDNAs, which are pumped out vertically. [Courtesy of Peter Artymiuk, University of Sheffield, U.K.]

cleave oppositely located strands at the Holliday junction. The resulting single-strand nicks in the now resolved dsDNAs are sealed by DNA ligase.

The X-ray structure of RuvC in complex with DNA has not been determined, although model building studies suggest that it binds Holliday junction DNA in its stacked-X conformation. However, Dietrich Suck determined the X-ray structure of bacteriophage **T4 endonuclease VII** in complex with a Holliday junction in the stacked-X conformation (Fig. 30-79). RuvC and the 157-residue T4 endonuclease VII exhibit no structural similarity but both are homodimers of relatively small subunits that have similar

**Figure 30-79 X-ray structure of bacteriophage T4 endonuclease VII resolving a Holliday junction as viewed along its pseudo-2-fold axis.** The Holliday junction DNA is drawn in ladder form with each of its four different 24-nt strands differently colored. The protein, a homodimer of 157-residue subunits, is shown in ribbon form embedded in its semitransparent molecular surface with one subunit red and the other blue. The arrows indicate the symmetrically located DNA cleavage sites. Compare the DNA in this structure to that in Fig. 30-68b. [Based on an X-ray structure by Dietrich Suck, European Molecular Biology Laboratory, Heidelberg, Germany. PDBid 2QNC.]

functions: the resolution of Holliday junctions into two duplex DNAs by introducing symmetrically placed nicks in equivalent strands (Fig. 30-67j).

The forgoing model of the **RuvABC resolvosome** provides a satisfying mechanism for branch migration and Holliday junction resolution. However, there is a fly in this particular ointment. The X-ray structure of an *M. leprae* RuvA–Holliday junction complex crystallized under conditions different from that in Fig. 30-76, determined by Laurence Pearl, resembles the complex in Fig. 30-76b but with a second RuvA tetramer in face-to-face contact with the concave (DNA-binding) side of the first. Hence, the Holliday junction is contained in two intersecting tunnels running through the resulting RuvA octamer. Are both RuvA–Holliday junction structures biologically relevant, or is one an artifact of crystallization? Pearl argues that the extensive complementary contacts between the two RuvA tetramers, which are strongly conserved, are unlikely to be artifactual and that a single RuvA tetramer is unlikely to withstand the torque exerted by the two (in effect) counter-rotating RuvB hexamers. However, if the RuvA octamer is biologically relevant, one of its tetramers would at some point have to dissociate in order to allow RuvC access to the Holliday junction. Yet, modeling studies indicate that the RuvC dimer cannot properly contact the RuvB tetramer-bound Holliday junction without it changing from its open-X to its stacked-X conformation. Further investigations are necessary to resolve these inconsistencies.

#### f. Recombination Repair Reconstitutes Damaged Replication Forks

Transformation, transduction, and conjugation are such rare events that the vast majority of bacterial cells never participate in these processes. Similarly, the only place in the metazoan life cycle at which gene shuffling through homologous recombination occurs is in meiosis (Section 1-4A). Why then do nearly all cells have elaborate systems for mediating homologous recombination? It is because damaged replication forks occur at a frequency of at least once per bacterial cell generation and perhaps 10 times per eukaryotic cell cycle. The DNA lesions that damage the replication forks can be circumvented via homologous recombination in a process named **recombination repair** [translesion synthesis, which is highly mutagenic, is a process of last resort (Section 30-5Db)]. Indeed, the rates of synthesis of RuvA and RuvB are greatly enhanced by the SOS response. Thus, as Michael Cox pointed out, *the primary function of homologous recombination is to repair damaged replication forks*. In what follows, we describe recombination repair as it occurs in *E. coli*.

Recombination repair is called into play when a replication fork encounters an unrepaired single-strand lesion (Fig. 30-80):

1. DNA replication is arrested at the lesion but continues on the opposing undamaged strand for some distance before the replisome fully collapses (Section 30-5Db).

2. The replication fork regresses to form a type of Holliday junction dubbed a “chicken foot.” This process may occur spontaneously as driven by the positive supercoiling that has built up ahead of the replication fork, it may be mediated by **RecA**, or it may be promoted by **RecG**, an

ATP-driven helicase that catalyzes branch migration at DNA junctions with three or four branches.

3. The single-strand gap at the collapsed replication fork, now an overhang, is filled in by Pol I.

4. Reverse branch migration mediated by RuvAB or RecG yields a reconstituted replication fork, which supports replication restart (see below).

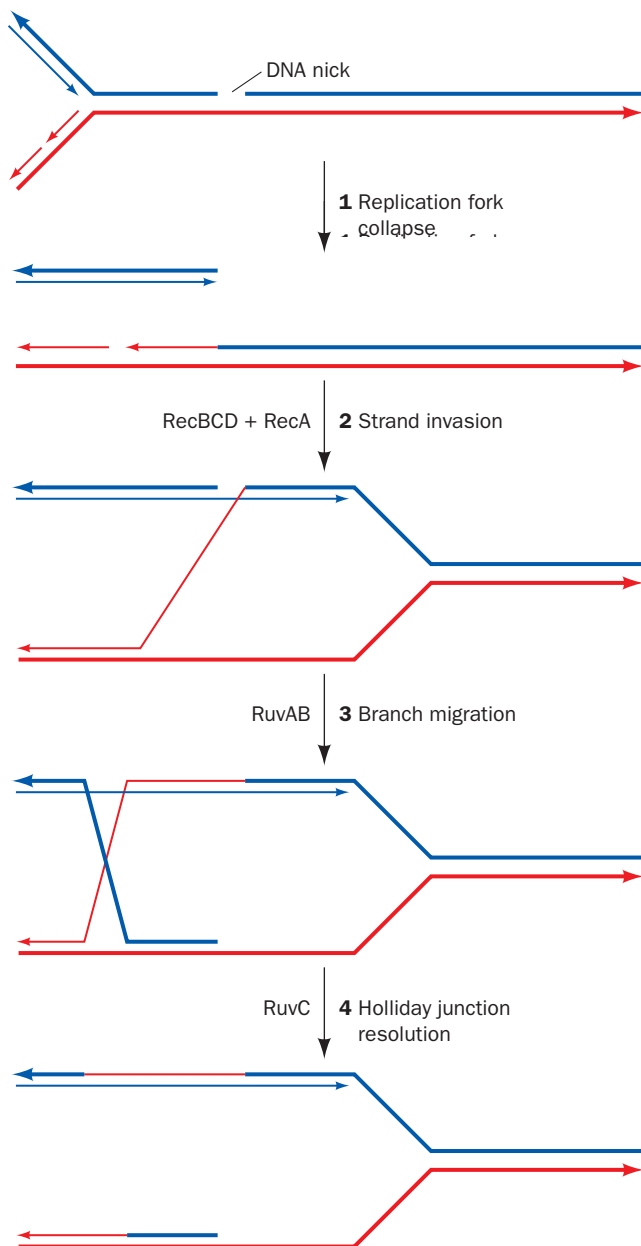

Note that this process does not actually repair the single-strand lesion that has caused the problem but instead reconstructs the replication fork in a way that permits the previously discussed DNA repair systems (Section 30-5) to eventually eliminate the lesion.

**Figure 30-80** The recombination repair of a replication fork that has encountered a single-strand lesion. Thick lines indicate parental DNA, thin lines indicate newly synthesized DNA, the cyan lines indicate DNA that was synthesized by Pol I, and the arrows point in the 5' → 3' direction. [After Cox, M.M., *Annu. Rev. Genet.* **35**, 53 (2001).]

A second situation that requires recombination repair is the encounter of a replication fork with an unrepaired single-strand nick (Fig. 30-81):

1. When a single-strand nick is encountered, the replication fork collapses.
2. The repair process begins via the RecBCD plus RecA-mediated invasion of the newly synthesized and undamaged 3'-ending strand into the homologous dsDNA starting at its broken end.
3. Branch migration, as mediated by RuvAB, then yields a Holliday junction, which exchanges the replication fork's 3'-ending strands.

**Figure 30-81** The recombination repair of a replication fork that has encountered a single-strand nick. Thick lines indicate parental DNA, thin lines indicate newly synthesized DNA, and the arrows point in the 5' → 3' direction. [After Cox, M.M., *Annu. Rev. Genet.* **35**, 53 (2001).]

4. RuvC then resolves the Holliday junction yielding a reconstituted replication fork ready for replication restart.

Thus, the 5'-ending strand of the nick has, in effect, become the 5' end of an Okazaki fragment.

The final step in the recombination repair process is the restart of DNA replication. This process is, of necessity, distinct from the replication initiation that occurs at *oriC* (Section 30-3Ca). **Origin-independent replication restart** is mediated by the same seven-protein primosome that initiates the minus strand replication of bacteriophage  $\phi$ X174 (Table 30-4), which has therefore been named the **restart primosome**.

### g. Recombination Repair Reconstitutes Double-Strand Breaks

We have seen that double-strand breaks (DSBs) in DNA can be rejoined, often mutagenically, by nonhomologous end-joining (NHEJ; Section 30-5E). DSBs may also be nonmutagenically repaired through a recombination repair process known as homologous end-joining, which occurs via two Holliday junctions (Fig. 30-82):

1. The DSB's double-stranded ends are resected to produce single-stranded ends. One of the 3'-ending strands invades the corresponding sequence of a homologous

**Figure 30-82** The repair of a double-strand break in DNA by homologous end-joining. Thick lines indicate parental DNA, thin lines indicate newly synthesized DNA, and the arrows point in the 5' → 3' direction. [After Haber, J.E., *Trends Genet.* **16**, 259 (2000).]

**Table 30-6** Properties of Some Insertion Elements

Insertion Element	Length (bp)	Inverted Terminal Repeat (bp)	Direct Repeat at Target (bp)	Number of Copies in <i>E. coli</i> Chromosome
IS1	768	23	9	5–8
IS2	1327	41	5	5
IS4	1428	18	11–13	5
IS5	1195	16	4	1–2

Source: Mainly Lewin, B., *Genes IX*, p. 524, Oxford University Press (2008).

chromosome to form a Holliday junction, a process that, in eukaryotes, is mediated by the RecA homolog RAD51. The other 3'-ending strand pairs with the displaced strand segment on the homologous chromosome to form a second Holliday junction.

2. DNA synthesis and ligation fills in the gaps and seals the joints.

3. Both Holliday junctions are resolved to yield two intact double strands.

Thus, the sequences that may have been expunged in the formation of the DSB are copied from the homologous chromosome. Of course, a limitation of homologous end-joining, particularly in haploid cells, is that a homologous chromosomal segment may not be available.

The importance of recombination repair in humans is demonstrated by the observation that defects in the proteins **BRCA1** (1863 residues) and **BRCA2** (3418 residues), both of which interact with RAD51, are associated with a greatly increased incidence of breast, ovarian, prostate, and pancreatic cancers. Indeed, individuals with mutant *BRCA1* or *BRCA2* genes have up to an 80% lifetime risk of developing cancer. Recombination can also function to elongate shortened telomeres without the need for telomerase.

### B. Transposition and Site-Specific Recombination

In the early 1950s, on the basis of genetic analysis, Barbara McClintock reported that the variegated pigmentation pattern of maize (Indian corn) kernels results from the action of genetic elements that can move about the maize genome. This proposal was resoundingly ignored because it was contrary to the then held genetic orthodoxy that chromosomes consist of genes linked in fixed order. Another 20 years were to pass before evidence of mobile genetic elements was found in another organism, *E. coli*.

It is now known that **transposable elements** or **transposons** are common in both prokaryotes and eukaryotes, where they influence the variation of phenotypic expression over the short term and evolutionary development over the long term. Each transposon codes for the enzymes that specifically insert it into the recipient DNA. This process has been described as **illegitimate recombination** because it requires no homology between donor and

recipient DNAs. Since the insertion site is chosen largely at random, transposition is a potentially dangerous process; the insertion of a transposon into an essential gene will kill a cell together with its resident transposons. Hence transposition is tightly regulated; it occurs at a rate of only  $10^{-5}$  to  $10^{-7}$  events per element per generation. The conditions that trigger transposition are, for the most part, unknown.

#### a. Prokaryotic Transposons

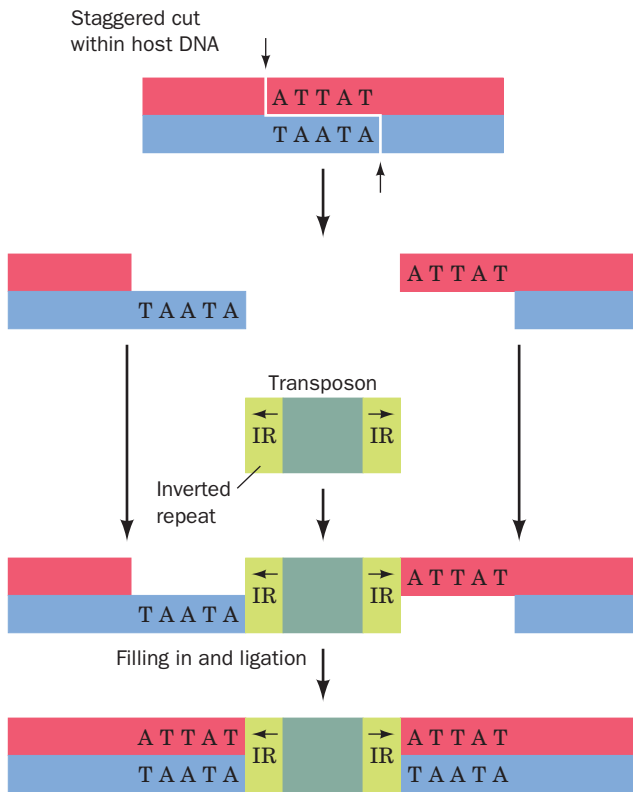

Prokaryotic transposons with three levels of complexity have been characterized:

1. The simplest transposons, and the first to be characterized, are named **insertion sequences** or **IS elements**. They are designated by “IS” followed by an identifying number. IS elements are normal constituents of bacterial chromosomes and plasmids. For example, a common *E. coli* strain has eight copies of **IS1** and five copies of **IS2**. IS elements generally consist of <2000 bp. These comprise a so-called **transposase** gene, and in some cases a regulatory gene, flanked by short inverted (having opposite orientation) terminal repeats (Fig. 30-83 and Table 30-6). The inverted repeats are essential for transposition; their genetic alteration invariably prevents this process. An inserted IS element is flanked by a directly (having the same orientation) repeated segment of host DNA (Fig. 30-83). This suggests that an IS element is inserted in the host DNA at a staggered cut that is later filled in (Fig. 30-84). The length of this target sequence (most commonly 5 to 9 bp), but not its sequence, is characteristic of the IS element.

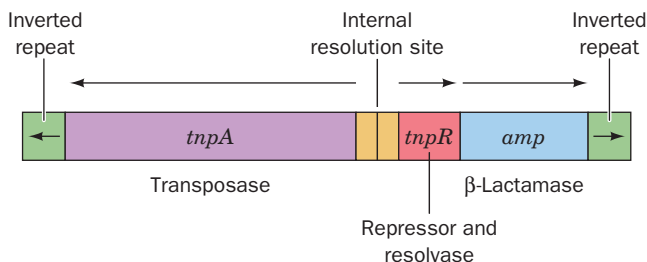

2. *More complex transposons carry genes not involved in the transposition process, for example, antibiotic resistance genes.* Such transposons are designated “Tn” followed

**Figure 30-83** Structure of IS elements. These and other transposons have inverted terminal repeats (*numerals*) and are flanked by direct repeats of host DNA target sequences (*letters*).

**Figure 30-84** A model for the generation of direct repeats of the target sequence by transposon insertion.

**Figure 30-85** A map of transposon Tn3.

**Figure 30-86** A composite transposon. This element consists of two identical or nearly identical IS-like modules (green) flanking a central region carrying various genes. The IS-like modules may have either (a) direct or (b) inverted relative orientations.

by an identifying number. For example, **Tn3** (Fig. 30-85) consists of 4957 bp and has inverted terminal repeats of 38 bp each. The central region of Tn3 codes for three proteins: (1) a 1015-residue transposase named **TnpA**; (2) a 185-residue protein known as **TnpR**, which mediates the **site-specific recombination** reaction necessary to complete the transposition process (see below) and also functions as a repressor for the expression of both *tnpA* and *tnpR*; and (3) a  **$\beta$ -lactamase** that inactivates ampicillin (Section 11-3Bb). The site-specific recombination occurs in an AT-rich region known as the **internal resolution site** that is located between *tnpA* and *tnpR*.

**3.** The so-called **composite transposons** (Fig. 30-86) consist of a gene-containing central region flanked by two identical or nearly identical IS-like modules that have either the same or an inverted relative orientation. It therefore seems that composite transposons arose by the association of two originally independent IS elements. Since the IS-like modules are themselves flanked by inverted repeats, the ends of either type of composite transposon must also be inverted repeats. Experiments demonstrate that composite transposons can transpose any sequence of DNA in their central region.

There are two modes of transposition: (1) **direct** or **simple transposition**, in which the transposon, as the name implies, physically moves from one DNA site to another; and (2) **replicative transposition**, in which the transposon remains at its original site and a copy of it is inserted at a target site. The two modes, as we shall see, have similar mechanistic features and, indeed, some transposons can move by either mode.

#### b. Direct Transposition of Tn5 Occurs by a Cut-and-Paste Mechanism

**Tn5** is a 5.8-kb composite transposon that contains the gene encoding the 476-residue **Tn5 transposase** together with three antibiotic resistance genes. It is flanked by inverted IS-like modules ending in 19-bp sequences called outside end (OE) sequences. Tn5 undergoes direct transposition via a “cut-and-paste” mechanism that was elucidated in large part by William Reznikoff (Fig. 30-87):

**1.** Each of Tn5’s two OE sequences on the donor DNA is bound by a monomer of Tn5 transposase.

**2.** The transposase dimerizes to form a catalytically active **synaptic complex** in which the transposon is held between the two transposase subunits.

**3.** Each transposase subunit activates a water molecule to nucleophilically attack the outermost nucleotide of its bound OE sequence, yielding a free 3'-OH group. This 3'-OH group is then activated to attack the opposite strand on the DNA to form a hairpin structure, thereby excising the transposon from the DNA. The hairpin is then hydrolyzed to yield a blunt-ended dsDNA at each end of the transposon, thus completing the “cut” portion of the transposition mechanism.

**4.** The synaptic complex binds to the target DNA.

**Figure 30-87** The cut-and-paste transposition mechanism catalyzed by Tn5 transposase. The reactions comprising Steps 3 and 5 are indicated by the braces to the right of these steps. [After Davies, D.R., Goryshin, I.Y., Reznikoff, W.S., and Rayment, I., *Science* **289**, 77 (2000).]

5. The transposon's 3'-OH groups nucleophilically attack the target DNA on opposite strands spaced 9 bp apart, thereby installing the transposon at the target site. Remarkably, this reaction and the three preceding lytic reactions are all mediated by the same catalytic site. The repair of the oppositely located single-strand gaps (Fig. 30-84) completes the "paste" portion of the mechanism.

Although, strictly speaking, not part of the transposition process, the double-strand break in the donor DNA left by the excision of the transposon must be repaired if the donor DNA is to be propagated (in bacteria, the donor DNA is often a plasmid so that its loss has little effect on the cell since plasmids are generally present in multiple copies).

The X-ray structure of a Tn5 synaptic complex (Fig. 30-88), determined by Reznikoff and Ivan Rayment, provides a model of the synaptic complex at the stage following its

**Figure 30-88** X-ray structure of Tn5 transposase in complex with a 20-bp DNA containing the OE sequence. The complex, which represents the product of Step 3 in Fig. 30-87, is viewed along its 2-fold axis with one of its two identical subunits colored in rainbow order from N-terminus (blue) to C-terminus (red) and the other subunit pink. The DNA is drawn in stick form with C green, N blue, O red, and P orange and with successive P atoms on the same polynucleotide connected by orange rods. The bound Mn<sup>2+</sup> ions, which mark the enzyme's active site, are represented by purple spheres. The DNAs' reactive 3'-OH groups are located at these active sites. [Based on an X-ray structure by William Reznikoff and Ivan Rayment, University of Wisconsin. PDBid 1MUS.]

cleavage from the donor DNA (the product of Step 3 in Fig. 30-87). This 2-fold symmetric complex consists of a dimer of Tn5 transposase subunits binding two 20-bp DNA segments containing the Tn5 transposon's 19-bp OE sequence with the outer end of each OE sequence bound to the protein (and whose opposite ends would, *in vivo*, be connected by the looped around transposon; Fig. 30-87). Both transposase subunits extensively participate in binding each DNA segment, thereby explaining why the individual subunits cannot cleave their bound DNA segments before forming the synaptic complex. The protein holds the DNA in a distorted B-DNA conformation with its two end pairs of nucleotides no longer base paired. Indeed, the penultimate base on the nontransferred strand is flipped out of the double helix and binds in a hydrophobic pocket. The transferred strand's free 3'-OH group, which occupies the active site, is bound in the vicinity of a cluster of three catalytically essential acidic residues, the so-called **DDE motif**, which is shared with other transposases. In the X-ray structure the DDE motif binds two Mn<sup>2+</sup> ions, although physiologically it probably binds two Mg<sup>2+</sup> ions. This suggests that transposases employ a metal-activated catalytic

mechanism similar to that of the DNA polymerases (Section 30-2Af). The facing surface of the protein in Fig. 30-88 is positively charged with a prominent groove running from upper left to lower right that forms the apparent binding site for the target DNA.

Wild-type Tn5 transposase has such low catalytic activity that it is undetectable *in vitro*. However, that in the X-ray structure is a hyperactive mutant form that contains the mutations E54K and L372P (an unusual circumstance in that it is far more common to mutationally inhibit an enzyme under crystallographic study so as to trap it at some specific stage along its reaction pathway). Lys 54 is hydrogen bonded to O4 of a thymine base on the transferred strand. In the wild-type transposase, Glu 54 would probably have an unfavorable charge–charge repulsion with a nearby phosphate group, thus providing a structural basis for the increased activity of the E54K mutant. The L372P mutation disorders the peptide segment between residues 373 and 391 (it is ordered in the X-ray structure of wild-type Tn5 transposase lacking its N-terminal 55 residues), thereby suggesting that this mutation facilitates a conformational change required for substrate binding.

### c. Replicative Transposition Occurs via Cointegrates

If a plasmid carrying a transposon resembling Tn3 is introduced into a bacterial cell carrying a plasmid that lacks the transposon, in some of the progeny cells both types of plasmid will contain the transposon (Fig. 30-89). Evidently, *such transposition involves the replication of the transposon into the recipient plasmid rather than its transfer from donor to recipient.*

Two plasmids, one containing a replicative transposon, will occasionally fuse to form a so-called **cointegrate** containing like-oriented copies of the transposon at both junctions of the original plasmids (Fig. 30-90). Yet, some of the progeny of a cointegrate-containing cell lack the cointegrate and instead contain both original plasmids, each with one copy of the transposon (Fig. 30-89). The cointegrate must therefore be an intermediate in the transposition process.

Although the mechanism of replicative transposition has not been fully elucidated, a plausible model for this process (and there are several) that accounts for the foregoing observations consists of the following steps (Fig. 30-91):

1. A pair of staggered single-strand cuts, such as is diagrammed in Fig. 30-84, is made by the transposon-encoded transposase at the target sequence of the recipient plasmid so as to liberate 3'-OH ends. Similarly, single-strand cuts are made on opposite strands to either side of the transposon. Note that these reactions resemble those catalyzed by Tn5 transposase (Fig. 30-87).
2. Each of the transposon's free ends is ligated to a protruding single strand at the insertion site. This forms a replication fork at each end of the transposon.
3. The transposon is replicated, thereby yielding a cointegrate.
4. Through a site-specific recombination between the internal resolution sites of the two transposons, the cointe-

**Figure 30-89 Replicative transposition.** This type of transposition inserts a copy of the transposon at the target site while another copy remains at the donor site.

**Figure 30-90 A cointegrate.** This structure forms by the fusion of two plasmids, one carrying a transposon, such that both junctions of the original plasmid are spanned by transposons with the same orientation (arrows).

grate is resolved into the two original plasmids, each of which contains a transposon. This crossover process is catalyzed by transposon-encoded **recombinases** (TnpR in Tn3; also known as **resolvases**) rather than RecA; transposition proceeds normally in *recA*<sup>-</sup> cells (although RecA will resolve a cointegrate containing a transposon with a mutant resolvase and/or an altered internal resolution site, albeit at a much reduced rate).

Site-specific recombinases fall into only two protein families, **serine recombinases** and **tyrosine recombinases**, which are named after the amino acid residue that forms a transient covalent linkage to the DNA during the recombinase reaction. As we shall, these two types of recombinases function via different mechanisms.

### d. $\gamma\delta$ Resolvase Catalyzes Site-Specific Recombination

The  $\gamma\delta$  resolvase, a serine recombinase that forms a homodimer in solution, is a TnpR homolog that is encoded by the  $\gamma\delta$  transposon (a member of the Tn3 family of replicative transposons; Fig. 30-85). It catalyzes a site-specific recombination event in which a cointegrate containing two copies of the  $\gamma\delta$  transposon is resolved, via double-strand DNA cleavage, strand exchange, and

**Figure 30-91** A model for transposition involving the intermediacy of a cointegrate. Here more lightly shaded bars represent newly synthesized DNA. [After Shapiro, J.A., *Proc. Natl. Acad. Sci.* **76**, 1934 (1979).]

religation (the last step in Fig. 30-91), into two catenated (linked) dsDNA circles that each contain one copy of the  $\gamma\delta$  transposon (it also serves as its own transcriptional repressor as does TnpR). The  $\gamma\delta$  transposon contains a 114-bp

*res* site that includes three binding sites for  $\gamma\delta$  resolvase dimers, each of which contains an inverted repeat of the  $\gamma\delta$  resolvase's 12-bp recognition sequence. The resolution of the cointegrate involves the binding of a  $\gamma\delta$  resolvase homodimer to all six of these binding sites in the cointegrate (three from each of its two transposons) as is diagrammed in Fig. 30-92. The reaction proceeds via the formation of a transient phosphoSer bond between Ser 10 and the 5'-phosphate at each cleavage site.

The X-ray structure of the  $\gamma\delta$  resolvase homotetramer in complex with two 34-bp palindromic dsDNA segments containing an inverted repeat of the 12-bp recognition sequence separated by a 4-bp spacer (Fig. 30-93), determined by Nigel Grindley and Steitz, reveals that this synaptic tetramer has  $D_2$  symmetry. Each 183-residue resolvase monomer consists of an N-terminal catalytic domain (residues 1–120) and a C-terminal DNA-binding domain (residues 148–183) connected by an extended arm (residues 121–147). Both dsDNAs, which are located at the periphery of the protein core, have been cleaved with each of the resulting four 5' ends in phosphoSer linkage to the resolvase. This preserves the free energy of the cleaved phosphodiester bond so that it can later be reformed with a different partner, much as occurs with topoisomerases (Section 29-3C).

Each centrally located catalytic domain approaches its bound DNA from its minor groove side with its C-terminal helix (helix E) binding over the minor groove (the segment of the E helix that contacts the DNA is disordered in the absence of the DNA). Each C-terminal domain binds over the major groove of its recognition sequence on the opposite side of the DNA from its attached catalytic domain with the extended arm that connects them running more or less along the DNA's minor groove. The two C-terminal domains of the resolvase subunits labeled L and R (and the symmetry-related L' and R' subunits) in Fig. 30-93 are thereby separated by two helical turns along the cleaved DNA, the segments of which closely assume the B-DNA conformation. Each C-terminal helix binds in the DNA's major groove and, together with its preceding helix, forms a **helix–turn–helix (HTH) motif**, a common sequence-specific DNA-binding motif that occurs mainly in prokaryotic transcriptional repressors and activators (Section 31-3Da).

The structure of the L–R dimer closely resembles that in the X-ray structure of the dimer bound to uncleaved site I DNA (the presynaptic dimer). This, and the short (17 Å) distance between the free 3'-OH group in the L subunit and the phosphoSer bond in the R subunit compared to other such distances in the complex (L–L' and L–R'), indicates that the L–R and L'–R' dimers correspond to the initial site I-bound dimers soon after cleavage or just before religation (Fig. 30-92). Consequently, the interface between the L–R and L'–R' dimers must be the newly formed synaptic interface.

How are the DNA strands in the synaptic complex exchanged, that is, how is the DNA bound to the L subunit ligated to the DNA bound to either the L' subunit or the R' subunit (and R to either R' or L')? In either case, the free 3'-OH group on each subunit is ~50 Å from the

phosphoSer group that it would have to nucleophilically attack in the religation step and the space between them is filled with protein. Clearly, the synaptic complex must undergo a dramatic structural change to accomplish the religation step.

**Figure 30-92** A model for the resolution of a cointegrate containing two  $\gamma\delta$  transposons to form two catenated dsDNA circles. (1) The  $\gamma\delta$  resolvase binds as six homodimers to its binding sites, I, II, and III, in each of the cointegrate's two *res* sites (yellow and green circles represent the  $\gamma\delta$  resolvase monomers initially bound to the red and blue *res* sites, respectively), which then associate to form synaptic tetramers. Although not shown as such, the synaptic tetramers bound to sites I associate with the synaptic tetramers bound to sites II and III to form, as seen in the electron microscope, a compact globule of unknown structure known as a **synptosome**. (2) The dsDNA at sites I both undergo staggered (by 2 bp) double-strand scissions via the transient formation of phosphoSer bonds between Ser 10 and the 5'-phosphates at the cleavage sites. The cleaved strands then exchange places (cross over) in a process that apparently requires the rotation of one of the pairs of resolvase monomers with respect to the other and are then ligated. (3) The dissociation of the synptosome yields the catenated dsDNA circles. [Courtesy of Gregory Mullen, University of Connecticut Health Center.]

**Figure 30-93** X-ray structure of a  $\gamma\delta$  resolvase synaptic tetramer in complex with two 34-bp palindromic, site I-containing dsDNAs. The  $D_2$ -symmetric complex is viewed with one of its 2-fold axes horizontal (the other 2-fold axes lie in the vertical plane labeled "Flat interface"). The DNAs (dark and light green and yellow and orange) have been cleaved into half-sites labeled L, R, L', and R' through the nucleophilic attack of the Ser 10 side chain (drawn in space-filling form with C blue and O red) on the 5'-phosphate group of A20 (drawn in stick form in green). The subunits of the resolvase tetramer, whose helices are drawn in tube form, are colored blue, green, red, and pink. The intact DNAs initially bind to the L-R and L'-R' dimers, the so-called site I dimers. The L-L' dimer and the symmetrically equivalent R-R' dimer form so-called antiparallel dimers whose D and E helices associate as four-helix bundles. In addition, a Val 114  $\rightarrow$  Cys mutation (V114C) disulfide-cross-links the E helices of the L-R and L'-R' dimers across the so-called flat interface. [Courtesy of Thomas Steitz, Yale University. PDBId 1ZR4.]

The observation that the interface between the L–L' and R–R' dimers is largely hydrophobic and unusually flat (Fig. 30-93) strongly suggests that the religation occurs after a 180° rotation of these dimers with respect to one another (about the horizontal 2-fold axis in Fig. 30-93), thus exchanging the positions of the R and R' subunits with respect to the L and L' subunits. The rotation is presumably driven by the superhelical tension in the naturally negatively supercoiled cointegrate. This model is supported by energy calculations and the observation that mutating Val 114 of the E helix to Cys, which, under oxidizing conditions, disulfide-links the E helices on the L and R (and L' and R') subunits (a mutation that was present in the foregoing structure), yields a complex that can form the covalent intermediate in Fig. 30-93 but cannot carry out the religation step—presumably because the disulfide bonds prevent the above rotation. However, reducing these disulfide bonds restores the complex's recombinational activity. Furthermore, mutation of Lys 136, an E helix residue located at the flat interface, to Cys prevents religation of the cleaved DNA when subjected to oxidizing conditions, even though it requires a 75° rotation of the L–L'/R–R' interface in the structure in Fig. 30-93 to bring the Cys 136 side chains on opposing subunits close enough to form a disulfide bond. Of course, a detailed understanding of the mechanism of the  $\gamma\delta$  resolvase reaction will require the knowledge of how all six  $\gamma\delta$  resolvase dimers that form the synaptosome participate in the reaction (Fig. 30-92).

#### e. Replicative Transposons Are Responsible for Much Genetic Remodeling in Prokaryotes

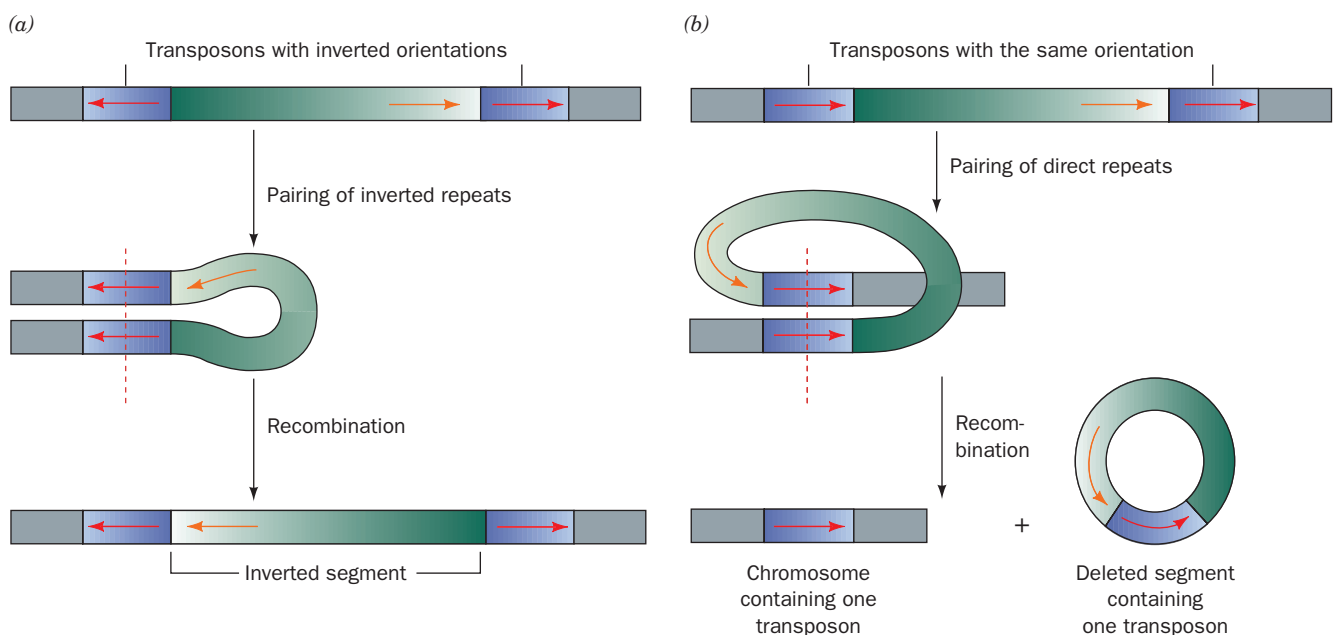

In addition to mediating their own insertion into DNA, *replicative transposons promote inversions, deletions, and rearrangements of the host DNA*. Inversions can occur

when the host DNA contains two copies of a transposon in inverted orientation. The recombination of these transposons inverts the region between them (Fig. 30-94a). If, instead, the two transposons have the same orientation, the resolution of this cointegrate-like structure deletes the segment between the two transposons (Fig. 30-94b; if the deleted segment lacks a replication origin, it will not be propagated). The deletion of a chromosomal segment in this manner, followed by its integration into the chromosome at a different site by a separate recombinational event, results in chromosomal rearrangement.

Transposition appears to be important in chromosomal and plasmid evolution. Indeed, it has been suggested that transposons are nature's genetic engineering "tools." For example, the rapid evolution, since antibiotics came into common use, of plasmids that confer resistance to several antibiotics (Section 5-5Ba) has resulted from the accumulation of the corresponding antibiotic-resistance transposons in these plasmids. Transposon-mediated rearrangements may well have been responsible for organizing originally distant genes into coordinately regulated operons (Section 5-4Aa) as well as for forming new proteins by linking two formerly independent gene segments. Moreover, *the occurrence of identical transposons in unrelated bacteria indicates that the transposon-mediated transfer of genetic information between organisms is not limited to related species, in contrast to genetic transfers mediated by homologous recombination*.

#### f. Phase Variation Is Mediated by Site-Specific Recombination

Phenotypic expression in bacteria can be regulated by site-specific recombination. For example, certain strains of

**Figure 30-94 Chromosomal rearrangement via recombination.** (a) The inversion of a DNA segment between two identical transposons with inverted orientations. (b) The deletion of a

DNA segment between two identical transposons with the same orientation. This process parcels one transposon each to the resulting two DNA segments.

**Figure 30-95** The mechanism of phase variation in *Salmonella*. (a) In Phase 2 bacteria, the *H2-rh1* promoter is oriented so that H2 flagellin and repressor are synthesized. Repressor binds to the *H1* gene, thereby preventing its expression. (b) In Phase 1 bacteria, the segment preceding the *H2-rh1* transcription unit has been inverted relative to its orientation in Phase 2 bacteria. Hence this transcription unit cannot be expressed because it lacks a promoter. This releases *H1* from repression and results in the synthesis of H1 flagellin. The inversion of the segment preceding the *H2-rh1* transcription unit is mediated by the Hin protein, which is expressed in either orientation by the *hin* gene.

*Salmonella typhimurium* make two antigenically distinct versions of the protein **flagellin** (the major component of the whiplike flagella with which bacteria propel themselves; Section 35-31) that are designated **H1** and **H2**. Only one of these proteins is expressed by any particular cell but about once every 1000 cell divisions, in a process known as **phase variation**, a cell switches the type of flagellin it synthesizes. It is thought that phase variation helps *Salmonella* evade its host's immunological defenses.

What is the mechanism of phase variation? The two flagellin genes reside on different parts of the bacterial chromosome. *H2* is linked to the *rh1* gene that encodes a repressor of H1 expression (Fig. 30-95; *rh1*, *H2*, and *H1* are also known as *fljA*, *fljB*, and *fljC*, respectively). Hence, when the *H2-rh1* transcription unit is expressed, H1 synthesis is

repressed; otherwise H1 is synthesized. Melvin Simon has shown that the expression of the *H2-rh1* unit is controlled by the orientation of a 995-bp segment that lies upstream of *H2* (Fig. 30-95) and that contains the following elements:

1. A promoter for *H2-rh1* expression.
2. The *hin* gene, which encodes the 190-residue **Hin DNA invertase**. Hin, a serine recombinase, mediates the inversion of the DNA segment in a manner similar to that diagrammed in Fig. 30-94a. In fact, Hin is ~40% identical in sequence with the  $\gamma\delta$  resolvase, which strongly suggests that these proteins have similar structures.
3. Two closely related 26-bp sites, *hixL* and *hixR*, that form the boundaries of the segment and hence contain its cleavage sites. They each consist of two imperfect 12-bp inverted repeats separated by 2 nt.

In the Phase 2 orientation (Fig. 30-95a), the properly oriented promoter is just upstream of *H2*, so this gene and *rh1* are coordinately expressed, thereby repressing H1 synthesis. In Phase 1 bacteria (Fig. 30-95b), however, this segment has the opposite orientation. Consequently, neither *H2* nor *rh1*, which then lacks a promoter, is expressed so that H1 is synthesized.

#### g. Cre-Mediated Site-Specific Recombination Occurs via 3'-PhosphoTyr Intermediates

Bacteriophages, as we have seen (Fig. 1-31), replicate themselves within their host bacterial cells which, in most cases, they then lyse to release the progeny phage, a lifestyle that is therefore known as the **lytic** mode. However, certain bacteriophages can assume an alternative, nondestructive lifestyle, the **lysogenic** mode, in which they install their DNA, usually in the host chromosome via site-specific recombination, so that the phage DNA is passively replicated with the host DNA. However, if the bacterial host encounters conditions in which it is unlikely to survive, the phage DNA is excised from the bacterial chromosome via a reversal of the site-specific recombination reaction and it reenters the lytic mode so as to escape the doomed host. We discuss the genetic factors that maintain the balance between the lytic and lysogenic lifestyles in **bacteriophage  $\lambda$**  in Section 33-3.

The enzymes that mediate the foregoing site-specific recombination reactions are members of the  **$\lambda$  integrase ( $\lambda$  Int; alternatively, tyrosine recombinase)** family, whose ~1000 known members also occur in prokaryotes and eukaryotes. These include the **XerC** and **XerD** proteins of *E. coli* which, operating in concert, function to decatenate the two linked circular dsDNA products of homologous recombination (Fig. 30-69g, left), as well as type IB topoisomerases (Section 29-3Cc).

The structurally best characterized member of the  $\lambda$  integrase family is the **Cre recombinase** of *E. coli* **bacteriophage P1**. In its lysogenic state, bacteriophage P1 is a single-copy circular plasmid (rather than being inserted in the host chromosome as is bacteriophage  $\lambda$ ), but in the phage head (the lytic mode), P1 DNA is a linear dsDNA that has a 34-bp *loxP* site at each end. The main function of Cre,

**Figure 30-96 The circularization of linear bacteriophage P1 DNA.** This occurs through the Cre-mediated site-specific recombination between its two terminally located *loxP* sites (red and green) to yield its lysogenic plasmid.

which is encoded by bacteriophage P1, is to mediate the site-specific recombination between these two *loxP* sites so as to circularize the linear DNA (Fig. 30-96).

The *loxP* site is palindromic except for its central 8-bp crossover region, which confers directionality on the site. In carrying out the recombination reaction, the 343-residue Cre subunits form a homotetramer that binds two *loxP* sites in an antiparallel orientation, with each Cre subunit binding half of a *loxP* site. Then, as is diagrammed in Fig. 30-97, oppositely located Cre subunits catalyze single-strand scissions on the 5' side of the crossover region on one strand of each of the two dsDNAs. This occurs through the nucleophilic attack of each of these active Cre subunit's conserved Tyr 324 residues on the DNA's scissile phosphoester bond to yield a 3'-phosphoTyr intermediate on one side of the cleaved bond and a free 5'-OH group on the other side (as similarly occurs in the reactions catalyzed by type IB topoisomerases; Section 29-3Cc). Each of the liberated 5'-OH groups then nucleophilically attacks the 3'-phosphoTyr group on the opposite duplex to form a Holliday junction, thereby releasing the Tyr residues. The Holliday

**Figure 30-97 The mechanism of Cre-*loxP* site-specific recombination.** The dashed lines represent the nonpalindromic crossover regions of the *loxP* sites. The green and magenta Cre subunits are active for cleavage in the top and bottom parts of the diagram, respectively, with their roles being switched by the isomerization step. Note that the mechanism does not require branch migration of the Holliday junction intermediate. [Courtesy of Gregory Van Duyne, University of Pennsylvania School of Medicine.]

junction is resolved into two recombined dsDNAs when the two Cre subunits that had not yet participated in the reaction mediate the same cleavage and strand exchange reactions on the two heretofore unreacted single strands. This latter process must be preceded by a structural rearrangement (isomerization) of the Cre tetramer that positions the catalytic Tyr residues in the latter pair of subunits to participate in the reaction while those in the former pair of subunits are similarly removed from the scene of the action. Note that this mechanism differs from that mediated by serine recombinases in that the latter cleave all four DNA strands prior to initiating their exchange and hence do not have a Holliday junction intermediate (Section 30-6Bd).

The X-ray structures of Cre tetramers in their complexes with several *loxP* model DNAs, determined by Gregory Van Duyne, have helped elucidate its mechanism. When the DNA had a single-strand nick past the second nucleotide from the 5' end of the crossover region, Cre-catalyzed strand scission yielded a free nucleotide (a CMP) that diffused away. Since this nucleotide contained the otherwise reactive 5'-OH group, the 3'-phosphoTyr intermediate was irreversibly trapped, that is, Cre could not carry out the strand exchange reaction in Fig. 30-97 (this nicked DNA is a suicide substrate for Cre; Section 28-3Bc). The X-ray structure of the Cre complex of this nicked DNA confirmed the presence of the 3'-phosphoTyr intermediate and indicated, through model building, that the 5'-OH group on the missing CMP residue would be well positioned to nucleophilically attack the 3'-phosphoTyr bond on the opposite strand (Fig. 30-98a). Note that this complex is only 2-fold symmetric although its four Cre subunits and much of the DNA are related by pseudo-4-fold symmetry. When the DNA was, instead, an immobile Holliday junction (Fig. 30-98b), the complex was also pseudo-4-fold symmetric with the single strands that had crossed over noticeably kinked at their centers. These structures revealed that the conformational changes necessary to carry out the strand exchange and isomerization reactions (Fig. 30-97) required surprisingly small movements on the part of the Cre subunits and that only the sugar-phosphate backbones of the strand-exchanged nucleotides needed to move in order to form the Holliday junction.

#### h. Most Transpositions in Eukaryotes Involve RNA Intermediates

Transposons similar to those in prokaryotes also occur in eukaryotes, including yeast, maize, *Drosophila*, and humans. In fact, ~3% of the human genome consists of DNA-based transposons although, in most cases, their sequences have mutated so as to render them inactive, that is, these transposons are evolutionary fossils. However, many eukaryotic transposons exhibit little similarity to those of prokaryotes. Rather, their base sequences resemble those of retroviruses (see below), which suggests that these transposons are degenerate retroviruses. The transposition of these so-called **retrotransposons** occurs via a pathway that resembles the replication of retroviral DNA (Section 15-4C): (1) their transcription to RNA, (2) the reverse transcriptase-mediated copying of this RNA to cDNA (Section 30-4C), and (3) the largely random insertion of this DNA into the host

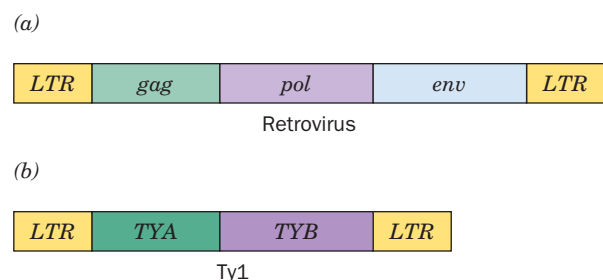

**Figure 30-98** X-ray structures of the Cre homotetramer in its complexes with model *loxP* DNAs. (a) Two identical dsDNAs that were nicked past the second nucleotide from the 5' end of their crossover regions; and (b) an immobile Holliday junction. The left panels show the Cre–DNA complexes as viewed along their exact 2-fold and pseudo-4-fold axes, with the active and inactive subunits green and magenta, respectively (as in Fig. 30-97), and with the DNA gold. The right panels show only the DNAs in the X-ray structures as viewed from below the left panels. In the right panel of Part a, the active site Tyr that is covalently linked

to the 3'-OH group of the cleaved DNA strand is shown in stick form (red) and the modeled-in position of the cleaved CMP's 5'-OH group is shown positioned to nucleophilically attack the 3'-phosphoTyr group on the opposite dsDNA (curved arrows). In the right panel of Part b, the three base pairs that form as a consequence of strand exchange are indicated. Note that the vertical strands in the crossovers are distinctly kinked at their centers, but not the horizontal strands are distinctly kinked at their centers. organism's genome as mediated by enzymes known as **integrases** (which catalyze reactions similar to and structurally resemble cut-and-paste DNA transposases).

The involvement of RNA in retrotransposon-mediated transposition was ingeniously shown by Gerald Fink through his remodeling of **Ty1**, the most common transposable element in budding yeast (which has ~35 copies of this 6.3-kb element comprising ~13% of its 1700 kb genome; Ty stands for Transposon yeast), so that it contained a yeast intron (a sequence that is excised from an RNA transcript and hence is absent in the mature RNA; Section 5-4Ac) and was preceded by a galactose-sensitive yeast promoter. The transposition rate of this remodeled Ty1 element varied with the galactose concentration in the medium and the transposed elements all lacked the intron, thereby demonstrating the participation of an RNA intermediate.

A retroviral genome (Fig. 30-99a) is flanked by direct long terminal repeats (**LTRs**) of 250 to 600 bp and typically contains the genes encoding three polyproteins: **gag**, which is

**Figure 30-99** Gene sequences of (a) retroviruses and (b) the Ty1 retrotransposon.

cleaved to the proteins comprising the viral core (Fig. 15-34); **pol**, which is cleaved to the above-mentioned reverse transcriptase and integrase, as well as the protease that catalyzes these cleavages; and **env**, which is cleaved to viral outer envelope proteins. Ty1 (Fig. 30-99b) is likewise flanked by LTRs (of 330 bp) but expresses only two polyproteins: **TYA** and **TYB**, the counterparts of gag and pol. Moreover, TYA and TYB, together with Ty1 RNA, form viruslike particles in the yeast cytoplasm. However, Ty1 lacks a counterpart of the retroviral *env* gene. Hence Ty1 is an “internal virus” that can only replicate within a genome, albeit at an extremely low rate compared to that of real retroviral infections.

**Figure 30-100** Proposed mechanism for the transposition of nonviral retrotransposons. **(1)** The retrotransposon-encoded reverse transcriptase/endonuclease nicks one strand of the target DNA and then recruits the RNA transcript of the retrotransposon to this site. **(2)** The DNA-primed reverse transcription of the retrotransposon RNA. **(3)** The RNA is degraded, and the second DNA strand is synthesized using the first strand as its template (normal reverse transcriptase reactions; Section 30-4C), followed by the insertion of the resulting nonviral retrotransposon into the target DNA via a poorly understood process.

*Copia* (Latin for abundance), the most abundant retrotransposon in the *Drosophila* genome (which contains 20–60 copies of copia), resembles Ty1.

The LTRs in retroviruses and retrotransposons such as Ty1 and *copia* are essential elements for their transcription and hence for their transposition. Yet, vertebrate genomes also contain retrotransposons that lack LTRs and hence cannot be transcribed analogously to retroviruses. A common family of these **nonviral retrotransposons**, the 1- to 7-kb **long interspersed nuclear elements (LINEs)**, each contain two open reading frames: *ORF1*, which contains sequences similar to those in *gag*; and *ORF2*, which contains sequences similar to those encoding reverse transcriptase. A proposed mechanism for the transposition of LINEs is diagrammed in Fig. 30-100.

Different types of transposons, DNA-only, retroviral, and nonviral, predominate in different organisms. Thus bacteria, as we have seen, contain nearly exclusively DNA-only transposons, yeast have mainly retroviral retrotransposons, *Drosophila* have all three types, and in humans LINEs predominate. In fact, the human genome contains an estimated 1.4 million LINEs or LINE fragments that comprise ~20% of the 3.0-billion-bp human genome (genomic organization is discussed in Section 34-2). The great majority of these molecular parasites have mutated to the point of inactivity but a few still appear capable of further transposition. Indeed, several hereditary diseases are caused by the insertion of a LINE into a gene. Several other types of retrotransposons also comprise significant fractions of the human genome as we shall see in Section 34-2.

## 7 DNA METHYLATION AND TRINUCLEOTIDE REPEAT EXPANSIONS

The A and C residues of DNA may be methylated, in a species-specific pattern, to form ***N*<sup>6</sup>-methyladenine (*m*<sup>6</sup>A)**, ***N*<sup>4</sup>-methylcytosine (*m*<sup>4</sup>C)**, and **5-methylcytosine (*m*<sup>5</sup>C)** residues, respectively.

***N*<sup>6</sup>-Methyladenine (*m*<sup>6</sup>A) residue**

***N*<sup>4</sup>-Methylcytosine (*m*<sup>4</sup>C) residue**

**5-Methylcytosine (*m*<sup>5</sup>C) residue**

These are the only types of modifications to which DNA is subjected in cellular organisms (although all the C residues of T-even phage DNAs are converted to **5-hydroxymethylcytosine** residues,

**5-Hydroxymethylcytosine residue**

which may, in turn, be glycosylated). These methyl groups project into B-DNA's major groove, where they can interact with DNA-binding proteins. In most cells, only a few percent of the susceptible bases are methylated, although this figure rises to >30% of the C residues in some plants.

Bacterial DNAs are methylated at their own particular restriction sites, thereby preventing the corresponding restriction endonucleases from degrading the DNA (Section 5-5A). These restriction-modification systems, however, account for only part of the methylation of bacterial DNAs. In *E. coli*, most DNA methylation is catalyzed by the products of the *dam* and *dcm* genes. The **Dam methyltransferase (Dam MTase)** methylates the A residue in all GATC sequences, whereas the **Dcm MTase** methylates both C residues in  $CC^A_{\uparrow}GG$  at their C5 positions. Note

that both of these sequences are palindromic. We have seen that *E. coli* uses Dam MTase-mediated methylation to differentiate parental from newly synthesized DNA in mismatch repair (Section 30-5C) and in limiting *oriC*-based DNA replication initiation to once per cell generation via sequestration (Section 30-3Cb).

**a. The MTase Reaction Occurs via a Covalent Intermediate in Which the Target Base Is Flipped Out**

The Dam and Dcm MTases, as do all known DNA MTases, use *S*-adenosylmethionine (SAM) as their methyl donor. Indeed, all  $m^5C$ -MTases share a set of conserved sequence motifs. Daniel Santi has proposed that the catalytic mechanism of these  $m^5C$ -MTases (Fig. 30-101) is similar to that of thymidylate synthase (Fig. 28-19) in that both types of enzymes transfer methyl groups to pyrimidine C5 atoms via a reaction that is initiated by the nucleophilic attack of a Cys thiolate group on the pyrimidine's C6 position. The pyrimidine's C5 atom is thereby activated as a resonance-stabilized carbanion that nucleophilically attacks the methyl donor's methyl group (which in thymidylate synthase is donated by  $N^5,N^{10}$ -methylene-THF rather than SAM) to yield a covalent intermediate. This intermediate subsequently decomposes to products through the enzymatic abstraction of the proton substituent to C5 and elimination of the enzyme. The Cys thiolate nucleophile is a component of a Pro-Cys dipeptide that is invariant in all known  $m^5C$ -MTases and thymidylate synthases.

**Figure 30-101** The catalytic mechanism of 5-methylcytosine methyltransferases ( $m^5C$ -MTases). The methyl group is supplied by SAM, which thereby becomes *S*-adenosylhomocysteine. In M.HhaI, the DNA MTase from *Haemophilus haemolyticus*, the

active site thiolate group,  $^-S-E$ , is on Cys 81, the enzyme general acid,  $E-A$ , is Glu 119, and the enzyme general base,  $E-B$ , has not been identified. [After Verdine, G.L., *Cell* **76**, 198 (1994).]

This mechanism is supported by the observation that the action of  $m^5C$ -MTases on a **5-fluorocytosine ( $f^5C$ )** residue

**5-Fluorocytosine ( $f^5C$ ) residue**

irreversibly traps the covalent intermediate (and hence inactivates the enzyme) because the enzyme cannot abstract fluorine, the most electronegative element, as an  $F^+$  ion (5-fluorodeoxyuridylate is likewise a suicide substrate for thymidylate synthase; Section 28-3Bc). Stereochemical principles dictate that the enzyme's Cys thiolate group can nucleophilically attack cytosine's C5 position only from above or below the ring. This is possible because, as we shall see below, the enzyme induces its cytosine target to flip out of the DNA double helix.

The DNA MTase from *Haemophilus haemolyticus* (**M.HhaI**), a 327-residue monomer, is a component of this bacterium's restriction–modification system. M.HhaI methylates its recognition sequence, 5'-GCGC-3' in double-stranded DNA, to yield 5'-G- $m^5C$ -GC-3'. Richard Roberts and Xiaodong Cheng determined the X-ray structure of the inactivated M.HhaI–DNA complex formed by incubating the enzyme with the self-complementary sequence d(TGATAG- **$f^5C$** -GCTATC) (in which the enzyme's recognition sequence is in bold) in the presence of SAM. The DNA binds to the enzyme in a large cleft between its two unequally sized domains (Fig. 30-102). The structure's most striking feature is that the  $f^5C$  nucleotide has flipped out of the minor groove in the otherwise largely undistorted B-DNA helix and has inserted into the enzyme's active site.

**Figure 30-102** X-ray structure of the M.HhaI DNA methyltransferase in complex with S-adenosylhomocysteine and a dsDNA containing a methylated 5-fluorocytosine base at the enzyme's target site.

The protein is represented by a semitransparent ribbon. The DNA is drawn in stick form colored according to atom type (C green, N blue, O red, and P orange). Its methylated 5-fluorocytosine residue (C atoms cyan) has swung out of the DNA helix into the enzyme's active site pocket, where its C6 forms a covalent bond with the S atom of an enzyme Cys residue (C atoms magenta and S yellow). The methyl group and a fluorine atom at C5 (which prevents the methylation reaction from going to completion) are represented by magenta and yellow-green spheres, respectively. The position of the flipped-out cytosine base in the DNA double helix is occupied by the side chain of a Gln residue (shown in space-filling form with C yellow), which hydrogen bonds to the "orphaned" guanine base. The S-adenosylmethionine, which has given up its methyl group, is drawn in stick form with its C atoms pink. [Based on an X-ray structure by Richard Roberts, New England Biolabs, Beverly, Massachusetts, and Xiaodong Cheng, Cold Spring Harbor Laboratory, New York. PDBid 1MHT.]

There, the  $f^5C$  has reacted with SAM so as to yield adenosylhomocysteine (SAM without its methyl group) and the methylated intermediate covalently linked to Cys 81. The side chain of Gln 237 fills the cavity in the DNA double helix left by the departure of the  $f^5C$  by hydrogen-bonding to the opposing G base. Comparison of this structure with that of M.HhaI in complex only with SAM indicates that on binding the DNA the protein's so-called active site loop (residues 80–99) swings around to contact the DNA, a movement of up to 25 Å. Nearly all base-specific interactions are made in the major groove by two Gly-rich loops (residues 233–240 and 250–257), the so-called recognition loops. The protein also makes extensive sequence-nonspecific contacts with DNA phosphate groups.

Base flipping was first observed in the above X-ray structure. However, as is now clear from the structures of other MTases as well as those of variety of DNA repair enzymes (e.g., Sections 30-5Aa and 30-5Be), *base flipping is a common mechanism through which enzymes gain access to the bases in dsDNA on which they perform chemistry.*

#### b. DNA Methylation in Eukaryotes Functions in Gene Regulation

5-Methylcytosine is the only methylated base in most eukaryotic DNAs, including those of vertebrates. This modification occurs largely in the CG dinucleotide of various palindromic sequences. CG is present in the vertebrate genome at only about one-fifth its randomly expected

frequency. The upstream regions of many genes, however, have normal CG frequencies and are therefore known as **CpG islands**.

The degree of eukaryotic DNA methylation and its pattern are conveniently assessed by comparing the Southern blots (Section 5-5D) of DNA cleaved by the restriction endonucleases HpaII (which cleaves CCGG but not C-m<sup>5</sup>C-GG) and MspI (which cleaves both). Such studies indicate that eukaryotic DNA methylation varies with the species, the tissue, and the position along a chromosome.

The m<sup>5</sup>C residues in a given DNA segment can be identified through **bisulfite sequencing**, in which the DNA is reacted with **bisulfite ion** (HSO<sub>3</sub><sup>-</sup>), which selectively deaminates C (but not m<sup>5</sup>C) residues to U, followed by PCR amplification (Section 5-5F), which copies these U's to T's and the m<sup>5</sup>C's to C's. Comparison of the sequences of the amplified DNA with that of untreated DNA reveals which C's in the untreated DNA are methylated.

There is clear evidence that *DNA methylation switches off eukaryotic gene expression, particularly when it occurs in the promoter regions upstream of a gene's transcribed sequences*. For example, globin genes are less methylated in erythroid cells than they are in nonerythroid cells and, in fact, the specific methylation of the control region in a recombinant globin gene inhibits its transcription in transfected cells. In further support of the inhibitory effect of DNA methylation is the observation that **5-azacytosine (5-azaC)**,

a base analog that cannot be methylated at its N5 position and that inhibits DNA MTases, stimulates the synthesis of several proteins and changes the cellular differentiation patterns of cultured eukaryotic cells. The observation that repetitive intragenic parasites such as LINES are highly methylated in somatic tissues has led to the hypothesis that CpG methylation in mammals arose to prevent the spurious transcriptional initiation of these retrotransposons.

The way in which DNA methylation prevents gene expression is poorly understood. One possibility is that DNA methylation can directly block the binding of transcriptional activators to their target sequences. However, in many cases, DNA methylation is recognized by a family of proteins that contain a conserved **methyl-CpG binding domain (MBD)**. Since the methyl groups of m<sup>5</sup>C residues extend into dsDNA's major groove, MBDs can bind to them without perturbing DNA's double helical structure. MBD-containing proteins inhibit the transcription of their bound promoter-methylated genes by recruiting protein complexes that induce the alteration of the local chromo-

some structure in a way that prevents the transcription of the associated gene (eukaryotic chromosome structure is discussed in Section 34-1). Another possibility has been raised by the observation that the methylation of synthetic poly(GC) stabilizes its Z-DNA conformation. Quite possibly, the formation of Z-DNA, which has been detected *in vivo* (Section 29-1Bb), acts as a conformational switch to turn off local gene expression.

### c. DNA Methylation in Eukaryotes Is Self-Perpetuating

The palindromic nature of DNA methylation sites in eukaryotes permits the methylation pattern on a parental DNA strand to direct the generation of the same pattern in its daughter strand (Fig. 30-103). This **maintenance methylation** would result in the stable “inheritance” of a methylation pattern in a cell line and hence cause these cells to all have the same differentiated phenotype. Such changes to the genome are described as being **epigenetic** (Greek: *epi*,

**Figure 30-103 Maintenance methylation.** The pattern of methylation on a parental DNA strand induces the corresponding methylation pattern in the complementary strand. In this way, a stable methylation pattern may be maintained in a cell line.

upon or beside) because they provide an additional layer of information that specifies when and where specific portions of the otherwise fixed genome are expressed (an epigenetic change that we have already encountered is the lengthening of telomeres in germ cells; Section 30-4D). Epigenetic characteristics, as we shall see, are not bound by the laws of Mendelian inheritance.

There is considerable experimental evidence favoring the existence of maintenance methylation, including the observation that artificially methylated viral DNA, on transfection into eukaryotic cells, maintains its methylation pattern for at least 30 cell generations. Maintenance methylation in mammals appears to be mediated mainly by the protein **DNMT1** (for *DNA methyltransferase 1*), which has a strong preference for methylating hemimethylated substrate DNAs. In contrast, prokaryotic DNA MTases such as *M.HhaI* do not differentiate between hemimethylated and unmethylated substrate DNAs. The importance of maintenance methylation is demonstrated by the observation that mice homozygous for deletion of the *DNMT1* gene die early in embryonic development.

The interaction energy provided a single methyl group in the major groove of DNA seems insufficient to permit a protein to reliably differentiate between an  $m^5C$  and a C residue. Nevertheless, the **SRA** (for SET and RING-associated) domain of the protein **UHRF1** (for ubiquitin-like, containing PHD and RING finger domains 1) does so and thereon recruits DNMT1 to the site. How does the SRA domain distinguish a single  $m^5C$  residue from unmethylated C?

The X-ray structure of the 210-residue SRA domain in complex with a 12-bp DNA containing a centrally located hemimethylated CpG was independently determined by Masahiro Shirakawa and Sirano Dhe-Paganon. It reveals that the DNA's  $m^5C$  residue has flipped out from the minor groove side of the largely straight B-form DNA to tightly bind deep within in a protein pocket (Fig. 30-104). Two loops reach around the resulting gap in the DNA helix from the major and minor grooves to interact with the other three bases of the hemimethylated CpG site. The  $m^5C$  base is replaced in the double helix by the side chain of an Arg residue extending from the minor groove loop, which hydrogen-bonds to the “orphaned” G residue without greatly disturbing its conformation.

DNMT1 has both a catalytic domain and a UHRF1-binding domain. The catalytic domain is thought to have a similar structure and mode of DNA binding as bacterial MTases such as *M.HhaI* (Fig. 30-102). However, a model of the DNMT1 catalytic domain–DNA–SRA domain complex based on the structures of the *M.HhaI*–DNA and SRA–DNA complexes indicates that it is unlikely that both the  $m^5C$  and C residues of a double helical CpG island could be simultaneously flipped out of the DNA. This suggests that the binding of the UHRF1-binding domain of DNMT1 to the SRA–DNA complex causes the  $m^5C$  to flip back into the DNA double helix while the C to be methylated flips out to bind to the catalytic domain of DNMT1.

**Figure 30-104** X-ray structure of the SRA domain of mouse **UHRF1** in complex with a hemimethylated 12-bp DNA. The protein is drawn in ribbon form (green) embedded in its semitransparent molecular surface. The DNA is shown in stick form colored according to atom type (DNA C gray except for the  $m^5C$  residue C which is magenta, N blue, O red, and P orange) with successive P atoms in the same strand connected by orange rods. The methyl group of the  $m^5C$  residue is represented by a magenta sphere. An Arg side chain (C cyan) fills the space in the DNA double helix vacated by the flipped-out  $m^5C$ . [Based on an X-ray structure by Masahiro Shirakawa, Kyoto University, Japan. PDBid 2ZDK.]

The pattern of DNA methylation in mammals varies in early embryological development. DNA methylation levels are high in mature gametes (sperm and ova) but are nearly eliminated by the time a fertilized ovum has become a **blastocyst** (a hollow ball of cells, the stage at which the embryo implants into the uterine wall; embryonic development is discussed in Section 34-4A). After this stage, however, the embryo's DNA methylation levels globally rise until, by the time the embryo has reached the developmental stage known as a **gastrula**, its DNA methylation levels have risen to adult levels, where they remain for the lifetime of the animal. This *de novo* (new) methylation appears to be mediated by two DNA MTases distinct from DNMT1 named **DNMT3a** and **DNMT3b**. An important exception to this remethylation process is that the CpG islands of germline cells (cells that give rise to sperm or ova) remain unmethylated. This ensures the faithful transmission of the CpG islands to the succeeding generation in the face of the strong mutagenic pressure of  $m^5C$  deamination (which yields T, a mutation that mismatch repair occasionally fails to correct).

The change in DNA methylation levels (epigenetic reprogramming) during embryonic development suggests that the pattern of genetic expression differs in embryonic and somatic cells. This explains the observed high failure

rate in cloning mammals (sheep, mice, cattle, etc.) by transferring the nucleus of an adult cell into an enucleated oocyte (immature ovum). Few of these animals survive to birth, many of those that do so die shortly thereafter, and most of the ~1% that do survive have a variety of abnormalities, most prominently an unusually large size. However, the survival of any embryos at all is indicative that the oocyte has the remarkable capacity to epigenetically reprogram somatic chromosomes (although it is rarely entirely successful in doing so) and that mammalian embryos are relatively tolerant of epigenetic abnormalities. Presumably, the reproductive cloning of humans from adult nuclei would result in similar abnormalities and for this reason (in addition to social and ethical prohibitions) should not be attempted.

#### d. Genomic Imprinting Results from Differential DNA Methylation

It has been known for thousands of years that maternal and paternal inheritance can differ. For example, a mule (the offspring of a mare and a male donkey) and a hinny (the offspring of a stallion and a female donkey) have obviously different physical characteristics, a hinny having shorter ears, a thicker mane and tail, and stronger legs than a mule. This is because, in mammals only, certain maternally and paternally supplied genes are differentially expressed, a phenomenon termed **genomic imprinting**. The genes that are subject to genomic imprinting are, as Rudolph Jaenisch has shown, differentially methylated in the two parents during gametogenesis and the resulting different methylation patterns are resistant to the wave of demethylation that occurs during the formation of the blastocyst and to the wave of *de novo* methylation that occurs thereafter.

The importance of genomic imprinting is demonstrated by the observation that an embryo derived from the transplantation of two male or two female pronuclei into an ovum fails to develop (pronuclei are the nuclei of mature sperm and ova before they fuse during fertilization). Inappropriate imprinting is also associated with certain diseases. For example, **Prader-Willi syndrome (PWS)**, which is characterized by the failure to thrive in infancy, small hands and feet, marked obesity, and variable mental retardation, is caused by a >5000-kb deletion in a specific region of the paternally inherited chromosome 15. In contrast, **Angelman syndrome (AS)**, which is manifested by severe mental retardation, a puppetlike ataxic (uncoordinated) gait, and bouts of inappropriate laughter, is caused by a deletion of the same region from the maternally inherited chromosome 15. These syndromes are also exhibited by those rare individuals who inherit both their chromosomes 15 from their mothers for PWS and from their fathers for AS. Evidently, certain genes on the deleted chromosomal region must be paternally inherited to avoid PWS and others must be maternally inherited to avoid AS. Several other human diseases are also associated with either maternal or paternal inheritance or lack thereof.

#### e. DNA Methylation Is Associated with Cancer

The mutation of an m<sup>5</sup>C residue to T (with its associated G to A mutation on the complementary strand) is, by far, the most prevalent mutational change in human cancers. Such mutations usually convert proto-oncogenes to oncogenes (Section 19-3B) or inactivate tumor suppressors (Section 34-4Ca). In addition, the hypomethylation of proto-oncogenes and the hypermethylation of genes encoding tumor suppressors are associated with cancers, although it is unclear whether these are initiating or consolidating events for malignancies.

#### f. Several Neurological Diseases Are Associated with Trinucleotide Repeat Expansions

**Fragile X syndrome**, whose major symptoms include mental retardation and a characteristic long, narrow face with large ears, afflicts 1 in 4500 males and 1 in 9000 females. Fragile X syndrome is so named because, in affected individuals, the tip of the X chromosome's long arm is connected to the rest of the chromosome by a slender thread that is easily broken. The genetics of this condition are bizarre. The maternal grandfathers of individuals having fragile X syndrome may be asymptomatic, both clinically and cytogenetically. Their daughters are likewise asymptomatic, but these daughters' children of either sex may have the syndrome. Evidently, the fragile X defect is activated by passage through a female. Moreover, the **penetrance** of the disease, that is, the probability of a child having fragile X syndrome, and its severity, increase with each succeeding generation, a phenomenon termed **genetic anticipation**.

The affected gene in fragile X syndrome, *FMRI* (for fragile X mental retardation 1), encodes a 632-residue RNA-binding protein named **FMRP** (for *FMR* protein), which apparently functions in the transport of certain mRNAs from the nucleus to the cytoplasm (Section 34-3C), where it probably regulates their translation. FMRP, which is highly conserved in vertebrates, is expressed in most tissues but most heavily in brain neurons, where a variety of evidence indicates that its participation is required for the proper formation and/or function of synapses.

In the general population, the 5' untranslated region of *FMRI* contains a polymorphic (CGG)<sub>n</sub> sequence with *n* ranging from 6 to 60 and often punctuated by one or two AGG interruptions. However, in certain asymptomatic individuals, *n* has increased from 60 to 200, a so-called premutation that males transmit in unchanged form to their daughters (they transmit a Y rather than an X chromosome to their sons). In the daughters' children, however, ~80% of the individuals inheriting a premutant *FMRI* gene exhibit an astonishing expansion (amplification) of the triplet repeat with *n* ranging from >200 to several thousand, as well as the symptoms of the disease, a so-called full mutation. These triplet repeats differ in size among siblings and often exhibit heterogeneity within an individual, suggesting that they are somatically generated.

These **dynamic mutations**, which expand more often than they contract, perhaps arise through slippage of the DNA during replication. One way that slippage might occur

**Figure 30-105** The loop-out mechanism for the alteration of the number of consecutive triplet repeats in DNA through its replication. Here the template strand is red and its nascent (newly synthesized) daughter strand is blue. With long tracts of repeating sequences, the probability of a loop-out occurring increases because its neighboring sequences will remain base-paired. The loop-out of a  $(CNG)_n$  repeat is stabilized by its ability to form a partially base-paired structure. (a) If the daughter strand loops out, the number of repeats increases. (b) If the template strand loops out, the number of repeats decreases.

is through the formation of loop-outs (Fig. 30-105) on either the newly synthesized strand (causing expansions) or on the template strand (causing contractions). Such  $(CNG)_n$  loops are likely stabilized by their ability to form imperfectly base-paired stems. As expected, the frequency of slippage increases with the number of repeats.

The peculiar genetics of fragile X syndrome is a consequence of genomic imprinting through methylation. The *FMRI* gene is unmethylated in normal individuals. However, it is hypermethylated in individuals with a maternally transmitted full mutation. This maintains the *FMRI* gene in a transcriptionally silent (inactive) state, thereby accounting for the symptoms of the disease. The lesser frequency and severity of fragile X syndrome in females are accounted for by the fact that females have two X chromosomes, one of which is unlikely to be mutated.

Over 30 other pathological instances of the expansion of DNA repeats, most of which are also neurological diseases, are known including the following:

**1. Myotonic dystrophy (DM)**, the most common adult form of **muscular dystrophy** (its estimated incidence is 1 in 8000). It is a multisystem autosomal dominant disorder that is mainly characterized by progressive muscle weakness and wasting, the severity of which increases with successive generations while the age of onset decreases (genetic anticipation). Its most severe form, congenital DM, is

exclusively maternally transmitted. DM arises from a trinucleotide expansion in the 3' untranslated region of the gene encoding **myotonic dystrophy protein kinase (MDPK)**, which is expressed in the neurons affected by DM. The repeating triplet,  $(CAG)_n$ , is present in between 5 and 30 copies in the MDPK gene of normal individuals but expands from at least 50 repeats in minimally affected individuals to ~2000 repeats in severely affected individuals.

**2. Huntington's disease (HD)**; previously called **Huntington's chorea**, a devastating neurodegenerative disorder characterized by progressively choreic (disordered) movements, cognitive decline, and emotional disturbances over an average 18-year course that is inevitably fatal. This dominant autosomal disorder, which affects ~1 in 10,000 individuals and has an average age of onset of ~40 years, is a consequence of the selective loss of certain groups of neurons in the brain. The *HD* gene, which encodes a widely expressed 3145-residue protein of unknown function named **huntingtin**, contains a polymorphic trinucleotide repeat,  $(CAG)_n$ , within its polypeptide coding sequence. The *HD* genes from 150 independent families with HD all contained between 37 and 86 repeat units, whereas those from normal individuals had 11 to 34 repeats. Moreover, the *HD* repeat length is unstable: >80% of meiotic transmissions show either increases or decreases, with the largest increases occurring in paternal transmissions (genomic imprinting). The number of repeats in afflicted individuals is inversely correlated with the age of onset of HD.

CAG is the codon for Gln (Table 5-3) and hence mutant huntingtin contains a long poly(Gln) tract. Synthetic poly(Gln) aggregates as  $\beta$  sheets that are linked by hydrogen bonds involving both their main chain and side chain amide groups. Indeed, the nuclei of HD-affected neurons contain inclusions that presumably consist of aggregates of huntingtin or its proteolytic products. It is these inclusions, as Max Perutz pointed out, that apparently kill the neurons in which they are contained, although the mechanism of how they do so is unknown. The long incubation period before the symptoms of HD become evident is attributed to the lengthy nucleation time for aggregate formation, much as occurs in the formation of amyloid fibrils (Section 9-5A).

**3. Spinocerebellar ataxia (SCA) type 1**, a progressive neurodegenerative disease whose age of onset is typically in the third or fourth decade, although it exhibits genetic anticipation. Like HD, it is caused by selective neuronal loss and is associated with an expansion of a CAG repeat in a coding region, in this case of a neuronal protein named **ataxin-1**. There it expands from ~28 to between 43 and 81 copies, thereby yielding a poly(Gln) tract of increased length (and tendency to aggregate). Four similar diseases, **SCA types 2, 3, 6, and 7**, are caused by  $(CAG)_n$  expansions in different neuronal proteins.

## CHAPTER SUMMARY

**1 and 2 DNA Replication** DNA is replicated in the 5' → 3' direction by the assembly of deoxynucleoside triphosphates on complementary DNA templates. Replication is initiated by the generation of short RNA primers, as mediated in *E. coli* by primase and RNA polymerase. The DNA is then extended from the 3' ends of the primers through the action of a DNA polymerase (Pol III in *E. coli*). The leading strand at a replication fork is synthesized continuously, whereas the lagging strand is synthesized discontinuously by the formation of Okazaki fragments. RNA primers on newly synthesized DNA are excised and replaced by DNA through Pol I-catalyzed (in *E. coli*) nick translation. The single-strand nicks are then sealed by DNA ligase. Mismatching errors during DNA synthesis are corrected by the 3' → 5' exonuclease functions of both Pol I and Pol III. The Klenow fragment of Pol I and other DNA polymerases of known structure have a right-hand-like structure with the active site located in the palm domain. Pol I recognizes the incoming nucleotide according to the shape of the base pair it forms with the template base and catalyzes the formation of a phosphodiester bond via a mechanism involving two metal ions. DNA synthesis by *E. coli* Pol III requires the participation of many auxiliary proteins including DNA gyrase, DnaB helicase, single-strand binding protein (SSB), primase, the  $\beta_2$  sliding clamp, and DNA ligase.

**3 Prokaryotic Replication** DNA synthesis commences from specific sites known as replication origins. In the synthesis of the bacteriophage M13 (–) strand on the (+) strand template, the origin is recognized and primer synthesis is initiated by RNA polymerase. The analogous process in bacteriophage  $\phi$ X174, as well as in *E. coli*, is mediated by a complex primase-containing particle known as the primosome.  $\phi$ X174 (+) strands are synthesized according to the looped rolling circle mode of DNA replication on (–) strand templates of the replicative form in a process that is directed by the virus-specific gene A protein.

The *E. coli* chromosome is bidirectionally replicated in the  $\theta$  mode from a single origin, *oriC*. It is recognized by DnaA protein, which together with DnaC protein, loads the DnaB helicase onto the developing replication forks. Leading strand synthesis is probably primed by RNA polymerase and primase working together, whereas Okazaki fragments are primed by primase in the primosome. The uncontrolled initiation of DNA replication is prevented by the sequestration of newly synthesized and hence hemimethylated *oriC* by membrane-associated SeqA protein, which prevents the *oriC* from becoming fully methylated at its multiple GATC sites. The  $\beta_2$  sliding clamp, which is responsible for Pol III's processivity, is loaded onto the DNA by the  $\gamma_3\delta\delta'$  clamp loader in an ATP-driven process. The  $\delta$  subunit, when unmasked by ATP binding to the  $\gamma$  subunits, acts as a molecular “wrench” to spring open the sliding clamp, thereby permitting the entry of a single-stranded template DNA. Replication termination is facilitated by Tus protein which, on binding to an appropriately oriented *Ter* site, arrests the motion of a replication fork by binding to DnaB helicase. The great complexity of the DNA replication process functions to ensure the enormous fidelity necessary to maintain genome integrity.

**4 Eukaryotic Replication** Progression through the eukaryotic cell cycle is mediated by cyclins complexed to their

cognate cyclin-dependent protein kinases (Cdks). Chromosomal DNA replication is initiated by pol  $\alpha$ /primase, which synthesizes a primer followed by a short length of DNA. Then, via polymerase switching mediated by replication factor C (RFC), the eukaryotic clamp loader, pol  $\delta$  processively synthesizes both the lagging and leading strands in complex with PCNA, the eukaryotic sliding clamp.

Eukaryotic chromosomal DNA is synthesized in multiple origin-containing segments known as replicons. Nevertheless, chromosomal DNA is synthesized once and only once per cell cycle. The re-replication of DNA is prevented because replication initiation is licensed only in the G<sub>1</sub> phase of the cell cycle by the formation of the pre-replicative complex (pre-RC) but DNA is synthesized only in S phase by the activation of the pre-RC. The pre-RC is assembled in G<sub>1</sub> phase by the binding of the origin recognition complex (ORC) to an origin, which recruits Cdc6/Cdc18 and Cdt1 followed by the MCM complex, the replicative helicase. The activation of the pre-RC begins in S phase with the addition of Mcm10 followed by the phosphorylation of many of the pre-RC's subunits by Cdks and Ddk. Cdc45 then binds followed by pol  $\alpha$ /primase, pol  $\epsilon$ , PCNA, and the replication protein A (RPA), the SSB counterpart, to yield the active initiation complex. Re-replication is prevented through the actions of Cdks, which cause the elimination of Cdc6/Cdc18 and inhibit the helicase activity of the MCM complex. In metazoan cells, re-replication is also prevented by the binding of geminin to Cdt1. Mitochondrial DNA is replicated by polymerase  $\gamma$  via a process in which the Okazaki fragments are entirely RNA.

Retroviruses produce DNA on RNA templates in a reaction sequence catalyzed by reverse transcriptase. Telomeric DNA, a G-rich repeating octamer on the 3'-ending strand, is synthesized by the RNA-containing enzyme telomerase. Telomerase is active in germ cells but not somatic cells, a phenomenon that is at least in part responsible for cellular senescence and aging. The observation that telomerase is active in nearly all cancer cells suggests that telomerase inactivation is a defense against the development of cancer. The free DNA ends of telomeres are capped to prevent them from triggering DNA damage checkpoints. The *O. nova* telomere heterodimer TEBP binds both single strands of telomere DNA and a G-quartet-containing dimer. Its counterparts in humans and yeast are POT1 and TPP1. Telomeric DNA forms T-loops which are formed by the TRF2-mediated invasion of the 3' telomeric overhang into repeating telomeric dsDNA to form a D-loop. POT1, TPP1, TRF1, together with TRF2, TIN2, and RAP1, form a complex on the telomere called shelterin that functions to protect telomeres from DNA repair processes and limit the size of the telomere.

**5 Repair of DNA** Cells have a great variety of DNA repair mechanisms. DNA damage may be directly reversed such as in the photoreactivation of UV-induced pyrimidine dimers or in the repair of O<sup>6</sup>-alkylguanine lesions by the transfer of the offending alkyl group to a repair protein. Pyrimidine dimers, as well as many other types of DNA lesions, may also be removed by nucleotide excision repair (NER), which in *E. coli* involves the UvrABC system. Xeroderma pigmentosum, an inherited human disease characterized by marked UV-induced skin changes and a greatly increased incidence of

cancer, is caused by defects in any of seven complementation groups that participate in NER. Cockayne syndrome is associated with defects in the proteins responsible for transcription-coupled repair (TCR), which repairs lesions in actively transcribing genes. In base excision repair (BER), DNA glycosylases specifically remove the corresponding chemically altered bases, including uracil, through mechanisms that involve base flip-outs to form AP sites. The AP sites are cleaved on one side by an AP endonuclease, removed together with adjacent residues by an exonuclease, and replaced through the actions of a DNA polymerase and a DNA ligase. In mismatch repair (MMR), base-pairing mismatches arising from replication errors are corrected. In *E. coli* MMR, MutS and MutL bind to the mismatch and then identify the daughter strand, which contains the error, according to which strand of the nearest hemimethylated GATC palindrome is unmethylated. MutH then cleaves this strand, which is excised past the mismatch and replaced.

DNA damage in *E. coli* induces the SOS response, a LexA- and RecA-mediated process in which the error-prone bypass DNA polymerases Pol IV and Pol V replicate a damaged template DNA even if it provides no information as to which base to incorporate. Double-strand break (DSB) repair by nonhomologous end-joining (NHEJ) is facilitated by Ku protein, which holds two dsDNA ends together for ligation by DNA ligase IV in complex with Xrcc4. The high correlation between mutagenesis and carcinogenesis permits the detection of carcinogens by the Ames test.

**6 Recombination and Mobile Genetic Elements** Genetic information may be exchanged between homologous DNA sequences through homologous recombination, a process that occurs according to the Holliday model. In *E. coli*, strand invasion to form Holliday junctions is mediated by RecA after the RecBCD-mediated generation of the single-strand nicks to which RecA binds. Branch migration is mediated by RuvAB, which consists of a homotetramer (or a homooctamer) of RuvA, which binds both a Holliday junction and two oppositely located RuvB hexamers. In an ATP-driven process, the RuvB hexamers (in effect) counter-rotate to pump the dsDNA stems into the center of the RuvA-bound Holliday junction, where each of its single strands exchange base-pairing partners to form new dsDNA stems, which are translocated toward the periphery of the complex. The Holliday junction is eventually resolved to its component dsDNAs by RuvC and sealed by DNA ligase.

The primary function of homologous recombination is to repair damaged replication forks resulting from the encounters of replisomes with unrepaired single-strand lesions or breaks. DSBs may be rejoined via a recombination repair process called homologous end-joining.

Chromosomes and plasmids may be rearranged through the action of transposons. These DNA segments carry the genes that encode the proteins that mediate the transposition process as well as other genes. Tn5 transposase catalyzes the cut-and-paste transposition of the Tn5 transposon. Replicative transposition proceeds via the intermediacy of cointegrates, which are resolved through the action of enzymes such as the  $\gamma\delta$  resolvase. Transposition may be important in chromosomal and plasmid evolution and has been implicated in the control of phenotypic expression such as phase alternation in *Salmonella*, a process that is catalyzed by the Hin DNA invertase, a homolog of the  $\gamma\delta$  resolvase. Members of the  $\lambda$  integrase family of proteins, such as Cre recombinase, insert dsDNA segments into their target sites via a Holliday junction intermediate in which transient covalent bonds are formed between active site Tyr side chains and the 3'-OH groups at the cleavage sites. Retrotransposons undergo transposition through an RNA intermediate. Many retrotransposons, such as yeast Ty1, are "internal" retroviruses that can only replicate within a genome. Nonviral retrotransposons, such as LINES, the dominant transposons in the human genome, have a different transpositional mechanism.

**7 DNA Methylation and Trinucleotide Repeat Expansions** Prokaryotic DNA may be methylated at its A or C bases. This prevents the action of restriction endonucleases and permits the correct mismatch repair of newly replicated DNA. In most eukaryotes, DNA methylation, which occurs, mainly at CpG islands, through the formation of m<sup>5</sup>C, has been implicated in the control of gene expression and, via maintenance methylation, in genomic imprinting.

Over 30 inherited, mostly neurological diseases, including fragile X syndrome, myotonic dystrophy, and Huntington's disease, are characterized by the genetically bizarre expansion of segments of (CNG)<sub>n</sub> triplets. If an expanded triplet repeat occurs in an upstream noncoding region of a gene, its aberrant methylation, perhaps through genomic imprinting, may lead to the gene's transcriptional silencing; if the expanded repeat is instead manifested as a poly(Gln) tract in a protein, the resulting protein aggregates may kill the neurons in which it occurs.

## PROBLEMS

1. Explain how certain mutant varieties of Pol I can be nearly devoid of DNA polymerase activity but retain almost normal levels of 5' → 3' exonuclease activity.
2. Why haven't Pol I mutants been found that completely lack 5' → 3' activity at all temperatures?
3. Why aren't type I topoisomerases necessary in *E. coli* DNA replication?

\*4. The 3' → 5' exonuclease activity of Pol I excises only unpaired 3'-terminal nucleotides from DNA, whereas this enzyme's pyrophosphorolysis activity removes only properly paired 3'-terminal nucleotides. Discuss the mechanistic significance of this phenomenon in terms of the polymerase reaction.

5. You have isolated *E. coli* with temperature-sensitive mutations in the following genes. What are their phenotypes above their restrictive temperatures? Be specific. (a) *dnaB*, (b) *dnaE*, (c) *dnaG*, (d) *lig*, (e) *polA*, (f) *rep*, (g) *ssb*, and (h) *recA*.

**6.** About how many Okazaki fragments are synthesized in the replication of an *E. coli* chromosome?

**\*7.** What are the minimum and maximum number of replication forks that occur in a contiguous chromosome of an *E. coli* that is dividing every 25 min; every 80 min?

**8.** To put the *E. coli* replication system on a human scale, let us imagine that the 20-Å-diameter B-DNA was expanded to 1 m in diameter. If everything were proportionally expanded, then each DNA polymerase III holoenzyme would be about the size of a medium-sized truck. In such an expanded system: (a) How fast would each replisome be moving? (b) How far would each replisome travel during a complete replication cycle? (c) What would be the length of an Okazaki fragment? (d) What would be the average distance a replisome would travel between each error it made? Provide your answers in km/hr and km.

**9.** Why can't linear duplex DNAs, such as occur in bacteriophage T7, be fully replicated by only *E. coli*-encoded proteins?

**\*10.** What is the half-life of a particular purine base in the human genome assuming that it is subject only to spontaneous depurination? What fraction of the purine bases in a human genome will have depurinated in the course of a single generation (assume 25 years)? The DNAs of ~4000-year-old Egyptian mummies have been sequenced. Assuming that mummification did not slow the rate of DNA depurination, what fraction of the purine bases originally present in the mummy would still be intact today.

**11.** Why is the methylation of DNA to form *O*<sup>6</sup>-methylguanine mutagenic?

**12.** A replication fork encountering a single-strand lesion may either dissociate or leave a single-strand gap. The latter process is more likely to occur during lagging strand synthesis than during leading strand synthesis. Explain.

**13.** The *E. coli* genome contains 1009 Chi sequences. Do these sequences occur at random, and, if not, how much more or less frequently than random do they occur?

**14.** *Deinococcus radiodurans*, which the *Guinness Book of World Records* has dubbed the world's toughest bacterium, can tolerate doses of ionizing radiation ~3000-fold greater than those that are lethal to humans (it was first discovered growing in a can of ground meat that had been "sterilized" by radiation). It appears to have several strategies to repair radiation damage to its DNA (which large doses of ionizing radiation fragment to many pieces) including a particularly large number of genes encoding proteins involved in DNA repair and 4 to 10 copies per cell of its genome, which consists of two circular chromosomes and two circular plasmids. Yet, these strategies, alone, do not account for *D. radiodurans*' enormously high radiation resistance. However, in an addi-

tional strategy, it organizes its multiple identical dsDNA circles into stacks in which, it is thought, the identical genes in the neighboring circles are aligned side by side. How would this latter strategy help *D. radiodurans* efficiently repair its fragmented DNA?

**15.** CpG islands occur in eukaryotic genomes at about one-fifth their expected random frequency. Suggest an evolutionary (mutational) process that eliminates CpG islands.

**16.** Explain why the brief exposure of a cultured eukaryotic cell line to 5-azacytosine results in permanent phenotypic changes to these cells.

**17.** Explain why chi structures, such as that shown in Fig. 30-70b, have two pairs of equal length arms.

**\*18.** Single-stranded circular DNAs containing a transposon have a characteristic stem-and-double-loop structure such as that shown in Fig. 30-106. What is the physical basis of this structure?

**Figure 30-106** Electron micrograph of a single-stranded circular DNA containing a transposon. [Courtesy of Stanley N. Cohen, Stanford University School of Medicine.]

**19.** A composite transposon integrated in a circular plasmid occasionally transposes the DNA comprising the original plasmid rather than the transposon's central region. Explain how this is possible.

**\*20.** Cre recombinase has an additional function to that of circularizing the linear P1 dsDNA (Fig. 30-96). It is also required to resolve the circular dimers of P1 plasmids that result from their recombinational repair during replication, thereby permitting both daughter cells to receive a copy of the P1 plasmid. Using simple line diagrams, outline how these plasmids become dimerized and how Cre resolves them to circular monomers.

## CHAPTER 31

### 1 The Role of RNA in Protein Synthesis

- A. Enzyme Induction
- B. Messenger RNA

### 2 RNA Polymerase

- A. Template Binding
- B. Chain Initiation
- C. Chain Elongation
- D. Chain Termination
- E. Eukaryotic RNA Polymerases

### 3 Control of Transcription in Prokaryotes

- A. Promoters
- B. *lac* Repressor I: Binding
- C. Catabolite Repression: An Example of Gene Activation
- D. Sequence-Specific Protein–DNA Interactions
- E. *araBAD* Operon: Positive and Negative Control by the Same Protein
- F. *lac* Repressor II: Structure
- G. *trp* Operon: Attenuation
- H. Riboswitches Are Metabolite-Sensing RNAs
- I. Regulation of Ribosomal RNA Synthesis: The Stringent Response

### 4 Post-Transcriptional Processing

- A. Messenger RNA Processing
- B. Ribosomal RNA Processing
- C. Transfer RNA Processing

There are three major classes of RNA, all of which participate in protein synthesis: **ribosomal RNA (rRNA)**, **transfer RNA (tRNA)**, and **messenger RNA (mRNA)**. All of these RNAs are synthesized under the direction of DNA templates, a process known as **transcription**.

RNA's involvement in protein synthesis became evident in the late 1930s through investigations by Torbjörn Caspersson and Jean Brachet. Caspersson, using microscopic techniques, found that DNA is confined almost exclusively to the eukaryotic cell nucleus, whereas RNA occurs largely in the cytosol. Brachet, who had devised methods for fractionating cellular organelles, came to similar conclusions based on direct chemical analyses. He found, in addition, that the cytosolic RNA-containing particles are also protein rich. Both investigators noted that the concentration of these RNA–protein particles (which were later named ribosomes) is correlated with the rate at which a cell synthesizes protein, implying a relationship be-

tween RNA and protein synthesis. Indeed, Brachet even suggested that *the RNA–protein particles are the site of protein synthesis*.

Brachet's suggestion was shown to be valid when radioactively labeled amino acids became available in the 1950s. A short time after injection of a rat with a labeled amino acid, most of the label that had been incorporated in proteins was associated with ribosomes. This experiment also established that *protein synthesis is not immediately directed by DNA because, at least in eukaryotes, DNA and ribosomes are never in contact*.

In 1958, Francis Crick summarized the then dimly perceived relationships among DNA, RNA, and protein by what he called the **central dogma** of molecular biology: *DNA directs its own replication and its transcription to RNA which, in turn, directs its translation to proteins* (Fig. 5-21). The peculiar use of the word “dogma,” one definition of which is a religious doctrine that the true believer cannot doubt, stemmed from a misunderstanding. When Crick formulated the central dogma, he was under the impression that dogma meant “an idea for which there was no reasonable evidence.”

We begin this chapter by discussing experiments that led to the elucidation of mRNA's central role in protein synthesis. We then study the mechanism of transcription and its control in prokaryotes. Finally, in the last section, we consider post-transcriptional processing of RNA in both prokaryotes and eukaryotes. Translation is the subject of Chapter 32. Note that these subjects were outlined in Section 5-4. Here we shall delve into much greater detail.

### 1 THE ROLE OF RNA IN PROTEIN SYNTHESIS

The idea that proteins are specified by mRNA and synthesized on ribosomes arose from the study of **enzyme induction**, a phenomenon in which bacteria vary the synthesis rates of specific enzymes in response to environmental changes. In this section, we discuss the classic experiments that explained the basis of enzyme induction and revealed the existence of mRNA. We shall see that *enzyme induction occurs as a consequence of the regulation of mRNA synthesis by proteins that specifically bind to the mRNA's DNA templates*.

## A. Enzyme Induction

*E. coli* can synthesize an estimated ~4300 different polypeptides. There is, however, enormous variation in the amounts of these different polypeptides that are produced. For instance, the various ribosomal proteins may each be present in over 10,000 copies per cell, whereas certain regulatory proteins (see below) normally occur in <10 copies per cell. Many enzymes, particularly those involved in basic cellular “housekeeping” functions, are synthesized at a more or less constant rate; they are called **constitutive enzymes**. Other enzymes, termed **adaptive** or **inducible enzymes**, are synthesized at rates that vary with the cell’s circumstances.

### a. Lactose-Metabolizing Enzymes Are Inducible

Bacteria, as has been recognized since 1900, adapt to their environments by producing enzymes that metabolize certain nutrients, for example, lactose, only when those substances are available. *E. coli* grown in the absence of lactose are initially unable to metabolize this disaccharide. To do so they require the presence of two proteins:  **$\beta$ -galactosidase**, which catalyzes the hydrolysis of lactose to its component monosaccharides,

and **galactoside permease** (also known as **lactose permease**; Section 20-4B), which transports lactose into the cell. *E. coli* grown in the absence of lactose contain only a few (<5) molecules of these proteins. Yet, a few minutes after lactose is introduced into their medium, *E. coli* increase the rate at which they synthesize these proteins by ~1000-fold (such that  $\beta$ -galactosidase can account for up to 10% of their soluble protein) and maintain this pace until lactose is no longer available. The synthesis rate then returns to its miniscule **basal level** (Fig. 31-1). *This ability to produce a series of proteins only when the substances they metabolize are present permits bacteria to adapt to their environment without the debilitating need to continuously synthesize large quantities of otherwise unnecessary substances.*

Lactose or one of its metabolic products must somehow trigger the synthesis of the above proteins. Such a sub-

stance is known as an **inducer**. The physiological inducer of the lactose system, the lactose isomer **1,6-allolactose**,

**1,6-Allolactose**

arises from lactose’s occasional transglycosylation by  $\beta$ -galactosidase. Most experimental studies of the lactose system use **isopropylthiogalactoside (IPTG)**,

**Isopropylthiogalactoside (IPTG)**

a potent inducer that structurally resembles allolactose but that is not degraded by  $\beta$ -galactosidase.

Lactose system inducers also stimulate the synthesis of **thiogalactoside transacetylase**, an enzyme that, *in vitro*, transfers an acetyl group from acetyl-CoA to the C6-OH group of a  $\beta$ -thiogalactoside such as IPTG. Since lactose fermentation proceeds normally in the absence of thiogalactoside transacetylase, however, this enzyme’s physiological role is unknown.

### b. *lac* System Genes Form an Operon

The genes specifying wild-type  $\beta$ -galactosidase, galactoside permease, and thiogalactoside transacetylase are designated  $Z^+$ ,  $Y^+$ , and  $A^+$ , respectively. Genetic mapping of the defective mutants  $Z^-$ ,  $Y^-$ , and  $A^-$  indicated that these

**Figure 31-1** The induction kinetics of  $\beta$ -galactosidase in *E. coli*. [After Cohn, M., *Bacteriol. Rev.* **21**, 156 (1957).]

**Figure 31-2 Genetic map of the *E. coli* *lac* operon.** The map shows the genes encoding the proteins mediating lactose metabolism and the genetic sites that control their expression. The Z, Y, and A genes, respectively, encode  $\beta$ -galactosidase, galactoside permease, and thiogalactoside transacetylase.

*lac* **structural genes** (genes that specify polypeptides) are contiguously arranged on the *E. coli* chromosome (Fig. 31-2). These genes, together with the control elements P and O, form a genetic unit called an **operon**, specifically the ***lac* operon**. The nature of the control elements is discussed below. The role of operons in prokaryotic gene expression is examined in Section 31-3.

### c. Bacteria Can Transmit Genes via Conjugation

An important clue as to how *E. coli* synthesizes protein was provided by a mutation that causes the proteins of the *lac* operon to be synthesized in large amounts in the absence of inducer. This so-called **constitutive mutation** occurs in a gene, designated *I*, that is distinct from although closely linked to the genes specifying the *lac* enzymes (Fig. 31-2). What is the nature of the *I* gene product? This riddle was solved in 1959 by Arthur Pardee, François Jacob, and Jacques Monod through an ingenious experiment that is known as the **PaJaMo experiment**. To understand this experiment, however, we must first consider **bacterial conjugation**.

Bacterial conjugation is a process, discovered in 1946 by Joshua Lederberg and Edward Tatum, through which some bacteria can transfer genetic information to others. The ability to conjugate (“mate”) is conferred on an otherwise indifferent bacterium by a plasmid named **F factor** (for fertility). Bacteria that possess an F factor (designated  $F^+$  or male) are covered by hairlike projections known as **F pili**. These bind to cell-surface receptors on bacteria that lack the F factor ( $F^-$  or female), which leads to the formation of

**Figure 31-3 Bacterial conjugation.** An electron micrograph in false color showing an  $F^+$  (left) and an  $F^-$  (right) *E. coli* engaged in sexual conjugation. [Dennis Kunkel/Phototake.]

a cytoplasmic bridge between these cells (Fig. 31-3). The F factor then replicates and, as the newly replicated single strand is formed, it passes through the cytoplasmic bridge to the  $F^-$  cell where the complementary strand is synthesized (Fig. 31-4). This converts the  $F^-$  cell to  $F^+$  so that the F factor is an infectious agent (a bacterial venereal disease?).

On very rare occasions, the F factor spontaneously integrates into the chromosome of the  $F^+$  cell. In the resulting

**Figure 31-4 Diagram showing how an  $F^-$  cell acquires an F factor from an  $F^+$  cell.** A single strand of the F factor is replicated, via the rolling circle mode (Section 30-3Bb), and is transferred to the  $F^-$  cell where its complementary strand is synthesized to form a new F factor.

**Hfr** (for *high frequency of recombination*) cells, the F factor behaves much as it does in the autonomous state. Its replication commences at a specific internal point in the F factor, and the replicated section passes through a cytoplasmic bridge to the  $F^-$  cell, where its complementary strand is synthesized. In this case, however, the replicated chromosome of the Hfr cell is also transmitted to the  $F^-$  cell (Fig. 31-5). *Bacterial genes are transferred from the Hfr cell to the  $F^-$  cell in fixed order.* This is because the F factor in a given Hfr strain is integrated into the bacterial chromosome at a specific site and because only a particular strand of the Hfr chromosomal DNA is replicated and transferred

**Figure 31-5** Transfer of the bacterial chromosome from an Hfr cell to an  $F^-$  cell and its subsequent recombination with the  $F^-$  chromosome. Here, Greek letters represent F factor genes, uppercase Roman letters represent bacterial genes from the Hfr cell, and lowercase Roman letters represent the corresponding alleles in the  $F^-$  cell. Since chromosomal transfer, which begins within the F factor, is rarely complete, the entire F factor is seldom transferred. Hence the recipient cell usually remains  $F^-$ .

to the  $F^-$  cell. Usually, only part of the Hfr bacterial chromosome is transferred during sexual conjugation because the cytoplasmic bridge almost always breaks off sometime during the  $\sim 90$  min required to complete the transfer process. In the resulting **merozygote** (a partially diploid bacterium), the chromosomal fragment, which lacks a complete F factor, neither transforms the  $F^-$  cell to Hfr nor is subsequently replicated. However, the transferred chromosomal fragment recombines with the chromosome of the  $F^-$  cell (Section 30-6A), thereby permanently endowing the  $F^-$  cell with some of the traits of the Hfr strain.

The integrated F factor in an Hfr cell occasionally undergoes spontaneous excision to yield an  $F^+$  cell. In rare instances, the F factor is aberrantly excised such that a portion of the adjacent bacterial chromosome is incorporated in the subsequently autonomously replicating F factor. Bacteria carrying such a so-called **F' factor** are permanently diploid for its bacterial genes.

#### d. *lac* Repressor Inhibits the Synthesis of *lac* Operon Proteins

In the PaJaMo experiment, Hfr bacteria of genotype  $I^+Z^+$  were mated to an  $F^-$  strain of genotype  $I^-Z^-$  in the absence of inducer while the  $\beta$ -galactosidase activity of the culture was monitored (Fig. 31-6). At first, as expected,

**Figure 31-6** The PaJaMo experiment. This experiment demonstrated the existence of the *lac* repressor through the appearance of  $\beta$ -galactosidase in the transient merozygotes (partial diploids) formed by mating  $I^+Z^+$  Hfr donors with  $I^-Z^-$   $F^-$  recipients. The  $F^-$  strain was also resistant to both **bacteriophage T6** and **streptomycin**, whereas the Hfr strain was sensitive to these agents. Both types of cells were grown and mated in the absence of inducer. After sufficient time had passed for the transfer of the *lac* genes, the Hfr cells were selectively killed by the addition of T6 phage and streptomycin. In the absence of inducer (*lower curve*),  $\beta$ -galactosidase synthesis commenced at around the time at which the *lac* genes had entered the  $F^-$  cells but stopped after  $\sim 1$  h. If inducer was added shortly after the Hfr donors had been killed (*upper curve*), enzyme synthesis continued unabated. This demonstrates that the cessation of  $\beta$ -galactosidase synthesis in uninduced cells is not due to the intrinsic loss of the ability to synthesize this enzyme but to the production of a repressor specified by the  $I^+$  gene. [After Pardee, A.B., Jacob, F., and Monod, J., *J. Mol. Biol.* **1**, 173 (1959).]

there was no  $\beta$ -galactosidase activity because the Hfr donors lacked inducer and the  $F^-$  recipients were unable to produce active enzyme (only DNA passes through the cytoplasmic bridge connecting mating bacteria). About 1 h after conjugation began, however, when the  $I^+Z^+$  genes had just entered the  $F^-$  cells,  $\beta$ -galactosidase synthesis began and only ceased after about another hour. The explanation for these observations is that the donated  $Z^+$  gene, on entering the cytoplasm of the  $F^-$  cell, directs the synthesis of  $\beta$ -galactosidase in a constitutive manner. Only after the donated  $I^+$  gene has had sufficient time to be expressed is it able to repress  $\beta$ -galactosidase synthesis. *The  $I^+$  gene must therefore give rise to a diffusible product, the lac repressor, which inhibits the synthesis of  $\beta$ -galactosidase (and the other lac proteins).* Inducers such as IPTG temporarily inactivate lac repressor, whereas  $F^-$  cells constitutively synthesize lac enzymes because they lack a functional repressor. Lac repressor, as we shall see in Section 31-3B, is a protein.

## B. Messenger RNA

The nature of the lac repressor's target molecule was deduced in 1961 through a penetrating genetic analysis by Jacob and Monod. A second type of constitutive mutation in the lactose system, designated  $O^c$  (for **operator constitutive**), which complementation analysis (Section 1-4Cc) has shown to be independent of the  $I$  gene, maps between the  $I$  and  $Z$  genes (Fig. 31-2). In the partially diploid  $F'$  strain  $O^cZ^-/F^+O^+Z^+$ ,  $\beta$ -galactosidase activity is inducible by IPTG, whereas the strain  $O^cZ^+/F^+O^+Z^-$  constitutively synthesizes this enzyme. *An  $O^+$  gene can therefore only control the expression of a  $Z$  gene on the same chromosome.* The same is true with the  $Y^+$  and  $A^+$  genes.

Jacob and Monod's observations led them to conclude that the proteins are synthesized in a two-stage process:

1. The structural genes on DNA are transcribed onto complementary strands of **messenger RNA (mRNA)**.
2. The mRNAs transiently associate with ribosomes, which they direct in polypeptide synthesis.

This hypothesis explains the behavior of the lac system that we previously outlined in Section 5-4Ab (Fig. 5-25;

 **See Guided Exploration 2: Regulation of gene expression by the lac repressor system.** *In the absence of inducer, the lac repressor specifically binds to the  $O$  gene (the **operator**) so as to prevent the enzymatic transcription of mRNA. On binding inducer, the repressor dissociates from the operator, thereby permitting the transcription and subsequent translation of the lac enzymes.* The operator–repressor–inducer system thereby acts as a molecular switch so that the lac operator can only control the expression of lac enzymes on the same chromosome. The  $O^c$  mutants constitutively synthesize lac enzymes because they are unable to bind repressor. The **coordinate** (simultaneous) expression of all three lac enzymes under the control of a single operator site arises, as Jacob and Monod theorized, from the

transcription of the lac operon as a single **polycistronic mRNA** which directs the ribosomal synthesis of each of these proteins (the term **cistron** is a somewhat archaic synonym for gene). This transcriptional control mechanism is further discussed in Section 31-3. [DNA sequences that are on the same DNA molecule are said to be “in cis” (Latin: on this side of), whereas those on different DNA molecules are said to be “in trans” (Latin: across). Control sequences such as the  $O$  gene, which are only active on the same DNA molecule as the genes they control, are called **cis-acting elements**. Genes such as lacI, which specify the synthesis of diffusible products and can therefore be located on a different DNA molecule from the genes they control, are said to direct the synthesis of **trans-acting factors**.]

### a. mRNAs Have Their Predicted Properties

The kinetics of enzyme induction, as indicated, for example, in Figs. 31-1 and 31-6, requires that the postulated mRNA be both rapidly synthesized and rapidly degraded. An RNA with such quick turnover had, in fact, been observed in T2-infected *E. coli*. Moreover, the base composition of this RNA fraction resembles that of the viral DNA rather than that of the bacterial RNA (keep in mind that base sequencing techniques would not be formulated for another ~15 years). Ribosomal RNA, which comprises up to 90% of a cell's RNA, turns over much more slowly than mRNA. Ribosomes are therefore not permanently committed to the synthesis of a particular protein (a once popular hypothesis). Rather, *ribosomes are nonspecific protein synthesizers that produce the polypeptide specified by the mRNA with which they are transiently associated.* A bacterium can therefore respond within a few minutes to changes in its environment.

Evidence favoring the Jacob and Monod model rapidly accumulated. Sydney Brenner, Jacob, and Matthew Meselson carried out experiments designed to characterize the RNA that *E. coli* synthesized after T4 phage infection. *E. coli* were grown in a medium containing  $^{15}\text{N}$  and  $^{13}\text{C}$  so as to label all cell constituents with these heavy isotopes. The cells were then infected with T4 phages and immediately transferred to an unlabeled medium (which contained only the light isotopes  $^{14}\text{N}$  and  $^{12}\text{C}$ ) so that cell components synthesized before and after phage infection could be separated by equilibrium density gradient ultracentrifugation in CsCl solution (Section 6-5Bb). No “light” ribosomes were observed, which indicates, in agreement with the above-mentioned T2 phage results, that no new ribosomes are synthesized after phage infection.

The growth medium also contained either  $^{32}\text{P}$  or  $^{35}\text{S}$  so as to radioactively label the newly synthesized and presumably phage-specific RNA and protein, respectively. Much of the  $^{32}\text{P}$ -labeled RNA was associated, as was postulated for mRNA, with the preexisting “heavy” ribosomes (Fig. 31-7). Likewise, the  $^{35}\text{S}$ -labeled proteins were transiently associated with, and therefore synthesized by, these ribosomes.

Sol Spiegelman developed the RNA–DNA hybridization technique (Section 5-3Cb) in 1961 to characterize the

**Figure 31-7** The distribution, in a CsCl density gradient, of  $^{32}\text{P}$ -labeled RNA that had been synthesized by *E. coli* after T4 phage infection. Free RNA, being relatively dense, bands at the bottom of the centrifugation cell (left). Much of the RNA, however, is associated with the  $^{15}\text{N}$ - and  $^{13}\text{C}$ -labeled “heavy” ribosomes that had been synthesized before the phage infection. The predicted position of unlabeled “light” ribosomes, which are not synthesized by phage-infected cells, is also indicated. [After Brenner, S., Jacob, F., and Meselson, M., *Nature* **190**, 579 (1961).]

**Figure 31-8** The hybridization of  $^{32}\text{P}$ -labeled RNA produced by T2-infected *E. coli* with  $^3\text{H}$ -labeled T2 DNA. On radioactive decay,  $^{32}\text{P}$  and  $^3\text{H}$  emit  $\beta$  particles (electrons) with characteristically different energies so that these isotopes can be independently detected. Although free RNA (left) in a CsCl density gradient is denser than DNA, much of the RNA bands with the DNA (right). This indicates that the two polynucleotides have hybridized and are therefore complementary in sequence. [After Hall, B.D. and Spiegelman, S., *Proc. Natl. Acad. Sci.* **47**, 141 (1961).]

RNA synthesized by T2-infected *E. coli*. He found that this phage-derived RNA hybridizes with T2 DNA (Fig. 31-8) but does not hybridize with DNAs from unrelated phage nor with the DNA from uninfected *E. coli*. This RNA must therefore be complementary to T2 DNA in agreement with Jacob and Monod’s prediction; that is, the phage-specific RNA is a messenger RNA. Hybridization studies have likewise shown that mRNAs from uninfected *E. coli* are complementary to portions of *E. coli* DNA. In fact, other RNAs, such as transfer RNA and ribosomal RNA, have corresponding complementary sequences on DNA from the same organism. Thus, *all cellular RNAs are transcribed from DNA templates.*

## 2 RNA POLYMERASE

**RNA polymerase (RNAP)**, the enzyme responsible for the DNA-directed synthesis of RNA, was discovered independently in 1960 by Samuel Weiss and Jerard Hurwitz. The enzyme couples together the ribonucleoside triphosphates ATP, CTP, GTP, and UTP on DNA templates in a reaction that is driven by the release and subsequent hydrolysis of  $\text{PP}_i$ :

All cells contain RNAP. In bacteria, one species of this enzyme synthesizes all of the cell’s RNA except the RNA primers employed in DNA replication (Section 30-1D). Various bacteriophages encode RNAPs that synthesize only phage-specific RNAs. Eukaryotic cells contain four or five RNAPs that each synthesize a different class of RNA. In this section we first consider the properties of the bacterial RNAPs and then consider the eukaryotic enzymes.

*E. coli* RNAP’s so-called **holoenzyme** is an ~459-kD protein with subunit composition  $\alpha_2\beta\beta'\omega\sigma$  (Table 31-1) in which the  $\beta$  and  $\beta'$  subunits contain several colinearly arranged homologous segments. Once RNA synthesis has been initiated, however, the  $\sigma$  subunit (also called  **$\sigma$  factor** or  **$\sigma^{70}$**  since its molecular mass is 70 kD) dissociates from the **core enzyme**,  $\alpha_2\beta\beta'\omega$ , which carries out the actual polymerization process (see below).

**Table 31-1** Components of *E. coli* RNA Polymerase Holoenzyme

Subunit	Number of Residues	Structural Gene
$\alpha$	329	<i>rpoA</i>
$\beta$	1342	<i>rpoB</i>
$\beta'$	1407	<i>rpoC</i>
$\omega$	91	<i>rpoZ</i>
$\sigma^{70}$	613	<i>rpsD</i>

**Figure 31-9** An electron micrograph of *E. coli* RNA polymerase (RNAP) holoenzyme attached to various promoter sites on bacteriophage T7 DNA. RNAP is one of the largest known soluble enzymes. [From Williams, R.C., *Proc. Natl. Acad. Sci.* **74**, 2313 (1977).]

Electron micrographs (Fig. 31-9) clearly indicate that RNAP, which has a characteristic large size, binds to DNA as a promoter. This large size is presumably a consequence of the holoenzyme's several complex functions including (1) template binding, (2) RNA chain initiation, (3) chain elongation, and (4) chain termination. We discuss these various functions below.

### A. Template Binding

RNA synthesis is normally initiated only at specific sites on the DNA template. This was first demonstrated through hybridization studies of bacteriophage  $\phi$ X174 DNA with the RNA produced by  $\phi$ X174-infected *E. coli*. Bacteriophage  $\phi$ X174 carries a single strand of DNA known as the (+) strand. On its injection into *E. coli*, the (+) strand directs the synthesis of the complementary (-) strand with which it combines to form a circular duplex DNA known as the replicative form (Section 30-3Ba). The RNA produced by  $\phi$ X174-infected *E. coli* does not hybridize with DNA from intact phages but does so with the replicative form. Thus only the (-) strand of  $\phi$ X174 DNA, the so-called **antisense strand**, is transcribed, that is, acts as a template; the (+) strand, the **sense strand** (or **coding strand**; so called because it has the same sequence as the transcribed RNA), does not do so. Similar studies indicate that in larger phages, such as T4 and  $\lambda$ , the two viral DNA strands are the antisense (template) strands for different sets of genes. The same is true of cellular organisms.

#### a. Holoenzyme Specifically Binds to Promoters

RNA polymerase binds to its initiation sites through base sequences known as **promoters** that are recognized

by the corresponding  $\sigma$  factor. The existence of promoters was originally suggested by mutations that enhance or diminish the transcription rates of certain genes, including those of the *lac* operon. Genetic mapping of such mutations indicated that the promoter consists of an  $\sim 40$ -bp sequence that is located on the 5' side of the transcription start site. [By convention, the sequence of template DNA is represented by its sense (nontemplate) strand so that it will have the same directionality as the transcribed RNA. A base pair in a promoter region is assigned a negative or positive number that indicates its position, upstream or downstream in the direction of RNAP travel, from the first nucleotide that is transcribed to RNA; this start site is +1 and there is no 0.] RNA, as we shall see, is synthesized in the 5'  $\rightarrow$  3' direction (Section 31-2C). Consequently, the promoter lies on the "upstream" side of the RNA's starting nucleotide. Sequencing studies indicate that the *lac* promoter (*lacP*) overlaps the *lac* operator (Fig. 31-2).

The holoenzyme forms tight complexes with promoters (dissociation constant  $K \approx 10^{-14} M$ ) and thereby protects the bound DNA segments from digestion by DNase I. The region from about -20 to +20 is protected against exhaustive DNase I degradation. The region extending upstream to about -60 is also protected but to a lesser extent, presumably because it binds holoenzyme less tightly.

Sequence determinations of the protected regions from numerous *E. coli* and phage genes have revealed the consensus sequence of *E. coli* promoters (Fig. 31-10). Their most conserved sequence is a hexamer centered at about the -10 position, the so-called **Pribnow box** (named after David Pribnow, who pointed out its existence in 1975). It has a consensus sequence of TATAAT in which the leading TA and final T are highly conserved. Upstream sequences around position -35 also have a region of sequence similarity, TTGACA, which is most evident in efficient promoters. The sequence of the segment between the -10 and the -35 sites is unimportant but its length is critical; it ranges from 16 to 19 bp in the great majority of promoters. The initiating (+1) nucleotide, which is nearly always A or G, is centered in a poorly conserved CAT or CGT sequence. Most promoter sequences vary considerably from the consensus sequence (Fig. 31-10). Nevertheless, a mutation in one of the partially conserved regions can greatly increase or decrease a promoter's initiation efficiency. In addition, Richard Gourse discovered that certain highly expressed genes contain an A + T-rich segment between positions -40 and -60, the **upstream promoter (UP) element**, which binds to the C-terminal domain of RNAP's  $\alpha$  subunits. The UP element-containing genes include those encoding the ribosomal RNAs, the *rrn* genes (e.g., Fig. 31-10), which collectively account for 60% of the RNA synthesized by *E. coli*. The rates at which genes are transcribed, which span a range of at least 1000, vary directly with the rate at which their promoters form stable initiation complexes with the holoenzyme. Promoter mutations that increase or decrease the rate at which the associated gene is transcribed are known as **up mutations** and **down mutations**.

**Figure 31-10** The sense (nontemplate) strand sequences of selected *E. coli* promoters. A 6-bp region centered around the -10 position (red shading) and a 6-bp sequence around the -35 region (blue shading) are both conserved. The transcription initiation sites (+1), which in most promoters occur at a single purine nucleotide, are shaded in green. The bottom row shows

the consensus sequence of 298 *E. coli* promoters with the number below each base indicating its percentage occurrence. The downstream portions of the *rrn* genes' UP elements can be seen. [After Rosenberg, M. and Court, D., *Annu. Rev. Genet.* **13**, 321-323 (1979). Consensus sequence from Lisser, S. and Margalit, H., *Nucleic Acids Res.* **21**, 1512 (1993).]

### b. Initiation Requires the Formation of an Open Complex

The promoter regions in contact with the holoenzyme were identified by determining where the enzyme alters the susceptibility of the DNA to alkylation by agents such as dimethyl sulfate (DMS), a procedure named **DMS footprinting** (Section 34-3Bh). These experiments demonstrated that the holoenzyme contacts the promoter mainly around its -10 and -35 regions. These protected sites are both on the same side of the B-DNA double helix as the initiation site, which suggests that holoenzyme binds to only one face of the promoter.

DMS methylates G residues at N7, A residues at N1 and N3, and C residues at N3. Since N1 on A and N3 on C participate in base pairing interactions, however, they can only react with DMS in single-stranded DNA. This differential methylation of single- and double-stranded DNAs provides a sensitive test for DNA strand separation or "melting." Such chemical footprinting studies indicate that the binding of holoenzyme "melts out" the promoter in a region of ~14 bp extending from the middle of the -10 region to just past the initiation site, thereby forming a so-called **transcription bubble**. The need to form this **open complex** explains why promoter efficiency tends to decrease with the number of G · C base pairs in the -10 region; this presumably increases the difficulty in opening the double helix as is required for chain initiation (recall that G · C pairs are more stable than A · T pairs).

Core enzyme, which does not specifically bind promoter (except when it has an UP element), tightly binds duplex

DNA (the complex's dissociation constant is  $K \approx 5 \times 10^{-12} M$  and its half-life is ~60 min). Holoenzyme, in contrast, binds to nonpromoter DNA comparatively loosely ( $K \approx 10^{-7} M$  and a half-life >1 s). Evidently, the  $\sigma$  subunit allows holoenzyme to move rapidly along a DNA strand in search of the  $\sigma$  subunit's corresponding promoter. Once transcription has been initiated and the  $\sigma$  subunit jettisoned, the tight binding of core enzyme to DNA apparently stabilizes the ternary enzyme-DNA-RNA complex.

### B. Chain Initiation

The 5'-terminal base of prokaryotic RNAs is almost always a purine with A occurring more often than G. The initiating reaction of transcription is simply the coupling of two nucleoside triphosphates in the reaction

and hence, unlike DNA replication, does not require a primer. Bacterial RNAs therefore have 5'-triphosphate groups as was demonstrated by the incorporation of radioactive label into RNA when it was synthesized with [ $\gamma$ - $^{32}\text{P}$ ]ATP. Only the 5' terminus of the RNA can retain the label because the internal phosphodiester groups of RNA are derived from the  $\alpha$ -phosphate groups of nucleoside triphosphates.

RNAP has a curious behavior: It frequently releases its newly synthesized RNA after only ~10 nt have been polymerized, a process known as **abortive initiation**. When RNAP initiates transcription, it keeps its grip on the pro-

moter (which is on the DNA's nontemplate/sense strand). Consequently, conformational tension builds up as the template/antisense strand is pulled through the RNAP's active site, a process called **scrunching** because the resulting increased size of the transcription bubble in the downstream direction must somehow be accommodated within the RNAP. In abortive initiation, the RNAP fails to escape the promoter and instead relieves the conformational tension by releasing the newly synthesized RNA fragment, thereby letting the transcription bubble relax to its normal size. The RNAP then reinitiates transcription from the +1 position. In successful initiation, the strain eventually provides sufficient energy to strip the promoter from the RNAP, which then commences the processive (continuous) transcription of the template. This process requires the dissociation of the  $\sigma$  factor from the core–DNA–RNA complex to form the elongation complex, although recent experiments indicate that this process often occurs stochastically (randomly) over several nucleotide additions. The  $\sigma$  factor can then join with another core to form a new initiation complex as was demonstrated by a burst of RNA synthesis on addition of core enzyme to a transcribing reaction mixture that initially contained only holoenzyme.

#### a. Bacterial RNAP Has a Highly Complex Structure

The X-ray structure of *E. coli* RNAP has not been determined. However, Seth Darst and Dmitry Vassylyev independently determined the X-ray structures of the closely similar *Thermus aquaticus* (Taq) and *Thermus thermophilus* (Tth) RNAP core enzymes and holoenzymes. The structure of the Tth core enzyme in complex with DNA and RNA, in agreement with EM studies of *E. coli* RNAP, has the overall shape of a crab claw whose two “pincers” are formed by the  $\beta$  and  $\beta'$  subunits (Fig. 31-11). The protein is  $\sim 150$  Å long (parallel to the pincers),  $\sim 115$  Å high, and  $\sim 110$  Å deep, with the tunnel between the two pincers  $\sim 27$  Å wide. The  $\beta$  and  $\beta'$  subunits extensively interact with one another, particularly at the base of the tunnel (also called the main channel) where an active site  $Mg^{2+}$  ion is located, which is also where their homologous segments converge. The  $\beta'$  subunit binds two  $Zn^{2+}$  ions, each via four Cys residues that are invariant in prokaryotes but not in eukaryotes. The outer surface of the RNAP is almost uniformly negatively charged, whereas those surfaces that interact with nucleic acids are positively charged.

The downstream dsDNA occupies the main channel, which directs the template strand to the active site. There it base-pairs with the incoming NTP (not present in this structure) at the so-called  $i + 1$  site near the  $Mg^{2+}$  ion. The 3' end of the RNA forms a 9-bp hybrid helix with the 5' end of the template DNA strand and then exits the protein through a channel between the  $\beta$  and  $\beta'$  subunits (the RNA exit channel) in which it adopts a conformation similar to that of a single strand within an RNA double helix. Thus the structure resembles that of a post-translocated elongation complex, although the paths taken by the template and nontemplate DNA strands to rejoin at the end of the transcription bubble are unclear.

The X-ray structure of the Tth holoenzyme indicates that its  $\sigma$  subunit ( $\sigma^{70}$ ) has three flexibly linked, largely  $\alpha$

**Figure 31-11** X-ray structure of Tth core RNAP in complex with a 23-nt template DNA, a 14-nt nontemplate DNA, and a 16-nt RNA. The protein is drawn in ribbon form with its two  $\alpha$  subunits yellow and green, its  $\beta$  subunit cyan, its  $\beta'$  subunit pink, and its  $\omega$  subunit gray. The bound  $Mg^{2+}$  and  $Zn^{2+}$  ions are represented by red and orange spheres, respectively. The DNA and RNA are shown in ladder form with template DNA green, nontemplate DNA blue, and RNA red. Note that residues 208 to 390 of the  $\beta'$  subunit, which extend from the tip of its pincer, are disordered and hence not visible, as are the 86-residue C-terminal domains of both  $\alpha$  subunits. [Based on an X-ray structure by Dmitry Vassylyev, University of Alabama at Birmingham. PDBid 5O5I.]

helical domains,  $\sigma_2$ ,  $\sigma_3$ , and  $\sigma_4$ , that extend across the top of the holoenzyme (Fig. 31-12;  $\sigma_1$  is not visible). The holoenzyme's pincers are  $\sim 10$  Å farther apart than in the elongation complex. The binding cavities for the downstream dsDNA and the transcription bubble are partially occupied by the  $\sigma$  subunit's  $\sigma_4$  domain and its  $\sigma_{3-4}$  linker. This partially accounts for the above-described nucleic acid scrunching that precedes the transition from the initiation complex to the elongation complex. Thus, the release of only these segments of the  $\sigma$  subunit from RNAP is compatible with the formation of an elongation complex, thereby accounting for the above-mentioned stochastic release of the  $\sigma$  subunit from a successfully initiated RNAP complex.

A low (6.5 Å) resolution X-ray structure of Taq holoenzyme in complex with a dsDNA segment containing the promoter's  $-10$  and  $-35$  elements reveals that the DNA lies across one face of the holoenzyme, completely outside of the main channel (Fig. 31-13). All sequence-specific contacts that the holoenzyme makes with the  $-10$  and  $-35$  elements as well as with the so-called extended  $-10$  region just upstream of the  $-10$  element are mediated by the  $\sigma$  subunit via conserved residues. This structure presumably resembles the so-called **closed complex** in which the DNA has not yet entered the main channel to form a transcription bubble. The mechanism through which this occurs is largely unknown.

**Figure 31-12** X-ray structure of Tth RNAP holoenzyme viewed similarly to Fig. 31-11. The subunits of the core enzyme are represented by their partially transparent molecular surface colored as in Fig. 31-11. The  $\sigma$  subunit is drawn with its  $\alpha$  helices as cylinders and colored in rainbow order from its N-terminus (blue) to its C-terminus (red). [Based on an X-ray structure by Dmitry Vassylyev, University of Alabama at Birmingham. PDBid 1IW7.]

**Figure 31-13** Low (6.5 Å) resolution X-ray structure of Taq RNAP holoenzyme in complex with a promoter-containing dsDNA viewed as in Fig. 31-12. The subunits of the core enzyme are represented by their partially transparent molecular surface colored as in Fig. 31-11 (which appears striated due to the structure's low resolution, which permits only the polypeptide backbones to be visualized). The  $\sigma$  subunit is drawn in worm form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The DNA's sugar-phosphate backbone is drawn in cartoon form with the template DNA strand blue and the non-template DNA's  $-10$  element red, its  $-35$  element purple, and its remaining portions orange. [Based on an X-ray structure by Seth Darst, The Rockefeller University. PDBid 1L9Z.]

### b. Rifamycins Inhibit Prokaryotic Transcription Initiation

Two related antibiotics, **rifamycin B**, which is produced by *Streptomyces mediterranei*, and its semisynthetic derivative **rifampicin**,

**Rifamycin B**  $R_1 = \text{CH}_2\text{COO}^-$ ;  $R_2 = \text{H}$

**Rifampicin**  $R_1 = \text{H}$ ;  $R_2 = \text{CH}=\text{N}-\text{N}(\text{CH}_2)_4-\text{CH}_3$

specifically inhibit transcription by prokaryotic, but not eukaryotic, RNAPs. This selectivity and their high potency (bacterial RNAP is 50% inhibited by  $2 \times 10^{-8}$  M rifampicin) made them medically useful bacteriocidal agents against gram-positive bacteria and tuberculosis. Indeed, few other antibiotics are effective against tuberculosis, which has reached epidemic levels in some parts of the world.

The finding that the  $\beta$  subunits of rifamycin-resistant mutants have altered electrophoretic mobilities first demonstrated that this subunit contains the rifamycin-binding site. Rifamycins inhibit neither the binding of RNAP to the promoter nor the formation of the first phosphodiester bond, but they prevent further chain elongation. The inactivated RNAP remains bound to the promoter, thereby blocking its initiation by uninhibited enzymes. Once RNA chain initiation has occurred, however, rifamycins have no effect on the subsequent elongation process. The rifamycins are therefore useful research tools because they permit the transcription process to be dissected into its initiation and its elongation phases.

The X-ray structure of Taq core enzyme in complex with rifampicin reveals how this antibiotic inhibits RNAP. Rifampicin binds with close complementary fit but little conformational change in a pocket in the  $\beta$  subunit that is located within the main channel,  $\sim 12$  Å distant from the active site  $\text{Mg}^{2+}$  ion. Model building indicates that the bound rifampicin would sterically interfere with the RNA transcript at positions  $-2$  to  $-5$  in the transcription bubble. Thus, as is observed, rifampicin would not interfere with the initiation of transcription but would mechanically block the extension of the RNA transcript. The residues lining the pocket in which rifampicin binds are highly conserved among prokaryotes but not in eukaryotes, thereby explaining why rifamycins inhibit only bacterial RNAPs.

### C. Chain Elongation

The direction of RNA chain elongation; that is, whether it occurs by the addition of incoming nucleotides to the 3' end of the nascent (growing) RNA chain ( $5' \rightarrow 3'$  growth; Fig. 31-14a) or by their addition to its 5' terminus ( $3' \rightarrow 5'$  growth; Fig. 31-14b), was established by determining the rate at which the radioactive label from  $[\gamma\text{-}^{32}\text{P}]\text{GTP}$  is incorporated into RNA. For  $5' \rightarrow 3'$  elongation, the 5'  $\gamma\text{-P}$  is permanently labeled and, hence, the chain's level of radioactivity would not change on replacement of the labeled GTP with unlabeled GTP. However, for  $3' \rightarrow 5'$  elongation, the 5'  $\gamma\text{-P}$  is replaced with the addition of every new nucleotide so that, on replacement of labeled with unlabeled GTP, the nascent RNA chains would lose their radioactivity. The former was observed. *Chain growth must therefore occur in the  $5' \rightarrow 3'$  direction (Fig. 31-14a), the same direction as DNA is synthesized.* This conclusion is corroborated by the observation that the antibiotic **cordycepin**,

an adenosine analog that lacks a 3'-OH group, inhibits bacterial RNA synthesis. Its addition to the 3' end of RNA, as is expected for  $5' \rightarrow 3'$  growth, prevents the RNA chain's

further elongation. Cordycepin would not have this effect if chain growth occurred in the opposite direction because it could not be appended to an RNA's 5' end.

#### a. Transcription Supercoils DNA

RNA chain elongation requires that the double-stranded DNA template be opened up at the point of RNA synthesis so that the template strand can be transcribed to its complementary RNA strand. In doing so, the RNA chain only transiently forms a short length of RNA–DNA hybrid duplex, as is indicated by the observation that transcription leaves the template duplex intact and yields single-stranded RNA. The unpaired transcription bubble of the DNA in the open initiation complex apparently travels along the DNA with the RNAP. There are two ways this might occur (Fig. 31-15):

1. If the RNAP followed the template strand in its helical path around the DNA, the DNA would build up little supercoiling because the DNA duplex would never be unwound by more than about a turn. However, the RNA transcript would wrap around the DNA, once per duplex turn. This model is implausible since it is unlikely that its DNA and RNA could be readily untangled: The RNA would not spontaneously unwind from the long and often circular DNA in any reasonable time, and no known topoisomerase can accelerate this process.

2. If the RNAP moves in a straight line while the DNA rotates, the RNA and DNA will not become entangled. Rather, the DNA's helical turns are pushed ahead of the advancing transcription bubble so as to more tightly wind the DNA ahead of the bubble (which promotes positive supercoiling), and the DNA behind the bubble becomes equivalently unwound (which promotes negative supercoiling, although note that the linking number of the entire DNA remains unchanged). This model is supported by the observa-

**Figure 31-14** The two possible modes of RNA chain growth. Growth may occur (a) by the addition of nucleotides to the 3'

end and (b) by the addition of nucleotides to the 5' end. RNA polymerase catalyzes the former reaction.

**Figure 31-15 RNA chain elongation by RNA polymerase.** In the region being transcribed, the DNA double helix is unwound by about a turn to permit the DNA's sense strand to form a short segment of DNA–RNA hybrid double helix with the RNA's 3' end. As the RNAP advances along the DNA template (here to the right), the DNA unwinds ahead of the RNA's growing 3' end and rewinds behind it, thereby stripping the newly synthesized RNA from the template (antisense) strand. (a) One way this might occur is by the RNAP following the path of the template strand about the DNA double helix, in which case the transcript would become wrapped about the DNA once per duplex turn.

(b) A second and more plausible possibility is that the RNA moves in a straight line while the DNA rotates beneath it. In this case the RNA would not wrap around the DNA but the DNA would become overwound ahead of the advancing transcription bubble and unwound behind it (consider the consequences of placing your finger between the twisted DNA strands in this model and pushing toward the right). The model presumes that the ends of the DNA, as well as the RNAP, are prevented from rotating by attachments within the cell (*black bars*). [After Futcher, B., *Trends Genet.* **4**, 271, 272 (1988).]

tions that the transcription of plasmids in *E. coli* causes their positive supercoiling in gyrase mutants (which cannot relax positive supercoils; Section 29-3Cd) and their negative supercoiling in topoisomerase I mutants (which cannot relax negative supercoils; Section 29-3Ca). In fact, by tethering RNAP to a glass surface and allowing it to transcribe DNA that had been fluorescently labeled at one end, Kazuhiko Kinoshita demonstrated, through fluorescence microscopy (using techniques similar to those showing that the  $F_1F_0$ -ATPase is a rotary engine; Section 22-3Ce), that single DNA molecules rotated in the expected direction during transcription.

Inappropriate superhelicity in the DNA being transcribed halts transcription (Section 29-3C). Quite possibly the torsional tension in the DNA generated by negative superhe-

licity behind the transcription bubble is required to help drive the transcriptional process, whereas too much such tension prevents the opening and maintenance of the transcription bubble.

#### b. Transcription Occurs Processively and Rapidly

The *in vivo* rate of transcription is 20 to 70 nucleotides per second. Once an RNAP molecule has initiated transcription and moved away from the promoter, another RNAP can follow suit. The synthesis of RNAs that are needed in large quantities, ribosomal RNAs, for example, is initiated as often as is sterically possible, about once per second (Fig. 31-16). Processivity is accomplished without an obvious clamplike structure such as the sliding clamp of

**Figure 31-16** An electron micrograph of three contiguous ribosomal genes from oocytes of the salamander *Pleurodeles waltl* undergoing transcription. The “arrowhead” structures result from the increasing lengths of the nascent RNA chains as

the RNAP molecules synthesizing them move from the initiation site on the DNA to the termination site. [Courtesy of Ulrich Scheer, University of Würzburg, Germany.]

*E. coli* DNA polymerase III (Fig. 30-14). However, the RNAP itself apparently functions as a sliding clamp by binding tightly but flexibly to the DNA–RNA complex. In experiments in which the RNAP was immobilized and a magnetic bead was attached to the DNA, the bead was observed to undergo up to 180 rotations (representing nearly 2000 base pairs at 10.4 bp per turn) before the polymerase slipped.

### c. Intercalating Agents Inhibit Both RNA and DNA Polymerases

#### Actinomycin D,

**Figure 31-17** NMR structure of actinomycin D in complex with a dsDNA of self-complementary sequence d(GAAGCTTC). The actinomycin D is drawn in space-filling form and the DNA is drawn in stick form with successive P atoms on the same strand connected by orange rods, all colored according to atom type with actinomycin C green, DNA C cyan, H white, N blue, O red, and P orange. The complex is viewed toward the DNA's major groove. The actinomycin D's two cyclic decapeptides are tightly wedged into the DNA's minor groove and the actinomycin D's phenoxazone ring system is intercalated between the DNA's central G · C base pairs. [Based on an NMR structure by Andrew Wang, University of Illinois. PDBid 1DSC.]

a useful antineoplastic (anticancer) agent produced by *Streptomyces antibioticus*, tightly binds to duplex DNA and, in doing so, strongly inhibits both transcription and DNA replication, presumably by interfering with the passage of RNA and DNA polymerases. The NMR structure of actinomycin D in complex with a duplex DNA composed of two strands of the self-complementary octamer d(GAAGCTTC) reveals that the DNA assumes a B-like conformation in which the actinomycin's **phenoxazone** ring system, as had previously been shown, is intercalated between the DNA's central G · C base pairs (Fig. 31-17). Consequently, the DNA helix is unwound by  $\sim 30^\circ$  at the intercalation site and the central G · C base pairs are separated by  $\sim 7 \text{ \AA}$ . The DNA helix is severely distorted from the normal B-DNA conformation such that it is bent toward its major groove by  $\sim 30^\circ$  and its minor groove is wide and

shallow in a manner resembling that of A-DNA. Actinomycin D's two chemically identical cyclic **decapeptides** (having both peptide bonds and ester linkages) extend in opposite directions from the intercalation site along the minor groove of the DNA. The complex is stabilized through the formation of base–peptide and phenoxazone–sugar–phosphate backbone hydrogen bonds, as well as by hydrophobic interactions, in a way that explains the preference of actinomycin D to bind to DNA with its phenoxazone ring intercalated between the base pairs of a 5'-GC-3' sequence. Several other intercalation agents, including ethidium and acridine orange (Sections 6-6Ca and 29-3Ba), also inhibit nucleic acid synthesis, presumably by similar mechanisms.

#### D. Chain Termination

Electron micrographs such as Fig. 31-16 suggest that DNA contains specific sites at which transcription is terminated. In this section we discuss how transcription is terminated in bacteria. The eukaryotic process is discussed in Section 31-4Ab.

**a. The RNA at Intrinsic Terminators Has an Oligo(U) Tract Preceded by a G + C-Rich Stem**

Around half the transcriptional termination sites in *E. coli* are **intrinsic** or **spontaneous terminators**, that is, they induce termination without assistance. The sequences of these terminators share two common features (Fig. 31-18):

1. A tract of 7 to 10 consecutive A · T's with the A's on the template strand, sometimes interrupted by one or more different base pairs. The transcribed RNA is terminated in or just past this sequence.
2. A G + C-rich segment with a palindromic (2-fold symmetric) sequence that is immediately upstream of the series of A · T's.

The RNA transcript of this region can therefore form a self-complementary “hairpin” structure that is terminated by several U residues (Fig. 31-18).

The stability of a terminator's G + C-rich hairpin and the weak base pairing of its oligo(U) tail to template DNA are important factors in ensuring proper chain termination. In fact, model studies have shown that oligo(dA · rU) forms a particularly unstable hybrid helix although oligo(dA · dT) forms a helix of normal stability. In fact, oligo(dA · rU) tracts as long as 8 or 9 bp are unstable at room temperature when not bound to RNAP. The formation of the G + C-rich hairpin causes RNAP to pause for several seconds at the termination site. Mutations in the termination site that decrease the strengths of these associations reduce the efficiency of chain termination (the fraction of transcripts that are terminated at that site) and often eliminate it. Termination efficiency is similarly diminished when *in vitro* transcription is carried out with GTP replaced by **inosine triphosphate (ITP)**:

I · C pairs are weaker than G · C pairs because the hypoxanthine base of I, which lacks the 2-amino group of G, can only make two hydrogen bonds to C, thereby decreasing the hairpin's stability.

Despite the foregoing, experiments by Michael Chamberlin in which segments of highly efficient terminators were swapped via recombinant DNA techniques indicate that the RNA terminator hairpin and U-rich 3' tail do not function independently of their corresponding DNA's upstream and downstream flanking regions. Indeed, terminators that lack a U-rich segment can be highly efficient when joined to the appropriate sequence immediately downstream from the termination site.

These and other observations have led to three not necessarily mutually exclusive models to explain how intrinsic terminators work:

1. The forward translocation model, in which hairpin formation pushes the RNAP forward without the concomitant elongation of the RNA transcript. This would shorten the RNA–DNA hybrid by as much as several base pairs, thereby destabilizing it.
2. The RNA pullout model, in which hairpin formation mechanically pulls the RNA out of the RNA–DNA hybrid.
3. The allosteric model, in which hairpin formation induces a conformational change in the RNAP that permits the upstream nontemplate DNA strand to displace the weakly bound oligo(U) tail from the template DNA strand.

In an effort to differentiate these models, Robert Landick and Steven Block used **optical traps** to exert a pulling force on one or the other end of the DNA that a single RNAP molecule was transcribing or on its RNA transcript. An optical trap consists of a highly focused laser beam that is typically generated by sending it through a microscope objective lens. The resulting strong electric field gradient across the constricted region of the beam attracts dielectric (insulating) particles such as submicrometer sized polystyrene beads to the center of the beam where the electric field is strongest. The force on the particle varies directly with its displacement from the center of the beam. By attaching a single macromolecule of interest to such a bead in an optical trap and fixing the macromolecule's other end or attaching it to a bead in a second optical trap,

**Figure 31-18** An *E. coli* intrinsic terminator. Its transcription yields an RNA (red) with a self-complementary G + C-rich segment that forms a base-paired hairpin immediately followed by a sequence of 4 to 10 consecutive U's that base-pair with the template A's in the transcription bubble. The oval symbol represents the binding site for an incoming NTP. [After a drawing by Park, J.-S. and Roberts, J.W., Cornell University.]

a force can be exerted on the molecule by laterally displacing the beam as little as subnanometer distances. Such a device is known as an **optical tweezers**.

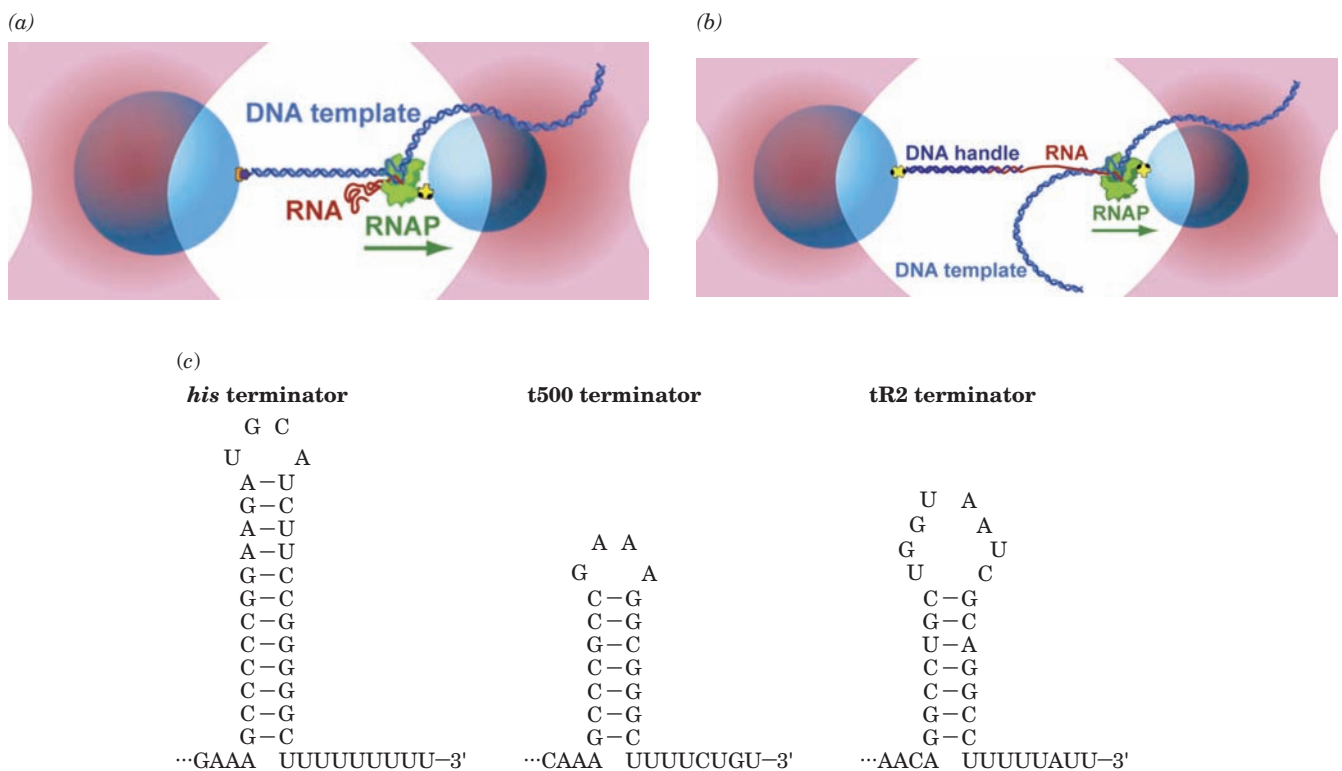

In the optical tweezers diagrammed in Fig. 31-19a, pulling apart the two optical traps would assist the RNAP in translocating along the DNA, whereas attaching the other end of the DNA to a bead would hinder this process. The application of either an assisting or hindering force to the DNA does not significantly affect the termination efficiencies of any of the three terminators shown in Fig. 31-19c. Evidently, forward translocation is not a general feature of intrinsic termination. However, the efficiency of the t500 terminator with a mutation in its hairpin varies with the force on the DNA, which indicates that forward translocation occurs with some terminators.

In the optical tweezers diagrammed in Fig. 31-19b, pulling on the RNA with sufficient force to disrupt the first 2 or 3 base pairs of the terminator hairpin reduces the ter-

mination efficiencies of all three terminators. If the force is greater than that required to fully unfold the hairpin, transcription efficiency is indistinguishable from that of the corresponding terminator containing only its oligo(U) tract. This suggests that the formation of the hairpin base pairs disrupts the adjacent RNA–DNA hybrid as predicted by the RNA pullout model.

Curiously, a force weaker than that required to disrupt hairpin base pairs increases termination efficiency. However, the presence of ssDNA complementary to the transcript eliminates this latter effect. Evidently, the RNA upstream of the terminator forms weakly base-paired secondary structures that compete with the formation of the terminator hairpin. In this way, the RNA sequence upstream of an intrinsic terminator modulates the efficiency of termination.

Since RNAP stabilizes the RNA–DNA hybrid, allosteric changes to RNAP by hairpin formation may also

**Figure 31-19** Apparatus for single molecule pulling assays on RNAP elongation complexes (not to scale). (a) A DNA-pulling assay. The RNAP (green; its direction of translocation is indicated by the green arrow) in an elongation complex was attached to an avidin-coated polystyrene bead (light blue) via a biotin–avidin linkage (yellow and black; Section 22-3Ce), and either the upstream end of the template DNA (dark blue) as shown or the downstream end was attached to a somewhat larger polystyrene bead via a digoxigenin–antidigoxigenin linkage [purple and orange; digoxigenin is a steroid related to digitalin (Fig. 20-21b) that has high antigenicity and antidigoxigenin is an antibody to which it specifically binds]. The RNA product of the complex (red) was untethered. The two beads were then placed in separate optical traps (pink) and the beads were pulled apart

while the elongation complex synthesized RNA. The horizontal displacement of a bead from the center of its optical trap is indicative of the pulling force on the bead. (b) An RNA-pulling assay. As in Part a but with the template DNA untethered and the RNA emerging from the RNAP attached to the second bead via a DNA handle (which had a 25-nt 3' overhang complementary to the 5' end of the RNA) tethered to the larger bead via a biotin–avidin linkage. (c) Structures of the three intrinsic terminators investigated in this study showing their hairpins and poly(U) tracts. The underlined bases are the transcript termination sites. The termination efficiencies of the *his*, t500, and tR2 terminators are normally 77%, 98%, and 46%, respectively. [Courtesy of Steven Block, Stanford University.]

influence termination efficiency. Indeed, mutations in the  $\beta$  subunit of RNAP can both increase and decrease termination efficiency. However, the way in which hairpin formation induces allosteric changes to RNAP is as yet unknown.

### b. Many Bacterial Terminators Require the Assistance of Rho Factor

Around half the termination sites in *E. coli* lack any obvious similarities and are unable to form strong hairpins; they require the participation of a protein known as **Rho factor** to terminate transcription. Rho factor was discovered through the observation that *in vivo* transcripts are often shorter than the corresponding *in vitro* transcripts. Rho factor, a RecA family hexameric helicase (Section 30-2Ca) of identical 419-residue subunits, enhances the termination efficiency of spontaneously terminating transcripts as well as inducing the termination of nonspontaneously terminating transcripts.

Several key observations have led to a model of Rho-dependent termination:

1. Rho unwinds RNA–DNA and RNA–RNA double helices by translocating along a single strand of RNA in its 5'  $\rightarrow$  3' direction. This process is powered by the hydrolysis of NTPs to NDPs +  $P_i$  with little preference for the identity of the base. NTPase activity is required for Rho-dependent termination as is demonstrated by its *in vitro* inhibition when the NTPs are replaced by their  $\beta,\gamma$ -imido analogs,

substances that are RNAP substrates but cannot be hydrolyzed by Rho.

2. Genetic manipulations indicate that Rho-dependent termination requires the presence of a specific recognition sequence on the newly transcribed RNA upstream of the termination site. The recognition sequence must be on the nascent RNA rather than the DNA as is demonstrated by Rho's inability to terminate transcription in the presence of pancreatic RNase A. The essential features of this termination site have not been fully elucidated; the construction of synthetic termination sites indicates that it consists of 80 to 100 nucleotides that lack a stable secondary structure and contain multiple regions that are rich in C and poor in G.

These observations suggest that Rho attaches to nascent RNA at its recognition sequence [named **rut** (for *Rho utilization*), a C-rich segment of at least 40 nt] and then translocates along the RNA in the 5'  $\rightarrow$  3' direction until it encounters an RNAP paused at the termination site (without the pause, Rho might not be able to overtake the RNA

polymerase). There, as Jeffrey Roberts has shown, Rho pushes the RNAP forward in a way that partially rewinds its dsDNA helix at the transcription bubble while unwinding the RNA–DNA hybrid helix (forward translocation), thus releasing the RNA. Rho-terminated transcripts have 3' ends that typically vary over a range of  $\sim 50$  nucleotides. This suggests that Rho pries the RNA away from the template DNA rather than “pushing” an RNA release “button.” TCRF (alternatively, Mfd), which functions during transcription-coupled repair in *E. coli* to release a stalled RNAP from a damaged template by stripping away its bound RNA (Section 30-5Bb), is an ATP-powered DNA translocase that is thought to mechanically act on RNAP in much the same way as Rho.

Each Rho subunit consists of two domains that can be separated by proteolysis: Its N-terminal domain binds single-stranded polynucleotides and its C-terminal domain, which is homologous to the  $\alpha$  and  $\beta$  subunits of the  $F_1$ -ATPase (Section 22-3Cb), binds an NTP. The X-ray structure of Rho in complex with AMPPNP and an 8-nt RNA, r(UC)<sub>4</sub> (Fig. 31-20a), determined by James Berger, reveals that Rho forms a hexameric lock washer-shaped helix that is 120 Å in diameter with an  $\sim 30$ -Å-diameter central hole and whose first and sixth subunits are separated by a 12-Å gap and a rise of 45 Å along the helix axis. The RNAs, only a single UC unit of which is visible in each chain, bind along the top of the helix to the so-called primary RNA binding sites on the N-terminal domains, whereas AMPPNP binds to the C-terminal domains (which are further from the viewer in Fig. 31-20a than the N-terminal domains) at the interface between subunits. This X-ray structure represents an open state that has bound to *rut* site mRNA and is poised to bind additional mRNA upon its entry into the central cavity through the gap.

In the X-ray structure of Rho in complex with rU<sub>12</sub> and the ATP mimic ADP  $\cdot$  BeF<sub>3</sub> (Fig. 31-20b), also determined by Berger, the helicase's six subunits have formed a closed ring in which each subunit has a different conformation. The RNA, only 6 nt of which are visible, assumes a right-handed helical conformation with its 5' end closest to the viewer in Fig. 31-20b and binds to Rho's N-terminal domains in the helicase's central channel, the so-called secondary RNA binding site. Protein loops that extend from the walls of the central channel to interact with the RNA are helically arranged like the steps of a right-handed spiral staircase such that they track the RNA's sugar–phosphate backbone, much like the central loops of E1 protein (an AAA+ family hexagonal helicase) tracks its centrally bound ssDNA (Section 30-2Ca). The different conformations of Rho's six subunits indicate that they sequentially undergo a series of six NTP-driven conformational changes and that these changes are allosterically coupled so that they progress around the hexamer in a wavelike manner. Since each of the foregoing loops maintains its grip on the same nucleotide during this process, the helicase translocates along its bound RNA, in much the same way that E1 protein translocates along its bound ssDNA. Why, then, do Rho and E1 protein move in opposite directions? Comparison of the structures of Rho and E1 protein

(a)

**Figure 31-20 X-ray structures of Rho factor.** (a) Rho in complex with r(UC)<sub>4</sub> (only one UC unit of which is visible) and AMPPNP. Each of the protein's six subunits are drawn in tube-and-arrow form in different colors with the upper right subunit colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The UC units and the AMPPNP are shown in space-filling form with UC C green, AMPPNP C gray, N blue, O red, and P orange. The hexamer has a lock washer-like shape with the blue subunit ~45 Å closer to the viewer than the pink

(b)

subunit. (b) Rho in complex with rU<sub>12</sub> (only 6 nt of which are visible) and ADP·BeF<sub>3</sub>. The protein is drawn and colored as in Part a. The RNA and ADP·BeF<sub>3</sub> are shown in stick and space-filling form, respectively, with RNA C green, ADP C gray, N blue, O red, P orange, Be light green, and F light blue. Note that each of the Rho subunits has a different conformation. [Based on X-ray structures by James Berger, University of California at Berkeley. PDBid 1PVO and 3ICE.]

indicates that the relative order of the conformational states around the hexamer for Rho is opposite that for E1 protein. Evidently, the “firing order” of Rho's NTPase sites around the hexamer is the reverse of that of E1 protein, thus accounting for their differing directions of translocation. Presumably, other RecA and AAA+ family hexagonal helicases otherwise have similar mechanisms.

### E. Eukaryotic RNA Polymerases

*Eukaryotic nuclei, as Robert Roeder and William Rutter discovered, contain three distinct types of RNAPs that differ in the RNAs they synthesize:*

**1. RNA polymerase I (RNAP I; also called Pol I and RNAP A),** which is located in the nucleoli (dense granular bodies in the nuclei that contain the ribosomal genes; Section 31-4Bb), synthesizes precursors of most ribosomal RNAs (rRNAs).

**2. RNA polymerase II (RNAP II; also called Pol II and RNAP B),** which occurs in the nucleoplasm, synthesizes mRNA precursors.

**3. RNA polymerase III (RNAP III; also called Pol III and RNAP C),** which also occurs in the nucleoplasm, syn-

thesizes the precursors of 5S ribosomal RNA, the tRNAs, and a variety of other small nuclear and cytosolic RNAs.

Eukaryotic nuclear RNAPs have considerably greater subunit complexity than those of prokaryotes. These enzymes have molecular masses of up to 600 kD and, as is indicated in Table 31-2, each contains two nonidentical “large” (>120 kD) subunits comprising ~65% of its mass that are homologs of the prokaryotic RNAP β' and β subunits and up to 12 additional “small” (<50 kD) subunits, two of which are homologs of prokaryotic RNAP α, and one of which is a homolog of prokaryotic RNAP ω. Of these small subunits, five are identical in all three eukaryotic RNAPs and two others (the RNAP α homologs) are identical in RNAPs I and III. Two of the RNAP II subunits, Rbp4 and Rbp7, are not essential for activity and, in fact, are present in RNAP II in less than stoichiometric amounts. (Curiously, Rbp7 has a 102-residue segment that is 30% identical to a portion of σ<sup>70</sup>, the predominant *E. coli* σ factor.) Thus 10 of the 12 RNAP II subunits are either identical or closely similar to subunits of RNAPs I and III (Table 31-2). Moreover, the sequences of these subunits are highly conserved (~50% identical) across species from yeast to humans (and to a lesser extent between eukaryotes and bac-

teria). In fact, in all ten cases tested, a human RNAP II subunit could replace its counterpart in yeast without loss of cell viability.

Rpb1, the β' homolog in RNAP II, has an extraordinary C-terminal domain (**CTD**). In mammals, it contains 52 highly conserved repeats of the heptad PTSPSYS (26 repeats in yeast with other eukaryotes having intermediate values). Five of the seven residues in these particularly hydrophilic repeats bear hydroxyl groups and at least 50 of them, predominantly those on the second Ser residue in each heptad, are subject to reversible phosphorylation by **CTD kinases** and **CTD phosphatases**. RNAP II initiates transcription only when the CTD is unphosphorylated but commences elongation only after the CTD has been phosphorylated, which suggests that this process triggers the conversion of RNAP II's initiation complex to its elongation complex. Charge–charge repulsions between nearby phosphate groups probably cause a highly phosphorylated CTD to project as far as 500 Å from the globular portion of RNAP II. Indeed, as we shall see, the phosphorylated CTD provides the binding sites for numerous auxiliary factors that have essential roles in the transcription process.

In contrast to the somewhat smaller prokaryotic RNAP holoenzymes, eukaryotic RNAPs do not independently bind their target DNAs. Rather, as we shall see in Section 34-3B, they are recruited to their target promoters through the mediation of complexes of transcription factors and their ancillary proteins that, in the case of RNAP II–transcribed genes, are so large and complicated that they collectively dwarf RNAP II.

In addition to the foregoing nuclear enzymes, eukaryotic cells contain separate mitochondrial and (in plants) chloroplast RNAPs. These small (~100 kD) single-subunit RNAPs, which resemble those encoded by certain bacteriophages, are much simpler than the nuclear RNAPs although they catalyze the same reaction.

#### a. X-Ray Structures of Yeast RNAP II Reveal a Transcribing Complex

In a crystallographic tour de force, Roger Kornberg determined the X-ray structure of yeast (*S. cerevisiae*) RNAP II that lacks its nonessential Rpb4 and Rpb7 subunits (Fig. 31-21). This enzyme, as expected, resembles Tth RNAP (Fig. 31-11) in its overall crab claw–like shape and in the positions and core folds of their homologous subunits although, of course, RNAP II is somewhat larger than and has several subunits that have no counterpart in bacterial RNAPs. RNAP II binds two Mg<sup>2+</sup> ions at its active site in the vicinity of five conserved acidic residues (although one of these Mg<sup>2+</sup> ions appears to be weakly bound and hence is only faintly visible in the X-ray structure; it apparently accompanies the incoming NTP). This suggests that RNAPs catalyze RNA elongation via a two-metal ion mechanism similar to that employed by DNA polymerases (Section 30-2Af). As is the case with bacterial RNAPs, the surface of RNAP II is almost entirely negatively charged except for its main channel and the region about the active site, which are positively charged.

Although, as mentioned above, RNAP II does not normally initiate transcription by itself, Kornberg found that it

**Figure 31-21 The X-ray structure of yeast RNAP II that lacks its Rpb4 and Rpb7 subunits.** (a) The enzyme is oriented similarly to Tth RNAP in Fig. 31-11 and its subunits are colored as is indicated in the accompanying diagram, with the subunits homologous to those of Tth RNAP given the same colors. The strongly bound  $Mn^{2+}$  ion (physiologically  $Mg^{2+}$ ) that marks the active site is shown as a red sphere and the enzyme's 8 bound  $Zn^{2+}$  ions are shown as orange spheres. The Rpb1 C-terminal

domain (CTD) is not visible due to disorder. In the accompanying diagram, the area of each numbered ellipsoid is proportional to the corresponding subunit's size and the width of each gray line connecting a pair of subunits is proportional to the surface area of their interface. (b) View of the enzyme from the right in Part a looking into its DNA-binding main channel. The black circle has the approximate diameter of B-DNA. [Based on an X-ray structure by Roger Kornberg, Stanford University. PDBid 1I50.]

will do so on a dsDNA bearing a 3' single-stranded tail at one end. Consequently, incubating yeast RNAP II with the DNA shown in Fig. 31-22a and all NTPs but UTP yielded the DNA–RNA hybrid helix diagrammed in Fig. 31-22a bound to RNAP II. The X-ray structure of this paused transcribing complex revealed, as expected, that the dsDNA had bound in the enzyme's main channel (Fig. 31-22b,c; transcription resumed on soaking the crystals in UTP, thereby demonstrating that the crystalline complex was active). In comparison with the X-ray structure of RNAP II alone, a massive (~50 kD) portion of Rpb1 and Rpb2 named the “clamp” has swung down over the DNA to trap it in the main channel, in large part accounting for the enzyme's essentially infinite processivity. The mainly rigid motion of the clamp is mediated by conformational changes at five so-called switch regions at the base of the clamp in which three of these switches, which are disordered in the structure of RNAP II alone, become ordered in the transcribing complex.

The DNA unwinds by three bases before entering the active site (which is contained on Rpb1). Past this point, however, a portion of Rpb2 dubbed the “wall” directs the

template strand out of the cleft in an  $\sim 90^\circ$  turn. As a consequence, the template base at the active ( $i + 1$ ) site points toward the floor of the cleft where it can be read out by the active site. This base is paired with the ribonucleotide at the 3' end of the RNA, which is positioned above a 12-Å-diameter pore at the end of a funnel to the protein exterior (also called the secondary channel) through which NTPs presumably gain access to the otherwise sealed off active site. The RNA–DNA hybrid helix adopts a nonstandard conformation intermediate between those of A- and B-DNAs, which is underwound relative to that in the X-ray structure of an RNA–DNA hybrid helix alone (Fig. 29-4). Nearly all contacts that the RNAP makes with the RNA and DNA are with their sugar–phosphate backbones; none are with the edges of their bases. The specificity of the enzyme for a ribonucleotide rather than a deoxyribonucleotide is attributed to the enzyme's recognition of both the incoming ribose sugar and the RNA–DNA hybrid helix. After about one turn of hybrid helix, a loop extending from the clamp called the “rudder” separates the RNA and template DNA strands, thereby permitting the DNA double helix to reform as it exits the enzyme (although the unpaired 5' tail of

the nontemplate strand and the 3' tail of the template strand are disordered in the X-ray structure).

How does RNAP translocate its bound RNA–DNA assembly in preparation for a new round of synthesis? The highly conserved helical segment of Rpb1, dubbed the “bridge” because it bridges the two pincers forming the enzyme’s cleft (Figs. 31-21 and 31-22), nonspecifically contacts

the template DNA base at the  $i + 1$  position. Although this helix is straight in all X-ray structures of RNAP II yet determined, it is bent in that of Taq core RNAP. If the bridge helix, in fact, alternates between its straight and bent conformations, it would move by 3 to 4 Å. Kornberg has therefore speculated that translocation occurs through the bending of the bridge helix so as to push the paired nucleotides at posi-

**Figure 31-23** Proposed transcription cycle and translocation mechanism of RNAP. (a) The nucleotide addition cycle in which the enzyme active site is marked by its strongly bound  $Mg^{2+}$  ion (magenta). The translocation of the transcribing RNA · DNA complex is proposed to be motivated by a conformational change of the bridge helix from straight (gray circle) to bent (violet circle). The relaxation of the bridge helix back to its straight form would complete the cycle by yielding an empty NTP binding site at the active ( $i + 1$ ) site. (b) The RNA · DNA complex in RNAP II viewed and colored as in Fig. 31-22b. The RNAP II bridge helix is gray and the superimposed (and bent) Taq polymerase bridge helix is violet. The side chains extending from the bent helix would sterically clash with the hybrid base pair at position  $i + 1$ . [Courtesy of Roger Kornberg, Stanford University.]

tion  $i + 1$  to position  $i - 1$  (Fig. 31-23). The recovery of the bridge helix to its straight conformation would then yield an empty site at position  $i + 1$  for entry of the next NTP, thereby preparing the enzyme for a new round of nucleotide addition. The reversal of this process is presumably prevented by the binding of the next substrate NTP and hence this mechanism is that of a **Brownian ratchet** [in which otherwise random thermal (Brownian) back-and-forth fluctuations are converted to coherent forward motion by inhibiting the backward motion; Section 12-4Bg].

RNAP II selects its substrate ribonucleotide through a two-stage process. The incoming NTP gains access to the active site through the funnel and pore (secondary channel) diagrammed in Fig. 31-22c. There it first binds to the so-called E (for entry) site (Fig. 31-24), which exhibits no selectivity for the identity of its base. The NTP then pivots to enter the A (for addition) site, which only accepts an NTP that forms a Watson–Crick base pair with the template base in the  $i + 1$  position. This process is mediated by the Rbp1 subunit's so-called trigger loop, which swings in beneath the correctly base-paired NTP in the A site to form an extensive hydrogen-bonded network involving both the NTP and other portions of the RNAP, interactions that acutely discriminate against dNTPs.

### b. Amatoxins Specifically Inhibit RNA Polymerases II and III

The poisonous mushroom *Amanita phalloides* (death cap), which is responsible for the majority of fatal mushroom poisonings, contains several types of toxic substances,

including a series of unusual bicyclic octapeptides known as **amatoxins**.  **$\alpha$ -Amanitin**,

**$\alpha$ -Amanitin**

which is representative of the amatoxins, forms a tight 1:1 complex with RNAP II ( $K = 10^{-8} M$ ) and a looser one with RNAP III ( $K = 10^{-6} M$ ). Its binding slows an RNAP's rate of RNA synthesis from several thousand to only a few nucleotides per minute.  $\alpha$ -Amanitin is therefore a useful tool for mechanistic studies of these enzymes. RNAP I as well as mitochondrial, chloroplast, and bacterial RNAPs are insensitive to  $\alpha$ -amanitin.

The X-ray structure of RNAP II in complex with  $\alpha$ -amanitin, also determined by Kornberg, reveals that  $\alpha$ -amanitin binds in the funnel beneath the protein's bridge helix (Fig. 31-22c), where it interacts with residues of the bridge helix and the trigger loop. The  $\alpha$ -amanitin binding site is too far away from the enzyme active site to directly interfere with NTP entry or RNA synthesis, consistent with the observation that  $\alpha$ -amanitin does not influence the affinity of RNAP II for NTPs, although it reduces its selectivity. Mutation of Rbp1 His 1085, an invariant member of the trigger loop, to Tyr mimics the effects of  $\alpha$ -amanitin. Moreover, this mutation renders RNAP II highly resistant to  $\alpha$ -amanitin, in agreement with an X-ray structure indicating that  $\alpha$ -amanitin interacts with the side chain of His 1085 so as to lock the trigger loop in a previously unobserved conformation. Evidently,  $\alpha$ -amanitin interferes with the conformational change of the trigger loop postulated to promote catalysis (Fig. 31-24), which further supports this mechanism.

Despite the amatoxins' high toxicity (5–6 mg, which occurs in ~40 g of fresh mushrooms, is sufficient to kill a human adult), they act slowly. Death, usually from liver dysfunction, occurs no earlier than several days after mushroom ingestion (and after recovery from the effects of other mushroom toxins). This, in part, reflects the slow turnover of eukaryotic mRNAs and proteins.

### c. RNAPs Can Correct Their Mistakes

RNAPs cannot read through a damaged template strand and consequently stall at the damage site. Moreover, if a deoxynucleotide or a mispaired ribonucleotide is mistakenly incorporated into RNA, the DNA–RNA hybrid helix becomes distorted, which also causes the RNAP

**Figure 31-24** The A and E sites and the trigger loop in RNA polymerase II. A cutaway view of the transcribing complex viewed as in Fig. 31-22*b*. Its bound nucleic acids and nucleotides are colored differently with template DNA cyan, nontemplate DNA green, newly transcribed RNA red, GTP in the A site

orange, and ATP in the E site blue. The trigger loop is magenta, the bridge helix is green, and the two  $Mg^{2+}$  ions at the active site are represented by magenta spheres. The RNAP II surface is gray. [Courtesy of Dong Wang and Roger Kornberg, Stanford University. PDBid 2E2H.]

to stall. How, then, do RNAPs avoid accumulating at damaged or mismatched sites, which, if it occurred on an essential gene, would be lethal?

RNAPs do not monotonically move forward along the template DNA. Instead, they frequently backtrack such that the RNA's penultimate nucleotide, which was in the  $i - 1$  position, has re-entered the  $i + 1$  position and the 3'-nucleotide, now in the  $i + 2$  position, enters the secondary channel where it binds in the so-called P (for *proofreading*) site. If the forward movement of the RNA is impeded by damage to the template or by mispairing, further backtracking becomes favored so that several more ribonucleotides enter the secondary channel. The backtracking of only one or a few nucleotides is reversible. Otherwise, transcription is arrested until the RNA is hydrolytically cleaved at the active site. In *E. coli*, this requires the assistance of the homologous proteins **GreA** and/or **GreB**, whereas with RNAP II, this function is carried out by the unrelated protein **TFIIS**. These proteins induce the RNAP active site to hydrolyze the phosphodiester bond between the ribonucleotides in the  $i + 1$  and  $i - 1$  positions (a reaction that is not the reverse of the polymerase reaction since this would be pyrophosphorolysis). In this way, RNAP can correct its mistakes and resume RNA synthesis. RNAP I and RNAP III also efficiently correct their mistakes.

Kornberg determined the X-ray structure of RNAP II in complex with TFIIS, a 28-nt template DNA, a 14-nt nontemplate DNA, and a 13-nt RNA that is complementary to 5' end of the template DNA except for the last two residues at the RNA's 3' end, which are mismatched (Fig. 31-25). The RNA–DNA hybrid has backtracked such that these latter residues occupy the  $i + 1$  and  $i + 2$  positions. The C-terminal domain of TFIIS is bound in the RNAP's funnel with one of its loops insinuated through the pore to interact with the RNAP's active site residues. There it presu-

**Figure 31-25** X-ray structure of backtracked RNA polymerase II in complex with DNA, RNA, and TFIIS. The RNAP, which is represented by its semitransparent surface diagram, is viewed as in Figs. 31-22*b* and 31-24 with its subunits colored as in Fig. 31-21*a*. The DNA and RNA are shown in ladder form with the RNA (13 nt) red, the template DNA (28 nt) green, and the nontemplate DNA (14 nt) blue. The base pairs at the  $i + 1$  and  $i + 2$  positions of the RNA · DNA hybrid are mismatched. An  $Mg^{2+}$  ion, which is represented by a red sphere near the  $i + 1$  position, marks the RNAP's active site. TFIIS is drawn in cartoon form in magenta. Its C-terminal domain is inserted into the RNAP's funnel (Fig. 31-22*c*) with a loop occupying the pore, where it is in proximity to the RNAP's active site. [Based on an X-ray structure by Roger Kornberg, Stanford University. PDBid 3GTM.]

ably facilitates the hydrolytic reaction, perhaps by liganding the active site  $Mg^{2+}$  ion that normally accompanies the incoming NTP (Section 31-2Ea) and/or positioning a hydrolytic water molecule. The trigger loop in this structure is in the “open” conformation. Interestingly, the cryo-EM-based structure of *E. coli* RNAP in complex with GreB indicates that GreB likewise inserts an extended protein finger in the RNAPs active site via its secondary channel, even though the structures of GreB and TFIIS are unrelated.

Despite the foregoing, transcription is less accurate than DNA replication: RNAPs incorporate one incorrect base for every  $\sim 10^4$  transcribed, whereas, for example, *E. coli* Pol I incorporates one incorrect base in  $\sim 10^7$  (Section 30-2Ab). Cells can tolerate the former rate because most genes are repeatedly transcribed. In contrast, errors in DNA synthesis alter all the affected gene’s transcripts in the cell in which the error occurred and all of its progeny.

#### d. Mammalian RNA Polymerase I Has a Bipartite Promoter

Since, as we shall see in Section 31-4B, the numerous rRNA genes in a given eukaryotic cell have essentially identical sequences, its RNAP I only recognizes one promoter. Yet, in contrast to the case for RNAPs II and III, RNAP I promoters are species specific, that is, an RNAP I only recognizes its own promoter and those of closely related species. This is because only closely related species exhibit recognizable sequence identities near the transcriptional start sites of their rRNA genes. RNAP I promoters were therefore identified by determining how the transcription rate of an rRNA gene is affected by a series of increasingly longer deletions approaching its start site from either its upstream or its downstream sides. Such studies have indicated, for example, that mammalian RNAPs I require the presence of a so-called **core promoter element**, which spans positions  $-31$  to  $+6$  and hence overlaps the transcribed region. However, efficient transcription additionally requires an **upstream promoter element**, which is located between residues  $-187$  and  $-107$ . These elements, which are G + C-rich and  $\sim 85\%$  identical, are bound by specific transcription factors which then recruit RNAP I to the transcription start site.

#### e. RNA Polymerase II Promoters Are Complex and Diverse

The promoters recognized by RNAP II are considerably longer and more diverse than those of prokaryotic genes but have not yet been fully described. The structural genes expressed in all tissues, the so-called **housekeeping genes**, which are thought to be constitutively transcribed, have one or more copies of the sequence GGGCGG or its complement (the **GC box**) located upstream from their transcription start sites. The analysis of deletion and point mutations in eukaryotic viruses such as SV40 indicates that GC boxes function analogously to prokaryotic promoters. On the other hand, structural genes that are selectively expressed in one or a few types of cells often lack these GC-rich sequences. Rather, *many contain a conserved AT-rich sequence located 25 to 30 bp upstream from their transcription start sites* (Fig. 31-26). Note that this so-called **TATA box** resembles the  $-10$  region of prokaryotic promoters (TATAAT), although they differ in their locations relative to the transcription start site ( $-27$  vs  $-10$ ). The functions of these two promoter elements are not strictly analogous, however, since the deletion of the TATA box does not necessarily eliminate transcription. Rather, TATA box deletion or mutation generates heterogeneities in the transcriptional start site, thereby indicating that the TATA box participates in selecting this site.

*The gene region extending between about  $-50$  and  $-110$  also contains promoter elements.* For instance, many eukaryotic structural genes, including those encoding the various globins, have a conserved sequence of consensus CCAAT (the **CCAAT box**) located between about  $-70$  and  $-90$  whose alteration greatly reduces the gene’s transcription rate. Globin genes have, in addition, a conserved **CACCC box** upstream from the CCAAT box that has also been implicated in transcriptional initiation. Evidently, the promoter sequences upstream of the TATA box form the initial DNA-binding sites for RNA polymerase II and the other proteins involved in transcriptional initiation (see below).

#### f. Enhancers Are Transcriptional Activators That Can Have Variable Positions and Orientations

*Perhaps the most surprising aspect of eukaryotic transcriptional control elements is that some of them need not*

**Figure 31-26** The promoter sequences of selected eukaryotic structural genes. The homologous segment, the TATA box, is shaded in red with the base at position  $-27$  underlined and the initial nucleotide to be transcribed ( $+1$ ) shaded in green. The bottom row indicates the consensus sequence of several such promoters with the subscripts indicating the percent occurrence of the corresponding base. [After Gannon, F., et al., *Nature* **278**, 433 (1978).]

have fixed positions and orientations relative to their corresponding transcribed sequences. For example, the SV40 genome, in which such elements were first discovered, contains two repeated sequences of 72 bp each that are located upstream from the promoter for early gene expression. Transcription is unaffected if one of these repeats is deleted but is nearly eliminated when both are absent. The analysis of a series of SV40 mutants containing only one of these repeats demonstrated that its ability to stimulate transcription from its corresponding promoter is all but independent of its position and orientation. Indeed, transcription is unimpaired when this segment is several thousand base pairs upstream or downstream from the transcription start site. Gene segments with such properties are named **enhancers** to indicate that they differ from promoters, with which they must be associated in order to trigger site-specific and strand-specific transcription initiation (although the characterization of numerous promoters and enhancers indicates that their functional properties are similar). Enhancers occur in both eukaryotic viruses and cellular genes.

*Enhancers are required for the full activities of their cognate promoters.* It was originally thought that enhancers somehow acted as entry points on DNA for RNAP II (perhaps by altering DNA's local conformation or through a lack of binding affinity for the histones that normally coat eukaryotic DNA; Section 34-1B). However, it is now clear that *enhancers are recognized by specific transcription factors that stimulate RNA polymerase II to bind to the corresponding but distant promoter.* This requires that the DNA between the enhancer and promoter loop around so that the transcription factor can simultaneously contact the enhancer and the RNAP II and/or its associated proteins at the promoter. Most cellular enhancers are associated with genes that are selectively expressed in specific tissues. It therefore seems, as we discuss in Section 34-3B, that *enhancers mediate much of the selective gene expression in eukaryotes.*

### g. RNA Polymerase III Promoters Can Be Located Downstream from Their Transcription Start Sites

*The promoters of genes transcribed by RNAP III can be located entirely within the genes' transcribed regions.* Donald Brown established this through the construction of a series of deletion mutants of a *Xenopus borealis* 5S RNA gene. Deletions of base sequences that start from outside one or the other end of the transcribed portion of the 5S gene only prevent transcription if they extend into the segment between nucleotides +40 and +80. Indeed, a fragment of the 5S RNA gene consisting of only nucleotides 41 to 87, when cloned in a bacterial plasmid, is sufficient to direct specific initiation by RNAP III at an upstream site. This is because, as was subsequently demonstrated, the sequence contains the binding site for transcription factors that stimulate the upstream binding of RNAP III. Further studies have shown, however, that the promoters of other RNAP III-transcribed genes lie entirely upstream of their start sites. These upstream sites also bind transcription factors that recruit RNAP III.

## 3 CONTROL OF TRANSCRIPTION IN PROKARYOTES

*Prokaryotes respond to sudden environmental changes, such as the influx of nutrients, by inducing the synthesis of the appropriate proteins.* This process takes only minutes because transcription and translation in prokaryotes are closely coupled: *Ribosomes commence translation near the 5' end of a nascent mRNA soon after it is extruded from RNA polymerase* (Fig. 31-27). Moreover, *most prokaryotic mRNAs are enzymatically degraded within 1 to 3 min of their synthesis*, thereby eliminating the wasteful synthesis of unneeded proteins after a change in conditions (protein degradation is discussed in Section 32-6). In fact, the 5' ends of some mRNAs are degraded before their 3' ends have been synthesized.

In contrast, the induction of new proteins in eukaryotic cells frequently takes hours or days, in part because transcription takes place in the nucleus and the resulting mRNAs must be transported to the cytoplasm, where translation occurs. However, eukaryotic cells, particularly those of multicellular organisms, have relatively stable environments; major changes in their transcription patterns usually occur only during cell differentiation.

**Figure 31-27** An electron micrograph and its interpretive drawing showing the simultaneous transcription and translation of an *E. coli* gene. RNA polymerase molecules are transcribing the DNA from right to left while ribosomes are translating the nascent RNAs (mostly from bottom to top). [Courtesy of Oscar L. Miller, Jr. and Barbara Hamkalo, University of Virginia.]

In this section we examine some of the ways in which prokaryotic gene expression is regulated through transcriptional control. Eukaryotes, being vastly more complex creatures than are prokaryotes, have a correspondingly more complicated transcriptional control system whose general outlines are beginning to come into focus. We therefore defer discussion of eukaryotic transcriptional control until Section 34-3B, where it can be considered in light of what we know about the structure and organization of the eukaryotic chromosome.

## A. Promoters

In the presence of high concentrations of inducer, the *lac* operon (Section 31-1Ab) is rapidly transcribed. In contrast, the *lacI* gene is transcribed at such a low rate that a typical *E. coli* cell contains <10 molecules of the *lac* repressor. Yet, the *I* gene has no repressor. Rather, it has such an inefficient promoter (Fig. 31-10) that it is transcribed an average of about once per bacterial generation. *Genes that are transcribed at high rates have efficient promoters.* In general, the more efficient a promoter, the more closely its sequence resembles that of the corresponding consensus sequence.

### a. Gene Expression Can Be Controlled by a Succession of $\sigma$ Factors

*The processes of development and differentiation involve the temporally ordered expression of sets of genes according to genetically specified programs.* Phage infections are among the simplest examples of developmental processes. Typically, only a subset of the phage genome, often referred to as *early* genes, are expressed in the host immediately after phage infection. As time passes, *middle* genes start to be expressed, and the *early* genes as well as the bacterial genes are turned off. In the final stages of phage infection, the *middle* genes give way to the *late* genes. Of course some phage types express more than three sets of genes and some genes may be expressed in more than one stage of an infection.

One way in which families of genes are sequentially expressed is through “cascades” of  $\sigma$  factors. In the infection of *Bacillus subtilis* by bacteriophage SP01, for example, the *early* gene promoters are recognized by the bacterial RNAP holoenzyme. Among these *early* genes is gene 28, whose gene product is a new  $\sigma$  subunit, designated  $\sigma^{gp28}$ , that displaces the bacterial  $\sigma$  subunit from the core enzyme. The reconstituted holoenzyme recognizes only the phage *middle* gene promoters, which all have similar  $-35$  and  $-10$  regions but bear little resemblance to the corresponding regions of bacterial and phage *early* genes. The *early* genes therefore become inactive once their corresponding mRNAs have been degraded. The phage *middle* genes include genes 33 and 34, which together specify yet another  $\sigma$  factor,  $\sigma^{gp33/34}$ , which, in turn, permits the transcription of only *late* phage genes.

Most bacteria, including *E. coli* and *B. subtilis*, likewise have several different  $\sigma$  factors (*E. coli* has seven). These are not necessarily utilized in a sequential manner. Rather,

those that differ from the predominant or primary  $\sigma$  factor ( $\sigma^{70}$  in *E. coli*) control the transcription of coordinately expressed groups of special purpose genes, whose promoters are quite different from those recognized by the primary  $\sigma$  factor. For example, in *E. coli*, the alternative  $\sigma$  factor  $\sigma^{32}$  is the master regulator of the heat shock response (Section 9-2C), whereas  $\sigma^{54}$  directs the expression of proteins involved in nitrogen assimilation. Likewise, sporulation in *B. subtilis*, a process in which the bacterial cell is asymmetrically partitioned into two compartments, the **forespore** (which becomes the **spore**, a germline cell from which subsequent progeny arise) and the **mother cell** (which synthesizes the spore’s protective cell wall and is eventually discarded), is governed by five  $\sigma$  factors in addition to that of the **vegetative** (nonsporulating) cell: one that is active before cell partition occurs, two that are sequentially active in the forespore, and two that are sequentially active in the mother cell. Cross-regulation of the compartmentalized  $\sigma$  factors permits the forespore and mother cell to tightly coordinate this differentiation process.

## B. *lac* Repressor I: Binding

In 1966, Benno Müller-Hill and Walter Gilbert isolated *lac* repressor on the basis of its ability to bind  $^{14}\text{C}$ -labeled IPTG (Section 31-1Aa) and demonstrated that it is a protein. This was an exceedingly difficult task because *lac* repressor comprises only  $\sim 0.002\%$  of the protein in wild-type *E. coli*. Now, however, *lac* repressor is available in quantity via molecular cloning techniques (Section 5-5G).

### a. *lac* Repressor Finds Its Operator by Sliding Along DNA

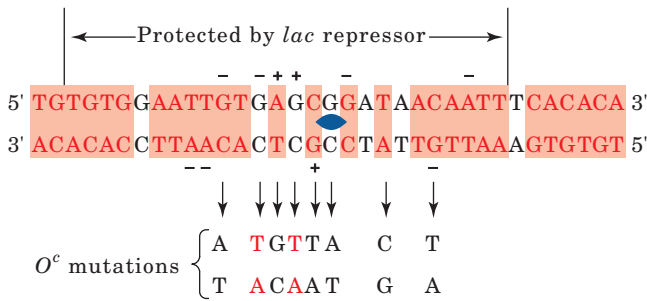

The *lac* repressor is a tetramer of identical 360-residue subunits, each of which binds one IPTG molecule with a dissociation constant of  $K = 10^{-6} M$ . In the absence of inducer, the repressor tetramer nonspecifically binds duplex DNA with a dissociation constant of  $K \approx 10^{-4} M$ . However, it specifically binds to the *lac* operator with far greater affinity:  $K \approx 10^{-13} M$ . Limited proteolysis of *lac* repressor with trypsin reveals that each subunit consists of two functional domains: Its 58-residue N-terminal peptide binds DNA but not IPTG, whereas the remaining “core tetramer” binds only IPTG.

The observed rate constant for the binding of *lac* repressor to *lac* operator is  $k_f \approx 10^{10} M^{-1} s^{-1}$ . This “on” rate is much greater than that calculated for the diffusion-controlled process in solution:  $k_f \approx 10^7 M^{-1} s^{-1}$  for molecules the size of *lac* repressor. Since it is impossible for a reaction to proceed faster than its diffusion-controlled rate, the *lac* repressor must not encounter operator from solution in a random three-dimensional search. Rather, *it appears that lac repressor finds operator by nonspecifically binding to DNA and diffusing along it in a far more efficient one-dimensional search.*

### b. *lac* Operator Has a Nearly Palindromic Sequence

The availability of large quantities of *lac* repressor made it possible to characterize the *lac* operator. *E. coli* DNA

**Figure 31-28** The base sequence of the *lac* operator. The symmetry related regions (red) comprise 28 of its 35 bp. A “+” denotes positions at which repressor binding enhances methylation by dimethyl sulfate (which methylates G at N7 and A at N3) and a “-” indicates where this footprinting reaction is inhibited. The bottom row indicates the positions and identities of different point mutations that prevent *lac* repressor binding (*O<sup>c</sup>* mutants). Those in red increase the operator’s symmetry. [After Sobell, H.M., in Goldberger, R.F. (Ed.), *Biological Regulation and Development*, Vol. 1, p. 193, Plenum Press (1979).]

that had been sonicated to small fragments was mixed with *lac* repressor and passed through a nitrocellulose filter. Protein, with or without bound DNA, sticks to nitrocellulose, whereas duplex DNA, by itself, does not. The DNA was released from the filter-bound protein by washing it with IPTG solution, recombined with *lac* repressor, and the resulting complex treated with DNase I. The DNA fragment that *lac* repressor protects from nuclease degradation consists of a run of 26 bp that is embedded in a nearly 2-fold symmetric sequence of 35 bp (Fig. 31-28, top). Such palindromic symmetry is a common feature of DNA segments that are specifically bound by proteins (recall, for example, that restriction endonuclease recognition sites are also palindromic; Section 5-5Aa).

Palindromic DNA sequences, as we have seen, bind to proteins that have matching 2-fold symmetry. However, methylation protection experiments on the *lac* repressor-

operator system do not fully support this model: There is an asymmetric pattern of differences between free and repressor-bound operator in the susceptibility of its bases to reaction with DMS (Fig. 31-28). Furthermore, point mutations that render it operator constitutive (*O<sup>c</sup>*), and that invariably weaken the binding of repressor to operator, may increase as well as decrease the operator’s 2-fold symmetry (Fig. 31-28).

**c. *lac* Repressor Prevents RNA Polymerase from Forming a Productive Initiation Complex**

Operator occupies positions -7 through +28 of the *lac* operon relative to the transcription start site (Fig. 31-29). Nuclease protection studies, it will be recalled, indicate that, in the initiation complex, RNA polymerase tightly binds to the DNA between positions -20 and +20 (Section 31-2Aa). Thus, the *lac* operator and promoter sites overlap. It was therefore widely assumed for many years that *lac* repressor simply physically obstructs the binding of RNA polymerase to the *lac* promoter. However, the observation that *lac* repressor and RNA polymerase can simultaneously bind to the *lac* operon indicates that *lac* repressor must act by somehow interfering with the initiation process. Closer investigation of this phenomenon revealed that, in the presence of bound *lac* repressor, RNA polymerase holoenzyme still abortively synthesizes oligonucleotides, although they tend to be shorter than those made in the absence of repressor. Evidently, *lac* repressor acts by somehow increasing the already high kinetic barrier for RNA polymerase to generate the open complex and commence processive elongation.

We discuss the *lac* repressor structure and further aspects of *lac* operator organization in Section 31-3F.

**C. Catabolite Repression: An Example of Gene Activation**

Glucose is *E. coli*’s metabolite of choice; the availability of adequate amounts of glucose prevents the full expression of >100 genes that encode proteins involved in the fermentation

**Figure 31-29** The nucleotide sequence of the *E. coli lac* promoter-operator region. The region extends from the C-terminal portion of *lacI* (left) to the N-terminal portion of *lacZ* (right). The palindromic sequences of the operator and

the CAP-binding site (Section 31-3C) are overscored or underscored. [After Dickson, R.C., Abelson, J., Barnes, W.M., and Reznikoff, W.A., *Science* 187, 32 (1975).]

**Figure 31-30** The kinetics of *lac* operon mRNA synthesis following its induction with IPTG, and of its degradation after glucose addition. *E. coli* were grown on a medium containing glycerol as their only carbon-energy source and  $^3\text{H}$ -labeled uridine. IPTG was added to the medium at the beginning of the experiment to induce the synthesis of the *lac* enzymes. After 3 min, glucose was added to stop the synthesis. The amount of  $^3\text{H}$ -labeled *lac* RNA was determined by hybridization with DNA containing the *lacZ* and *lacY* genes. [After Adesnik, M. and Levinthal, C., *Cold Spring Harbor Symp. Quant. Biol.* **35**, 457 (1970).]

of numerous other catabolites, including lactose (Fig. 31-30), arabinose, and galactose, even when these metabolites are present in high concentrations. This phenomenon, which is known as **catabolite repression**, prevents the wasteful duplication of energy-producing enzyme systems.

#### a. cAMP Signals the Lack of Glucose

The first indication of the mechanism of catabolite repression was the observation that, in *E. coli*, the level of cAMP, which was known to be a second messenger in animal cells (Section 18-3Cb), is greatly diminished in the presence of glucose. This observation led to the finding that the addition of cAMP to *E. coli* cultures overcomes catabolite repression by glucose. Recall that, in *E. coli*, adenylate cyclase is activated by the phosphorylated enzyme EIIA<sup>glc</sup> (or possibly inactivated by dephospho-EIIA<sup>glc</sup>), which is dephosphorylated on the transport of glucose across the cell membrane (Section 20-3D). *The presence of glucose, therefore, normally lowers the cAMP level in E. coli.*

#### b. CAP-cAMP Complex Stimulates the Transcription of Catabolite Repressed Operons

Certain *E. coli* mutants, in which the absence of glucose does not relieve catabolite repression, are missing a cAMP-

binding protein that is synonymously named **catabolite gene activator protein (CAP)** and **cAMP receptor protein (CRP)**. CAP is a homodimer of 209-residue subunits that undergoes a large conformational change on binding cAMP. Its function was elucidated by Ira Pastan, who showed that *CAP-cAMP complex, but not CAP itself, binds to the lac operon (among others) and stimulates transcription from its otherwise low-efficiency promoter in the absence of lac repressor.* CAP is therefore a **positive regulator** (turns on transcription), in contrast to *lac* repressor, which is a **negative regulator** (turns off transcription).

The X-ray structure, by Thomas Steitz, of CAP-cAMP in complex with a palindromic 30-bp segment of duplex DNA whose sequence resembles that of the CAP binding sequence (Fig. 31-29) reveals that the DNA is bent by  $\sim 90^\circ$  around the protein (Fig. 31-31a). The bend arises from two  $\sim 45^\circ$  kinks in the DNA between the fifth and sixth bases out from the complex's 2-fold axis in both directions. This distortion results in the closing of the major groove and an enormous widening of the minor groove at each kink.

Why is the CAP-cAMP complex necessary to stimulate the transcription of its target operons? And how does it do so? The *lac* operon has a weak (low efficiency) promoter; its  $-10$  and  $-35$  sequences (TATGTT and TTTACA; Fig. 31-10) differ significantly from the corresponding consensus sequences of strong (high-efficiency) promoters (TATAAT and TTGACA; Fig. 31-10). Such weak promoters evidently require some sort of help for efficient transcriptional initiation.

Richard Ebright has shown that CAP interacts directly with RNAP via the C-terminal domain of its 85-residue  $\alpha$  subunit ( $\alpha\text{CTD}$ ) in a way that stimulates RNAP to initiate transcription from a nearby promoter. The  $\alpha\text{CTD}$  also binds dsDNA nonspecifically but does so with higher affinity at A + T-rich sites such as those of UP elements (Section 31-2Aa). It is flexibly linked to the rest of the  $\alpha$  subunit and hence is not seen in the X-ray structure of Tth RNAP (Fig. 31-11) due to disorder.

Three classes of the over one hundred CAP-dependent promoters have been characterized:

1. Class I promoters, such as that of the *lac* operon, require only CAP-cAMP for transcriptional activation. The CAP binding site on the DNA can be located at various distances from the promoter provided that CAP and RNAP bind to the same face of the DNA helix. Thus, CAP-cAMP activates the transcription of the *lac* operon if its DNA binding site is centered near positions  $-62$  (its wild-type position; Fig. 31-29),  $-72$ ,  $-83$ ,  $-93$ , or  $-103$ , all of which are one helical turn apart. For the latter sites, this requires that the DNA loop around to permit CAP-cAMP to contact the  $\alpha\text{CTD}$ . Such looping is likely to be facilitated by the bending of the DNA around CAP-cAMP.

2. Class II promoters also require only CAP-cAMP for transcriptional activation. However, in class II promoters, the CAP binding site only occupies a fixed position that overlaps the RNAP binding site, apparently by replacing the promoter's  $-35$  promoter region. CAP then interacts

**Figure 31-31** X-ray structures of CAP-cAMP-dsDNA complexes. The dsDNA and cAMP in these 2-fold symmetric complexes are colored according to atom type with DNA C white, cAMP green, N blue, O red, and P orange. (a) CAP-cAMP in complex with a palindromic 30-bp self-complementary DNA viewed with its 2-fold axis horizontal. The protein is drawn in ribbon form with its identical subunits pink and blue and with their C-terminal domains in darker shades. The DNA is shown in stick form with successive P atoms in the same strand connected by orange rods and with the cAMP drawn in space-filling form. (b) CAP-cAMP in complex with a 44-bp palindromic DNA and four  $\alpha$ CTD subunits. The DNA, CAP, and cAMP are viewed as in

Part a with the DNA drawn in space-filling form. The  $\alpha$ CTD subunits are drawn in ribbon form with the  $\alpha$ CTD<sup>CARDNA</sup> green and the  $\alpha$ CTD<sup>DNA</sup> dark green. (c) The same structure as in Part a showing the binding of the CAP dimer's two helix-turn-helix (HTH) motifs in successive major grooves of the DNA. The view is rotated 45° about the vertical axis relative to Part a. Note how CAP's F (recognition) helix is inserted into the DNA's major groove, as can also be seen in Parts a and b. [Parts a and c based on an X-ray structure by Thomas Steitz, Yale University. PDBid 1CGP. Part b based on an X-ray structure by Helen Berman and Richard Ebright, Rutgers University. PDBid 1LB2.]

 See Interactive Exercise 38

with RNAP via interactions with both the  $\alpha$ CTD and the  $\alpha$  subunit's N-terminal domain.

3. Class III promoters require multiple activators to maximally stimulate transcription. These may be two or more CAP-cAMP complexes or a CAP-cAMP complex acting in concert with promoter-specific activators as occurs in the *araBAD* operon (Section 31-3E).

The X-ray structure of CAP-cAMP in complex with the *E. coli*  $\alpha$ CTD and a 44-bp palindromic DNA containing the 22-bp CAP-cAMP binding site and 5'-AAAAAA-3' at each end, determined by Helen Berman and Ebright, reveals how these components interact (Fig. 31-31b). The 2-fold symmetric CAP-cAMP- $\alpha$ CTD complex contains two differently located pairs of  $\alpha$ CTDs. Each member of the pair designated  $\alpha$ CTD<sup>CARDNA</sup> binds to both CAP and to the DNA. CAP and

$\alpha$ CTD<sup>CARDNA</sup> interact over a surprisingly small surface area involving only six residues on each protein that mutagenesis experiments had previously implicated.  $\alpha$ CTD<sup>CARDNA</sup> also interacts with the minor groove of a 6-bp segment of the DNA (5'-AAAAAG-3') centered 19 bp from the center of the DNA. Each member of the other pair of  $\alpha$ CTDs, designated  $\alpha$ CTD<sup>DNA</sup>, interacts with the minor groove of an UP element-like sequence (5'-GAAAAA-3') that is fortuitously present in the DNA but it makes no contacts with other protein molecules. The common portions of the two CAP complexes pictured in Fig. 31-31a,b are closely superimposable, thereby indicating that the conformation of CAP and its interaction with DNA are not significantly altered by its association with the  $\alpha$ CTD. Evidently, CAP-cAMP transcriptionally activates RNAP via a simple “adhesive” mechanism that facilitates and/or stabilizes its interaction with the

promoter DNA. The structures of  $\alpha\text{CTD}^{\text{CAPDNA}}$  and  $\alpha\text{CTD}^{\text{CAP}}$  and their interactions with DNA are nearly identical, thereby suggesting that they are representative of the interaction of an  $\alpha\text{CTD}$  with an UP element.

### D. Sequence-Specific Protein–DNA Interactions

Since genetic expression is controlled by proteins such as CAP and *lac* repressor, an important issue in the study of gene regulation is how these proteins recognize their target base sequences on DNA. Sequence-specific DNA-binding proteins generally do not disrupt the base pairs of the duplex DNA to which they bind. Consequently, these proteins can only discriminate among the four base pairs (A · T, T · A, G · C, and C · G) according to the functional groups of these base pairs that project into DNA's major and minor grooves. An inspection of Fig. 5-12 reveals that the groups exposed in the major groove have a greater variation in their types and arrangements than do those that are exposed in the minor groove. Indeed, the positions of the hydrogen bonding acceptors in the major groove vary with both the identity and orientation of the base pair, whereas in the minor groove they are largely sequence independent. Moreover, the  $\sim 5\text{-}\text{\AA}$ -wide and  $\sim 8\text{-}\text{\AA}$ -deep minor groove of canonical (ideal) B-DNA is too narrow to admit protein structural elements such as an  $\alpha$  helix, whereas its  $\sim 12\text{-}\text{\AA}$ -wide and  $\sim 8\text{-}\text{\AA}$ -deep major groove can do so. Thus, in the absence of major conformational changes to B-DNA, it would be expected that proteins could more readily differentiate base sequences from its major groove than from its minor groove. We shall see below that this is, in fact, the case.

#### a. The Helix–Turn–Helix Motif Is a Common DNA Recognition Element in Prokaryotes

 See Guided Exploration 30: Transcription factor–DNA interactions  
The CAP dimer's two symmetrically disposed F helices protrude from the protein surface in such a way that they fit into successive major grooves of B-DNA (Fig. 31-31). CAP's E and F helices form a **helix–turn–helix (HTH) motif** (supersecondary structure) that conformationally resembles analogous HTH motifs in numerous other prokaryotic repressors of known X-ray and NMR structure, including the *lac* repressor, the *E. coli* **trp repressor** (Section 31-3G), and the **cl repressors** and **Cro proteins** from bacteriophages  $\lambda$  and 434 (Section 33-3D). HTH motifs are  $\sim 20$ -residue polypeptide segments that form two  $\alpha$  helices which cross at  $\sim 120^\circ$  (Fig. 31-31c). They occur as components of domains that otherwise have widely varying structures, although all of them bind DNA. Note that HTH motifs are structurally stable only when they are components of larger proteins.

The X-ray and NMR structures of a number of protein–DNA complexes (see below) indicate that DNA-binding proteins containing an HTH motif associate with their target base pairs mainly via the side chains extending from the second helix of the HTH motif, the so-called **recognition helix** (helix F in CAP, E in *trp* repressor, and  $\alpha 3$  in the phage proteins). Indeed, replacing the outward-facing

residues of the 434 repressor's recognition helix with the corresponding residues of the related **bacteriophage P22** yields a hybrid repressor that binds to P22 operators but not to those of 434. Moreover, the HTH motifs in all these proteins have amino acid sequences that are similar to each other and to polypeptide segments in numerous other prokaryotic DNA-binding proteins, including *lac* repressor. Evidently, *these proteins are evolutionarily related and bind their target DNAs in a similar manner.*

How does the recognition helix recognize its target sequence? Since each base pair presents a different and presumably readily differentiated constellation of hydrogen bonding groups in DNA's major groove, it seemed likely that there would be a simple correspondence, analogous to Watson–Crick base pairing, between the amino acid residues of the recognition helix and the bases they contact in forming sequence-specific associations. The above X-ray structures, however, indicate this idea to be incorrect. Rather, base sequence recognition arises from complex structural interactions. For instance:

1. The X-ray structures of the 48% identical N-terminal domain of 434 repressor (residues 1–69) and the entire 71-residue 434 Cro protein in their complexes with the identical 20-bp target DNA (the expression of phage 434 is regulated through the differential binding of these proteins to the same DNA segments; Section 33-3Db) were both determined by Stephen Harrison. Both homodimeric proteins, as seen for CAP (Fig. 31-31), associate with the DNA in a 2-fold symmetric manner with their recognition helices bound in successive turns of the DNA's major groove (Figs. 31-32 and 31-33). In both complexes, the protein closely conforms to the DNA surface and interacts with its paired bases and sugar–phosphate chains through elaborate networks of hydrogen bonds, salt bridges, and van der Waals contacts. Nevertheless, the detailed geometries of these associations are significantly different. In the repressor–DNA complex (Fig. 31-32), the DNA bends around the protein in an arc of radius  $\sim 65\text{ \AA}$  which compresses the minor groove by  $\sim 2.5\text{ \AA}$  near its center (between the two protein monomers) and widens it by  $\sim 2.5\text{ \AA}$  toward its ends. In contrast, the DNA in complex with Cro (Fig. 31-33), although also bent, is nearly straight at its center and has a less compressed minor groove (compare Figs. 31-32a and 31-33a). This explains why the simultaneous replacement of three residues in the repressor's recognition helix with those occurring in Cro does not cause the resulting hybrid protein to bind DNA with Cro-like affinity: *The different conformations of the DNA in the repressor and Cro complexes prevents any particular side chain from interacting identically with the DNA in the two complexes.*

2. Paul Sigler determined the X-ray structure of *E. coli* *trp* repressor in complex with a DNA containing an 18-bp palindrome (TGTACTAGTTAACTAGTAC, where the *trp* repressor's target sequence is underlined) that closely resembles the *trp* operator (Section 31-3G). The dimeric protein's recognition helices bind, as expected, in successive major grooves of the DNA, each in contact with an

(a)

schematic drawing indicating how the HTH motif, which encompasses helices  $\alpha 2$  and  $\alpha 3$ , interacts with its target DNA. Short bars emanating from the polypeptide chain represent peptide NH groups, hydrogen bonds are represented by dashed lines, and DNA phosphates are represented by numbered circles. The small circle is a water molecule. [Part *a* based on an X-ray structure by and Part *b* courtesy of Aneel Aggarwal, John Anderson, and Stephen Harrison, Harvard University. PDBid 2OR1.]  See [Interactive Exercise 39](#) and [Kinemage Exercise 18-1](#)

(a)

**Figure 31-33** X-ray structure of the 71-residue 434 Cro protein in complex with the same 20-bp DNA shown in Fig. 31-32. Parts *a* and *b* correspond to those in Fig. 31-32. Note the close but not identical correspondence between the two structures and, in particular, the difference in the widths of the

(b)

minor groove between the two subunits in each structure. [Part *a* based on an X-ray structure by and Part *b* courtesy of Alfonso Mondragón, Cynthia Wolberger, and Stephen Harrison, Harvard University. PDBid 3CRO.]

**Figure 31-34** X-ray structure of an *E. coli* *trp* repressor–operator–tryptophan complex. The complex is viewed with its molecular 2-fold axis horizontal. The protein’s two identical subunits are drawn in ribbon form colored pink and blue with their HTH motifs (helices D and E) more deeply colored. The 18-bp-containing self-complementary dsDNA is shown in stick form with C white, N blue, O red, P orange, and with successive P atoms in the same chain connected by orange rods. The *trp* repressor binds its operator only when L-tryptophan, drawn in space-filling form with C green, is simultaneously bound. Note that the protein’s recognition helices (E) bind, as expected, in successive major grooves of the DNA but extend approximately perpendicular to the DNA duplex axis. In contrast, the recognition helices of 434 repressor and Cro proteins are nearly parallel to the major grooves of their bound DNAs (Figs. 31-32 and 31-33), whereas those of CAP assume an intermediate orientation (Fig. 31-31). [Based on an X-ray structure by Paul Sigler, Yale University. PDBid 1TRO.]

 See Interactive Exercise 40

operator half-site (ACTAGT; Fig. 31-34). There are numerous hydrogen bonding contacts between the *trp* repressor and its bound DNA’s nonesterified phosphate oxygens. Astoundingly, however, *there are no direct hydrogen bonds or nonpolar contacts that can explain the repressor’s specificity for its operator. Rather, all but one of the side chain–base hydrogen bonding interactions are mediated by bridging water molecules* (the one direct interaction involves a base that can be mutated without greatly affecting repressor binding affinity). Such buried water molecules have therefore been described as “honorary” protein side chains. In addition, the operator contains several base pairs that are not in contact with the repressor but whose mutation nevertheless greatly decreases repressor binding affinity. This suggests that the operator assumes a sequence-specific conformation that makes favorable contacts with the repressor. Indeed, comparison of the X-ray structure of an uncomplexed 10-bp self-complementary DNA containing the *trp* operator’s half-site (CCACTAGTGG) with that of the DNA in the *trp* repressor–operator complex reveals that the ACTAGT half-site assumes nearly identical idiosyncratic conformations and patterns of hydration in both structures. However, the B-DNA helix, which is straight in the DNA 10-mer, is bent by 15° toward the major groove in each operator half-site of the repressor–operator complex. Other DNA sequences could conceivably assume the repressor-bound operator’s conformation but at too high an energy cost to form a stable complex with repressor (*trp* repressor’s measured 10<sup>4</sup>-fold preference for its operator over other DNAs implies an ~23 kJ · mol<sup>-1</sup> difference in their binding free energies). This phenomenon, in which a protein senses the base

sequence of DNA through the DNA’s backbone conformation and/or flexibility, is referred to as **indirect readout**. 434 repressor apparently also employs indirect readout: Replacing the central A · T base pair of the operator shown in Fig. 31-32 with G · C reduces repressor binding affinity by 50-fold even though 434 repressor does not contact this region of the DNA.

It therefore appears that *there are no simple rules governing how particular amino acid residues interact with bases. Rather, sequence specificity results from an ensemble of mutually favorable interactions between a protein and its target DNA.*

#### **b. The *met* Repressor Contains a Two-Stranded Antiparallel $\beta$ Sheet That Binds in Its Target DNA’s Major Groove**

The *E. coli* ***met* repressor (MetJ)**, when complexed with S-adenosylmethionine (SAM; Fig. 26-18), represses the transcription of its own gene and those encoding enzymes involved in the synthesis of methionine (Fig. 26-60) and SAM. The X-ray structure of the *met* repressor–SAM–operator complex (Fig. 31-35), determined by Simon Phillips, reveals a symmetric dimer of intertwined homodimers that lacks an HTH motif. Rather, *met* repressor binds to its palindromic target DNA sequence through two symmetry-related pairs of symmetrical two-stranded antiparallel  $\beta$  sheets (called  **$\beta$  ribbons**) that are inserted in successive major grooves of the DNA. Each  $\beta$  ribbon makes sequence-specific contacts with its target DNA sequence via hydrogen bonding and, probably, indirect readout.

**Figure 31-35** X-ray structure of the *E. coli met* repressor–SAM–operator complex. (a) The overall structure of the complex as viewed along its 2-fold axis of symmetry. The self-complementary 18-bp DNA is drawn in stick form, and SAM, which must be bound to the repressor for it to also bind DNA, is shown in space-filling form with the DNA C white, SAM C green, N blue, O red, P orange, and S yellow. The DNA binds four identical 104-residue repressor subunits. Pairs of subunits (*light cyan and lavender*) form symmetric dimers in which each subunit donates one strand of the 2-stranded antiparallel  $\beta$  ribbon that is inserted in the DNA's major groove

(*upper left and lower right*). Two such dimers pair across the complex's 2-fold axis via their antiparallel N-terminal helices, which contact one another over the DNA's minor groove. (b) Detailed view of the lower half of Part a showing the 2-stranded antiparallel  $\beta$  ribbon (residues 21–29) inserted into the DNA's major groove, as viewed along its local 2-fold axis (rotated relative to Part a by  $50^\circ$  about the vertical axis). The DNA is shown in space-filling form and the polypeptide chains are drawn in stick form with C green. [Based on an X-ray structure by Simon Phillips, University of Leeds, U.K. PDBid 1CMA.]  
 See Interactive Exercise 41

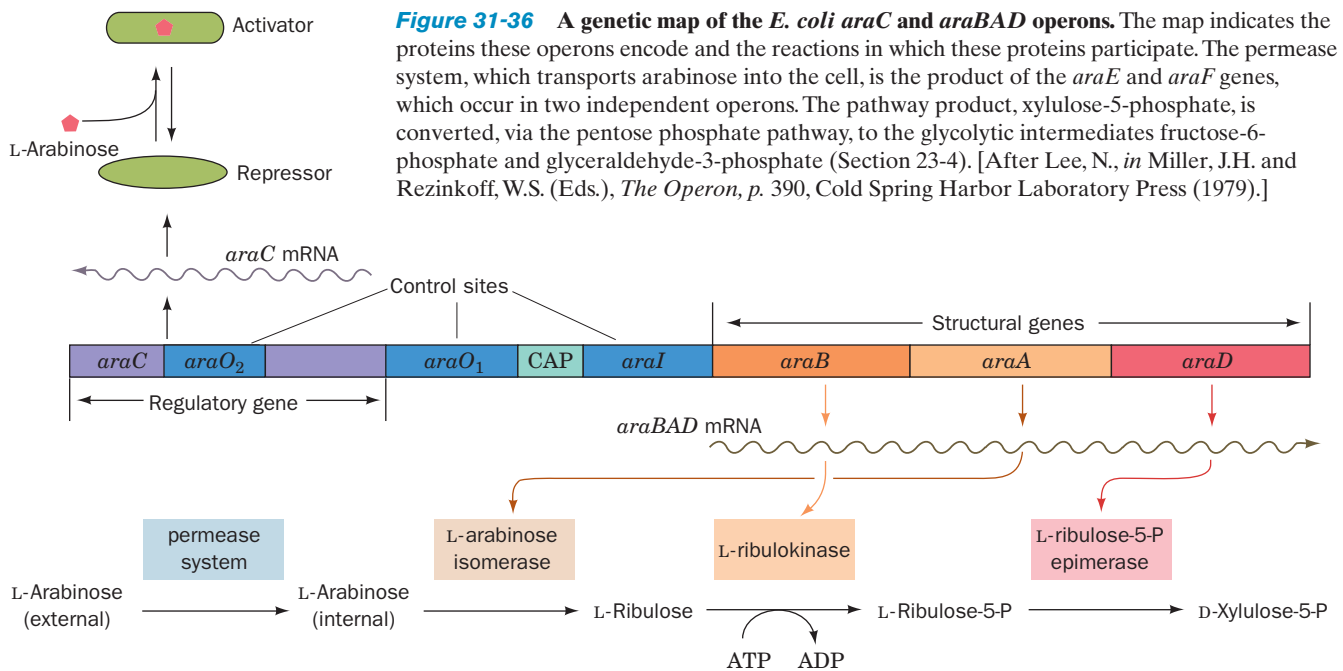

Phillips first determined the X-ray structure of *met* repressor in the absence of DNA. Model building studies aimed at elucidating how *met* repressor binds to its palindromic target DNA assumed that the 2-fold rotation axes of both molecules would be coincident, as they are in all prokaryotic protein–DNA complexes of known structure. There were, consequently, two reasonable choices: (1) The protein could dock to the DNA with the above pairs of  $\beta$  ribbons entering successive major grooves; or (2) a symmetry-related pair of protruding  $\alpha$  helices on the opposite face of the protein could do so in a manner resembling the way in which the recognition helices of HTH motifs interact with DNA. A variety of structural criteria suggested that the  $\alpha$  helices make significantly better contacts with the DNA than do the  $\beta$  ribbons. Thus, the observation that it is, in fact, the  $\beta$  ribbons that bind to the DNA provides an important lesson: *The results of model building studies must be treated with utmost caution.* This is because our imprecise understanding of the energetics of intermolecular interactions (Sections 8-4 and 29-2) prevents us from reliably predicting how associating macromolecules conform to one another. In the case of the *met* repressor, unpredicted mutual structural accommodations of the protein and DNA yielded a significantly more extensive interface than

had been predicted by simply docking the uncomplexed *Met* repressor to canonical B-DNA.

The numerous prokaryotic transcriptional regulators of known structure either contain an HTH motif or pairs of  $\beta$  ribbons like the *met* repressor (although numerous prokaryotic DNA-binding proteins, including CAP, contain an elaboration of the HTH motif known as the **winged helix** motif in which two protein loops, one of which contacts the DNA's minor groove, flank the HTH recognition helix like the wings of a butterfly). Moreover, most of these proteins are homodimers that bind to palindromic or pseudopalindromic DNA target sequences. However, eukaryotic transcription factors, as we shall see in Section 34-3B, employ a much wider variety of structural motifs to bind their target DNAs, many of which lack symmetry.

### **E. araBAD Operon: Positive and Negative Control by the Same Protein**

Humans neither metabolize nor intestinally absorb the plant sugar L-arabinose. Hence, the *E. coli* that normally inhabit the human gut are periodically presented with a banquet of this pentose. Three of the five *E. coli* enzymes that

**Figure 31-36** A genetic map of the *E. coli* *araC* and *araBAD* operons. The map indicates the proteins these operons encode and the reactions in which these proteins participate. The permease system, which transports arabinose into the cell, is the product of the *araE* and *araF* genes, which occur in two independent operons. The pathway product, xylulose-5-phosphate, is converted, via the pentose phosphate pathway, to the glycolytic intermediates fructose-6-phosphate and glyceraldehyde-3-phosphate (Section 23-4). [After Lee, N., in Miller, J.H. and Reznikoff, W.S. (Eds.), *The Operon*, p. 390, Cold Spring Harbor Laboratory Press (1979).]

metabolize arabinose are products of the catabolite repressible ***araBAD* operon** (Fig. 31-36).

The *araBAD* operon, as Robert Schleif has shown, contains, moving upstream from its transcriptional start site, the *araI*, *araO<sub>1</sub>*, and *araO<sub>2</sub>* control sites (Fig. 31-37a). The *araI* site (*I* for inducer) consists of two closely similar 17-bp half-sites, *araI<sub>1</sub>* and *araI<sub>2</sub>*, that are direct repeats separated by 4 bp and are oriented such that *araI<sub>2</sub>*, which overlaps the  $-35$  region of the *araBAD* promoter, is downstream of *araI<sub>1</sub>*. Likewise, *araO<sub>1</sub>* consists of two directly repeating half-sites, *O<sub>1L</sub>* and *O<sub>1R</sub>*. Intriguingly, however, *araO<sub>2</sub>* consists of a single half-site that is located in a noncoding upstream region of the *araC* gene (see below), at position  $-270$  relative to the *araBAD* start site.

The transcription of the *araBAD* operon is regulated by both CAP-cAMP and the arabinose-binding protein **AraC**. Each 292-subunit of the homodimeric AraC consists of an N-terminal, arabinose-binding, dimerization domain (residues 1–170) connected via a flexible linker to a C-terminal DNA-binding domain (residues 178–292). Regulation of the *araBAD* operon occurs as follows (Fig. 31-37):

1. In the absence of AraC, RNA polymerase initiates transcription of the *araC* gene in the direction away from its upstream neighbor, *araBAD*. The *araBAD* operon is expressed at a low basal level.

2. When AraC is present, but neither arabinose nor CAP-cAMP (high glucose), AraC binds to *araO<sub>2</sub>* and *araI<sub>1</sub>* via two HTH motifs in each of its subunits. The binding of AraC to *araI<sub>1</sub>* prevents RNAP from initiating transcription of the *araBAD* operon (negative control). A series of deletion mutations indicate that the presence of *araO<sub>2</sub>* is also required for the repression of *araBAD*. The remarkably large 210-bp separation between *araO<sub>2</sub>* and *araI<sub>1</sub>* therefore

strongly suggests that the DNA between them is looped such that a dimeric molecule of AraC protein simultaneously binds to both *araO<sub>2</sub>* and *araI<sub>1</sub>*. This is corroborated by the observation that the level of repression is greatly diminished by the insertion of 5 bp (half a turn) of DNA between these two sites, thereby transferring *araO<sub>2</sub>* to the opposite face of the DNA helix relative to *araI<sub>1</sub>* in the putative loop. Yet, the insertion of 11 bp (one turn) of DNA has no such effect. Moreover, looping does not readily occur unless the DNA is supercoiled, which presumably drives the looping process. The AraC dimer also binds to *araO<sub>1</sub>*, the operator of the *araC* gene, so as to block the transcription of *araC* but only at high concentrations. Thus, it is likely that DNA looping itself represses the transcription of *araC*. In either case, the expression of *araC* is autoregulatory.

3. When arabinose is present, it allosterically induces the AraC subunit bound to *araO<sub>2</sub>* to instead bind to *araI<sub>2</sub>*. This activates RNAP to transcribe the *araBAD* genes (positive control). When the cAMP level is high (low glucose), CAP-cAMP, whose presence is required to achieve the maximum level of transcriptional activation, binds to a site between *araO<sub>1</sub>* and *araI<sub>1</sub>*, where it functions to help break the loop between *araO<sub>2</sub>* and *araI<sub>1</sub>* and hence to increase the affinity of AraC for *araI<sub>2</sub>*. The orientation of *araO<sub>1</sub>* with respect to *araC* is opposite to that of *araI<sub>1</sub>* with respect to *araBAD*, and hence the binding of AraC-arabinose at *araO<sub>1</sub>* blocks RNAP binding at the *araC* promoter, that is, it represses the expression of AraC.

If the *araI<sub>2</sub>* subsite is mutated so as to increase AraC's affinity for it, arabinose is no longer required for transcriptional activation. This suggests that arabinose does not conformationally transform AraC to an activator but, rather, weakens its binding affinity for *araO<sub>2</sub>*. If the *araI* site is

**Figure 31-37 The mechanism of *araBAD* regulation.** (a) In the absence of AraC, RNAP initiates the transcription of *araC*. *araBAD* is also expressed but at a low basal level. (b) When AraC is present, but not L-arabinose or cAMP, AraC links together *araO*<sub>2</sub> and *araI*<sub>1</sub> to form a DNA loop, thereby repressing both *araC* and *araBAD*. (c) When AraC and L-arabinose are

both present and cAMP is abundant, the resulting AraC–arabinose complex releases *araO*<sub>2</sub> and instead binds *araI*<sub>2</sub>, thereby activating *araBAD* transcription. This process is facilitated by the binding of CAP–cAMP. *araC* is repressed by the binding of AraC–arabinose to *araO*<sub>1</sub>.

turned around or if it is moved upstream so that *araI*<sub>2</sub> does not overlap the *araBAD* promoter, AraC cannot stimulate transcription. Evidently, *AraC* activates RNAP through specific and relatively inflexible protein–protein interactions.

The X-ray structures of the N-terminal domain of AraC (residues 2–178), in both the presence and the absence of arabinose, were determined by Schleif and Cynthia Wolberger. In the presence of arabinose, this domain consists of an 8-stranded  $\beta$  barrel followed by two antiparallel  $\alpha$  helices (Fig. 31-38). Two such domains associate via an antiparallel coiled coil between each of their C-terminal helices to form the protein's dimerization interface. An arabinose molecule binds in a pocket of each  $\beta$  barrel via a network of direct and water-mediated hydrogen bonds with side chains that line the pocket. Residues 7 to 18 of the N-terminal arm lie across the mouth of the sugar-binding pocket (residues 2–6 are disordered), thereby fully enclosing the arabinose. The structure of the N-terminal domain in the absence of arabinose is largely superimposable on that in the complex with arabinose, with the exception that

**Figure 31-38 X-ray structure of *E. coli* AraC in complex with L-arabinose.** The homodimeric protein is viewed along its 2-fold axis with each of its subunits colored in rainbow order from N-terminus (blue) to C-terminus (red). The arabinose is drawn in space-filling form with C green and O red. [Based on an X-ray structure by Robert Schleif and Cynthia Wolberger, Johns Hopkins University. PDBid 2ARC.]

the N-terminal arm is disordered, a not unexpected observation considering that it interacts with bound arabinose via a series of hydrogen bonds.

How does arabinose binding induce the AraC subunit bound at *araO*<sub>2</sub> to instead bind to *araI*<sub>2</sub>? Several lines of evidence indicate that, in the absence of arabinose, AraC's N-terminal arm binds to its DNA-binding domain in a way that favors loop formation: (1) the deletion of the N-terminal arm beyond its sixth residue makes AraC act as if arabinose is present; (2) mutations to surface residues on the DNA-binding domain that presumably eliminate its binding of the N-terminal arm also constitutively activate AraC; and (3) mutations in the DNA-binding domain that weaken the binding of arabinose to the protein, presumably by strengthening the binding of the N-terminal arm, can be suppressed by a second mutation in the N-terminal arm or by the deletion of its five N-terminal residues. Evidently, *the binding of the N-terminal arms to the DNA-binding domains in the absence of arabinose rigidifies the AraC dimer such that it cannot simultaneously bind to the directly repeated araI<sub>1</sub> and araI<sub>2</sub> and hence induce the transcription of araBAD*. This is corroborated by the observations that (1) joining two AraC DNA-binding domains by flexible polypeptide linkers yields proteins that behave like AraC in the presence of arabinose, and (2) a construct consisting of two double-stranded *araI*<sub>1</sub> half-sites flexibly connected by a 24-nt segment of ssDNA binds wild-type AraC with an affinity that is unaffected by arabinose.

## F. *lac* Repressor II: Structure

Here we continue our discussions of the *lac* repressor, but now in terms of the concepts learned in Sections 31-3C–E.

### a. Loop Formation Is Important in the Expression of the *lac* Operon

DNA loop formation, which is now known to occur in numerous bacterial and eukaryotic systems, apparently permits several regulatory proteins and/or regulatory sites on one protein to simultaneously influence transcription initiation by RNAP. In fact, *the lac repressor has three binding sites on the lac operon*: the primary operator (Fig. 31-28), now known as *O*<sub>1</sub>, and two so-called pseudo-operators (previously thought to be nonfunctional evolutionary fossils), *O*<sub>2</sub> and *O*<sub>3</sub>, which are located 401 bp downstream and 92 bp upstream of *O*<sub>1</sub> (within the *lacZ* gene and overlapping the CAP binding site, respectively). Müller-Hill determined the relative contributions of these various operators to the repression of the *lac* operon through the construction of a set of eight plasmids: Each contained the *lacZ* gene under the control of the natural *lac* promoter as well as the three *lac* operators (*O*<sub>1</sub>, *O*<sub>2</sub>, and *O*<sub>3</sub>), which were either active or mutagenically inactive in all possible combinations. When all three operators are active, *lacZ* expression is repressed 1300-fold relative to when all three operators are inactive. The inactivation of only *O*<sub>1</sub> results in almost complete loss of repression whereas the inactivation of only *O*<sub>2</sub> or *O*<sub>3</sub> causes only a ~2-fold loss in repression. However, when *O*<sub>2</sub> and *O*<sub>3</sub> are both inactive, repres-

sion is decreased ~70-fold. These results suggest that efficient repression requires the formation of a DNA loop between *O*<sub>1</sub> and either *O*<sub>2</sub> or *O*<sub>3</sub>. Indeed, such loop formation, and/or the cooperativity of repressor binding arising from it, appears to be a greater contributor to repression than repressor binding to *O*<sub>1</sub> alone, which provides only 19-fold repression.

### b. The *lac* Repressor Is a Dimer of Dimers

Ponzy Lu and Mitchell Lewis determined the X-ray structures of the *lac* repressor alone, in its complex with IPTG, and in its complex with a 21-bp duplex DNA segment whose sequence is a palindrome of the left half of *O*<sub>1</sub> (Fig. 31-28). Each repressor subunit consists of five functional units (Fig. 31-39): (1) an N-terminal DNA-binding domain (residues 1–49) which is known as the “headpiece” because it is readily proteolytically cleaved away from the remaining still tetrameric “core” protein; (2) a hinge helix (residues 50–58) that also binds to the DNA; (3 and 4) a sugar-binding domain (residues 62–333) that is divided into an N-subdomain and a C-subdomain; and (5) a C-terminal tetramerization helix (residues 340–360).

**Figure 31-39** X-ray structure of the *lac* repressor subunit. The DNA-binding domain (the headpiece), which contains an HTH motif, is red, the DNA-binding hinge helix is yellow, the N-subdomain of the sugar-binding domain is light blue, its C-subdomain is dark blue, and the tetramerization helix is purple. [Courtesy of Ponzy Lu and Mitchell Lewis, University of Pennsylvania. PDBid 1LBI.]

The *lac* repressor has an unusual quaternary structure (Fig. 31-40a). Whereas nearly all homotetrameric nonmembrane proteins of known structure have  $D_2$  symmetry (three mutually perpendicular 2-fold axes; Fig. 8-65b), *lac* repressor is a V-shaped protein that has only 2-fold symmetry. Each leg of the V consists of a locally symmetric dimer of closely associated repressor subunits. Two such dimers

**Figure 31-40** The structure of the *lac* repressor in complex with DNA. (a) The X-ray structure of the *lac* repressor tetramer bound to two 21-bp segments of symmetric *lac* operator DNA. The protein subunits are shown in ribbon form in yellow, cyan, green, and orange and the dsDNA segments are drawn in space-filling form with C white, N blue, O red, and P orange. [Courtesy of Ponzy Lu and Mitchell Lewis with coordinates generated by Benjamin Weider, University of Pennsylvania. PDBid 1LBG.] (b) The NMR structure of the 23-bp  $O_1$  *lac* operator DNA in complex with two identical segments of the *lac* repressor consisting of its DNA-binding domain and its hinge helix. Each of the protein subunits is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The DNA is represented in stick form with C white, N blue, O red, and P orange and with successive P atoms in the same chain connected by orange rods. The complex is viewed with its 2-fold axis vertical. Note that the protein dimer's two HTH motifs are inserted in successive major grooves at the periphery of the complex and that the insertion of the two centrally located hinge helices into the DNA's minor groove greatly widens and flattens the minor groove at this point and kinks the DNA in an upward bend. [Based on an NMR structure by Robert Kaptein and Rolf Boelens, Utrecht University, The Netherlands. PDBid 2KEI.]

associate rather tenuously, but with 2-fold symmetry, at the base (point) of the V to form a dimer of dimers.

In the structures of *lac* repressor alone and that of its IPTG complex, the DNA-binding domain is not visible, apparently because the hinge region that loosely tethers it to the rest of the protein is disordered. However, in the DNA complex, in which one DNA duplex binds to each of the two dimers forming the repressor tetramer, the DNA domain forms a compact globule containing three helices, the first two of which form a helix–turn–helix (HTH) motif. The two DNA-binding domains extending from each repressor dimer (at the top of each leg of the V) bind in successive major grooves of a DNA molecule via their HTH motifs, much as is seen, for example, in the complexes of 434 phage repressor and *trp* repressor with their target DNAs (Figs. 31-32 and 31-34). The binding of the *lac* repressor distorts the operator DNA such that it bends away from the DNA-binding domain with an  $\sim 60$  Å radius of curvature due to an  $\sim 45^\circ$  kink at the center of the operator that widens the DNA's minor groove to over 11 Å and reduces its depth to less than 1 Å. These distortions permit the now ordered hinge helix to bind in the minor groove so as to contact the identically bound hinge helix from the other subunit of the same dimer. NMR structures by Robert Kaptein and Rolf Boelens reveal that the DNA-binding domain, when cleaved from the repressor, binds to the *lac* operator without distorting the DNA, but that the DNA-binding domain together with the hinge helix forms a complex with the *lac* operator in which the hinge helix binds in the DNA's distorted minor groove (Fig. 31-40b) as in the X-ray structure. Thus, the binding of the two hinge helices to the *lac* operator appears necessary for DNA distortion. The two DNA duplexes that are bound to each repressor tetramer are  $\sim 25$  Å apart and do not interact.

The sugar-binding domain consists of two topologically similar subdomains that are bridged by three polypeptide segments (Fig. 31-39). The two sugar-binding domains of a dimer make extensive contacts (Fig. 31-40a). IPTG binds to each sugar-binding domain between its subdomains. This does not significantly change the conformations of these subdomains, but it changes the angle between them. Although the hinge helix is not visible in the IPTG complex, model building indicates that, since the dimer's two hinge helices extend from its sugar-binding domains, this conformation change levers apart these hinge helices by 3.5 Å such that they and their attached HTH motifs can no longer simultaneously bind to their operator half-sites. Thus, inducer binding, which is allosteric within the dimer (has a positive homotropic effect; Section 10-4), greatly loosens the repressor's grip on the operator.

The C-terminal helices from each subunit, which are located on the opposite end of each subunit from the DNA-binding portion (at the point of the V), associate to form a bundle of four parallel helices that holds together the two repressor dimers, thereby forming the tetramer (Fig. 31-40a). The allosteric effects of inducer binding within each dimer are apparently not transmitted between dimers.

Moreover, the *E. coli* **purine repressor (PurR)**, which is homologous to the *lac* repressor but lacks its C-terminal helix, crystallizes as a dimer whose X-ray structure closely resembles that of the *lac* repressor dimer. What then is the function of *lac* repressor tetramerization?

Model building suggests that when the *lac* repressor tetramer simultaneously binds to both the  $O_1$  and  $O_3$  operators, the 93-bp DNA segment containing them forms a loop  $\sim 80$  Å in diameter (Fig. 31-41). Furthermore, the CAP–cAMP binding site is exposed on the inner surface of the loop. Adding the CAP–cAMP at its proper position to this model reveals that the  $\sim 90^\circ$  curvature which CAP–cAMP binding imposes on DNA (Fig. 31-31) has the correct direction and magnitude to stabilize the DNA loop, thereby stabilizing this putative CAP–cAMP–*lac* repressor–DNA complex. It may seem paradoxical that the binding of CAP–cAMP, a transcriptional activator, stabilizes the repressor–DNA complex. However, when both glucose and lactose are in short supply, it is important that the bacterium lower its basal rate of *lac* operon expression in order to conserve energy. The binding site (promoter) for RNAP is also located on the inner surface of the loop. Thus, the large size of the RNAP molecule would prevent

it from fully engaging the promoter in this looped complex, thereby maximizing repression.

### c. Combining Genetic and Structural Studies of the *lac* Repressor Reveals Its Allosterically Important Residues

The phenotypes of 4042 point mutations of the *lac* repressor, which encompass nearly all of its 360 residues (making the *lac* repressor the most exhaustively mutationally characterized protein known) have been mapped onto its X-ray structure. Mutations with an  $I^-$  phenotype (*lac* repressors that fail to bind to the *lac* operator, so that  $\beta$ -galactosidase is constitutively synthesized) are located at the *lac* repressor's DNA-binding interface, at its dimer interface, or at internal residues of its inducer-binding core domain. Residues whose mutations result in the  $I^S$  phenotype (S for super-repressed; *lac* repressors that, in the presence of inducer, continue to repress the synthesis of  $\beta$ -galactosidase) appear to be of two types: (1) residues that are in direct contact with the inducer, whose alteration therefore interferes with inducer binding; and (2) residues at the dimer interface that are  $>8$  Å from (not in direct contact with) the inducer-binding site. These latter mutations reveal which residues mediate the *lac* repressor's allosteric mechanism rather than directly binding the inducer or the DNA. Most of the allosterically important residues are located at the dimer interface and are members of the N-subdomain of the core domain, which links the inducer-binding sites to the operator DNA-binding sites. This is consistent with the observation that inducer binding causes a relative twist and translation of the N-subdomain, a movement which is propagated to the hinge helix and DNA-binding domain. This study demonstrates the power of combining genetic analysis with structural studies to elucidate structure–function relationships.

**Figure 31-41** Model of the 93-bp DNA loop formed when *lac* repressor binds to  $O_1$  and  $O_3$ . The proteins are represented by their  $C_\alpha$  backbones and the DNA is drawn in stick form with its sugar–phosphate backbones traced by helical ribbons. The model was constructed from the X-ray structure of the *lac* repressor (magenta) in complex with two 21-bp operator DNA segments (red) and the X-ray structure of CAP–cAMP (blue) in complex with its 30-bp target DNA (cyan; Fig. 31-28). The remainder of the DNA loop was generated by applying a smooth curvature to canonical B-DNA (white) with the  $-10$  and  $-35$  regions of the *lac* promoter highlighted in green. [Courtesy of Ponzy Lu and Mitchell Lewis, University of Pennsylvania.]

### G. *trp* Operon: Attenuation

We now discuss a sophisticated transcriptional control mechanism named **attenuation** through which bacteria regulate the expression of certain operons involved in amino acid biosynthesis. This mechanism was discovered through the study of the *E. coli* ***trp* operon** (Fig. 31-42), which encodes five polypeptides comprising three enzymes that mediate the synthesis of tryptophan from chorismate (Section 26-5Bc). Charles Yanofsky established that the *trp* operon genes are coordinately expressed under the control of the *trp* repressor, a dimeric protein of identical 107-residue subunits that is the product of the *trpR* gene (which forms an independent operon). The *trp* repressor binds L-tryptophan, the pathway's end product, to form a complex that specifically binds to *trp* operator (*trpO*, Fig. 31-43) so as to reduce the rate of *trp* operon transcription 70-fold. The X-ray structure of the *trp* repressor–operator complex (Section 31-3Da) indicates that tryptophan binding allosterically orients *trp* repressor's two symmetry related helix–turn–helix “DNA reading heads” so that they can simultaneously bind to *trpO* (Fig. 31-34). Moreover, the bound tryptophan forms a hydrogen bond to a DNA phosphate group, thereby

**Figure 31-42** A genetic map of the *E. coli trp* operon indicating the enzymes it specifies and the reactions they catalyze. The gene product of *trpC* catalyzes two sequential

reactions in the synthesis of tryptophan. [After Yanofsky, C., *J. Am. Med. Assoc.* **218**, 1027 (1971).]

strengthening the repressor–operator association. Tryptophan therefore acts as a **corepressor**; its presence prevents what is then superfluous tryptophan biosynthesis (SAM similarly functions as a corepressor with the *met* repressor; Fig. 31-35a). The *trp* repressor also controls the synthesis of at least two other operons: the ***trpR* operon** and the ***aroH* operon** (which encodes one of three isozymes that catalyze the initial reaction of chorismate biosynthesis; Section 26-5Bc).

**a. Tryptophan Biosynthesis Is Also Regulated by Attenuation**

The *trp* repressor–operator system was at first thought to fully account for the regulation of tryptophan biosynthesis in *E. coli*. However, the discovery of *trp* deletion mu-

**Figure 31-43** The base sequence of the *trp* operator. The nearly palindromic sequence is boxed and its -10 region is overscored.

tants located downstream from *trpO* that increase *trp* operon expression 6-fold indicated the existence of an additional transcriptional control element. Sequence analysis established that *trpE*, the *trp* operon’s leading structural gene, is preceded by a 162-nucleotide **leader sequence** (*trpL*). Genetic analysis indicated that the new control element is located in *trpL*, ~30 to 60 nucleotides upstream of *trpE* (Fig. 31-42).

When tryptophan is scarce, the entire 6720-nucleotide polycistronic *trp* mRNA, including the *trpL* sequence, is synthesized. As the tryptophan concentration increases, the rate of *trp* transcription decreases as a result of the *trp* repressor–corepressor complex’s consequent greater abundance. Of the *trp* mRNA that is transcribed, however, an increasing proportion consists of only a 140-nucleotide segment corresponding to the 5’ end of *trpL*. *The availability of tryptophan therefore results in the premature termination of trp operon transcription.* The control element responsible for this effect is consequently termed an **attenuator**.

**b. The *trp* Attenuator’s Transcription Terminator Is Masked when Tryptophan Is Scarce**

What is the mechanism of attenuation? The attenuator transcript contains four complementary segments that can form one of two sets of mutually exclusive base-paired

**Figure 31-44** The alternative secondary structures of *trpL* mRNA. The formation of the base paired 2 • 3 (antiterminator) hairpin (right) precludes the formation of the 1 • 2 and 3 • 4 (terminator) hairpins (left) and vice versa. Attenuation results in the premature termination of transcription immediately after

nucleotide 140 when the 3 • 4 hairpin is present. The arrow indicates the mRNA site past which RNA polymerase pauses until approached by an active ribosome. [After Fisher, R.F. and Yanofsky, C., *J. Biol. Chem.* **258**, 8147 (1983).]

hairpins (Fig. 31-44). Segments 3 and 4 together with the succeeding residues comprise a normal intrinsic transcription terminator (Section 31-2Da): a G + C-rich sequence that can form a self-complementary hairpin structure followed by several sequential U's (compare with Fig. 31-18). Transcription rarely proceeds beyond this termination site unless tryptophan is in short supply.

A section of the leader sequence, which includes segment 1 of the attenuator, is translated to form a 14-residue polypeptide that contains two consecutive Trp residues (Fig. 31-44, left). The position of this particularly rare dipeptide segment (1.1% of the residues in *E. coli* proteins are Trp; Table 4-1) provided an important clue to the mechanism of attenuation. An additional essential aspect of this mechanism is that ribosomes commence the translation of a prokaryotic mRNA shortly after its 5' end has been synthesized.

The above considerations led Yanofsky to propose the following model of attenuation (Fig. 31-45). An RNA polymerase that has escaped repression initiates *trp* operon transcription. Soon after the ribosomal initiation site of the *trpL* gene has been transcribed, a ribosome attaches to it and begins translation of the leader peptide. When tryptophan is abundant, so that there is a plentiful supply of **tryptophanyl-tRNA<sup>Trp</sup>** (the transfer RNA specific for Trp with

an attached Trp residue; Section 32-2C), the ribosome follows closely behind the transcribing RNA polymerase so as to sterically block the formation of the 2 • 3 hairpin. Indeed, RNA polymerase pauses past position 92 of the transcript and only continues transcription on the approach of a ribosome, thereby ensuring the proximity of these two entities at this critical position. The prevention of 2 • 3 hairpin formation permits the formation of the 3 • 4 hairpin, the transcription terminator pause site, which results in the termination of transcription (Fig. 31-45a). When tryptophan is scarce, however, the ribosome stalls at the tandem UGG codons (which specify Trp; Table 5-3) because of the lack of tryptophanyl-tRNA<sup>Trp</sup>. As transcription continues, the newly synthesized segments 2 and 3 form a hairpin because the stalled ribosome prevents the otherwise competitive formation of the 1 • 2 hairpin (Fig. 31-45b). The formation of the transcriptional terminator's 3 • 4 hairpin is thereby pre-empted for sufficient time for RNA polymerase to transcribe through it and consequently through the remainder of the *trp* operon. The cell is thus provided with a regulatory mechanism that is responsive to the tryptophanyl-tRNA<sup>Trp</sup> level, which, in turn, depends on the protein synthesis rate as well as on the tryptophan supply.

There is considerable evidence supporting this model of attenuation. The *trpL* transcript is resistant to limited

**Figure 31-45 Attenuation in the *trp* operon.** (a) When tryptophanyl-tRNA<sup>Trp</sup> is abundant, the ribosome translates *trpL* mRNA. The presence of the ribosome on segment 2 prevents the formation of the base-paired 2·3 hairpin. The 3·4 hairpin, an essential component of the transcriptional terminator, can thereby form, thus aborting transcription. (b) When tryptophanyl-

tRNA<sup>Trp</sup> is scarce, the ribosome stalls on the tandem Trp codons of segment 1. This situation permits the formation of the 2·3 hairpin which, in turn, precludes the formation of the 3·4 hairpin. RNA polymerase therefore transcribes through this unformed terminator and continues *trp* operon transcription.

RNase T1 digestion, indicating that it has extensive secondary structure. The significance of the tandem Trp codons in the *trpL* transcript is corroborated by their presence in *trp* leader regions of several other bacterial species. Moreover, the leader peptides of the five other amino acid-biosynthesizing operons known to be regulated by attenuation (most exclusively so) are all rich in their corresponding amino acid residues (Table 31-3). For example, the *E. coli his* operon, which specifies enzymes synthesizing histidine (Fig. 26-65), has seven tandem His residues in its leader peptide whereas the *ilv* operon, which specifies enzymes participating in isoleucine, leucine, and valine biosynthesis

(Fig. 26-61), has five Ile's, three Leu's, and six Val's in its leader peptide. Finally, the leader transcripts of these operons resemble that of the *trp* operon in their capacity to form two alternative secondary structures, one of which contains a trailing termination structure.

#### H. Riboswitches Are Metabolite-Sensing RNAs

We have just seen how the formation of secondary structure in a growing RNA transcript can regulate gene expression through attenuation. The conformational flexibility of mRNA also allows it to regulate genes by directly interacting

with certain cellular metabolites, thereby eliminating the need for sensor proteins such as the *lac* repressor, CAP, and the *trp* repressor.

In *E. coli*, the biosynthesis of thiamine pyrophosphate (TPP; Section 17-3Ba) requires the action of several proteins whose levels vary according to the cell's need for TPP. In at least two of the relevant genes the untranslated regions at the 5' end of the mRNA include a highly conserved sequence called the *thi* box. The susceptibility of the *thi* box to chemical or enzymatic cleavage, as Ronald Breaker showed, differs in the presence and absence of TPP, suggesting that the RNA changes its secondary structure when TPP binds to it (the binding of a metabolite by RNA is not unprecedented; synthetic oligonucleotides known as **ap-tamers** bind specific molecules with high specificity and affinity; Section 7-6C). The TPP-sensing mRNA element has been dubbed a **riboswitch**.

The predicted secondary structure of the TPP-sensing riboswitch and its proposed mechanism are shown in Fig. 31-46a. In the absence of TPP, the mRNA assumes a con-

formation that allows a ribosome to begin translation. In the presence of TPP, an alternative secondary structure masks the sequence that identifies its translational initiation site to the ribosome (its so-called **Shine–Dalgarno sequence**; Section 32-3Cb) so that the ribosome cannot initiate the mRNA's translation. Thus, *the concentration of a metabolite can regulate the expression of genes required for its synthesis*. The X-ray structure of the 80-nt TPP-binding domain from the *E. coli* TPP-sensing riboswitch, determined by Breaker and Dinshaw Patel, reveals an intricately folded RNA that binds TPP in an extended conformation (Fig. 31-46b).

Over 20 classes of riboswitches have as yet been identified, including those that regulate the expression of enzymes involved in the metabolism of coenzyme B<sub>12</sub> (Fig. 25-21), riboflavin (Fig. 16-8), *S*-adenosylmethionine (SAM; Fig. 26-18), lysine, and adenine. In general, they consist of two components, an aptamer that binds an effector and a so-called **expression platform** that transduces effector binding to a change in gene expression. In some cases, the

**Figure 31-46** Structure of the TPP-sensing riboswitch from *E. coli*. (a) The predicted secondary structure of a 165-residue segment at the 5' end of the *thiM* gene is shown in the absence (left) and presence (right) of TPP. The TPP-binding conformation masks the Shine–Dalgarno sequence (orange) required by the ribosome to initiate translation at the AUG start codon (red) just downstream. [After Winkler, W., Nahvi, A., and Breaker, R.R., *Nature* **419**, 952 (2002).] (b) The X-ray structure of the riboswitch's 90-nt TPP-sensing domain. The RNA is drawn in

cartoon form with its sugar–phosphate backbone represented by an orange rod and its bases represented by paddles with C green, N blue, and O red. The TPP is drawn in space-filling form with C cyan, N blue, O red, and S yellow. Mg<sup>2+</sup> ions are represented by lavender spheres. [Based on an X-ray structure by Ronald Breaker, Yale University, and Dinshaw Patel, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 2GDI.]

activated expression platform forms an intrinsic transcription termination site (Section 31-2Da) so that transcription beyond this site proceeds only when the effector is absent. In others, the activated expression platform cleaves itself, thereby inactivating the mRNA (the ability of RNA to act as an enzyme is discussed in Section 31-4Ae).

Riboswitches collectively regulate >2% of the genes in certain bacteria. Plants and fungi also contain riboswitches (although the above TPP-sensing riboswitch could not function in eukaryotes because eukaryotic ribosomes do not bind Shine–Dalgarno sequences; Section 32-3Cd). The fact that the interaction of riboswitches with their effectors does not require the participation of proteins suggests that they are relics of the RNA world (Section 1-5Ca) and hence among the oldest regulatory systems.

### I. Regulation of Ribosomal RNA Synthesis: The Stringent Response

*E. coli* cells growing under optimal conditions divide every 20 min. Such cells contain up to 20,000 ribosomes and hence must synthesize ~10,000 ribosomes per cell division cycle. Yet RNAP can initiate the transcription of an rRNA gene no faster than about once per second. If *E. coli* contained only one copy of each of the three types of rRNA genes (those specifying the so-called 23S, 16S, and 5S rRNAs; Section 32-3A), fast-growing cells could synthesize no more than ~1200 ribosomes during their cell division cycle. However, the *E. coli* genome contains seven separately located rRNA operons, all of which contain one nearly identical copy of each type of rRNA gene. Moreover, rapidly growing cells contain multiple copies of their replicating chromosomes (Section 30-3Cb), thereby accounting for the observed rRNA synthesis rate.

Cells have the remarkable ability to coordinate the rates at which their thousands of components are synthesized. For example, *E. coli* adjust their ribosome content to match the rate at which they can synthesize proteins under the prevailing growth conditions. The rate of rRNA synthesis is therefore proportional to the rate of protein synthesis. One mechanism by which this occurs is known as the **stringent response**: *A shortage of any species of amino acid–charged tRNA (usually a result of “stringent” or poor growth conditions) that limits the rate of protein synthesis triggers a sweeping metabolic readjustment.* A major facet of this change is an abrupt 10- to 20-fold reduction in the rate of rRNA and tRNA synthesis. This **stringent control**, moreover, depresses numerous metabolic processes (including DNA replication and the biosynthesis of carbohydrates, lipids, nucleotides, proteoglycans, and glycolytic intermediates) while stimulating others (such as amino acid biosynthesis). The cell is thereby prepared to withstand nutritional deprivation.

#### a. (p)ppGpp Mediates the Stringent Response

*The stringent response is correlated with a rapid intracellular accumulation of two unusual nucleotides, ppGpp and pppGpp [known collectively as (p)ppGpp], and their prompt decay when amino acids become available.* The ob-

servation that mutants, designated *relA*<sup>−</sup>, which do not exhibit the stringent response (they are said to have **relaxed control**) lack (p)ppGpp suggests that these substances mediate the stringent response. This idea was corroborated by *in vitro* studies demonstrating, for example, that (p)ppGpp inhibits the transcription of rRNA genes but stimulates the transcription of the *trp* and *lac* operons as does the stringent response *in vivo*. Apparently, (p)ppGpp acts by somehow altering RNAP’s promoter specificity at stringently controlled operons, a hypothesis that is supported by the isolation of RNAP mutants that exhibit reduced responses to (p)ppGpp. In addition, (p)ppGpp causes an increased frequency of pausing in RNAPs engaged in elongation, thereby reducing the rate of transcription.

The protein encoded by the wild-type *relA* gene, named **stringent factor (RelA)**, catalyzes the reaction

and, to a lesser extent,

However, several ribosomal proteins convert pppGpp to ppGpp so that ppGpp is the stringent response’s usual effector. Stringent factor is only active in association with a ribosome that is actively engaged in translation. (p)ppGpp synthesis occurs when a ribosome binds its mRNA-specified but uncharged tRNA (lacking an appended amino acid residue). The binding of a specified and charged tRNA greatly reduces the rate of (p)ppGpp synthesis. *The ribosome apparently signals the shortage of an amino acid by stimulating the synthesis of (p)ppGpp which, acting as an intracellular messenger, influences the rates at which a great variety of operons are transcribed.*

(p)ppGpp degradation is catalyzed by the *spoT* gene product. The *spoT*<sup>−</sup> mutants show a normal increase in (p)ppGpp level on amino acid starvation but an abnormally slow decay of (p)ppGpp to basal levels when amino acids again become available. The *spoT*<sup>−</sup> mutants therefore exhibit a sluggish recovery from the stringent response. *The (p)ppGpp level is apparently regulated by the counterbalancing activities of stringent factor and the spoT gene product.*

## 4 POST-TRANSCRIPTIONAL PROCESSING

The immediate products of transcription, the **primary transcripts**, are not necessarily functional entities. In order to acquire biological activity, many of them must be specifically altered in several ways: (1) by the exo- and endonucleolytic removal of polynucleotide segments; (2) by appending nucleotide sequences to their 3′ and 5′ ends; and (3) by the modification of specific nucleosides. The three major classes of RNAs, mRNA, rRNA, and tRNA, are altered in different ways in prokaryotes and in eukaryotes. In this section we shall outline these **post-transcriptional modification** processes.

### A. Messenger RNA Processing

In prokaryotes, most primary mRNA transcripts function in translation without further modification. Indeed, as we have seen, ribosomes in prokaryotes usually commence translation on nascent mRNAs. In eukaryotes, however, mRNAs are synthesized in the cell nucleus, whereas translation occurs in the cytosol. Eukaryotic mRNA transcripts can therefore undergo extensive post-transcriptional processing while still in the nucleus.

#### a. Eukaryotic mRNAs Are Capped

Eukaryotic mRNAs have a peculiar enzymatically appended **cap structure** consisting of a **7-methylguanosine ( $m^7G$ ) residue joined to the transcript's initial (5') nucleoside via a 5'-5' triphosphate bridge (Fig. 31-47). This  $m^7$  cap, which is added to the growing transcript before it is ~30 nucleotides long, defines the eukaryotic translational start site (Section 32-3Cd). A cap may be  $O^2$ -methylated at the transcript's leading nucleoside (**cap-1**, the predominant cap in multicellular organisms), at its first two nucleosides (**cap-2**), or at neither of these positions (**cap-0**, the predominant cap in unicellular eukaryotes). If the leading nucleoside is adenosine (it is usually a purine), it may also be  $N^6$ -methylated.**

Capping involves several enzymatic reactions: (1) the removal of the leading phosphate group from the mRNA's 5' terminal triphosphate group by an **RNA triphosphatase**; (2) the guanylation of the mRNA by **capping enzyme**, which requires GTP and yields the 5'-5' triphosphate bridge and PP<sub>i</sub>; (3) the methylation of guanine by **guanine-7-methyltransferase** in which the methyl group is supplied by *S*-adenosylmethionine (SAM); and possibly (4) the  $O^2$  methylation of the mRNA's first and perhaps its second nucleotide by a SAM-requiring **2'-*O*-methyltransferase**. Both the capping enzyme and the guanine-7-methyltransferase bind to RNAP II's phosphorylated CTD (Section 31-2E). Hence it is likely that capping marks the completion of RNAP II's switch from transcription initiation to elongation.

#### b. Eukaryotic mRNAs Have Poly(A) Tails

Eukaryotic mRNAs, unlike those of prokaryotes, are invariably monocistronic. Moreover, in contrast to the case in bacteria (Section 31-2D), no eukaryotic transcriptional termination sequence has been identified (but see below). In fact, the eukaryotic termination process is imprecise; that is, the primary transcripts of a given structural gene have heterogeneous 3' sequences. Nevertheless, mature eukaryotic mRNAs have well-defined 3' ends; *almost all of them in mammals have 3'-poly(A) tails of ~250 nucleotides (~80 in yeast)*. The poly(A) tails are enzymatically appended to the primary transcripts in two reactions that are mediated by a 500- to 1000-kD complex that consists of at least six proteins:

**1.** A transcript is cleaved to yield a free 3'-OH group at a specific site that is 15 to 25 nucleotides past an AAUAAA sequence and within 50 nucleotides before a

**Figure 31-47** The structure of the 5' cap of eukaryotic mRNAs. It is known as cap-0, cap-1, or cap-2, respectively, if it has no further modifications, if the leading nucleoside of the transcript is  $O^2$ -methylated, or if its first two nucleosides are  $O^2$ -methylated.

U-rich or G + U-rich sequence. The AAUAAA sequence is highly conserved in higher eukaryotes (but not yeast) in which its mutation abolishes cleavage and polyadenylation. The precision of the cleavage reaction has apparently eliminated the need for accurate transcriptional termination. Nevertheless, the identity of the endonuclease that cleaves the RNA is uncertain although **cleavage factors I and II (CFI and CFII)** are required for this process.

**2.** The poly(A) tail is subsequently generated from ATP through the stepwise action of **poly(A) polymerase (PAP)**. This enzyme, which by itself only weakly binds RNA, is recruited by **cleavage and polyadenylation specificity factor (CPSF)** on this heterotetramer's recognition of the AAUAAA sequence, which it does with almost no tolerance for sequence variation. The downstream G + U-rich element is recognized by the heterotrimeric **cleavage stimulation factor (CstF)**, which increases the affinity with which CPSF binds the AAUAAA sequence. However,

once the poly(A) tail has grown to  $\sim 10$  residues, the AAUAAA sequence is no longer required for further chain elongation. This suggests that CPSF becomes disengaged from its recognition site in a manner reminiscent of the way  $\sigma$  factor is released from the transcriptional initiation site once the elongation of prokaryotic mRNA is under way (Section 31-2B). The final length of the poly(A) tail is controlled by **poly(A)-binding protein II (PAB II)**, multiple copies of which bind to successive segments of poly(A). PAB II also increases the processivity of PAP.

Both CPSF and CstF bind to the phosphorylated RNAP II CTD (Section 31-2E); deleting the CTD inhibits polyadenylation. Evidently, the CTD couples polyadenylation to transcription. The mechanism that controls the length of a poly(A) tail is unclear.

PAP is a template-independent RNA polymerase that elongates an mRNA primer with a free 3'-OH group. The X-ray structure of the 530-residue D154A mutant form of yeast PAP (D154 is a catalytically essential active site residue) in complex with  $A_5$  and ATP, determined by Andrew Bohm, reveals that this monomeric protein consists of three domains that form a prominent U-shaped cleft (Fig. 31-48). Hence it has the handlike domain arrangement of template-directed polymerases (Section 30-2Ad). Indeed, PAP's N-terminal domain, which contains the enzyme's active site, is homologous to the palm domain of

**Figure 31-48** X-ray structure of the D154A mutant of yeast poly(A) polymerase (PAP) in complex with  $A_5$  and ATP. PAP is drawn in ribbon form with its N-terminal domain lavender, its central domain yellow-green, and its C-terminal domain light blue. The  $A_5$  and ATP are drawn in stick form with  $A_5$  C white, ATP C cyan, N blue, O red, and P orange. [Based on an X-ray structure by Andrew Bohm, Tufts University School of Medicine. PDBid 2Q66.]

DNA polymerase  $\beta$ , although it forms the thumb side of the cleft rather than its base. PAP's central domain, which forms the base of the cleft, is functionally but not structurally analogous to the fingers domain of template-directed polymerases in that it interacts with the  $\beta$  and  $\gamma$  phosphates of the incoming ATP. However, the C-terminal domain shows no resemblance to a fingers domain. Rather, it is topologically similar to the **RNA-recognition motif [RRM; also known as the RNA-binding domain (RBD)]** that occurs in  $>200$  different RNA-binding proteins (see below). The  $A_5$  binds in the cleft in an extended conformation such that, in contrast to the nucleic acids bound to template-dependent polymerases, its bases are not in contact. However, the 3'-terminal base of the  $A_5$  stacks on the base of the ATP.

In comparison to the X-ray structure of yeast PAP in complex with 3'-dATP, also determined by Bohm, the N-terminal domain in the PAP- $A_5$ -ATP structure has undergone an  $\sim 23^\circ$  hingelike motion toward the C-terminal domain to form a closed conformation resembling that observed in the structure of Taq DNA polymerase I in complex with its substrates (Section 30-2Ae). This motion forms several new interactions, both direct and water-mediated, between PAP and its ATP substrate that helps differentiate adenine from other bases. In contrast, in template-dependent polymerases, the incoming base only makes sequence-specific contacts with the template base (Section 30-2Ae).

*In vitro* studies indicate that a poly(A) tail is not required for mRNA translation. Rather, the observations that an mRNA's poly(A) tail shortens as it ages in the cytosol and that unadenylated mRNAs have abbreviated cytosolic lifetimes suggest that poly(A) tails have a protective role. In fact, the only mature mRNAs that lack poly(A) tails, those of histones (which, with few exceptions, lack the AAUAAA cleavage-polyadenylation signal), have lifetimes of  $<30$  min in the cytosol, whereas most other mRNAs last hours or days. The poly(A) tails are specifically complexed in the cytosol by **poly(A) binding protein (PABP; not related to PAB II)**, which organizes poly(A)-bearing mRNAs into ribonucleoprotein particles. PABP is thought to protect mRNA from degradation as is suggested, for example, by the observation that the addition of PABP to a cell-free system containing mRNA and mRNA-degrading nucleases greatly reduces the rate at which the mRNAs are degraded and the rate at which their poly(A) tails are shortened.

All known PABPs contain four tandem and highly conserved RNA-recognition motifs (RRMs) followed by a less conserved Pro-rich C-terminal segment of variable length. A variety of evidence suggests that PABP's first two RRM support most of the biochemical functions of full-length PABP. The X-ray structure of the first two RRM of human PABP (RRM1/2; the N-terminal 190 residues of this 636-residue protein) in complex with  $A_{11}$ , determined by Stephen Burley, reveals that RRM1/2 forms a continuous trough-shaped surface in which the poly(A) binds in an extended conformation via interactions with conserved

**Figure 31-49** X-ray structure of the N-terminal two RNA-recognition motifs (RRMs) of human PABP in complex with A<sub>11</sub>. RRM1 is cyan, RRM2 is gold, and their linking segment is lavender. The poly(A), only nine of whose nucleotides are observed, is drawn in stick form with C green, N blue, O red, and P magenta. [Based on an X-ray structure by Stephen Burley, The Rockefeller University. PDBid 1CVJ.]

residues (Fig. 31-49). Each RRM, as also seen in the structures of a variety of other RNA-binding proteins, consists of a compact globule made of a 4-stranded antiparallel sheet that forms the RNA-binding surface backed by two helices.

The cleavage of a transcript past its AAUAAA sequence does not, in itself, terminate transcription. However, in yeast, the protein **Rtt103**, which binds to the phosphorylated CTD of RNAP II, recognizes the AAUAAA sequence and recruits the 5' → 3' exonuclease known as **Rat1** (**Xrn2** in humans). Then, in what is termed the **torpedo model**, the highly processive Rat1/Xrn2 loads onto the newly liberated 5' end of the still nascent RNA and rapidly degrades it until it intercepts the RNAP and induces it to terminate RNA synthesis. It has been hypothesized that this occurs in much the same way as Rho factor terminates bacterial transcription (Section 31-2Db). This frees the RNAP to initiate a new round of transcription.

### c. Eukaryotic Genes Consist of Alternating Expressed and Unexpressed Sequences

*The most striking difference between eukaryotic and prokaryotic structural genes is that the coding sequences of*

*most eukaryotic genes are interspersed with unexpressed regions.* Early investigations of eukaryotic structural gene transcription found, quite surprisingly, that primary transcripts are highly heterogeneous in length (from ~2000 to well over 20,000 nucleotides) and are much larger than was expected from the known sizes of eukaryotic proteins. Rapid labeling experiments demonstrated that little of this so-called **heterogeneous nuclear RNA (hnRNA)** is ever transported to the cytosol; most of it is quickly turned over (degraded) in the nucleus. Yet, the hnRNA's 5' caps and 3' tails eventually appear in cytosolic mRNAs. *The straightforward explanation of these observations, that pre-mRNAs are processed by the excision of internal sequences, seemed so bizarre that it came as a great surprise in 1977 when Phillip Sharp and Richard Roberts independently demonstrated that this is actually the case.* In fact, mammalian pre-mRNAs typically contain eight noncoding **intervening sequences (introns)** whose aggregate length averages 4 to 10 times that of their flanking **expressed sequences (exons)**. This situation is graphically illustrated in Fig. 31-50, which is an electron micrograph of chicken **ovalbumin** mRNA hybridized to the antisense strand of the ovalbumin gene (ovalbumin is the major protein component of egg white).

**Figure 31-50** An electron micrograph and its interpretive drawing of a hybrid between the antisense strand of the chicken ovalbumin gene and its corresponding mRNA. The complementary segments of the DNA (purple line in the drawing) and mRNA (red dashed line) have annealed to reveal the exon positions (L, 1–7). The looped-out segments (I–VII), which have no complementary sequences in the mRNA, are the introns. [From Chambon, P., *Sci. Am.* **244**(5), 61 (1981).]

**Figure 31-51** The sequence of steps in the production of mature eukaryotic mRNA as shown for the chicken ovalbumin gene. Following transcription, the primary transcript is capped

and polyadenylated. The introns are then excised and the exons spliced together to form the mature mRNA. However, splicing may also occur cotranscriptionally.

Exons have lengths that range up to 17,106 nt (in the gene encoding the 34,350-residue muscle protein **titin**, the largest known single-chain protein; Section 35-3Ae) but with most <300 nt (and averaging 150 nt in humans). Introns, in contrast, are usually much longer, with lengths averaging ~3500 nt and as high as ~800,000 nt [in the gene encoding the muscle protein **dystrophin** (Section 35-3Ae), whose length is ~2400 kb and hence is the largest human gene] with no obvious periodicity. Moreover, the corresponding introns from genes in two vertebrate species can vary extensively in both length and sequence so as to bear little resemblance to one another. The number of introns in a gene averages 7.8 in the human genome and varies from none to 364 (with the latter number occurring in the gene encoding titin).

The formation of eukaryotic mRNA begins with the transcription of an entire structural gene, including its introns, to form pre-mRNA (Fig. 31-51). Then, following capping, the introns are excised and their flanking exons are

connected, a process called **gene splicing** or just **splicing**, that often occurs cotranscriptionally. *The most striking aspect of gene splicing is its precision; if one nucleotide too few or too many were excised, the resulting mRNA could not be translated properly (Section 32-1B).* Moreover, exons are never shuffled; their order in the mature mRNA is exactly the same as that in the gene from which it is transcribed.

#### d. Exons Are Spliced in a Two-Stage Reaction

Sequence comparisons of exon–intron junctions from a diverse group of eukaryotes indicate that they have a high degree of homology (Fig. 31-52), including, as Richard Breathnach and Pierre Chambon first pointed out, an *invariant GU at the intron's 5' boundary and an invariant AG at its 3' boundary. These sequences are necessary and sufficient to define a splice junction:* Mutations that alter the sequences interfere with splicing, whereas mutations that change a nonjunction to a consensus-like sequence can generate a new splice junction.

**Figure 31-52** The consensus sequence at the exon–intron junctions of vertebrate pre-mRNAs. The subscripts indicate the percentage of pre-mRNAs in which the specified base(s) occurs. Note that the 3' splice site is preceded by a tract of 11

predominantly pyrimidine nucleotides. [Based on data from Padgett, R.A., Grabowski, P.J., Konarska, M.M., Seiler, S.S., and Sharp, P.A., *Annu. Rev. Biochem.* **55**, 1123 (1986).]

Investigations of both cell-free and *in vivo* splicing systems by Argiris Efstratiadis, Tom Maniatis, Michael Rosbash, and Sharp established that intron excision occurs via two transesterification reactions that are remarkably similar from yeast to humans (Fig. 31-53):

**1.** The formation of a 2',5'-phosphodiester bond between an intron adenosine residue and its 5'-terminal phosphate group with the concomitant liberation of the 5' exon's 3'-OH group. *The intron thereby assumes a novel lariat structure.* The adenosine residue at the lariat branch has been identified in yeast as the last A in the highly conserved sequence UACUAAC and in vertebrates as the A in the equivalent but more permissive sequence YNCURAY [where R represents purines (A or G), Y represents pyrimidines (C or U), and N represents any nucleotide]. In yeast and vertebrates, the branch point A occurs ~50 and 18 to 40 residues upstream of the associated 3' splice site, respectively. In yeast, which have relatively few introns, mutations that change this branch point A residue abolish splicing at that site. However, in higher eukaryotes, the mutation or deletion of a branch site often activates a so-called **cryptic branch site** that is also near the 3' splice site. Evidently, the branch site functions to identify the nearest 3' splice site as a target for linkage to the 5' splice site.

**2.** The now free 3'-OH group of the 5' exon forms a phosphodiester bond with the 5'-terminal phosphate of the 3' exon yielding the spliced product and releasing the intron lariat with a free 3'-OH group. The intron lariat is then

debranched (linearized) and, *in vivo*, is rapidly degraded. Mutations that alter the conserved AG at the 3' splice site block this second step, although they do not interfere with lariat formation.

Note that the splicing process proceeds without free energy input; its transesterification reactions preserve the free energy of each cleaved phosphodiester bond through the concomitant formation of a new one.

The sequences required for splicing are the short consensus sequences at the 3' and 5' splice sites and at the branch site. Nevertheless, these sequences are poorly conserved. However, other short sequence elements within exons and introns that are known as **exonic and intronic splicing enhancers (ESEs and ISEs)** and **silencers (ESSs and ISSs)** also play important roles in splice site selection although their characteristics are poorly understood (even highly sophisticated computer programs are only ~50% successful in predicting actual splice sites over apparently equally good candidates that are not). In contrast, large portions of most introns can be deleted without impeding splicing.

#### e. Some Eukaryotic Genes Are Self-Splicing

It is now recognized that there are eight distinct types of introns, seven of which occur in eukaryotes (Table 31-4). **Group I introns** occur in the nuclei, mitochondria, and chloroplasts of diverse eukaryotes (but not vertebrates), and even in some bacteria. Thomas Cech's study of how

**Figure 31-53** The sequence of transesterification reactions that splice together the exons of eukaryotic pre-mRNAs. The exons and introns are drawn in blue and orange, and R and Y represent purine and pyrimidine residues. **(1)** The 2'-OH group of a specific intron A residue nucleophilically attacks the 5'-phosphate at the 5' intron boundary to yield an unusual 2',5'-phosphodiester bond and thus form a lariat structure. **(2)** The liberated 3'-OH group forms a 3',5'-phosphodiester bond with the 5' terminal residue of the 3' exon, thereby splicing the two exons together and releasing the intron in lariat form with a free 3'-OH.

**Table 31-4** Types of Introns

Intron Type	Where Found
GU-AG introns	Eukaryotic nuclear pre-mRNA
AU-AC introns	Eukaryotic nuclear pre-mRNA
Group I	Eukaryotic nuclear pre-mRNA, organelle RNAs, a few bacterial RNAs
Group II	Organelle RNAs, a few prokaryotic RNAs
Group III	Organelle RNAs
Twintrons (composites of two and/or more group II or III introns)	Organelle RNAs
Pre-tRNA introns	Eukaryotic nuclear pre-tRNAs
Archaeal introns	Various RNAs

Source: Brown, T.A., *Genomes* (3rd ed.), Garland Science, p. 355 (2007).

group I introns are spliced in the ciliated protozoan *Tetrahymena thermophila* led to an astonishing discovery: RNA can act as an enzyme. When the isolated pre-rRNA of this organism is incubated with guanosine or a free guanine nucleotide (GMP, GDP, or GTP), but in the absence of protein, its single 421-nucleotide intron excises itself and splices together its flanking exons; that is, this pre-rRNA is self-splicing. The three-step reaction sequence of this process (Fig. 31-54) resembles that of mRNA splicing:

1. The 3'-OH group of the guanosine forms a phosphodiester bond with the intron's 5' end, liberating the 5' exon.
2. The 3'-terminal OH group of the newly liberated 5' exon forms a phosphodiester bond with the 5'-terminal phosphate of the 3' exon, thereby splicing together the two exons and releasing the intron.
3. The 3'-terminal OH group of the intron forms a phosphodiester bond with the phosphate of the nucleotide 15 residues from the intron's 5' end, yielding the 5'-terminal fragment with the remainder of the intron in cyclic form.

This self-splicing process consists of a series of transesterifications and therefore does not require free energy input. Cech further established the enzymatic properties of the

**Figure 31-54** The sequence of reactions in the self-splicing of *Tetrahymena* group I intron. (1) The 3'-OH group of a guanine nucleotide attacks the intron's 5'-terminal phosphate so as to form a phosphodiester bond and release the 5' exon. (2) The newly generated 3'-OH group of the 5' exon attacks the 5'-terminal phosphate of the 3' exon, thereby splicing the two exons and releasing the intron. (3) The 3'-OH group of the intron attacks the phosphate of the nucleotide that is 15 residues from the 5' end so as to cyclize the intron and release its 5'-terminal fragment. Throughout this process, the RNA maintains a folded, internally hydrogen bonded conformation that permits the precise excision of the intron.

*Tetrahymena* intron, which stem from its three-dimensional structure, by demonstrating that it catalyzes the *in vitro* cleavage of poly(C) with an enhancement factor of  $10^{10}$  over the rate of spontaneous hydrolysis. Indeed, this RNA catalyst even exhibits Michaelis–Menten kinetics ( $K_M = 42 \mu\text{M}$  and  $k_{\text{cat}} = 0.033 \text{ s}^{-1}$  for  $C_5$ ). Such RNA enzymes have been named **ribozymes**.

Although the idea that an RNA can have enzymatic properties may seem unorthodox, *there is no fundamental reason why an RNA, or any other macromolecule, cannot have catalytic activity* (recall that it was likewise once generally accepted that nucleic acids lack the complexity to carry hereditary information; Section 5-2). Of course, in order to be an efficient catalyst, a macromolecule must be able to assume a stable structure but, as we shall see below and in Sections 32-2B and 32-3Ae, RNAs, including tRNAs and rRNAs, can do so. In fact, the *Tetrahymena* intron undergoes a series of well-defined conformational changes during its reaction sequence. [Synthetic ssDNAs are also known to have catalytic properties although such **deoxyribozymes** are unknown in biology.]

The **group II introns**, which occur in the mitochondria of fungi and plants and comprise the majority of the introns in chloroplasts, are also self-splicing. They generally employ an internal A residue as their initial attacking nucleophile (instead of an external G) to form a lariat intermediate, a process that resembles the splicing of nuclear pre-mRNAs (Fig. 31-53). We shall see below that nuclear pre-mRNA splicing is mediated by complex ribonucleoprotein particles known as **spliceosomes**. The chemical similarities of the pre-mRNA and group II intron splicing reactions therefore suggest that *spliceosomes are ribozymal systems whose RNA components have evolved from primordial self-splicing RNAs and that their protein components serve mainly to fine-tune ribozymal structure and function*. Similarly, the RNA components of ribosomes, which are two-thirds RNA and one-third protein, clearly have a catalytic function in addition to the structural and recognition roles traditionally attributed to them (Section 32-3). Thus, the observations that nucleic acids but not proteins can direct their own synthesis, that cells contain batteries of protein-based enzymes for manipulating DNA but relatively few for processing RNA, and that many coenzymes are ribonucleotides (e.g., ATP,  $\text{NAD}^+$ , and CoA), led to the hypothesis that *RNAs were the original biological catalysts in precellular times (the RNA world) and that the chemically more versatile proteins were relative latecomers in macromolecular evolution (Section 1-5Ca)*.

#### f. The X-Ray Structures of a Group I Ribozyme

Group I introns are the most abundant self-splicing introns, with >2000 such sequences known. The sequence of the 413-nt *Tetrahymena* group I intron, together with phylogenetic comparisons, indicates that it contains nine double helical segments that are designated P1 through P9 (Fig. 31-55a; P for base-paired segment). Such analysis further indicates that the conserved catalytic core of group I introns consists of sets of coaxially stacked helices inter-

spersed with internal loops that are organized into two domains, the P4-P5-P6 domain (also called P4-P6) and the P3-P7-P8-P9 domain (also called P3-P9).

Cech designed a 247-nt RNA (Fig. 31-55a) that encompasses both the P4-P6 and P3-P9 domains of the *Tetrahymena* group I intron (it lacks the P1-P2 domain and the attached exons), with the addition of a 3' G ( $\omega\text{G}$ ), which functions as an internal guanosine nucleophile. This RNA is catalytically active; it binds the P1-P2 domain via tertiary interactions and, with the assistance of  $\omega\text{G}$ , cleaves P1 in a manner similar to the intact intron.

The X-ray structure of this RNA (Fig. 31-55b,c) reveals that it is largely composed of three coaxially stacked sets of A-RNA-like helices with P4-P6 consisting of two pseudo-continuous and straight parallel helices connected by a sharp bend and P3-P9 consisting of a curved helix that wraps around one side of P4-P6 through extensive interdomain interactions that form the ribozyme's active site. Of particular note are its so-called A-rich bulge, a 7-nt sequence about halfway along the short arm of the U-shaped P4-P6, and the 6-nt sequence at the tip of the short arm of the U, whose central GAAA assumes a characteristic conformation known as a **tetraloop**. In both of these substructures, the bases are splayed outward so as to stack on each other and to associate in the minor groove of specific segments of the long arm of the U via hydrogen bonding interactions involving ribose residues as well as bases. In many such interactions, the close packing of phosphate groups is mediated by hydrated  $\text{Mg}^{2+}$  ions. Throughout this structure, the defining characteristic of RNA, its 2'-OH group, is both a donor and an acceptor of hydrogen bonds to phosphates, bases, and other 2'-OH groups. Interestingly, although this overall fold is highly conserved among group I introns, their sequences are poorly conserved with the exception of a few crucial active site residues.

In the initial reaction catalyzed by group I ribozymes, the 3'-OH group of  $\omega\text{G}$  nucleophilically attacks the phosphate group linking the 5' exon to the ribozyme (Fig. 31-54). But how is only this 3'-OH group activated as a nucleophile? The binding site for the  $\omega\text{G}$  substrate is composed of four coplanar base triples with the  $\omega\text{G}$ -G264-C311 triple sandwiched by three other base triples (Fig. 31-56). Consequently, the base of  $\omega\text{G}$  is stacked between those of A261 and C262 (Fig. 31-56a), which stabilizes the binding of  $\omega\text{G}$  to this site through base stacking.

Divalent metal ions, usually  $\text{Mg}^{2+}$ , are often required for both the structural stability and the catalytic activity of ribozymes. Unfortunately, the relatively low (3.8 Å) resolution of the ribozyme X-ray structure precluded the direct observation of  $\text{Mg}^{2+}$  ions (which have the same number of electrons as water molecules). However, there is good evidence that the heavy metal ions (Eu and Ir) used to solve the X-ray structure occupied many of the same positions in the ribozyme as do  $\text{Mg}^{2+}$  ions and moreover, several of these sites were observed to contain  $\text{Mg}^{2+}$  ions in other group I introns whose X-ray structures are known. In particular, an  $\text{Mg}^{2+}$  ion is in contact with the 2'-OH group of  $\omega\text{G}$  as well as being liganded by the phosphate groups of

**Figure 31-55** The group I intron from *Tetrahymena thermophila*. (a) The secondary structure of the 414-nt ribozyme. Its P4-P6 and P3-P9 domains are shaded in blue and green, respectively, with the catalytically active 3'  $\omega$ G residue shaded in yellow, the base triples of the P7 domain shaded in red, and the A-rich bulge, the tetraloop, and the tetraloop receptor on the P4-P6 domain shaded in brown, pink, and cyan, respectively. Watson-Crick and non-Watson-Crick base pairing interactions are represented by short horizontal lines and small filled circles, whereas interdomain interactions are indicated by magenta lines. Every tenth residue is marked by an outwardly pointing dash. The positions of five residues that have been mutated to stabilize the ribozyme structure are circled and those of the seven mutations that facilitated crystallization are bracketed (this mutant form retains its catalytic activity). (b) The X-ray structure of the ribozyme, drawn in cartoon form with its bases shown as paddles, and colored as in Part a. The inferred positions of  $Mg^{2+}$  ions are represented by orange spheres. (c) As in Part b but rotated  $140^\circ$  about the vertical axis to better show the A-rich bulge and the interaction between the tetraloop and the tetraloop receptor. three surrounding nucleotides. This both orients the ribose group of  $\omega$ G and nucleophilically activates its 3'-OH group. Biochemical studies indicate that a second  $Mg^{2+}$  ion, which accompanies the phosphate group of the RNA

substrate, also participates in the catalytic reaction. Note that two  $Mg^{2+}$  ions similarly participate in the phosphoryl-transfer reactions catalyzed by protein enzymes such as DNA polymerase (Section 30-2Af).

(a) Side view of the four coplanar base triples at the ribozymal active site in P7 (colored in red in Fig. 31-55). The sugar-phosphate backbone is drawn in stick form and the bases are drawn in paddle form. The nucleotides at each level have the same color with the exception of the C413- $\omega$ G dinucleotide, which is yellow. (b) Top view of the base triple interactions between  $\omega$ G and the G264 · C311 base pair. (c) Top view of the base triple of C262, A263, and G312, which is located above that containing  $\omega$ G. (d) Top view of the base triple of A261, A265, and U310, which is located below that containing  $\omega$ G. [Courtesy of Thomas Cech, University of Colorado. PDB ID 1X8W.]

### g. Hammerhead Ribozymes Catalyze an In-Line Nucleophilic Attack

One of the best-characterized types of ribozymes is the **hammerhead ribozyme**, so called because of the superficial resemblance of its secondary structure, as it was originally laid out, to a hammer. This minimally  $\sim 40$ -nt RNA participates in the replication of certain viruslike RNAs that infect plants and also occurs in schistosomes (species of parasitic flatworms). The hammerhead ribozyme catalyzes the site-specific cleavage of one of its own phosphodiester bonds with an  $\sim 10^7$ -fold rate enhancement. However, it is not a true catalyst because it cannot return to its original state.

The secondary structure of the 63-nt hammerhead ribozyme from *Schistosoma mansoni* has three duplex stems and an active site core of two nonhelical segments (Fig. 31-57a). This ribozyme cleaves itself between its C-17 and C-1.1 nucleotides to yield a cyclic 2',3'-phosphodiester on C-17 with inversion of configuration about the P atom, together with a free 5'-OH on C-1.1, much like the intermediate product in the RNA hydrolysis reaction catalyzed by RNase A (Section 15-1Ab). This suggests that the reaction proceeds via an “in-line” mechanism such as that diagrammed in Fig. 16-6b with the transition state forming a trigonal bipyramidal intermediate in which the attacking

nucleophile, the 2'-OH group (Y in Fig. 16-6b), and the leaving group, which forms the free 5'-OH group (X in Fig. 16-6b), occupy the axial positions.

The X-ray structure of the *S. mansoni* hammerhead ribozyme, determined by William Scott, reveals that its stem II, stem III and the terminal end of stem I are coaxially stacked. The remainder of stem I curves around in a manner that more closely resembles the handle of a suitcase than that of a hammer to form a junction with stems II and III that contains the ribozyme's active site core (Fig. 31-57b). The nucleotides in the helical stems mainly form normal Watson-Crick base pairs, whereas the nucleotides of the active site core participate in non-Watson-Crick base pairs. This explains the observations that most helical positions can be occupied by any Watson-Crick base pair but that few core bases can be changed without significantly reducing ribozymal activity.

The bases of the active site core participate in a hydrogen bonded network (Fig. 31-57c). This helps position C-17 such that its O2' atom is properly oriented for an in-line

**Figure 31-57** Structure of the *Schistosoma mansoni* hammerhead ribozyme. (a) The sequence and schematic structural organization of the ribozyme colored to match the X-ray structure drawn in Part b. Base pairs and tertiary interactions are represented by dashes and dotted lines, respectively. Nucleotides are labeled according to the universal numbering system for hammerhead ribozymes. (b) X-ray structure of the ribozyme drawn in paddle form with C atoms the same color as in Part a except that those of G-12 are light green and those of C-1.1 are light blue, N blue, O red, and P orange. Adjacent P atoms in the same strand are connected by thin orange rods. The P atom of the scissile phosphate group (bridging C-17 and C-1.1) and the nucleophile (O2' of C-17) are represented by small spheres. (c) The ribozyme's active site residues, which are drawn in stick form with C green, O red, N blue, and P orange. Hydrogen bonds are represented by dashed black lines. The proposed reaction mechanism is indicated by the curved arrows with the dotted black line marking the in-line trajectory taken by atom O2' of C-17 in nucleophilically attacking the P atom of the scissile phosphate group. [Part a courtesy of and Parts b and c based on an X-ray structure by William Scott, University of California at Santa Cruz. PDBid 2GOZ.]  See **Interactive Exercise 43**

nucleophilic attack on the P atom that links atom O3' of C-17 to atom O5' of C-1.1. The N1 of the invariant G-12 when deprotonated and the 2'-OH of the invariant G-8 appear to be properly positioned to respectively act as base and acid catalysts in this reaction (Fig. 31-57c), which strongly suggests that the reaction occurs via a concerted acid-base catalyzed mechanism. This reaction mechanism does not involve the participation of metal ions and none are observed in the ribozyme's catalytic core. However, in solution, the presence of divalent metal ions provides an ~50-fold enhancement rate over the presence of only monovalent metal ions. Perhaps divalent metal ions stabilize the negative charge on the trigonal bipyramidal intermediate (Fig. 16-6b) and/or they may help position and orient reactive groups.

#### h. Splicing of Pre-mRNAs Is Mediated by snRNPs in the Spliceosome

How are the splice junctions of pre-mRNAs recognized and how are the two exons to be joined brought together in the splicing process? Part of the answer to this question was established by Joan Steitz going on the assumption that one nucleic acid is best recognized by another. The eukaryotic nucleus, as has been known since the 1960s, contains numerous copies of several highly conserved 60- to 300-nucleotide RNAs called **small nuclear RNAs**

(snRNAs), which form protein complexes termed **small nuclear ribonucleoproteins (snRNPs; pronounced “snurps”)**. Steitz recognized that the 5' end of one of these snRNAs, **U1-snRNA** (so called because it is a member of a U-rich subfamily of snRNAs), is partially complementary to the consensus sequence of the 5' splice site. The consequent hypothesis, that *U1-snRNA recognizes the 5' splice site*, was

**Figure 31-58** An electron micrograph of spliceosomes in action. A *Drosophila* gene that is ~6 kb long enters from the upper left of the micrograph and exits at the lower left. Transcription initiates near the point marked by an asterisk. The growing RNA chains appear as fibrils of increasing lengths that emanate from the DNA. The transcripts are undergoing cotranslational splicing as revealed by the progressive formation and loss of intron loops near the 5' ends of the RNA transcripts (arrows). The beads at the base of each intron loop as well as elsewhere on the transcripts are the spliceosomes. The large arrow points to a transcript near the 3' end of the gene that is no longer attached to the DNA template and hence appears to have recently been terminated and released. The bar is 200 nm long. [Courtesy of Ann Beyer and Yvonne Osheim, University of Virginia.]

corroborated by the observations that splicing is inhibited by the selective destruction of the U1-snRNA sequences that are complementary to the 5' splice site or by the presence of anti-U1-snRNP antibodies (produced by patients suffering from **systemic lupus erythematosus**, an often fatal autoimmune disease). Three other snRNPs are also implicated in splicing: **U2-snRNP**, **U4–U6-snRNP** (in which the **U4-** and **U6-snRNAs** associate via base pairing), and **U5-snRNP**.

Splicing takes place in an as yet poorly characterized ~2700 kD particle dubbed the **spliceosome** (Fig. 31-58). The spliceosome brings together a pre-mRNA, the foregoing four snRNPs, and a variety of pre-mRNA binding proteins. Note that the spliceosome, which consists of 5 RNAs and ~150 polypeptides, is comparable in size and complexity to the ribosome (which in *E. coli* consists of 3 RNAs and 52 polypeptides with an aggregate mass of ~2500 kD; Section 32-3A).

In addition to its size and complexity, the spliceosome is a highly dynamic entity, with its various components associating and dissociating during specific stages of the splicing reaction (Fig. 31-59), while undergoing a variety of ATP-driven conformational changes. For example, to carry out the first transesterification reaction yielding the lariet structure (Fig. 31-53), the spliceosome undergoes a complex series of rearrangements that are schematically diagrammed in Fig. 31-60. Similarly extensive rearrangements are required to carry out the second transesterification reaction and to recycle the spliceosome for subsequent splicing reactions.

Although spliceosomal transesterification reactions were initially assumed to be mediated by protein catalysts, their chemical resemblance to the reactions carried out by the self-splicing group II introns suggests, as is noted above, that it is really the snRNAs that catalyze the splicing of pre-mRNAs (pre-mRNA introns have such varied sequences outside of their splice and branch sites that they are unlikely to play an active role in splicing). In fact, James Manley has shown that, in the absence of protein, segments of human U2- and U6-snRNAs catalyze an  $Mg^{2+}$ -dependent reaction in an intron branch site sequence-containing RNA that resembles splicing's first transesterification reaction.

#### i. Splicing Also Requires the Participation of Splicing Factors

Around 170 different proteins known as **splicing-associated factors** that are extrinsic to spliceosomes also participate in splicing, with individual assembly intermediates (e.g., complexes A, B, and C in Fig. 31-59) each associated with ~125 such proteins. Among them are **branch point-binding protein [BBP; also known as splicing factor 1 (SF1)]** and **U2-snRNP auxiliary factor (U2AF)**, which cooperate to select the intron's branch point. U2AF binds to the polypyrimidine tract upstream of the 3' splice site (Fig. 31-52), whereas BBP recognizes the nearby branch point sequence (Figs. 31-53 and 31-60). The NMR structure of the 131-residue RNA-binding segment of the 638-residue BBP in complex with an 11-nt RNA containing a branch

**Figure 31-59 The spliceosomal assembly/disassembly cycle.** The sequential actions of the spliceosomal snRNPs (colored circles), but not the non-snRNP proteins, are diagrammed in the process of excising an intron from a pre-RNA containing two exons (blue). Here 5'SS, BP, and 3'SS stand for the pre-mRNA's 5' splice site, its branch point, and its 3' splice site, respectively.

Eight conserved DExD/H box-containing RNA-dependent RNA ATPases/helicases as well as the GTPase **Snu114** act in specific steps of the splicing cycle to motivate RNA-RNA rearrangements and RNP remodeling reactions. [Courtesy of Reinhard Lührmann, Max-Planck-Institut für biophysikalische Chemie, Göttingen, Germany.]

**Figure 31-60 Schematic diagram of six rearrangements that the spliceosome undergoes in mediating the first transesterification reaction in pre-mRNA splicing.** The RNA is color coded to indicate segments that become base-paired. The black and green lines represent snRNA and pre-mRNA, and BBP stands for branch point-binding protein. U5, which participates in the second transesterification reaction, has been omitted for clarity. (1) Exchange of U1 for U6 in base pairing to the intron's 5' splice site. (2) Exchange of BBP for U2 in binding to the intron's branch site. (3) Intramolecular rearrangement in

U2. (4) Disruption of a base-paired stem between U4 and U6 to form a stem-loop in U6. (5) Disruption of a second stem between U4 and U6 to form a stem between U2 and U6. (6) Disruption of a stem-loop in U2 to form a second stem between U2 and U6. The order of these rearrangements is unclear. The transesterification reaction is represented by the arrow from the A in the yellow segment of the pre-mRNA (right panel) to the 3' end of the 5' exon. [Adapted from Staley, J.P. and Guthrie, C., *Cell* **92**, 315 (1998).]

**Figure 31-61** The NMR structure of the RNA-binding portion of human branch point-binding protein (BBP) in complex with its target RNA. The 11-nt RNA contains the sequence 5'-UAUACUAACAA-3' in which the branch site sequence for both yeast and vertebrates is underlined and the branch point A is in bold. The protein is drawn in cartoon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The RNA is drawn in paddle form with C green except for the C atoms of the branch point A, which are yellow, N blue, and O red and with successive P atoms connected by an orange rod. The branch point O2' is represented by a small red sphere. [Based on an NMR structure by Michael Sattler, European Molecular Biology Laboratory, Heidelberg, Germany. PDBid 1K1G.]

point sequence, determined by Michael Sattler, reveals that the RNA assumes an extended conformation and is largely buried in a groove that is lined with both aliphatic and basic residues (Fig. 31-61). The branch point adenosine, whose mutation abolishes BBP binding, is deeply buried and binds to BBP via hydrogen bonds that mimic Watson-Crick base pairing with uracil.

Other splicing factors include **SR proteins** and several members of the **heterogeneous nuclear ribonucleoprotein (hnRNP)** family. SR proteins each have one or more RRM (RNA recognition motifs) near their N-terminus and a distinctive C-terminal **RS domain** that contains numerous Ser-Arg (SR) repeats and which participates in protein-protein interactions. SR proteins, when appropriately phosphorylated on their RS domains, specifically bind to their corresponding exonic splicing enhancers (ESEs) via their RRMs and thereby recruit the splicing machinery to the flanking 5' and 3' splice sites. The hnRNP proteins, which are highly abundant RNA-binding proteins, lack RS domains and hence cannot recruit the splicing machinery. Instead, they bind to their corresponding ESSs and ISSs (exonic and intronic splicing silencers) so as to block the binding of the splicing machinery at the flanking splice sites.

A simplistic interpretation of Fig. 31-53 suggests that any 5' splice site could be joined with any following 3' splice site, thereby eliminating all the intervening exons together with the introns joining them. However, such **exon skipping** does not normally take place (but see below). Rather, all of a pre-mRNA's introns are individually excised in what appears to be a largely fixed order that more or less proceeds in the 5' → 3' direction. This occurs, at least in part, because splicing takes place cotranscriptionally (Fig. 31-58). Thus, as a newly synthesized exon emerges

from an RNAP II, it is bound by splicing factors that are also bound to the RNAP II's highly phosphorylated C-terminal domain (CTD; Section 31-2E). This tethers the exon and its associated spliceosome to the CTD so as to ensure that splicing occurs when the next exon emerges from the RNAP II.

#### j. Spliceosomal Structures

All four snRNPs involved in pre-mRNA splicing contain the same so-called **snRNP core protein**, which consists of seven **Sm proteins** (so called because they react with autoantibodies of the Sm serotype from patients with systemic lupus erythematosus), which are named **B, D1, D2, D3, E, F, and G proteins**. Each of these Sm proteins contains two conserved segments, Sm1 and Sm2, that are separated by a linker of variable length. The seven Sm proteins collectively bind to a conserved RNA sequence, the **Sm RNA motif**, which occurs in U1-, U2-, U4-, and U5-snRNAs and which has the single-stranded sequence AAUU-UGUG. However, in the absence of a U-snRNA, the Sm proteins form three stable complexes D1-D2, D3-B, and E-F-G. None of these complexes alone bind U-snRNA. However, the D1-D2 and E-F-G complexes form a stable subcore snRNP with U-snRNA, to which D3-B binds to form the complete **Sm core domain**.

The X-ray structures of the D3-B and D1-D2 heterodimers, determined by Reinhard Lührmann and Kiyoshi Nagai, reveals that these four proteins share a common fold which consists of an N-terminal helix followed by a 5-stranded antiparallel  $\beta$  sheet that is strongly bent so as to form a hydrophobic core (Fig. 31-62a). The subunits of both dimers associate in a similar manner with the  $\beta$ 5 strands of D3 and D1 binding to the  $\beta$ 4 strands of B and D2, respectively, so as to join their  $\beta$

**Figure 31-62** X-ray structures of Sm proteins. (a) The structure of D3 protein. The N-terminal helix and the  $\beta$  strands of its Sm1 domain are red and blue and the  $\beta$  strands of its Sm2 domain are yellow. The B, D1, and D2 Sm proteins have similar structures with their L4 loops and N-terminal segments, including helix A, comprising their most variable portions. Several highly conserved residues are shown in stick form (with C gray, N blue, and O red), and a conserved hydrogen bonding network is represented by green dotted lines. (b) The D3–B dimer with D3 gold and B blue. The  $\beta 5$  strand of D3 associates with the  $\beta 4$  strand of B to form a continuous antiparallel  $\beta$  sheet. Note that their corresponding loops extend in similar directions. [Courtesy of Kiyoshi Nagai, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1D3B.]

sheets (Fig. 31-62b). This, together with biochemical and mutagenic experiments, indicates that the Sm proteins form a closed heteroheptameric ring whose subunits are arranged in the order –B–D3–G–E–F–D2–D1–. This model is corroborated by the X-ray structure of an Sm-like protein from the hyperthermophilic archeon *Pyrobaculum aerophilum*, determined by David Eisenberg, that forms a homoheptameric ring that is structurally similar to the heteroheptameric model. This structure also supports the hypothesis that the seven eukaryotic Sm proteins arose through a series of duplications of an archaeal Sm-like protein gene.

Mammalian U1-snRNP consists of U1-snRNA and ten proteins, the seven Sm proteins that are common to all U-snRNPs as well as three that are specific to U1-snRNP: **U1-70K**, **U1-A**, and **U1-C** (437, 282, and 159 residues, respectively, in humans). The predicted secondary structure of the 165-nt U1-snRNA contains five double helical stems, four of which come together at a 4-way junction (Fig. 31-63a). U1-70K and U1-A bind directly to RNA stem-loops 1 and 2 (SL1 and SL2), respectively, whereas U1-C is bound by other proteins.

Nagai determined the X-ray structure of human U1 snRNP at 5.5 Å resolution. At this low resolution the major and minor grooves of the double-stranded RNA stems are visible. Moreover, the helices and sheets of the proteins are apparent, which allows the placement of protein folds of known structure. SL2 of the U1-snRNA had been altered and shortened to promote crystallization. This eliminated the binding site for U1-A. However, U1 snRNP in which U1-A is depleted is active in a splicing assay.

SL1 and SL2 are stacked coaxially as are SL3 and helix H, and these two stacked helices cross at an angle of  $\sim 90^\circ$ . The Sm proteins form the predicted heteroheptameric ring, which is  $\sim 70$  Å in diameter (Fig. 31-63b). The Sm RNA motif together with SL4 are threaded through the ring's funnel-shaped central hole such the Sm RNA motif interacts with the Sm proteins (Fig. 31-63c). U1-C associates with the Sm ring via an interaction between its zinc finger domain and the D3 subunit (Fig. 31-63c). An RRM in the C-terminal segment of U1-70K interacts with the loop of SL1 and this protein's N-terminal segment is draped across the external face of the Sm ring.

Fortuitously, the 5' ends of two neighboring U1-snRNAs in the crystal form a double helical segment. Since, in the spliceosome, the 5' end of U1-snRNA base-pairs with the 5' splice site of the pre-RNA (Fig. 31-60), this interaction provides a model of how the spliceosome recognizes the 5' splice site. The zinc finger domain of U1-C interacts with this double helix (left side of Fig. 31-63c) and presumably stabilizes it. This is consistent with the observation that mutants of U1-C in this region cannot initiate spliceosome formation (the first reaction in Fig. 31-59).

Difficulties in obtaining homogeneous preparations of spliceosomal subassemblies and their poor stabilities have hindered their crystallization and limited the resolution of their cryo-EM-based images. Nevertheless, the cryo-EM-based structures of a variety of spliceosomal components have been reported. For example, the  $\sim 40$ -Å resolution structure of human complex B after it has released U1-snRNP but before it has released U4-snRNP (Fig. 31-59) was determined by Lüthmann and Holger

**Figure 31-63** X-ray structure of human U1-snRNP. (a) The predicted secondary structure of U1-snRNA with the RNA segments at which the proteins U1-70K and U1-A bind indicated.  $\Psi$  is the symbol for pseudouridine residues (Section 30-5Be). (b) View of the X-ray structure along the axis of the Sm ring. The proteins are drawn in ribbon form in different colors and the RNA is shown in paddle form in gray. SL4 has been deleted for clarity. The yellow spheres represent the selenium atoms in selenoMet residues (Met with its S atom replaced by Se), which were mutagenically inserted into the proteins to aid in solving the structure. Their known positions in the polypeptide chains helped trace the polypeptides' paths. (c) The structure as viewed from above in Part a. The  $\text{Zn}^{2+}$  ion bound to the zinc finger motif of U1-C is represented by a green sphere. The 5' terminal portion of the U1-snRNA forms a double helical segment with the 5' end of a neighboring U1-snRNA, which is drawn in paddle form in purple. [Part a modified from a drawing by, and Parts b and c courtesy of, Kiyoshi Nagai, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 3CW1.]

Stark (Fig. 31-64). This  $370 \times 270 \times 170 \text{ \AA}$  particle, which is named B $\Delta$ U1, has a roughly triangular body connected to a head domain. Other spliceosome components are equally irregular.

### k. The Significance of Gene Splicing

The analysis of the large body of known DNA sequences reveals that introns are rare in prokaryotic structural genes, uncommon in lower eukaryotes such as yeast (which has a total of 239 introns in its  $\sim 6600$  genes and, with two exceptions, only one intron per polypeptide), and abundant in higher eukaryotes (the only known vertebrate structural genes lacking introns are those encoding histones and the antiviral proteins known as interferons). Pre-mRNA introns, as we have seen, can be quite long and many genes contain large numbers of them. Consequently, unexpressed sequences constitute  $\sim 80\%$  of a typical vertebrate structural gene and  $\sim 99\%$  of a few of them.

**Figure 31-64** Cryo-EM-based structure of the human spliceosome at its B $\Delta$ U1 stage of assembly/disassembly at  $40 \text{ \AA}$  resolution. The bar represents  $100 \text{ \AA}$ . [Courtesy of Holger Stark, Max-Planck Institute for Biophysical Chemistry, Göttingen, Germany.]

The argument that introns are only molecular parasites (**junk DNA**) seems untenable since it would then be difficult to rationalize why the evolution of complex splicing machinery offered any selective advantage over the elimination of the split genes. What then is the function of gene splicing? Although, since its discovery, the significance of gene splicing has been often vehemently debated, two important roles for it have emerged: (1) It is an agent for rapid protein evolution; and (2) through **alternative splicing**, it permits a single gene to encode several (sometimes many) proteins that may have significantly different functions. In the following paragraphs, we discuss these aspects of gene splicing.

### I. Many Eukaryotic Proteins Consist of Modules That Also Occur in Other Proteins

The 839-residue LDL receptor is a plasma membrane protein that functions to bind low-density lipoprotein (LDL) to coated pits for transport into the cell via endocytosis (Section 12-5Bc). LDL receptor's 45-kb gene contains 18 exons, most of which encode specific functional domains of the protein. *Moreover, 13 of these exons specify polypeptide segments that are homologous to segments in other proteins:*

1. Five exons encode a 7-fold repeat of a 40-residue sequence that occurs once in **complement C9** (an immune system protein; Section 35-2F).
2. Three exons each encode a 40-residue repeat similar to that occurring four times in **epidermal growth factor**

(**EGF**; Section 19-3A) and once each in three blood clotting system proteins: **factor IX**, **factor X**, and **protein C** (Section 35-1).

3. Five exons encode a 400-residue sequence that is 33% identical with a polypeptide segment that is shared only with EGF.

Evidently, the LDL receptor gene is modularly constructed from exons that also encode portions of other proteins. Numerous other eukaryotic proteins are similarly constituted including, as we have seen, many of the proteins involved in signal transduction (e.g., those containing SH2 and SH3 domains; Section 19-3C). Moreover, many exons encode complete domains that frequently have independent functions. *It therefore appears that the genes encoding these modular proteins arose by the stepwise collection of exons that were assembled by (aberrant) recombination between their neighboring introns.*

### m. Alternative Splicing Greatly Increases the Number of Proteins Encoded by Eukaryotic Genomes

*The expression of numerous cellular genes is modulated by the selection of alternative splice sites.* Thus, certain exons in one type of cell may be introns in another. For example, a single rat gene encodes seven tissue-specific isoforms (splice variants) of the muscle protein  **$\alpha$ -tropomyosin** (Section 35-3Ca) through the selection of alternative splice sites (Fig. 31-65).

**Figure 31-65** The organization of the rat  $\alpha$ -tropomyosin gene and the seven alternative splicing pathways that give rise to cell-specific  $\alpha$ -tropomyosin isoforms. The thin kinked lines indicate the positions occupied by the introns before they are spliced out to form the mature mRNAs. Tissue-specific exons are indicated together with the amino acid (aa) residues they encode: “constitutive” exons (those expressed in all tissues) are

green, those expressed only in smooth muscle (SM) are brown, those expressed only in striated muscle (STR) are purple, and those variably expressed are yellow. Note that the smooth and striated muscle exons encoding amino acid residues 39 to 80 are mutually exclusive; likewise, there are alternative 3'-untranslated (UT) exons. [After Breitbart, R.E., Andreadis, A., and Nadal-Ginard, B., *Annu. Rev. Biochem.* **56**, 481 (1987).]

Alternative splicing occurs in all metazoa and is especially prevalent in vertebrates. In fact, microarray-based comparisons of the cDNAs obtained from various tissues indicate that ~95% of human structural genes are subject to at least one alternative splicing event. This rationalizes the discrepancy between the ~23,000 genes identified in the human genome (Section 7-2Bc) and earlier estimates that it contains 50,000 to 140,000 structural genes.

The variation in mRNA sequence can take several different forms: Exons can be retained in an mRNA or they can be skipped; introns may be excised or retained; and the positions of 5' and 3' splice sites can be shifted to make exons shorter or longer. Alterations in the transcriptional start site and/or the polyadenylation site can further contribute to the diversity of the mRNAs that are transcribed from a single gene. In a particularly striking example, the *Drosophila* protein **Dscam** (for *Down syndrome cell-adhesion molecule*), which functions in neuronal development, is encoded by 24 exons of which there are 12 mutually exclusive variants of exon 4, 48 of exon 6, 33 of exon 9, and 2 of exon 17 (which are therefore known as **cassette exons**) for total of 38,016 possible isoforms of this protein (compared to ~14,000 identified genes in the *Drosophila* genome). Although it is unknown if all possible Dscam isoforms are produced, experimental evidence suggests that the *Dscam* gene expresses many thousands of them. [Dscam is a membrane-anchored cell-surface protein of the immunoglobulin superfamily. The specific isoform expressed in a given neuron binds to itself but rarely to other isoforms. This permits the neuron to distinguish its own processes (axons and dendrites) from those of other neurons and thereby plays an essential role in neural patterning. However, the precise identity of a given isoform appears to be unimportant.] Clearly, the number of genes in an organism's genome does not by itself provide an adequate assessment of its protein diversity. Indeed, it has been estimated that, on average, each human structural gene encodes three different proteins.

*The types of changes that alternative splicing confers on expressed proteins spans the entire spectrum of protein properties and functions.* Entire functional domains or even single amino acid residues may be inserted into or deleted from a protein, and the insertion of a stop codon may truncate the expressed polypeptide. Splice variations may, for example, control whether a protein is soluble or membrane bound, whether it is phosphorylated by a specific kinase, the subcellular location to which it is targeted, whether an enzyme binds a particular allosteric effector, and the affinity with which a receptor binds a ligand. Changes in an mRNA, particularly in its noncoding regions, may also influence the rate at which it is transcribed and its susceptibility to degradation. Since the selection of alternative splice sites is both tissue- and developmental stage-specific, splice site choice must be tightly regulated in both space and time. In fact, it is estimated that from ~15% to 50% of human genetic diseases are caused by point mutations that result in pre-mRNA splicing defects. Some of these mutations delete functional splice sites, thereby activating nearby pre-existing **cryptic splice sites**. Others generate

new splice sites that are used instead of the normal ones and yet others are in the genes encoding components of the splicing machinery. In addition, tumor progression is correlated with changes in levels of proteins implicated in alternative splice site selection.

How are alternative splice sites selected? Well-understood examples of such processes occur in the pathway responsible for sex determination in *Drosophila*, two of which we discuss here:

1. Exon 2 of *transformer (tra)* pre-mRNA contains two alternative 3' splice sites (which succeed the excised intron), with the proximal (close; to exon 1) site used in males and the distal (far) site used in females (Fig. 31-66a). The region between these two sites contains a Stop codon (UAG). In males, the splicing factor U2AF binds to the proximal 3' splice site to yield an mRNA containing this premature stop codon, which thereby directs the synthesis of truncated and hence nonfunctional **TRA** protein. In females, however, the proximal 3' splice site is bound by the female-specific **SXL** protein, the product of the *sex-lethal (sxl)* gene (which is only expressed in females), so as to block the binding of U2AF, which then binds to the distal 3' splice site, thereby excising the UAG and inducing the expression of functional TRA protein (U2AF and TRA both contain RS domains but not RRM's so that neither is an SR protein).

2. In *doublesex (dsx)* pre-mRNA, the first three exons are constitutively spliced in both males and females. However, the branch site immediately upstream of exon 4 has a suboptimal pyrimidine tract to which U2AF does not bind (Fig. 31-66b). Hence in males, exon 4 is not included in *dsx* mRNA, leading to the synthesis of male-specific **DSX-M** protein that functions as a repressor of female-specific genes. However, in females, TRA protein promotes the cooperative binding of the SR protein **RBP1** and the SR-like protein **TRA2** [the product of the *transformer 2 (tra-2)* gene] to six copies of an exonic splice enhancer (ESE) within exon 4. This heterotrimeric complex recruits the splicing machinery to the upstream 3' splice site of exon 4, leading to its inclusion in *dsx* mRNA. The resulting female-specific **DSX-F** protein is a repressor of male-specific genes.

Thus, the synthesis of functional TRA protein involves the repression of a splice site, whereas the synthesis of female-specific DSX-F protein involves the activation of a splice site. Similar mechanisms of alternative splice site selection have been identified in vertebrates.

In general, the decision as to whether an alternative exon is kept or eliminated is determined by the activities and concentrations of its various regulators, many of which are SR proteins and hnRNPs. Hence the tissue-specific expression of these regulators and the phosphorylation state of the SR proteins are important contributors to the complex regulation of mRNA splicing. Moreover, extensive analysis of the sequences of numerous alternative splice sites has revealed the existence of a "splicing code" that uses combinations of over 200 RNA features that are

**Figure 31-66** Mechanisms of alternative splice site selection in the *Drosophila* sex-determination pathway as described in the text. In all panels, exons are represented by colored rectangles and introns are shown as pale gray lines. (a) Alternative splicing in *tra* pre-mRNA. UAG is a Stop codon. (b) Alternative splicing in *dsx* pre-mRNA. The six ESEs (exonic splice enhancers) in

exon 4 are indicated by green rectangles and S represents the splicing machinery. In females, polyadenylation (pA) of *dsx* mRNA occurs downstream of exon 4, whereas in males, it occurs downstream of exon 6. [After a drawing by Maniatis, T. and Tasic, B., *Nature* **418**, 236 (2002).]

present in both introns and exons and which are recognized by the foregoing regulators.

Riboswitches (Section 31-3H) have been implicated in controlling alternative splicing in eukaryotes. For example, as Breaker has shown, in the *NMT1* gene of the bread mold *Neurospora crassa* [which expresses an enzyme that participates in the metabolism of TPP (thiamine pyrophosphate)], a TPP-sensing riboswitch is contained in an intron that is located upstream of the mRNA's normal AUG translational start codon. This intron contains one 3' splice site and two 5' splice sites with two AUG start codons between them. When the concentration of TPP is low so that it does not bind to the riboswitch, one strand of the riboswitch's P4–P5 segment base-pairs with the second (downstream) splice site so as to inactivate it (Fig. 31-67a). The spliceosome then efficiently excises the entire intron yielding an mRNA that is readily translated (I-3; Fig. 31-67b). However, when the concentration of TPP is high so that it binds to the riboswitch, the riboswitch assumes a conformation that activates the second splice site but occludes the branch point A (Fig. 31-67c). Consequently, the spliceosome inefficiently excises only the downstream portion of the intron. The two upstream AUG codons, which are present in both the unspliced mRNA (I-1) and in the spliced mRNA containing only the upstream portion of the intron (I-2), compete for ribosomes with mRNA's normal AUG

start codon and thereby repress the mRNA's translation (Fig. 31-67c).

#### n. AU-AC Introns Are Excised by a Novel Spliceosome

A small fraction of introns (~0.3%) have AU rather than GU at their 5' ends and AC rather than AG at their 3' ends, but are nevertheless excised via a lariat structure to an internal intron A. These so-called **AU-AC introns** (alternatively, **AT-AC introns** after their DNA sequences), which occur in organisms as diverse as *Drosophila*, plants, and humans, are excised by a novel so-called **AU-AC spliceosome** (alternatively, an **AT-AC spliceosome**) that has one snRNP, U5, in common with the major (GU-AG) spliceosome, and three others, **U11**, **U12**, and **U4atac-U6atac**, which are distinct from but structurally and functionally analogous to U1, U2, and U4-U6. Curiously, all genes known to contain AU-AC introns also contain multiple major class introns. Moreover, AU-AC introns are not conserved in either length or position in their host genes. Thus, the functional and evolutionary significance of the AU-AC spliceosome and introns is obscure.

#### o. Trans-Splicing

The types of splicing we have so far considered occur within single RNA molecules and hence are known as

**Figure 31-67** Control of translation by the *N. crassa* TPP-sensing riboswitch through alternative splicing. (a) The predicted secondary structure of the TPP aptamer, which resides in the 5' untranslated region of the *NMT1* mRNA. The sequence of one strand of the P4-P5 stem is complementary (orange shading) to a segment that overlaps the second 5' splice site. (b) At low TPP concentrations, the aptamer inhibits (red tee) splicing from the second 5' splice site while activating (green arrow) the branch point A so that the spliceosome excises the RNA between the first 5' splice site and the 3' splice site, yielding an ORF (open reading frame; I-3) that is normally translated from its AUG start codon. (c) At high TPP concentrations, the binding of TPP to the aptamer activates the second 5' splice site but occludes the branch point A. The spliceosome therefore inefficiently excises the intron's downstream portion yielding an mRNA (I-2) that contains two uORFs (upstream ORFs) that compete with the translation of the primary ORF. The unspliced mRNA (I-1) also contains the two uORFs and hence is likewise inefficiently translated. [Courtesy of Ronald Breaker, Yale University.]

**cis-splicing.** The chemistry of the spliceosomal cis-splicing reaction, however, is the same as would occur if the two exons to be joined initially resided on two different RNA molecules, a process called **trans-splicing**. This, in fact, occurs in trypanosomes (kinetoplastid protozoa; the cause of African sleeping sickness). Trypanosomal mRNAs all have the same 35-nt noncoding leader sequence, although this leader sequence is not present in the corresponding genes. Rather, this sequence is part of a so-called **spliced leader (SL) RNA** that is transcribed from an independent gene. The 5' splice site that succeeds the SL RNA leader sequence, and the branch site and 3' splice site that precede the exon sequence have the same consensus sequences as occur in the RNAs spliced by the major spliceosome. Consequently, the SL RNA leader and the pre-mRNA are joined in a trans-splicing reaction that resembles the spliceosomal cis-splicing reaction (Fig. 31-53) with the exception that the product of the first transesterification reaction is necessarily Y-shaped rather than lariat-shaped (Fig. 31-68). Trypanosomes, whose pre-mRNAs lack introns, nevertheless have U2- and U4-U6-snRNPs but lack U1- and U5-snRNPs. However, the SL RNA, which is predicted to fold into three stem-loops and a single-stranded Sm RNA-like motif as does U1-snRNA (Fig. 31-63a), apparently carries out the functions of U1-snRNA in the trans-splicing reaction.

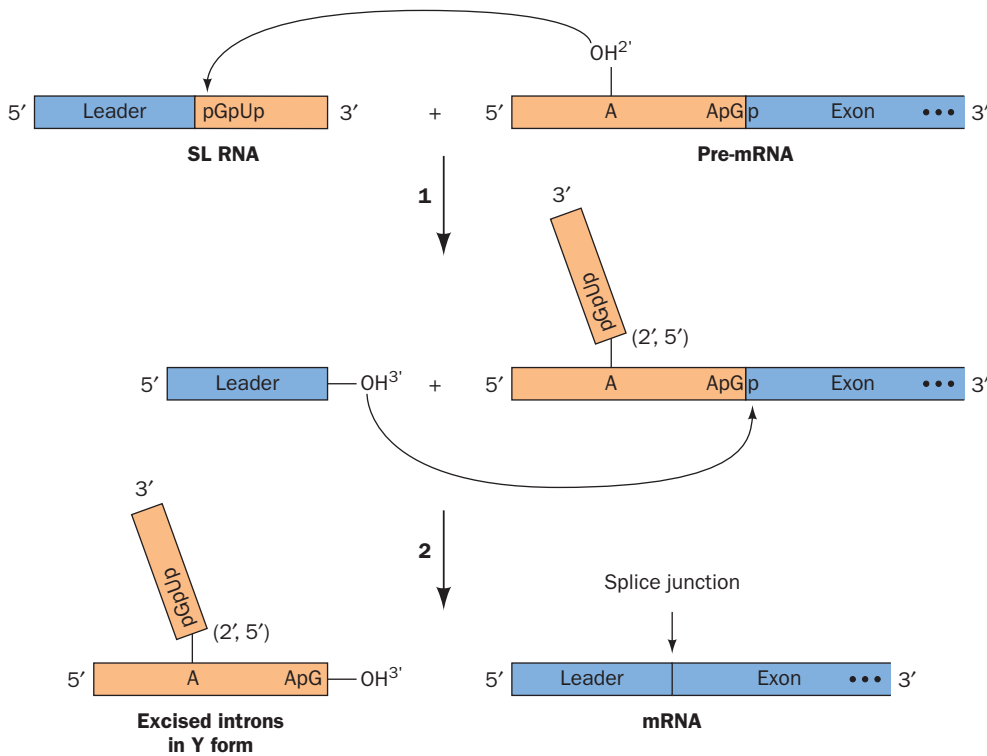

Trans-splicing has been shown to occur in nematodes (roundworms; e.g., *C. elegans*) and flatworms. These organisms also carry out cis-splicing and, indeed, perform both types of splicing on the same pre-mRNA. There are also several reports that trans-splicing occurs in higher eukaryotes such as *Drosophila* and vertebrates, but if it does occur, it does so in only a few pre-mRNAs and at a very low level.

#### p. mRNA Is Methylated at Certain Adenylate Residues

During or shortly after the synthesis of vertebrate pre-mRNAs, ~0.1% of their A residues are methylated at their N6 atoms. These m<sup>6</sup>A's tend to occur in the sequence RRM<sup>6</sup>ACX, where X is rarely G. Although the functional significance of these methylated A's is unknown, it should be noted that a large fraction of them are components of the corresponding mature mRNAs.

#### q. RNA Can Be Edited by the Insertion or Deletion of Specific Nucleotides

Certain mRNAs from a variety of eukaryotic organisms have been found to differ from their corresponding genes in several unexpected ways, including C → U and U → C changes, the insertion or deletion of U residues, and the insertion of multiple G or C residues. The most extreme examples of this phenomenon, which occur in the mitochondria

**Figure 31-68** The sequence of transesterification reaction that occurs in trans-splicing.

The chemistry is closely similar to that of pre-mRNA cis-splicing (Fig. 31-53).

dria of trypanosomes (whose DNA encodes only 20 genes), involve the addition and removal of up to hundreds of U's to and from 12 otherwise untranslatable mRNAs. The process whereby a transcript is altered in this manner is called **RNA editing** because it originally seemed that the required enzymatic reactions occurred without the direction of a nucleic acid template and hence violated the central dogma of molecular biology (Fig. 5-21). Eventually, however, a new class of trypanosomal mitochondrial transcripts called **guide RNAs (gRNAs)** was identified. gRNAs, which consist of 40 to 80 nucleotides, have 3' oligo(U) tails, an internal segment that is precisely complementary

to the edited portion of the pre-edited mRNA (if G · U pairs, which are common in RNAs, are taken to be complementary), and a 10- to 15-nt so-called anchor sequence near the 5' end that is largely complementary in the Watson-Crick sense to a segment of the mRNA that is not edited.

An unedited transcript presumably associates with the corresponding gRNA via its anchor sequence (Fig. 31-69). Then, in a process mediated by the appropriate enzymatic machinery in an ~20S RNP named the **editosome**, the gRNA's internal segment is used as a template to “correct” the transcript, thereby yielding the edited mRNA. Inser-

**Figure 31-69** A schematic diagram indicating how gRNAs direct the editing of trypanosomal pre-edited mRNAs. The red U's in the edited mRNA are insertions and the triangle ( $\Delta$ ) marks a deletion. Several gRNAs may be necessary to direct the

editing of consecutive segments of a pre-edited mRNA. [After Bass, B.L., in Gesteland, R.F. and Atkins, J.F. (Eds.), *The RNA World*, p. 387, Cold Spring Harbor Laboratory Press (1993).]

**Figure 31-70** Trypanosomal RNA editing pathways. The RNAs being edited (*black*) are shown base-paired to the gRNAs (*blue*) with the U's that are (a) inserted by TUTase or (b) deleted by 3'-U-exo drawn in red. The arrowheads indicate the positions that are cleaved by the endonuclease. [After Madison-Antenucci, S., Grams, J., and Hajduk, S.L., *Cell* **108**, 435 (2002).]

tion editing requires at least three enzymatic activities that, somewhat surprisingly, are encoded by nuclear genes (Fig. 31-70a): (1) an endonuclease at a mismatch between the gRNA and the pre-edited mRNA to cleave the pre-edited mRNA on the 5' side of the insertion point; (2) **terminal uridylyltransferase (TUTase)** to insert the new U(s); and (3) an **RNA ligase** to reseal the RNA. Deletion requires similar enzymatic apparatus with the exceptions that the endonuclease cleaves the RNA being edited on the 3' side of the U(s) to be deleted and TUTase is replaced by **3'-U-exonuclease (3'-U-exo)**, which excises the U(s) at the deletion site (Fig. 31-70b). A single gRNA mediates the editing of a block of 1 to 10 sites. Thus, the genetic information specifying an edited mRNA is derived from two or more genes. The functional advantage of this complicated process, either presently or more likely in some ancestral organism, is obscure.

### r. RNA Can Be Edited by Base Deamination

Humans express two forms of **apolipoprotein B (apoB)**: **apoB-48**, which is made only in the small intestine and functions in chylomicrons to transport triacylglycerols from the intestine to the liver and peripheral tissues; and **apoB-100**, which is made only in the liver and functions in VLDL, IDL, and LDL to transport cholesterol from the

liver to the peripheral tissues (Sections 12-5A and 12-5B). ApoB-100 is an enormous 4536-residue protein, whereas apoB-48 consists of apoB-100's N-terminal 2152 residues and therefore lacks the C-terminal domain of apoB-100 that mediates LDL receptor binding.

Despite their differences, both apoB-48 and apoB-100 are expressed from the same gene. How does this occur? Comparison of the mRNAs encoding the two proteins indicates that they differ by a single C → U change: The codon for Gln 2153 (CAA) in apoB-100 mRNA is, in apoB-48 mRNA, a UAA Stop codon. The activity that catalyzes this conversion is a protein: It is destroyed by proteases and protein-specific reagents but not by nucleases. When apoB mRNA is synthesized with [ $\alpha$ - $^{32}$ P]CTP, *in vitro* editing yields a [ $^{32}$ P]UMP residue solely at the editing site. Evidently, the editing activity is a site-specific **cytidine deaminase**. This type of RNA editing differs in character from that in trypanosomal mitochondria, which inserts and deletes multiple U's into mRNAs under the direction of gRNAs. ApoB mRNA editing therefore falls into a different class of RNA editing that is called **substitutional editing**.

The several other known examples of pre-mRNA substitutional editing all occur on pre-mRNAs that encode ion channels and G protein-coupled receptors in nerve tissue. Among them is vertebrate brain **glutamate receptor** pre-mRNA, which undergoes an A → I deamination [where I is inosine (guanosine lacking its 2-amino group), which the translational apparatus reads as G] that transforms a Gln codon (CAG) to that of a functionally important Arg (CIG; normally CGG). The vertebrate enzymes that catalyze such A → I RNA editing of pre-mRNAs, **ADAR1** (1200 residues), **ADAR2** (729 residues), and **ADAR3** (739 residues; ADAR for *adenosine deaminases acting on RNA*), have the curious requirement that their target A residues must be members of RNA double helices that are formed between the editing site and a complementary sequence that is usually located in a downstream intron (Fig. 31-71). Hence, ADAR-mediated editing must precede splicing.

Substitutional editing may contribute to protein diversity. For example, *Drosophila cacophony* pre-mRNA that encodes a voltage-gated Ca<sup>2+</sup> channel subunit contains 10 different substitutional editing sites and hence has the potential of generating 1000 different isoforms in the absence of alternative splicing.

Substitutional editing can also generate alternative splice sites. For example, rat ADAR2 edits its own pre-mRNA by converting an intronic AA dinucleotide to AI, which mimics the AG normally found at 3' splice sites (Fig. 31-53). The consequent new splice site adds 47 nucleotides near the 5' end of the ADAR2 mRNA so as to generate a new translational initiation site. The resulting ADAR2 isozyme is catalytically active but is produced in smaller amounts than that from unedited transcripts, perhaps due to a less efficient translational initiation site. Thus, rat ADAR2 appears to regulate its own rate of expression.

ADAR1 contains an N-terminal Z-DNA-binding domain, Zab, that is composed of two subdomains, Z $\alpha$  and Z $\beta$ . We have seen that in the X-ray structure of Z $\alpha$  in complex with Z-DNA (Fig. 29-3), Z $\alpha$  binds Z-DNA via

**Figure 31-71** The recognition of ADAR editing sites. Both ADAR1 and ADAR2 bind to a 9- to 15-bp double-stranded RNA that is formed between the editing site (orange) on a pre-mRNA exon and a so-called **editing site complementary sequence (ECS; pink)** that is often located in a downstream intron (brown). A represents the adenosine that the ADAR (green) converts to inosine. [After Keegan, L.P., Gallo, A., and O'Connell, M.A., *Nature Rev. Genet.* **2**, 869 (2001).]

sequence-independent complementary surfaces (Section 29-1Bb). What is the function of Zab? Alexander Rich has proposed that since the negative supercoiling of the DNA immediately behind actively transcribing RNAP (Section 31-2Ca) stimulates the transient formation of Z-DNA (recall that Z-DNA has a left-handed helix), Zab targets ADAR1 to genes that are undergoing transcription. This would facilitate rapid A → I editing, which must take place before the next splicing reaction occurs.

### s. RNA Interference Degrades mRNAs

Since the 1990s it has become increasingly clear that noncoding RNAs have important roles in controlling gene expression. One of the first indications of this phenomenon occurred in Richard Jorgensen's attempt to genetically engineer more vividly purple petunias by introducing extra copies of the gene that directs the synthesis of the purple pigment. Surprisingly, the resulting transgenic plants had variegated and often entirely white flowers. Apparently, the purple-making genes somehow switched each other off. Similarly, it is well known that **antisense RNA** (RNA that is complementary to at least a portion of an mRNA) prevents the translation of the corresponding mRNA because ribosomes cannot translate double-stranded RNA.

Yet, injecting **sense RNA** (RNA with the same sequence as an mRNA) into the nematode *Caenorhabditis elegans* also blocks protein production. Since the added RNA somehow interferes with gene expression, this phenomenon is known as **RNA interference (RNAi)**. RNAi is now known to occur in all eukaryotes investigated except baker's yeast.

The mechanism of RNAi began to come to light in 1998 when Andrew Fire and Craig Mello showed that double-stranded RNA (**dsRNA**) was substantially more effective in causing RNAi in *C. elegans* than were either of its component strands alone. RNAi is induced by only a few molecules of dsRNA per affected cell, suggesting that RNAi is a catalytic rather than a stoichiometric effect. Further investigations, in large part in *Drosophila*, have led to the elucidation of the following pathway mediating RNAi (Fig. 31-72):

1. The trigger dsRNA, as Phillip Zamore discovered, is chopped up into ~21- to 25-nt-long double-stranded fragments known as **small interfering RNAs (siRNAs)**, each of

**Figure 31-72** A mechanism for RNA interference (RNAi). See the text for details. ATP is required for Dicer-catalyzed cleavage of RNA and for RISC-associated helicase unwinding of double-stranded RNA. Depending on the species, the mRNA may not be completely degraded.

whose strands has a 2-nt overhang at its 3' end and a 5' phosphate. This reaction is mediated by an ATP-dependent RNase named **Dicer**, a homodimer of ~1900-residue subunits in animals that is a member of the **RNase III** family of double-strand-specific RNA endonucleases.

2. An siRNA is transferred to a 250- to 500-kD multi-subunit complex known as **RNA-induced silencing complex (RISC)**. RISC has at least four protein components, one of which is an ATP-dependent RNA helicase that separates the two strands of the siRNA. The strand whose 5' end has the lower free energy of binding, the **guide RNA**, is bound by the RISC whereas its complementary strand, the **passenger RNA**, is cleaved and discarded. In some species, but apparently not in humans, the original siRNA signal is amplified by the action of an **RNA-dependent RNA polymerase (RdRP)**.

3. The **guide RNA** recruits the RISC complex to an mRNA with the complementary sequence.

4. An RNase III component of RISC known as **Argonaute (AGO; also called Slicer)** cleaves the mRNA opposite the bound guide RNA. The cleaved mRNA is then further degraded by cellular nucleases, thereby preventing its translation.

The X-ray structure of Dicer from the parasitic protozoan *Giardia intestinalis*, determined by Jennifer Doudna, reveals that its shape resembles that of a hatchet, with its two RNase III domains forming the blade and its PAZ domain (named for three proteins in which it is contained, *PIWI*, *Argonaute*, and *Zwille*) forming the base of its handle (Fig. 31-73; Dicers from higher eukaryotes additionally contain an N-terminal DEXD/H box helicase domain and a C-terminal dsRNA-binding domain). The two RNase III domains form an internal heterodimer that resembles the homodimeric structure of bacterial RNase III. Four conserved acidic residues in each RNase III domain bind two  $Mg^{2+}$  ions and hence are postulated to cleave an RNA strand via a two-metal-ion mechanism (Section 30-2Af). The two RNase III active sites are 17.5 Å apart, the width of dsRNA's major groove, and thus appear positioned to cleave the two strands of a bound dsRNA. The PAZ domain specifically binds dsRNA ends that have a 3' two-nt overhang. The distance between this binding site and its closest RNase III domain active site is 65 Å, the length of a 25-bp dsRNA. This explains how Dicer cleaves an ~25-bp segment from the end of dsRNA.

Argonaute proteins consist of four domains: an N-terminal (N), a PAZ, a middle (Mid), and a PIWI (for *P*-element induced *wimpy testis*) domain. The X-ray structures of several bacterial Argonaute proteins reveal that they have a bilobal architecture with the N and PAZ domains forming one lobe and the Mid and PIWI domains forming the other. The PIWI domain has an RNase H fold (RNase H cleaves the RNA strand of an RNA · DNA hybrid helix), which strongly suggests that it mediates Argonaute's "slicer" activity (bacterial Argonautes preferentially bind **guide DNA** over RNA). The X-ray structure of *T. thermophilus* Argonaute in ternary complex with a 21-nt

**Figure 31-73** X-ray structure of Dicer from *G. intestinalis*.

The protein is represented by its molecular surface colored according to its surface charge with red negative, blue positive, and white neutral. Bound  $Mg^{2+}$  ions, which are represented by green spheres, mark the active site of each of the protein's two RNase III domains. A dsRNA has been modeled into the structure with its 3' overhang entering the PAZ domain's binding pocket (*asterisk*). The white arrows point to the dsRNA's scissile phosphate groups. Note that much of the surface to which the anionic dsRNA is presumably bound is positively charged (the calculated surface charge does not take into account the bound  $Mg^{2+}$  ions). [Courtesy of Jennifer Doudna, University of California at Berkeley. PDBid 2FFL.]

guide DNA and a 19-nt target RNA (Fig. 31-74), determined by Patel, reveals that the DNA · RNA hybrid helix binds in the cleft between Argonaute's two lobes with the phosphate group bridging RNA nucleotides 10 and 11 positioned for cleavage at the PIWI active site. The comparison of this structure with those of similar complexes that lack the target RNA or in which the target RNA has 12 or 15 nucleotides indicates that the guide DNA (and presumably the guide RNA in eukaryotes) initially binds to Argonaute with its 3' end in the PAZ binding pocket, but as the hybrid helix lengthens beyond one turn, this 3' end is released, which facilitates further winding of the hybrid helix.

#### t. RNAi Defends against Viral Infection and Regulates Gene Expression

What is the physiological function of RNAi? Since many eukaryotic viruses store and replicate their genomes as RNA (Chapter 33), it seems likely that RNAi arose as a defense against viral infections. Indeed, many plant viruses contain genes that suppress various steps of RNAi and which are essential for pathogenesis. RNAi has also been

**Figure 31-74** X-ray structure of *T. thermophilus* Argonaute in ternary complex with a 21-nt guide DNA and a 19-nt target RNA. The protein is shown in ribbon form with its N, PAZ, Mid, and PIWI domains cyan, magenta, orange, and green, respectively, and with the linkers connecting these domains gray. The guide DNA and target RNA are drawn in stick form in red and blue with their P atoms yellow. Only DNA nucleotides 1 to 16 and RNA nucleotides 2 to 16 are visible. [Courtesy of Dinshaw Patel, Memorial-Sloan Kettering Cancer Center, New York, New York. PDBid 3HK2.]

shown to inhibit the intragenomic spread of retrotransposons (Section 30-6Bh).

A wide variety of eukaryotes, including plants, nematodes, flies, fish, and mammals, use RNAi to control gene expression. Certain mRNAs expressed by these organisms contain ~70-nt, imperfectly base-paired, stem-loop structures that are excised by a 1374-residue RNase III named **Drosha** (Fig. 31-75). The stem-loops are exported from the nucleus to the cytosol where they are cleaved by Dicer to liberate ~22-bp dsRNAs known as **microRNAs (miRNAs)**; so called to differentiate these endogenous RNAs from exogenous siRNAs). The transcripts from which miRNAs are derived are known as **pri-miRNAs** (pri for primary), whereas the stem-loops are called **pre-miRNAs** (pre for precursor). Pre-miRNAs can be located within both the introns and, less commonly, the exons of a pri-miRNA. The miRNAs bind to RISC in which they function to identify the tens to hundreds of mRNAs containing segments that are partially complementary to the miRNA.

The RISC-bound miRNA binds to its targets site, which is usually in the 3' untranslated region (3'UTR) of an

**Figure 31-75** The generation of miRNAs from pri-miRNAs and their RISC-mediated binding to target mRNAs. See the text for details.

mRNA. A lack of perfect complementarity prevents Argonaute from cleaving the mRNA (Argonaute's PIWI domain catalyzes slicing only if there is perfect complementarity to the miRNA's so-called **seed sequence**, which consists of nucleotides 2–8 from its 5' end), and in fact, some species of Argonaute lack the catalytic residues to do so. Instead, miRNA-mediated silencing is thought to occur through the removal of its target mRNA's poly(A) tail or its m<sup>7</sup>G cap, which leads to the mRNA's degradation (Section 31-4Av), and/or the RISC-mediated repression of the target mRNA's translation by interfering with ribosomal initiation (Section 32-3Cd) and sequestering or degrading the mRNA in cytoplasmic granules known as **P bodies** (P for processing).

In 1993, Victor Ambros discovered the first known miRNA, which is encoded by the *lin-4* gene of *C. elegans* (Fig. 31-76a). The *lin-4* gene was known to control the timing of larval development, although it was thought that it encoded a protein that repressed the expression of the *lin-14* gene. In fact, the *lin-4* miRNA is complementary to seven sites on the 3'UTR of the *lin-14* gene, which had previously been shown to mediate the repression of *lin-14* by the *lin-4* gene product. A puzzling observation at the time was that this regulation greatly reduces the amount of LIN-14 protein produced without altering the level of *lin-14* mRNA. These findings were eventually followed by the discovery that the *C. elegans let-7* gene encodes what is now known to be an miRNA (Fig. 31-76b) that controls the transition from larval to adult stages of development. Subsequently, *let-7* homologs were identified in the *Drosophila* and human genomes and *let-7* RNA was detected in these organisms as well as in numerous other animals.

Both the *lin-4* and *let-7* miRNAs were discovered by genetic analyses. However most of the nearly 10,000 miRNAs in plants and animals that are now known, including those in Fig. 31-76c, were identified through bioinformatic approaches (Section 7-4). The known miRNAs are catalogued in the miRBase database (<http://www.mirbase.org/>). Nearly all miRNAs are conserved among closely related animals (e.g., mice and humans) and many are more broadly conserved throughout animal lineages (e.g., over one-third of the 174 *C. elegans* miRNAs have homologs in humans). *The significance of miRNAs is indicated by the fact that humans express over 720 miRNAs that participate in regulating ~30% of their protein-coding genes.*

RNAi has become the method of choice for “knocking out” specific genes in plants and invertebrates. For example, in *C. elegans*, RNAi has been used to systematically inactivate over 16,000 of its ~19,000 protein-coding genes in an attempt to assign a function to each gene. *C. elegans* is particularly amenable to the RNAi approach, since these worms eat *E. coli* cells, and it is relatively easy to genetically engineer the bacterial cells to express double-stranded RNA that becomes part of the worms’ diet. One limitation of the RNAi method is that it permits only the effects of gene inactivation—not gene activation—to be examined.

RNAi is of similar use in mammalian systems, even though mammals lack the mechanisms that amplify silencing in plants and nonvertebrates so that the effects of RNAi in mammals are transient. The exquisite specificity of RNAi may make it possible to prevent viral infections and to silence disease-causing mutant genes such as oncogenes. In fact, experiments have demonstrated that it is possible to use RNAi to block the liver’s inflammatory response to a hepatitis virus, at least in mice, and to prevent HIV replication in cultured human cells. One challenge for the future is to devise protocols for more specific and longer-lasting gene silencing that would make it possible to prevent viral infections or to block the effects of disease-causing mutant genes.

#### u. Mature Eukaryotic mRNAs Are Actively Transported from the Nucleus to the Cytoplasm

The translation of prokaryotic mRNAs is often initiated, as we have seen in Fig. 31-27, before their synthesis is

**Figure 31-76** The predicted stem-loops of some pre-miRNAs. The miRNAs contained in these pre-mRNAs, all of which are from *C. elegans*, are red. (a) *lin-4*, (b) *let-7*, and (c) miR-1 and miR-1\* (in blue), which are largely complementary to each other.

complete. This cannot occur in eukaryotes because the transcription and post-transcriptional processing of eukaryotic mRNAs occurs in the nucleus but their translation takes place in the cytosol. Consequently, mature mRNAs must be transported from the nucleus to the cytoplasm. This is a highly selective process because mature mRNAs comprise only a small fraction of the RNAs present in the nucleus, the remainder being pre-mRNAs, excised introns (which are usually much larger than the exons from which they were liberated), rRNAs, tRNAs, snRNAs, and a variety of RNAs that participate in the processing of rRNAs and tRNAs (Sections 31-4B and 31-4C). Indeed, only ~5% of the RNA that is synthesized ever leaves the nucleus.

How are mature mRNAs recognized and transported? As we have seen, throughout their residency in the nucleus, pre-mRNAs are continually associated with numerous proteins, including those that participate in synthesizing their m<sup>7</sup>G caps and poly(A) tails, and in splicing out their introns. In addition, the **exon junction complex (EJC)**, which consists of four core proteins and several transiently associating proteins, is deposited onto mRNA during the splicing process at a site that is 20 to 24 nt upstream of the splice junction without regard to its sequence. The population of proteins bound to an mRNA changes as the mRNA is processed but some of the proteins, including SR proteins, hnRNPs (Section 31-4Ai), and EJCs remain associ-

ated with mature mRNAs in the nucleus. However, it appears that it is its entire collection of bound proteins rather than any individual protein that serves to identify an mRNA to the nuclear export machinery.

The eukaryotic nucleus (Fig. 1-5) is a double membrane-enveloped organelle that in animals is penetrated by an average of ~3000 pores. These are formed by **nuclear pore complexes (NPCs)**, which are massive (~120,000 kD), 8-fold symmetric assemblies of ~30 different proteins known as **nucleoporins**. NPCs, which have inner diameters of ~90 Å (although this may be expandable to as much as 260 Å), allow the free diffusion of molecules of up to 50 kD, but most macromolecules, including mRNAs in their complexes with proteins, require an active transport process to pass through an NPC. Some of the proteins associated with mature mRNAs bear nuclear export signals that are recognized by a protein receptor that in yeast is named **Dbp5**. This 482-residue DExD/H box protein (Dbp5 stands for *DExD/H box protein 5*) is an ATP-driven RNA helicase that also binds to the NPC. This permits Dbp5 to pull the mRNA out into the cytosol while simultaneously stripping away many of its bound proteins. These proteins are later recycled by returning them to the nucleus through the NPCs.

#### v. mRNA Degradation Is Elaborately Controlled

The synthesis and maturation of mRNAs, as we have seen, are subject to multiple controls. The same is true of their degradation. Indeed, the range of mRNA stability in eukaryotic cells, measured in half-lives, varies from a few minutes to many hours or days. The mRNA molecules themselves contain elements that dictate their decay rates. These elements include the 3' poly(A) tail and the 5' m<sup>7</sup>G cap, which protect against exonucleases, as well as sequences that are located within the coding region.

A major route for mRNA degradation begins with the progressive removal of its poly(A) tail, a process catalyzed by **deadenylases** that are located throughout the cytosol. When the residual poly(A) tail is less than ~10 nt long and hence no longer capable of binding poly(A) binding protein (Section 31-4Ab), the mRNA becomes a substrate for a **decapping enzyme**, which hydrolytically excises the mRNA's m<sup>7</sup>G cap. This is possible because the translational initiation factor **eIF4G** interacts with both poly(A) binding protein and cap binding protein (Section 32-3Cd), thereby circularizing the mRNA so that events at its 3' end can be coupled to events at its 5' end. The decapped and deadenylated mRNA is then degraded by exonucleases, mainly the 1706-residue 5' → 3' exonuclease **Xrn1** and the 3' → 5' exonuclease complex named the **exosome**. A decapping enzyme, 5' → 3' exonucleases, and accessory proteins form P bodies (Section 31-4At) that function to either degrade mRNA or store it in an inactive form.

Proteins that bind to **AU-rich elements (AREs)** in the 3' untranslated region of mRNAs also appear to increase or decrease the rate of mRNA degradation, although their exact action is poorly understood. RNA secondary structure and RNA-binding proteins, which may be susceptible to modification by cellular signaling pathways, are thought to play a role in regulating mRNA stability.

The eukaryotic core exosome consists of single copies of nine different subunits. Its X-ray structure (Fig. 31-77), de-

termined by Christopher Lima, reveals that six of these subunits, **Rpr41** (Rpr for *rRNA processing*; the exosome was discovered as an activity that processed the 3' ends of rRNAs), **Rrp42**, **Mtr3**, **Rrp43**, **Rrp46**, and **Rrp45**, form a six-membered ring with the remaining three subunits, **Rrp4**, **Csl4**, and **Rrp40**, bound to the same face of this ring. These subunits are arranged such that the core exosome contains an ~9-Å-wide central channel that allows the entrance of only single-stranded RNAs.

The archeal exosome appears to be a simpler version of the eukaryotic core exosome. Its six-membered ring consists of only two types of subunits, Rrp41 and Rrp42, that alternate around the ring, with three copies of Rrp4 bound to the same face of the ring. Only Rrp41 contains an active site although Rrp42 is required for activity. Not surprisingly, eukaryotic Rrp4, Mtr3, and Rrp46 are homologs of archeal Rrp41, eukaryotic Rrp42, Rrp43, and Rrp45 are homologs of archeal Rrp42, and eukaryotic Rrp4, Csl4, and Rrp40 are homologs of archeal Rrp4. Nevertheless, despite the fact that each of its core subunits are essential for viability, eukaryotic core exosomes, from yeast to humans, are catalytically inactive due to changes in active site residues relative to their archeal homologs. However, the core exosome associates with two 3'-exonucleases, **Rrp6** and **Rrp44**, whose catalytically inactive mutants are individually viable in yeast but lethal in combination. Moreover, the core exosome interacts with numerous mostly multisubunit cofactors that carry out a variety of RNA processing activities in both the nucleus and the cytosol. Thus, the eukaryotic core exosome appears to be a structural platform upon which many RNA processing enzymes can be mounted.

**Figure 31-77** X-ray structure of the human core exosome. The protein complex is drawn in ribbon form embedded in its semitransparent molecular surface, with each of its nine different subunits separately colored. The view is toward the face of the six-membered ring of subunits opposite that to which the three other subunits bind. [Based on an X-ray structure by Christopher Lima, Sloan-Kettering Institute, New York, New York. PDBid 2NN6.]

## B. Ribosomal RNA Processing

The seven *E. coli* rRNA operons all contain one (nearly identical) copy of each of the three types of rRNA genes (Section 32-3A). Their polycistronic primary transcripts, which are ~5500 nucleotides in length, contain 16S rRNA at their 5' ends followed by the transcripts for 1 or 2 tRNAs, 23S rRNA, 5S rRNA, and, in some rRNA operons, 1 or 2 more tRNAs at the 3' end (Fig. 31-78). The steps in processing these primary transcripts to mature rRNAs were elucidated with the aid of mutants defective in one or more of the processing enzymes.

The initial processing, which yields products known as **pre-rRNAs**, commences while the primary transcript is still being synthesized. It consists of specific endonucleolytic cleavages by **RNase III**, **RNase P**, **RNase E**, and **RNase F** at the sites indicated in Fig. 31-78. The base sequence of the primary transcript suggests the existence of several base-paired stems. The RNase III cleavages occur in a stem consisting of complementary sequences flanking the 5' and 3' ends of the 23S segment (Fig. 31-79) as well as that of the 16S segment. Presumably, certain features of these stems constitute the RNase III recognition site.

The 5' and 3' ends of the pre-rRNAs are trimmed away in secondary processing steps (Fig. 31-78) through the action of **RNases D**, **M16**, **M23**, and **M5** to produce the mature rRNAs. These final cleavages only occur after the pre-rRNAs become associated with ribosomal proteins.

### a. Ribosomal RNAs Are Methylated

During ribosomal assembly, the 16S and 23S rRNAs are methylated at a total of 24 specific nucleosides. The methylation reactions, which employ *S*-adenosylmethionine (Section 26-3Ea) as a methyl donor, yield  $N^6,N^6$ -dimethyladenine and  $O^2$ -methylribose residues.  $O^2$ -methyl groups may protect adjacent phosphodiester bonds from degradation by intracellular RNases (the mechanism of RNase hydrolysis involves utilization of the free 2'-OH group of ribose to eliminate the

substituent on the 3'-phosphoryl group via the formation of a 2',3'-cyclic phosphate intermediate; Figs. 5-3 and 15-3). However, the function of base methylation is unknown.

### b. Eukaryotic rRNA Processing Is Guided by snoRNAs

The eukaryotic genome typically has several hundred tandemly repeated copies of rRNA genes that are contained in small, dark-staining nuclear bodies known as **nucleoli** (the site of rRNA transcription and processing and ribosomal subunit assembly; Fig. 1-5; note that nucleoli are not membrane enveloped). The primary rRNA transcript is an ~7500-nucleotide 45S RNA that contains, starting from its 5' end, the 18S, 5.8S, and 28S rRNAs separated by spacer sequences (Fig. 31-80). In the first stage of its processing, 45S RNA is specifically methylated at numerous sites (106 in humans) that occur mostly in its rRNA sequences. About 80% of these modifications yield  $O^2$ -methylribose residues and the remainder form methylated bases such as  $N^6,N^6$ -dimethyladenine and 2-methylguanine. In addition, many pre-rRNA U's (95 in humans) are converted to pseudouridines ( $\Psi$ 's) (Section 30-5Be), which may contribute to the rRNA's tertiary stability through hydrogen bonding involving its newly acquired ring NH group. The subsequent cleavage and trimming of the 45S RNA superficially resembles that of prokaryotic rRNAs. In fact, enzymes exhibiting RNase III- and RNase P-like activities occur in eukaryotes. The 5S eukaryotic rRNA is separately processed in a manner resembling that of tRNA (Section 31-4C).

The methylation sites in eukaryotic rRNAs occur exclusively within conserved domains that are therefore likely to participate in fundamental ribosomal processes. Indeed, the methylation sites generally occur in invariant sequences among yeast and vertebrates although the methylations themselves are not always conserved. These methylations do not appear to have a consensus structure

**Figure 31-78** The post-transcriptional processing of *E. coli* rRNA. The transcriptional map is shown approximately to scale. The labeled arrows indicate the positions of the various nucleolytic cuts and the nucleases that generate them. [After

Apiron, D., Ghora, B.K., Plantz, G., Misra, T.K., and Gegenheimer, P., in Söll, D., Abelson, J.N., and Schimmel P.R. (Eds.), *Transfer RNA: Biological Aspects*, p. 148, Cold Spring Harbor Laboratory Press (1980).]

corresponding amino acid is appended in the amino acid-charged tRNA. The **anticodon** (which is complementary to the codon specifying the tRNA's corresponding amino acid) occurs in the loop of the cloverleaf structure opposite the stem containing the terminal nucleotides.

The *E. coli* chromosome contains ~60 tRNA genes. Some of them are components of rRNA operons (Section 31-4B); the others are distributed, often in clusters, throughout the chromosome. The primary tRNA transcripts, which contain from one to as many as four or five identical tRNA copies, have extra nucleotides at the 3' and 5' ends of each tRNA sequence. The excision and trimming of these tRNA sequences resemble those for *E. coli* rRNAs (Section 31-4B) in that both processes employ some of the same nucleases.

### a. RNase P Is a Ribozyme

RNase P, which generates the 5' ends of tRNAs (Fig. 31-78), is a particularly interesting enzyme because it has, in *E. coli*, a 377-nucleotide RNA component (~125 kD vs 14 kD for its 119-residue protein subunit) that is essential for its enzymatic activity. The enzyme's RNA was, quite understandably, first proposed to function in recognizing the sub-

strate RNA through base pairing and to thereby guide the protein subunit, which was presumed to be the actual nuclease, to the cleavage site. However, Sidney Altman demonstrated that *the RNA component of RNase P is, in fact, the enzyme's catalytic subunit* by showing that protein-free RNase P RNA catalyzes the cleavage of substrate RNA at high salt concentrations. RNase P protein, which is basic, evidently functions at physiological salt concentrations to electrostatically reduce the repulsions between the polyanionic ribozyme and substrate RNAs. The argument that trace quantities of RNase P protein are really responsible for the RNase P reaction was disposed of by showing that catalytic activity is exhibited by RNase P RNA that has been transcribed in a cell-free system. RNase P activity occurs in eukaryotes (nuclei, mitochondria, and chloroplasts) as well as in prokaryotes although eukaryotic nuclear RNase P's have 9 or 10 protein subunits, none of which are related to the bacterial protein. Indeed, RNase P

**Figure 31-82** Structure of the RNA component of *T. maritima* RNase P. (a) Its sequence and secondary structure. The various segments (P for paired region, J for joining region, and L for loop) are shown in different colors. The black lines indicate major interactions that are observed in the X-ray structure, dashes indicate Watson-Crick base pairs, and small

filled circles represent non-Watson-Crick base pairs. (b) Its X-ray structure, which is colored as in Part a. Of its 338 nucleotides, 309 are visible. The lower view is related to the upper view by a 90° rotation about the horizontal axis. [Courtesy of Alfonso Mondragón, Northwestern University. PDBid 2A2E.]

mediates one of the two ribozymal activities that occur in all cellular life, the other being associated with ribosomes (Section 32-3Dg).

The X-ray structures of the RNA components of RNase P from *Thermotoga maritima* (338 nt) and *Bacillus stearothermophilus* (417 nt), which were independently determined by Alfonso Mondragón and Norman Pace, reveal that these ribozymes consist mainly of stacked helical stems with overall compact structures typical of protein enzymes (Fig. 31-82). Biochemical studies and modeling indicate that the RNase active site lies in a cleft between the P2/P3 region (cyan in Fig. 31-82) and the P1/P4/P5 region (dark blue in Fig. 31-82). That portion of the structure encompassing P1 through P4, P9 through P11, J11-12 and J12-11 is present in all known RNase P's and hence is known as the universal minimum consensus structure. This structure was presumably present in the primordial RNase P.

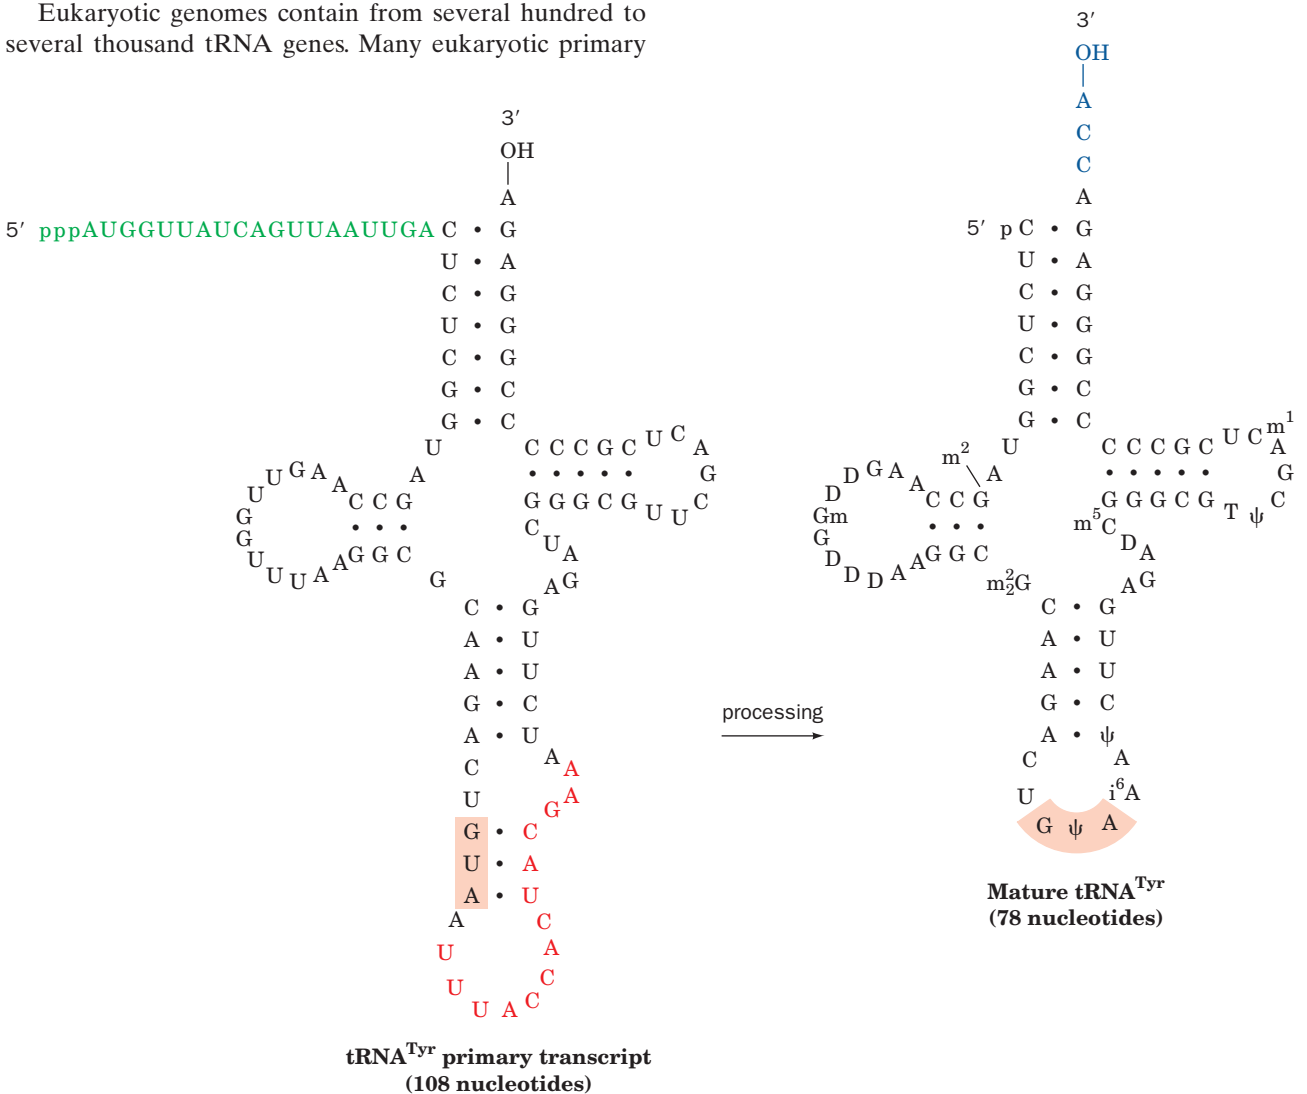

**b. Many Eukaryotic Pre-tRNAs Contain Introns**

Eukaryotic genomes contain from several hundred to several thousand tRNA genes. Many eukaryotic primary

tRNA transcripts, for example, that of yeast tRNA<sup>Tyr</sup> (Fig. 31-83), contain a small intron adjacent to their anticodons as well as extra nucleotides at their 5' and 3' ends. Note that this intron is unlikely to disrupt the tRNA's cloverleaf structure.

**c. The -CCA Ends of Eukaryotic tRNAs Are Post-Transcriptionally Appended**

Eukaryotic tRNA transcripts lack the obligatory —CCA sequence at their 3' ends. This is appended to the immature tRNAs by the enzyme **CCA-adding polymerase**, which sequentially adds two C's and an A to tRNA using CTP and ATP as substrates. This enzyme also occurs in prokaryotes, although, at least in *E. coli*, the tRNA genes all encode a —CCA terminus. The *E. coli* CCA-adding polymerase is therefore likely to function in the repair of degraded tRNAs.

**Figure 31-83** The post-transcriptional processing of yeast tRNA<sup>Tyr</sup>. A 14-nucleotide intervening sequence (red) and a 19-nucleotide 5'-terminal sequence (green) are excised from the primary transcript, a —CCA (blue) is appended to the 3' end,

and several of the bases are modified (their symbols are defined in Fig. 32-13) to form the mature tRNA. The anticodon is shaded. [After DeRobertis, E.M. and Olsen, M.V., *Nature* 278, 142 (1989).]

## CHAPTER SUMMARY

**1 The Role of RNA in Protein Synthesis** The central dogma of molecular biology states that “DNA makes RNA makes protein” (although RNA can also “make” DNA). There is, however, enormous variation among the rates at which the various proteins are made. Certain enzymes, such as those of the *lac* operon, are synthesized only when the substances whose metabolism they catalyze are present. The *lac* operon consists of the control sequences *lacP* and *lacO* followed by the tandemly arranged genes for  $\beta$ -galactosidase (*lacZ*), galactoside permease (*lacY*), and thiogalactoside transacetylase (*lacA*). In the absence of inducer, physiologically allolactose, the *lac* repressor, the product of the *lacI* gene, binds to operator (*lacO*) so as to prevent the transcription of the *lac* operon by RNA polymerase. The binding of inducer causes the repressor to release the operator that allows the *lac* structural genes to be transcribed onto a single polycistronic mRNA. The mRNAs transiently associate with ribosomes so as to direct them to synthesize their encoded polypeptides.

**2 RNA Polymerase** The holoenzymes of bacterial RNA polymerases (RNAPs) have the subunit structure  $\alpha_2\beta\beta'\omega\sigma$ . They initiate transcription on the antisense (template) strand of a gene at a position designated by its promoter. In *E. coli* the most conserved region of the promoter is centered at about the  $-10$  position and has the consensus sequence TATAAT. The  $-35$  region is also conserved in efficient promoters. DMS footprinting studies indicate that the RNAP holoenzyme forms an open initiation complex with the promoter in which the template and nontemplate DNA strands are separated to form an  $\sim 14$ -nt transcription bubble. RNAPs have the shape of a crab claw. In the elongation complex, the template strand in the transcription bubble passes through a tunnel in the core enzyme to the active site, where it pairs with incoming ribonucleotides. The RNA product exits the enzyme through a channel between its  $\beta$  and  $\beta'$  subunits. In the closed complex of the bacterial RNAP holoenzyme, the  $\sigma$  subunit, which extends along the “top” of the holoenzyme, makes all the sequence-specific contacts with the promoter. After the initiation of RNA synthesis, the  $\sigma$  subunit dissociates from the core enzyme, which then autonomously catalyzes chain elongation in the  $5' \rightarrow 3'$  direction. RNA synthesis is terminated by a segment of the transcript that forms a G + C-rich hairpin with an oligo(U) tail that spontaneously dissociates from the DNA. Termination sites that lack these sequences require the assistance of Rho factor for proper chain termination.

In the nuclei of eukaryotic cells, RNAPs I, II, and III, respectively, synthesize rRNA precursors, mRNA precursors, and tRNAs + 5S RNA. The structure of yeast RNAP II resembles that of bacterial RNAPs but is somewhat larger and has more subunits. The structure of its transcribing complex reveals a one-turn segment of RNA · DNA hybrid helix at the active site, which is in contact with the solvent via a pore leading into a funnel through which NTPs presumably pass. RNAPs can hydrolytically correct their mistakes with the aid of TFIIIS in eukaryotes and GreA and GreB in bacteria. The minimal RNA polymerase I promoter extends between nucleotides  $-31$  and  $+6$ . Many RNA polymerase II promoters contain a conserved TATAAAA sequence, the TATA box, located around position  $-27$ . Enhancers are transcriptional activators that can have variable positions and orientations rela-

tive to the transcription start site. RNA polymerase III promoters are located within the transcribed regions of their gene between positions  $+40$  and  $+80$ .

**3 Control of Transcription in Prokaryotes** Prokaryotes can respond rapidly to environmental changes, in part because the translation of mRNAs commences during their transcription and because most mRNAs are degraded within 1 to 3 min of their synthesis. The expression of specific sets of genes is controlled, in most bacteria and some bacteriophages, by  $\sigma$  factors. The *lac* repressor is a tetrameric protein of identical subunits that, in the absence of inducer, nonspecifically binds to duplex DNA but binds much more tightly to *lac* promoter. The promoter sequence that *lac* repressor protects from nuclease digestion has nearly palindromic symmetry. Yet, methylation protection and mutational studies indicate that repressor is not symmetrically bound to promoter. *lac* repressor prevents RNA polymerase from properly initiating transcription at the *lac* promoter.

The presence of glucose represses the transcription of operons specifying certain catabolic enzymes through the mediation of cAMP. On binding cAMP, which accumulates only in the absence of glucose, catabolite gene activator protein (CAP) binds at or immediately upstream of the promoters of these operons, including the *lac* operon, thereby activating their transcription through the binding to the C-terminal domain of the associated RNAP's  $\alpha$  subunit ( $\alpha$ CTD). CAP's two symmetry equivalent DNA-binding domains each bind in the major groove of their target DNA via a helix–turn–helix (HTH) motif that also occurs in numerous prokaryotic repressors. The binding between these repressors and their target DNAs is mediated by mutually favorable associations between these macromolecules rather than any specific interactions between particular base pairs and amino acid side chains analogous to Watson–Crick base pairing. Sequence-specific interactions between the *met* repressor and its target DNA occur through a 2-fold symmetric antiparallel  $\beta$  ribbon that this protein inserts into the DNA's major groove. *araBAD* transcription is controlled by the levels of L-arabinose and CAP–cAMP through a remarkable complex of the control protein AraC to two binding sites, *araO*<sub>2</sub> and *araI*<sub>1</sub>, that forms an inhibitory DNA loop. On binding L-arabinose and when CAP–cAMP is adjacently bound, AraC releases *araO*<sub>2</sub> and instead binds *araI*<sub>2</sub>, thereby releasing the loop and activating RNA polymerase to transcribe the *araBAD* operon. The expression of the *lac* operon is also in part controlled by DNA loop formation. The *lac* repressor is a dimer of homodimers, one of which binds to the operator *lacO*<sub>1</sub> and the other to *lacO*<sub>2</sub> or *lacO*<sub>3</sub> to form a DNA loop that may interfere with RNAP binding to the *lac* promoter. The binding of an inducer such as IPTG to a *lac* repressor dimer core domain alters the angle between its two attached DNA-binding domains such that they cannot simultaneously bind to the *lac* operator, thereby weakening the repressor's grip on the DNA.

The expression of the *E. coli trp* operon is regulated by both attenuation and repression. On binding tryptophan, its corepressor, *trp* repressor binds to the *trp* operator, thereby blocking *trp* operon transcription. When tryptophan is available, much of the *trp* transcript that has escaped repression is prematurely terminated in the *trpL* sequence because its

transcript contains a segment that forms a normal intrinsic terminator. When tryptophanyl-tRNA<sup>Trp</sup> is scarce, ribosomes stall at the transcript's two tandem Trp codons. This permits the newly synthesized RNA to form a base-paired stem and loop that prevents the formation of the terminator structure. Several other operons are similarly regulated by attenuation. Riboswitches are mRNA components that regulate gene expression by specifically binding metabolites. The stringent response is another mechanism by which *E. coli* match the rate of transcription to charged tRNA availability. When a specified charged tRNA is scarce, stringent factor on active ribosomes synthesizes ppGpp, which inhibits the transcription of rRNA and some mRNAs while stimulating the transcription of other mRNAs.

**4 Post-Transcriptional Processing** Most prokaryotic mRNA transcripts require no additional processing. However, eukaryotic mRNAs have an enzymatically appended 5' cap and, in most cases, an enzymatically generated poly(A) tail. Moreover, the introns of eukaryotic mRNA primary transcripts (hnRNAs) are precisely excised via lariat intermediates and their flanking exons are spliced together. Group I and group II introns are self-splicing, that is, their RNAs function as ribozymes (RNA enzymes). Ribozymes, such as the *Tetrahymena* pre-rRNA and hammerhead ribozymes, have complex structures containing several base-paired stems. Pre-mRNAs are spliced by large and complex particles named spliceosomes that consist of four different small nuclear ribonucleoproteins (snRNPs) and which are assisted by the participation of a variety of protein splicing factors. Many eukaryotic proteins consist of modules that also occur in other proteins and hence appear to have evolved via the stepwise collection of exons through recombination events. The alternative splicing of pre-mRNAs greatly increases the variety of proteins expressed by eukaryotic genomes. Certain mRNAs are subject to RNA editing, either by the replacement, inser-

tion, or deletion of specific bases in a process that is directed by guide RNAs (gRNAs), or by substitutional editing mediated by cytidine deaminases or adenosine deaminases.

In RNA interference (RNAi), dsRNA is cleaved by the endoribonuclease Dicer to small interfering RNAs (siRNAs) that guide the hydrolytic cleavage of the complementary mRNAs by the Argonaute component of the RNA-induced silencing complex (RISC), thereby preventing the mRNAs' transcription. MicroRNAs (miRNAs) are generated through the excision of imperfectly base paired stem-loop structures from pri-miRNAs through the actions of Drosha and Dicer. The guide RNA strand of miRNAs binds to RISC and directs it to partially complementary sequences on 3' untranslated regions (3'UTRs) of its target mRNAs, thus inhibiting the expression of the mRNAs and providing a major although only recently recognized mechanism for the regulation of gene expression. Mature eukaryotic mRNAs are selectively and actively transported from the nucleus to the cytosol via the nuclear pore complex. The degradation of mRNAs, which is elaborately controlled, is mediated in part by exosomes.

The primary transcript of *E. coli* rRNAs contains all three rRNAs together with some tRNAs. These are excised and trimmed by specific endonucleases and exonucleases. The eukaryotic 18S, 5.8S, and 28S rRNAs are similarly transcribed as a 45S precursor, which is processed in a manner resembling that of *E. coli* rRNAs. Eukaryotic rRNAs are modified by the methylation of specific nucleosides, as are prokaryotic rRNA, and by the conversion of certain U's to pseudouridines ( $\Psi$ 's). These processes are guided by small nucleolar RNAs (snoRNAs). Prokaryotic tRNAs are excised from their primary transcripts and trimmed in much the same way as are rRNAs. In RNase P, one of the enzymes mediating this process, the catalytic subunit is an RNA. Eukaryotic tRNA transcripts also require the excision of a short intron and the enzymatic addition of a 3'-terminal —CCA to form the mature tRNA.

## PROBLEMS

1. Indicate the phenotypes of the following *E. coli lac* partial diploids in terms of inducibility and active enzymes synthesized.

- $I^+ P^+ O^+ Z^+ Y^- / I^+ P^- O^+ Z^+ Y^+$
- $I^+ P^+ O^c Z^+ Y^- / I^+ P^+ O^+ Z^- Y^+$
- $I^+ P^+ O^c Z^+ Y^+ / I^+ P^+ O^+ Z^+ Y^+$
- $I^+ P^- O^c Z^+ Y^+ / I^+ P^+ O^c Z^- Y^-$

2. **Superrepressed** mutants,  $I^S$ , encode *lac* repressors that bind operator but do not respond to the presence of inducer. Indicate the phenotypes of the following genotypes in terms of inducibility and enzyme production.

- $I^S O^+ Z^+$
- $I^S O^c Z^+$
- $I^+ O^+ Z^+ / I^S O^+ Z^+$

3. Why do *lacZ*<sup>-</sup> *E. coli* fail to show galactoside permease activity after the addition of lactose in the absence of glucose? Why do *lac Y*<sup>-</sup> mutants lack β-galactosidase activity under the same conditions?

4. What is the experimental advantage of using IPTG instead of 1,6-allocolactose as an inducer of the *lac* operon?

5. Describe the probable genetic defect that abolishes the sensitivity of the *lac* operon to the absence of glucose when other metabolic operons continue to be sensitive to the absence of glucose.

6. Indicate the -10 region, the -35 region, and the initiating nucleotide on the sense strand of the *E. coli* tRNA<sup>Tyr</sup> promoter shown below.

```
5' CAACGTAACACTTTACAGCGGCGCGTCATTTGATATGATGCGCCCGCTTCCCGATA 3'
3' GTTGCATTGTGAAATGTCGCCGCGCAGTAACTATACTACGCGGGCGGAAGGGCTAT 5'
```

7. Why are *E. coli* that are diploid for rifamycin resistance and rifamycin sensitivity (*rif<sup>R</sup>/rif<sup>S</sup>*) sensitive to rifamycin?

**8.** Why does promoter efficiency tend to decrease with the number of G · C base pairs in the -10 region of a prokaryotic gene?

**9.** A eukaryotic ribosome contains 4 different rRNA molecules and ~82 different proteins. Why does a cell contain many more copies of the rRNA genes than the ribosomal protein genes?

**10.** What is the probability that the 4026-nucleotide DNA sequence coding for the  $\beta$  subunit of *E. coli* RNA polymerase will be transcribed with the correct base sequence? Perform the calculations for the probabilities of 0.0001, 0.001, and 0.01 that each base is incorrectly transcribed.

**11.** If an enhancer is placed on one plasmid and its corresponding promoter is placed on a second plasmid that is catenated (linked) with the first, initiation is almost as efficient as when the enhancer and promoter are on the same plasmid. However, initiation does not occur when the two plasmids are unlinked. Explain.

**12.** What is the probability that the symmetry of the *lac* operator is merely accidental?

**13.** Why does the inhibition of DNA gyrase in *E. coli* inhibit the expression of catabolite-sensitive operons?

**14.** Describe the transcription of the *trp* operon in the absence of active ribosomes and tryptophan.

**15.** Why can't eukaryotic transcription be regulated by attenuation?

**16.** Predict the effect of deleting the leader peptide sequence on regulation of the *trp* operon.

**17.** Charles Yanofsky and his associates have synthesized a 15-nucleotide RNA that is complementary to segment 1 of *trpL* mRNA (but only partially complementary to segment 3). What is its effect on the *in vitro* transcription of the *trp* operon? What is its effect if the *trpL* gene contains a mutation in segment 2 that destabilizes the 2 · 3 stem and loop?

**18.** Why are *relA*<sup>-</sup> mutants defective in the *in vivo* transcription of *his* and *trp* operons?

**19.** Why aren't primary rRNA transcripts present in wild-type *E. coli*?

**20.** Why can't hammerhead ribozymes catalyze the cleavage of ssDNA?

**21.** Explain why the active site of poly(A) polymerase is much narrower than that of DNA and RNA polymerases.

**22.** Would you expect spliceosome-catalyzed intron removal to be reversible in a highly purified *in vitro* system and *in vivo*? Explain.

**23.** Introns in eukaryotic protein-coding genes may be quite large, but almost none are smaller than about 65 bp. What is the reason for this minimum intron size?

**24.** Infection with certain viruses inhibits snRNA processing in eukaryotic cells. Explain why this favors the expression of viral genes in the host cell.

**25.** Explain why RNAi would be a less efficient mechanism for regulating the expression of specific genes if Dicer hydrolyzed double-stranded RNA every 11 bp rather than every 22 bp.

### 6 Protein Degradation

- A. Degradation Specificity
- B. Degradation Mechanisms

In this chapter we consider **translation**, the mRNA-directed biosynthesis of polypeptides. Although peptide bond formation is a relatively simple chemical reaction, the complexity of the translational process, which involves the coordinated participation of over 100 macromolecules, is mandated by the need to link 20 different amino acid residues accurately in the order specified by a particular mRNA. Note that we previewed this process in Section 5-4B.

We begin by discussing the **genetic code**, the correspondence between nucleic acid sequences and polypeptide sequences. Next, we examine the structures and properties of **tRNAs**, the amino acid-bearing entities that mediate the

translation process. Following this, we consider the structure and functions of **ribosomes**, the complex molecular machines that catalyze peptide bond formation between the mRNA-specified amino acids. Peptide bond formation, however, does not necessarily yield a functional protein; many polypeptides must first be post-translationally modified as we discuss in the subsequent section. Finally, we study how cells degrade proteins, a process that must balance protein synthesis.

## 1 THE GENETIC CODE

How does DNA encode genetic information? According to the one gene-one polypeptide hypothesis, the genetic message dictates the amino acid sequences of proteins. Since the base sequence of DNA is the only variable element in this otherwise monotonously repeating polymer, the amino acid sequence of a protein must somehow be specified by the base sequence of the corresponding segment of DNA.

A DNA base sequence might specify an amino acid sequence in many conceivable ways. With only 4 bases to code for 20 amino acids, a group of several bases, termed a **codon**, is necessary to specify a single amino acid. A triplet code, that is, one with 3 bases per codon, is minimally required since there are  $4^3 = 64$  different triplets of bases, whereas there can be only  $4^2 = 16$  different doublets, which is insufficient to specify all the amino acids. In a triplet code, as many as 44 codons might not code for amino acids. On the other hand, many amino acids could be specified by more than one codon. Such a code, in a term borrowed from mathematics, is said to be **degenerate**.

Another mystery was, how does the polypeptide synthesizing apparatus group DNA's continuous sequence of bases into codons? For example, the code might be overlapping; that is, in the sequence

ABCDEFGHIJ...

ABC might code for one amino acid, BCD for a second, CDE for a third, and so on. Alternatively, the code might be nonoverlapping, so that ABC specifies one amino acid, DEF a second, GHI a third, and so on. The code might also contain internal "punctuation" such as in the nonoverlapping triplet code

ABC,DEF,GHI,...

**5-Bromouracil (5BU)**  
(keto tautomer)      **5BU**  
(enol tautomer)      **Guanine**

**Figure 32-1 5-Bromouracil.** Its keto form (left) is its most common tautomer. However, it frequently assumes the enol form (right), which base pairs with guanine.

in which the commas represent particular bases or base sequences. A related question is, how does the genetic code specify the beginning and the end of a polypeptide chain?

The genetic code is, in fact, a nonoverlapping, comma-free, degenerate, triplet code. How this was determined and how the genetic code dictionary was elucidated are the subjects of this section.

### A. Chemical Mutagenesis

The triplet character of the genetic code, as we shall see below, was established through the use of **chemical mutagens**, substances that chemically induce mutations. We therefore precede our study of the genetic code with a discussion of these substances. There are two major classes of mutations:

**1. Point mutations**, in which one base pair replaces another. These are subclassified as

**(a) Transitions**, in which one purine (or pyrimidine) is replaced by another.

**(b) Transversions**, in which a purine is replaced by a pyrimidine or vice versa.

**2. Insertion/deletion mutations**, in which one or more nucleotide pairs are inserted in or deleted from DNA.

A mutation in any of these three categories may be reversed by a subsequent mutation of the same but not another category.

#### a. Point Mutations Are Generated by Altered Bases

Point mutations can result from the treatment of an organism with base analogs or with substances that chemically alter bases. For example, the base analog **5-bromouracil (5BU)** sterically resembles thymine (5-methyluracil) but, through the influence of its electronegative Br atom, frequently assumes a tautomeric form that base pairs with guanine instead of adenine (Fig. 32-1). Consequently, when 5BU is incorporated into DNA in place of thymine, as it usually is, it occasionally induces an A · T → G · C transition in subsequent rounds of DNA replication. Occasionally, 5BU is also incorporated into DNA in place of cytosine, which instead generates a G · C → A · T transition.

The adenine analog **2-aminopurine (2AP)**, normally base pairs with thymine (Fig. 32-2a) but occasionally forms an undistorted but singly hydrogen bonded base pair with cytosine (Fig. 32-2b). Thus 2AP generates A · T → G · C transitions.

In aqueous solutions, **nitrous acid** (HNO<sub>2</sub>) oxidatively deaminates aromatic primary amines so that it converts cytosine to uracil (Fig. 32-3a) and adenine to the guaninelike **hypoxanthine** (which forms two of guanine's three hydrogen

**2-Aminopurine (2AP)**      **Thymine**

**2AP**      **Cytosine**

**Figure 32-2 Base pairing by the adenine analog 2-aminopurine.** It normally base pairs with thymine (a) but occasionally also does so with cytosine (b).

**Cytosine**      **Uracil**      **Adenine**

**Adenine**      **Hypoxanthine**      **Cytosine**

**Figure 32-3 Oxidative deamination by nitrous acid.** (a) Cytosine is converted to uracil, which base pairs with adenine. (b) Adenine is converted to hypoxanthine, a guanine derivative (it lacks guanine's 2-amino group) that base pairs with cytosine.

**Figure 32-4** Reaction with hydroxylamine converts cytosine to a derivative that base pairs with adenine.

bonds with cytosine; Fig. 32-3b). Hence, treatment of DNA with nitrous acid, or compounds such as **nitrosamines**

that react to form nitrous acid, results in both  $A \cdot T \rightarrow G \cdot C$  and  $G \cdot C \rightarrow A \cdot T$  transitions. **Hydroxylamine** ( $\text{NH}_2\text{OH}$ ) also induces  $G \cdot C \rightarrow A \cdot T$  transitions by specifically reacting with cytosine to convert it to a compound that base pairs with adenine (Fig. 32-4).

**Nitrite**, the conjugate base of nitrous acid, has long been used as a preservative of prepared meats such as frankfurters. However, the observation that many mutagens are also carcinogens (Section 30-5Fa) suggests that the consumption of nitrite-containing meat is harmful to humans. Proponents of nitrite preservation nevertheless argue that to stop it would result in far more fatalities. This is because lack of such treatment would greatly increase the incidence of **botulism**, an often fatal form of food poisoning caused by the ingestion of protein neurotoxins secreted by the anaerobic bacterium *Clostridium botulinum* (Section 12-4Dd).

The use of alkylating agents such as dimethyl sulfate, **nitrogen mustard**, and **ethylnitrosourea**

often generates transversions. The alkylation of the N7 position of a purine nucleotide causes its subsequent depurination. The resulting gap in the sequence is filled in by an error-prone repair system (Section 30-5D). Transversions arise when the missing purine is replaced by a pyrimidine. The repair of DNA that has been damaged by UV radiation may also generate transversions.

### b. Insertion/Deletion Mutations Are Generated by Intercalating Agents

*Insertion/deletion mutations (also called indels), may arise from the treatment of DNA with intercalating agents such as acridine orange (Section 6-6Ca) or proflavin.*

The distance between two consecutive base pairs is doubled by the intercalation of such a molecule between them. The replication of such a distorted DNA occasionally results in the insertion or deletion of one or more nucleotides in the newly synthesized polynucleotide. (Insertions and deletions of large DNA segments generally arise from aberrant crossover events; Section 34-2De.)

### B. Codons Are Triplets

In 1961, Francis Crick and Sydney Brenner, through genetic investigations into the previously unknown character of proflavin-induced mutations, determined the triplet character of the genetic code. In bacteriophage T4, a particular proflavin-induced mutation, designated *FC0*, maps in the *rIIB* cistron (Section 1-4Eb). The growth of this mutant phage on a permissive host (*E. coli* B) resulted in the occasional spontaneous appearance of phenotypically wild-type phages as was demonstrated by their ability to grow on a restrictive host [*E. coli* K12( $\lambda$ ); recall that *rIIB* mutants form characteristically large plaques on *E. coli* B but cannot lyse *E. coli* K12( $\lambda$ ); Section 1-4Eb]. Yet, these doubly mutated phages are not genotypically wild type; the simultaneous infection of a permissive host by one of them and true wild-type phage yielded recombinant progeny that have either the *FC0* mutation or a new mutation designated *FC1*. Thus the phenotypically wild-type phage is a double mutant that actually contains both *FC0* and *FC1*. *These two genes are therefore suppressors of one another; that is, they cancel each other's mutant properties.* Furthermore, since they map together in the *rIIB* cistron, they are mutual **intragenic suppressors** (suppressors in the same gene).

The treatment of *FC1* in a manner identical to that described for *FC0* provided similar results: the appearance of a new mutant, *FC2*, that is an intragenic suppressor of *FC1*. By proceeding in this iterative manner, Crick and Brenner collected a series of different *rIIB* mutants, *FC3*, *FC4*, *FC5*, etc., in which each mutant *FC(n)* is an intragenic suppressor of its predecessor, *FC(n - 1)*. Recombination studies showed, moreover, that odd-numbered mutations are intragenic suppressors of even-numbered mutations, but neither pairs of different odd-numbered mutations nor pairs of different even-numbered mutations suppress each other. However, recombinants containing three odd-numbered mutations or three even-numbered mutations all are phenotypically wild type.

Crick and Brenner accounted for these observations by the following set of hypotheses:

1. The proflavin-induced mutation *FC0* is either an insertion or a deletion of one nucleotide pair from the *rIIB* cistron. If it is a deletion then *FC1* is an insertion, *FC2* is a deletion, and so on, and vice versa.

2. The code is read in a sequential manner starting from a fixed point in the gene. The insertion or deletion of a nucleotide shifts the **frame** (grouping) in which succeeding nucleotides are read as codons (insertions or deletions of nucleotides are therefore also known as **frameshift mutations**). Thus the code has no internal punctuation that indicates the reading frame; that is, *the code is comma free*.

3. The code is a triplet code.

4. All or nearly all of the 64 triplet codons code for an amino acid; that is, *the code is degenerate*.

These principles are illustrated by the following analogy. Consider a sentence (gene) in which the words (codons) each consist of three letters (bases).

### THE BIG RED FOX ATE THE EGG

(Here the spaces separating the words have no physical significance; they are only present to indicate the reading frame.) The deletion of the fourth letter, which shifts the reading frame, changes the sentence to

### THE IGR EDF OXA TET HEE GG

so that all words past the point of deletion are unintelligible (specify the wrong amino acids). An insertion of any letter, however, say an X in the ninth position,

### THE IGR EDX FOX ATE THE EGG

restores the original reading frame. Consequently, only the words between the two changes (mutations) are altered. As in this example, such a sentence might still be intelligible (the gene could still specify a functional protein), particularly if the changes are close together. Two deletions or two insertions, no matter how close together, would not suppress each other but just shift the reading frame. However, three insertions, say X, Y, and Z in the fifth, eighth, and twelfth positions, respectively, would change the sentence to

### THE BXI GYR EDZ FOX ATE THE EGG

which, after the third insertion, restores the original reading frame. The same would be true of three deletions. As before, if all three changes were close together, the sentence might still retain much of its meaning.

Crick and Brenner did not unambiguously demonstrate that the genetic code is a triplet code because they had no proof that their insertions and deletions involved only single nucleotides. Strictly speaking, they showed that a codon consists of  $3r$  nucleotides where  $r$  is the number of nucleotides in an insertion or deletion. Although it was generally assumed at the time that  $r = 1$ , proof of this assertion had to await the elucidation of the genetic code (Section 32-1C).

## C. Deciphering the Genetic Code

The genetic code could, in principle, be determined by simply comparing the base sequence of an mRNA with the amino acid sequence of the polypeptide it specifies. In the 1960s, however, techniques for isolating and sequencing

mRNAs had not yet been developed. The elucidation of the genetic code dictionary therefore proved to be a difficult task.

### a. UUU Specifies Phe

The major breakthrough in deciphering the genetic code came in 1961 when Marshall Nirenberg and Heinrich Matthaei established that UUU is the codon specifying Phe. They did so by demonstrating that the addition of poly(U) to a cell-free protein synthesizing system stimulates only the synthesis of poly(Phe). The cell-free protein synthesizing system was prepared by gently breaking open *E. coli* cells by grinding them with powdered alumina and centrifuging the resulting cell sap to remove the cell walls and membranes. This extract contained DNA, mRNA, ribosomes, enzymes, and other cell constituents necessary for protein synthesis. When fortified with ATP, GTP, and amino acids, the system synthesized small amounts of proteins. This was demonstrated by the incubation of the system with  $^{14}\text{C}$ -labeled amino acids followed by the precipitation of its proteins by the addition of trichloroacetic acid. The precipitate proved to be radioactive.

A cell-free protein synthesizing system, of course, produces proteins specified by the cell's DNA. On addition of DNase, however, protein synthesis stops within a few minutes because the system can no longer synthesize mRNA, whereas the mRNA originally present is rapidly degraded. Nirenberg found that crude mRNA-containing fractions from other organisms were highly active in stimulating protein synthesis in a DNase-treated protein synthesizing system. This system is likewise responsive to synthetic mRNAs.

The synthetic mRNAs that Nirenberg used in subsequent experiments were synthesized by the *Azotobacter vinelandii* enzyme **polynucleotide phosphorylase**. This enzyme, which was discovered by Severo Ochoa and Mari- anne Grunberg-Manago, links together nucleotides in the reaction

In contrast to RNA polymerase, however, polynucleotide phosphorylase does not utilize a template. Rather, it randomly links together the available NDPs so that the base composition of the product RNA reflects that of the reactant NDP mixture.

Nirenberg and Matthaei demonstrated that poly(U) stimulates the synthesis of poly(Phe) by incubating poly(U) and a mixture of 1 radioactive and 19 unlabeled amino acids in a DNase-treated protein synthesizing system. Significant radioactivity appeared in the protein precipitate only when phenylalanine was labeled. *UUU must therefore be the codon specifying Phe*. In similar experiments using poly(A) and poly(C), it was found that poly(Lys) and poly(Pro), respectively, were synthesized. Thus *AAA specifies Lys and CCC specifies Pro*. [Poly(G) cannot function as a synthetic mRNA because, even under denaturing conditions, it aggregates to form a four-stranded helix (Section 30-4De). An mRNA must be single stranded to direct its translation; Section 32-2D.]

**Table 32-1** Amino Acid Incorporation Stimulated by a Random Copolymer of U and G in Mole Ratio 0.76 : 0.24

Codon	Probability of Occurrence	Relative Incidence <sup>a</sup>	Amino Acid	Relative Amount of Amino Acid Incorporated
UUU	0.44	100	Phe	100
UUG	0.14	32	Leu	36
UGU	0.14	32	Cys	35
GUU	0.14	32	Val	37
UGG	0.04	9	Trp	14
GUG	0.04	9		
GGU	0.04	9	Gly	12
GGG	0.01	2		

<sup>a</sup>Relative incidence is defined here as  $100 \times \text{probability of occurrence}/0.44$ .

Source: Matthaei, J.H., Jones, O.W., Martin, R.G., and Nirenberg, M., *Proc. Natl. Acad. Sci.* **48**, 666 (1962).

Nirenberg and Ochoa independently employed ribonucleotide copolymers to further elucidate the genetic code. For example, in a poly(UG) composed of 76% U and 24% G, the probability of a given triplet being UUU is  $0.76 \times 0.76 \times 0.76 = 0.44$ . Likewise, the probability of a particular triplet consisting of 2U's and 1G, that is, UUG, UGU, or GUU, is  $0.76 \times 0.76 \times 0.24 = 0.14$ . The use of this poly(UG) as an mRNA therefore indicated the base compositions, but not the sequences, of the codons specifying several amino acids (Table 32-1). Through the use of copolymers containing two, three, and four bases, the base compositions of codons specifying each of the 20 amino acids were inferred. Moreover, *these experiments demonstrated that the genetic code is degenerate since, for example, poly(UA), poly(UC), and poly(UG) all direct the incorporation of Leu into a polypeptide.*

### b. The Genetic Code Was Elucidated through Triplet Binding Assays and the Use of Polyribonucleotides with Known Sequences

In the absence of GTP, which is necessary for protein synthesis, trinucleotides but not dinucleotides are almost as effective as mRNAs in promoting the ribosomal binding of specific tRNAs. This phenomenon, which Nirenberg and Philip Leder discovered in 1964, permitted the various codons to be identified by a simple binding assay. Ribosomes, together with their bound tRNAs, are retained by a nitrocellulose filter but free tRNA is not. The bound tRNA was identified by using charged tRNA mixtures in which only one of the pendent amino acid residues was radioactively labeled. For instance, it was found, as expected, that UUU stimulates the ribosomal binding of only Phe tRNA. Likewise, UUG, UGU, and GUU stimulate the binding of Leu, Cys, and Val tRNAs, respectively. Hence

UUG, UGU, and GUU must be codons that specify Leu, Cys, and Val, respectively. In this way, the amino acids specified by some 50 codons were identified. For the remaining codons, the binding assay was either negative (no tRNA bound) or ambiguous.

The genetic code dictionary was completed and previous results confirmed through H. Gobind Khorana's synthesis of polyribonucleotides with specified repeating sequences (Section 7-6A). In a cell-free protein synthesizing system, UCUCUCUC... , for example, is read

so that it specifies a polypeptide chain of two alternating amino acid residues. In fact, it was observed that this mRNA stimulated the production of

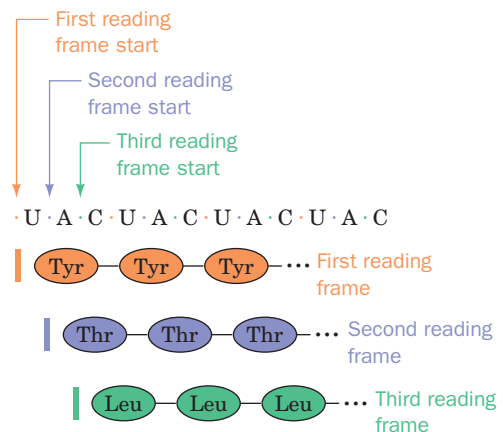

which indicates that either UCU or CUC specifies Ser and the other specifies Leu. This information, together with the tRNA-binding data, permitted the conclusion that UCU codes for Ser and CUC codes for Leu. These data also prove that codons consist of an odd number of nucleotides, thereby relieving any residual suspicions that codons consist of six rather than three nucleotides.

Alternating sequences of three nucleotides, such as poly(UAC), specify three different homopolypeptides because ribosomes may initiate polypeptide synthesis on these synthetic mRNAs in any of the three possible reading frames (Fig. 32-5). Analyses of the polypeptides specified by various alternating sequences of two and three nucleotides confirmed the identity of many codons and filled out missing portions of the genetic code.

### c. mRNAs Are Read in the 5' → 3' Direction

The use of repeating tetranucleotides indicated the reading direction of the code and identified the chain

**Figure 32-5** The three potential reading frames of an mRNA. Each reading frame would yield a different polypeptide.

termination codons. Poly(UAUC) specifies, as expected, a polypeptide with a tetrapeptide repeat:

The amino acid sequence of this polypeptide indicates that the mRNA's 5' end corresponds to the polypeptide's N-terminus; that is, *mRNA is read in the 5' → 3' direction*.

#### d. UAG, UAA, and UGA Are Stop Codons

In contrast to the above results, poly(AUAG) yields only dipeptides and tripeptides. This is because *UAG is a signal to the ribosome to terminate protein synthesis*:

Likewise, poly(GUAA) yields dipeptides and tripeptides because UAA is also a chain termination signal:

UGA is a third stop signal. These **Stop codons**, whose existence was first inferred from genetic experiments, are known, somewhat inappropriately, as **nonsense codons** because they are the only codons that do not specify amino acids. UAG, UAA, and UGA are sometimes referred to as **amber**, **ochre**, and **opal** codons. [They were so named as the result of a laboratory joke: The German word for amber is Bernstein, the name of an individual who helped discover *amber* mutations (mutations that change some other codon to UAG); *ochre* and *opal* are puns on *amber*.]

#### e. AUG and GUG Are Chain Initiation Codons

The codons AUG, and less frequently GUG, form part of the chain initiation sequence (Section 32-3Ca). However, they also specify the amino acid residues Met and Val, respectively, at internal positions of polypeptide chains. (Nirenberg and Matthaei's discovery that UUU specifies Phe was only possible because ribosomes indiscriminately initiate polypeptide synthesis on an mRNA when the  $\text{Mg}^{2+}$  concentration is unphysiologically high as it was, serendipitously, in their experiments.)

### D. The Nature of the Code

The genetic code dictionary, as elucidated by the above methods, is presented in Table 32-2 as well as in Table 5-3. Examination of the table indicates that the genetic code has several remarkable features:

**1. The code is highly degenerate.** Three amino acids, Arg, Leu, and Ser, are each specified by six codons, and

**Table 32-2** The "Standard" Genetic Code<sup>a</sup>

First position (5' end)	Second position				Third position (3' end)
	U	C	A	G	
U	UUU Phe	UCU	UAU Tyr	UGU Cys	U
	UUC	UCC Ser	UAC Tyr	UGC Cys	C
	UUA Leu	UCA	UAA Stop	UGA Stop	A
	UUG	UCG	UAG Stop	UGG Trp	G
C	CUU	CCU	CAU His	CGU Arg	U
	CUC Leu	CCC Pro	CAC His	CGC Arg	C
	CUA	CCA	CAA Gln	CGA Arg	A
	CUG	CCG	CAG Gln	CGG Arg	G
A	AUU	ACU	AAU Asn	AGU Ser	U
	AUC Ile	ACC Thr	AAC Asn	AGC Ser	C
	AUA	ACA	AAA Lys	AGA Arg	A
	AUG Met <sup>b</sup>	ACG	AAG Lys	AGG Arg	G
G	GUU	GCU	GAU Asp	GGU Gly	U
	GUC Val	GCC Ala	GAC Asp	GGC Gly	C
	GUA	GCA	GAA Glu	GGA Gly	A
	GUG	GCG	GAG Glu	GGG Gly	G

<sup>a</sup>Nonpolar amino acid residues are tan, basic residues are blue, acidic residues are red, and nonpolar uncharged residues are purple.

<sup>b</sup>AUG forms part of the initiation signal as well as coding for internal Met residues.

most of the rest are specified by either four, three, or two codons. Only Met and Trp, two of the least common amino acids in proteins (Table 4-1), are represented by a single codon. Codons that specify the same amino acid are termed **synonyms**.

**2. The arrangement of the code table is nonrandom.** Most synonyms occupy the same box in Table 32-2; that is, they differ only in their third nucleotide. The only exceptions are Arg, Leu, and Ser, which, having six codons each, must occupy more than one box. XYU and XYC always specify the same amino acid; XYA and XYG do so in all but two cases. Moreover, changes in the first codon position tend to specify similar (if not the same) amino acids, whereas codons with second position pyrimidines encode mostly hydrophobic amino acids (tan in Table 32-2), and those with second position purines encode mostly polar amino acids (blue, red, and purple in Table 32-2). Apparently *the code evolved so as to minimize the deleterious effects of mutations*.

Many of the mutations causing amino acid substitutions in a protein can be rationalized, according to the genetic code, as single point mutations. *As a consequence of the genetic code's degeneracy, however, many point mutations at a third codon position are phenotypically silent; that is, the*

mutated codon specifies the same amino acid as the wild type. Degeneracy may account for as much as 33% of the 25 to 75% range in the G + C content among the DNAs of different organisms (Section 5-1Ba). The frequent occurrence of Arg, Ala, Gly, and Pro also tends to give a high G + C content, whereas Asn, Ile, Lys, Met, Phe, and Tyr contribute to a low G + C content.

#### a. Some Phage DNA Segments Contain Overlapping Genes in Different Reading Frames

Since any nucleotide sequence may have three reading frames, it is possible, at least in principle, for a polynucleotide to encode two or even three different polypeptides. This idea was never seriously entertained, however, because it seemed that the constraints on even two overlapping genes in different reading frames would be too great for them to evolve so that both could specify sensible proteins. It therefore came as a great surprise, in 1976, when Frederick Sanger reported that the 5386-nucleotide DNA of bacteriophage  $\phi$ X174 (which, at the time, was the largest DNA to have been sequenced) contains two genes that are completely contained within larger genes of different reading frames (Fig. 32-6). Moreover, the end of the overlapping D and E genes contains the control sequence for the ribosomal initiation of the J gene so that this short DNA segment performs triple duty. Bacteria

**Figure 32-6** Genetic map of bacteriophage  $\phi$ X174 as determined by DNA sequence analysis. Genes are labeled A, B, C, etc. Note that gene B is wholly contained within gene A and gene E is wholly contained within gene D. These pairs of genes are read in different reading frames and therefore specify unrelated proteins. The unlabeled regions correspond to untranslated control sequences.

also exhibit such coding economy; the ribosomal initiation sequence of one gene in a polycistronic mRNA often overlaps the end of the preceding gene. Nevertheless, completely overlapping genes have only been found in small single-stranded DNA phages, which presumably must make maximal use of the little DNA that they can pack inside their capsids.

#### b. The “Standard” Genetic Code Is Widespread but Not Universal

For many years it was thought that the “standard” genetic code (that given in Table 32-2) is universal. This assumption was, in part, based on the observations that one kind of organism (e.g., *E. coli*) can accurately translate the genes from quite different organisms (e.g., humans). This phenomenon is, in fact, the basis of genetic engineering. Once the “standard” genetic code had been established, presumably during the time of prebiotic evolution (Section 1-5B), any mutation that would alter the way the code is translated would result in numerous, often deleterious, protein sequence changes. Undoubtedly there is strong selection against such mutations.

Despite the foregoing, DNA sequencing studies in 1981 revealed that *the genetic codes of certain mitochondria (mitochondria contain their own genes and protein synthesizing systems but produce only a few mitochondrial proteins; Section 12-4E) are variants of the “standard” genetic code* (Table 32-3). For example, in mammalian mitochondria, AUA, as well as the standard AUG, is a Met/initiation codon; UGA specifies Trp rather than “Stop”; and AGA and AGG are “Stop” rather than Arg. Note that all mitochondrial genetic codes except those of plants simplify the “standard” code by increasing its degeneracy. For example, in the mammalian mitochondrial code, each amino acid is specified by at least two codons that differ only in their third nucleotide. Apparently the constraints preventing alterations of the genetic code are eased by the small sizes of mitochondrial genomes. More recent

**Table 32-3** Mitochondrial Deviations from the “Standard” Genetic Code

Mitochondrion	UGA	AUA	CUN <sup>a</sup>	AGA <sup>c</sup>	CGG
Mammalian	Trp	Met <sup>b</sup>		Stop	
Baker’s yeast	Trp	Met <sup>b</sup>	Thr		
<i>Neurospora crassa</i>	Trp				
<i>Drosophila</i>	Trp	Met <sup>b</sup>		Ser <sup>c</sup>	
Protozoan	Trp				
Plant					Trp
“Standard” code	Stop	Ile	Leu	Arg	Arg

<sup>a</sup>N represents any of the four nucleotides.

<sup>b</sup>Also acts as part of an initiation signal.

<sup>c</sup>AGA only; no AGG codons occur in *Drosophila* mitochondrial DNA.

studies, however, have revealed that in ciliated protozoa, the codons UAA and UAG specify Gln rather than “Stop.” Perhaps UAA and UAG were sufficiently rare codons in a primordial ciliate (which molecular phylogenetic studies indicate branched off very early in eukaryotic evolution) to permit the code change without unacceptable deleterious effects. At any rate, *the “standard” genetic code, although very widely utilized, is not universal.* Indeed, as we shall see in Section 32-2De, under the proper context in mRNA, certain codons can specify “nonstandard” amino acids.

## 2 TRANSFER RNA AND ITS AMINOACYLATION

The establishment of the genetic function of DNA led to the realization that cells somehow “translate” the language of base sequences into the language of polypeptides. Yet, nucleic acids originally appeared unable to bind specific amino acids [more recently RNA aptamers for specific amino acids have been generated; aptamers are nucleic acids that have been selected for their ability to bind specific ligands (Section 7-6C)]. In 1955, Crick, in what became known as the **adaptor hypothesis**, postulated that translation occurs through the mediation of “adaptor” molecules. Each adaptor was postulated to carry a specific enzymatically appended amino acid and to recognize the corresponding codon (Fig. 32-7). Crick suggested that these adaptors contain RNA because codon recognition could then occur by complementary base pairing. At about this time, Paul Zamecnik and Mahlon Hoagland discovered that in the course of protein synthesis,  $^{14}\text{C}$ -labeled amino acids became transiently bound to a low molecular mass fraction of RNA. Further investigations indicated that these RNAs, which at first were called “soluble RNA” or “sRNA” but are now known as **transfer RNA (tRNA)**, are, in fact, Crick’s putative adaptor molecules.

### A. Primary and Secondary Structures of tRNA

 **See Guided Exploration 26: The structure of tRNA** In 1965, after a 7-year effort, Robert Holley reported the first known base sequence of a biologically significant nucleic acid, that of yeast **alanine tRNA (tRNA<sup>Ala</sup>)**; Fig. 32-8). To do so Holley had to overcome several major obstacles:

1. All organisms contain many species of tRNAs (usually at least one for each of the 20 amino acids) which, because of their nearly identical properties (see below), are not easily separated. Preparative techniques had to be developed to provide the gram or so of pure yeast tRNA<sup>Ala</sup> Holley required for its sequence determination.

2. Holley had to invent the methods that were initially used to sequence RNA (Section 7-2).

3. Ten of the 76 bases of yeast tRNA<sup>Ala</sup> are modified (see below). Their structural formulas had to be elucidated

**Figure 32-7 The adaptor hypothesis.** It postulates that the genetic code is read by molecules that recognize a particular codon and carry the corresponding amino acid.

although they were never available in more than milligram quantities.

Since 1965, the techniques for tRNA purification and sequencing have vastly improved. A tRNA may now be sequenced in a few hours’ time with only  $\sim 1\ \mu\text{g}$  of material. Presently, the base sequences of many thousands of tRNAs from nearly 800 organisms are known, most from genomic sequences (they are compiled at the Genomic

**Figure 32-8 Base sequence of yeast tRNA<sup>Ala</sup> drawn in the cloverleaf form.** The symbols for the modified nucleosides (color) are explained in Fig. 32-10.

tRNA Database, <http://gtrnadb.ucsc.edu/>). They vary in length from 54 to 100 nucleotides (18–28 kD) although most have ~76 nucleotides.

Almost all known tRNAs, as Holley first recognized, may be schematically arranged in the so-called cloverleaf secondary structure (Fig. 32-9). Starting from the 5' end, they have the following common features:

1. A 5'-terminal phosphate group.
2. A 7-bp stem that includes the 5'-terminal nucleotide and that may contain non-Watson–Crick base pairs such as G · U. This assembly is known as the **acceptor** or **amino acid stem** because the amino acid residue carried by the tRNA is appended to its 3'-terminal OH group (Section 32-2C).
3. A 3- or 4-bp stem ending in a loop that frequently contains the modified base **dihydrouridine (D; see below)**. This stem and loop are therefore collectively termed the **D arm**.
4. A 5-bp stem ending in a loop that contains the **anticodon**, the triplet of bases that is complementary to the codon specifying the tRNA. These features are known as the **anticodon arm**.

**Figure 32-9** Cloverleaf secondary structure of tRNA. Filled circles connected by dots represent Watson–Crick base pairs, and open circles in the double-helical regions indicate bases involved in non-Watson–Crick base pairing. Invariant positions are indicated: R and Y represent invariant purines and pyrimidines and  $\psi$  signifies pseudouridine. The starred nucleosides are often modified. The dashed regions in the D and variable arms contain different numbers of nucleotides in the various tRNAs.

5. A 5-bp stem ending in a loop that usually contains the sequence T $\psi$ C (where  $\psi$  is the symbol for **pseudouridine**; see below). This assembly is called the **T $\psi$ C** or **T arm**.

6. All tRNAs terminate in the sequence CCA with a free 3'-OH group. The CCA may be genetically specified or enzymatically appended to immature tRNA (Section 31-4Cc).

7. There are 15 invariant positions (always have the same base) and 8 **semi-invariant** positions (only a purine or only a pyrimidine) that occur mostly in the loop regions. These regions also contain **correlated invariants**, that is, pairs of nonstem nucleotides that are base paired in all tRNAs. The purine on the 3' side of the anticodon is invariably modified. The structural significance of these features is examined below.

The site of greatest variability among the known tRNAs occurs in the so-called **variable arm**. It has from 3 to 21 nucleotides and may have a stem consisting of up to 7 bp. The D loop also varies in length from 5 to 7 nucleotides.

#### a. Transfer RNAs Have Numerous Modified Bases

One of the most striking characteristics of tRNAs is their large proportion, up to 25%, of post-translationally modified or hypermodified bases. Nearly 80 such bases, found at >60 different tRNA positions, have been characterized. A few of them, together with their standard abbreviations, are indicated in Fig. 32-10. Hypermodified nucleosides, such as  $i^6$ A, are usually adjacent to the anticodon's 3' nucleotide when it is A or U. Their low polarities probably strengthen the otherwise relatively weak pairing associations of these bases with the codon, thereby increasing translational fidelity. Conversely, certain methylations block base pairing and hence prevent inappropriate structures from forming. Some of these modifications form important recognition elements for the enzyme that attaches the correct amino acid to a tRNA (Section 32-2Cb). However, none of them are essential for maintaining a tRNA's structural integrity (see below) or for its proper binding to the ribosome. Nevertheless, mutant bacteria unable to form certain modified bases compete poorly against the corresponding normal bacteria.

#### B. Tertiary Structure of tRNA

 **See Guided Exploration 26: The structure of tRNA** The earliest physicochemical investigations of tRNA indicated that it has a well-defined conformation. Yet, despite numerous hydrodynamic, spectroscopic, and chemical cross-linking studies, its three-dimensional structure remained an enigma until 1974. In that year, the 2.5-Å resolution X-ray crystal structure of yeast **tRNA<sup>Phe</sup>** was separately elucidated by Alexander Rich in collaboration with Sung-Hou Kim and, in a different crystal form, by Aaron Klug. *The molecule assumes an L-shaped conformation in which one leg of the L is formed by the acceptor and T stems folded into a continuous A-RNA-like double helix (Section 29-1Ba) and the other leg is similarly composed of the D and*

*anticodon stems* (Fig. 32-11). Each leg of the L is ~60 Å long and the anticodon and amino acid acceptor sites are at opposite ends of the molecule, some 76 Å apart. The narrow 20- to 25-Å width of native tRNA is essential to its biological function: During protein synthesis, three RNA molecules must simultaneously bind in close proximity at adjacent codons on mRNA (Section 32-3Ae).

#### a. tRNA's Complex Tertiary Structure Is Maintained by Hydrogen Bonding and Stacking Interactions

The structural complexity of yeast tRNA<sup>Phe</sup> is reminiscent of that of a protein. Although only 42 of its 76 bases occur in double helical stems, 71 of them participate in *stacking associations* (Fig. 32-12). The structure also contains 9 base pairing interactions that cross-link its tertiary structure (Figs. 32-11a and 32-12). Remarkably, all but one of these tertiary interactions, which appear to be the mainstays of the molecular structure, are non-Watson-Crick associations. Moreover, most of the bases involved in these interactions are either invariant or semi-invariant, which strongly suggests that all tRNAs have similar conformations (see below). The structure is also stabilized by several

unusual hydrogen bonds between bases and either phosphate groups or the 2'-OH groups of ribose residues.

The compact structure of yeast tRNA<sup>Phe</sup> results from its large number of intramolecular associations, which renders most of its bases inaccessible to solvent. The most notable exceptions to this are the anticodon bases and those of the amino acid-bearing—CCA terminus. Both of these groupings must be accessible in order to carry out their biological functions.

The observation that the molecular structures of yeast tRNA<sup>Phe</sup> in two different crystal forms are essentially identical lends much credence to the supposition that its crystal structure closely resembles its solution structure. Transfer RNAs other than yeast tRNA<sup>Phe</sup> have, unfortunately, been notoriously difficult to crystallize. As yet, the X-ray structures of only three other uncomplexed tRNAs have been reported (although the X-ray structures of numerous tRNAs in complex with the enzymes that append their corresponding amino acids and with ribosomes have been elucidated; Sections 32-2C and 32-3D). The major structural differences among them result from an apparent flexibility in the anticodon loop and the—CCA terminus as well as from a

**Figure 32-12** Tertiary base pairing interactions in yeast  $\text{tRNA}^{\text{Phe}}$ . Note that all but one of these nine interactions involve non-Watson–Crick pairs and that they are all located near the corner of the L. [After Kim, S.H., in Schimmel, P.R., Söll, D., and

See Kinemage Exercise 19-3

hingelike mobility between the two legs of the L that gives, for instance, yeast  $\text{tRNA}^{\text{Asp}}$  a boomerang-like shape. Such observations are in accord with the expectation that all tRNAs fit into the same ribosomal cavities.

### C. Aminoacyl-tRNA Synthetases

See Guided Exploration 27: The structures of aminoacyl-tRNA synthetases and their interactions with tRNAs. Accurate translation requires two equally important recognition steps: (1) the choice of the correct amino acid for covalent attachment to a tRNA; and (2) the selection of the amino acid-charged tRNA specified by mRNA. The first of these steps, which is catalyzed by amino acid-specific enzymes known as **aminoacyl-tRNA synthetases (aaRSs)**, appends an amino acid to the 3'-terminal ribose residue of its cognate tRNA to form an aminoacyl-tRNA (Fig. 32-13). This otherwise unfavorable process is driven by the hydrolysis of ATP in two sequential reactions that are catalyzed by a single enzyme.

**Aminoacyl-tRNA**

**Figure 32-13** An aminoacyl-tRNA. The amino acid residue is esterified to the tRNA's 3'-terminal nucleoside at either its 3'-OH group, as shown here, or its 2'-OH group.

participate in ATP binding and are implicated in catalysis. The Class II synthetases lack the foregoing sequences but have three other sequences in common. Their X-ray structures reveal that these sequences occur in a so-called signature motif, a fold found only in Class II enzymes that consists of a 7-stranded antiparallel  $\beta$  sheet with three flanking helices, which forms the core of their catalytic domains.

Many Class I aaRSs require anticodon recognition to aminoacylate their cognate tRNAs. In contrast, several Class II enzymes, including **AlaRS** and **SerRS**, do not interact with their bound tRNA's anticodon. Indeed, several class II aaRSs accurately aminoacylate "microhelices" derived from only the acceptor stems of their cognate tRNAs. Another difference between Class I and Class II synthetases is that all Class I enzymes aminoacylate their bound tRNA's 3'-terminal 2'-OH group, whereas Class II enzymes, with the exception of **PheRS**, all charge the 3'-OH group. The amino acids for which the Class I synthetases are specific tend to be larger and more hydrophobic than those used by Class II synthetases. Finally, as Table 32-4 indicates, Class I aaRSs are mainly monomers, whereas most Class II aaRSs are homodimers.

**LysRS** has been classified as a Class II aaRS. However, a search of the genome sequences of *Methanococcus jannaschii* and *Methanobacterium thermoautotrophicum* failed to reveal the presence of such a LysRS. This led to the discovery that the LysRSs expressed by these archaeobacteria are Class I rather than Class II enzymes. This raises the interesting question of how Class I LysRS evolved.

Prokaryotic aaRSs occur as individual protein molecules. However, in many higher eukaryotes (e.g., *Drosophila* and mammals), 9 aaRSs, some of each class, associate to form a multienzyme particle in which the glutamyl and prolyl synthetase functions are fused into a single polypeptide named **GluProRS**. The advantages of these systems are unknown.

### b. The Structural Features Recognized by Aminoacyl-tRNA Synthetases May Be Quite Simple

As we shall see in Section 32-2D, ribosomes select aminoacyl-tRNAs only via codon-anticodon interactions, not according to the identities of their aminoacyl groups. *Accurate translation therefore requires not only that each tRNA be aminoacylated by its cognate aaRS but that it not be aminoacylated by any of its 19 noncognate aaRSs.* Moreover, since most cells express only one aaRS for each amino acid, each aaRS must aminoacylate all of the several, if not many, **isoaccepting tRNAs** (different tRNAs that are specific for the same amino acid) in each cell.

Considerable effort has therefore been expended, notably by LaDonne Schulman, Paul Schimmel, Olke Uhlenbeck, and John Abelson, in elucidating how aaRSs manage this feat, despite the close structural similarities of nearly all tRNAs. The experimental methods employed involved the use of specific tRNA fragments, mutationally altered tRNAs, chemical cross-linking agents, computerized sequence comparisons, and X-ray crystallography. The most common synthetase contact sites on tRNA occur on the inner (concave) face of the L. Other than that, there appears to be little regularity in how the various tRNAs are recognized by their cognate synthetases. Indeed, as we shall see, some aaRSs recognize only their cognate tRNA's acceptor stem, whereas others also interact with its anticodon region. Additional tRNA regions may also be recognized.

Genetic manipulations by Schimmel revealed that the tRNA features recognized by at least one type of aaRS are surprisingly simple. Numerous sequence alterations of *E. coli* tRNA<sup>Ala</sup> do not appreciably affect its capacity to be aminoacylated with alanine. Yet, most base substitutions in the G3 · U70 base pair located in the tRNA's acceptor stem (Fig. 32-14a) greatly diminish this reaction. Moreover, the introduction of a G · U base pair into the analogous

**Figure 32-14 Major identity elements in four tRNAs.** Each base in the tRNA is represented by a filled circle. Red circles indicate positions that have been shown to be identity elements for the recognition of the tRNA by its cognate aminoacyl-tRNA synthetase. The anticodon bases that are identity elements are

underlined. In each case, additional identity elements may yet be discovered. The base at position 73, which is an identity element in all four tRNAs shown here, is known as the **discriminator base**.

**Figure 32-15** Three-dimensional model of *E. coli* tRNA<sup>Ala</sup>. This model is based on the X-ray structure of yeast tRNA<sup>Phe</sup> (Fig. 32-11*b*) in which the nucleotides that are different in *E. coli* tRNA<sup>Cys</sup> are highlighted in cyan and the G3 · U70 base pair is highlighted in ivory. [Courtesy of Ya-Ming Hou, MIT.]

position of tRNA<sup>Cys</sup> and tRNA<sup>Phe</sup> causes them to be aminoacylated with alanine even though there are few other sequence identities between these mutant tRNAs and tRNA<sup>Ala</sup> (e.g., Fig. 32-15). In fact, *E. coli* AlaRS even efficiently aminoacylates a 24-nt “microhelix” derived from only the G3 · U70-containing acceptor stem of *E. coli* tRNA<sup>Ala</sup>. Since the only *E. coli* tRNAs that normally have a G3 · U70 base pair are the tRNA<sup>Ala</sup>, and this base pair is also present in the tRNA<sup>Ala</sup> from many organisms including yeast (Fig. 32-8), the foregoing observations strongly suggest that *the G3 · U70 base pair is a major feature recognized by AlaRSs*. These enzymes presumably recognize the distorted shape of the G · U base pair (Fig. 32-12), a hypothesis corroborated by the observation that base changes at G3 · U70 which least affect the acceptor identity of tRNA<sup>Ala</sup> yield base pairs that structurally resemble G · U.

The elements of three other tRNAs, which are recognized by their cognate tRNA synthetases, are indicated in Fig. 32-14. As with tRNA<sup>Ala</sup>, these identity elements appear to comprise only a few bases. Note that the anticodon forms an identity element in two of these tRNAs. In another example of an anticodon identifier, the *E. coli* tRNA<sup>Ile</sup> specific for the codon AUA has the anticodon LAU, where L is **lysidine**, a modified cytosine whose 2-keto group is replaced by the amino acid lysine (Fig. 32-10). The L in this context pairs with A rather than G, a rare instance of base modification altering base pairing specificity. The replacement of this L with unmodified C, as expected, yields a tRNA that recognizes the Met codon AUG (codons bind anticodons in an antiparallel fashion). Surprisingly, how-

ever, this altered tRNA<sup>Ile</sup> is also a much better substrate for **MetRS** than it is for **IleRS**. Thus, both the codon and the amino acid specificity of this tRNA are changed by a single post-transcriptional modification. The *N*<sup>1</sup>-methylation of G37 in yeast tRNA<sup>Asp</sup> (Fig. 32-14*b*) provides another example of a base modification forming an identity element. In the absence of this *N*<sup>1</sup>-methyl group, tRNA<sup>Asp</sup> is recognized by **ArgRS**, largely via its C36 and G37, whereas ArgRS normally recognizes only tRNA<sup>Arg</sup>, mainly via its C35 and U36.

*The available experimental evidence has largely located the various tRNA identifiers in the acceptor stem and the anticodon loop* (Fig. 32-16). The X-ray structures of several aaRS · tRNA complexes, which we consider next, have structurally rationalized some of these observations.

### c. The X-Ray Structure of GlnRS · tRNA<sup>Gln</sup>, a Class I Complex

The X-ray structures of all 20 different amino acid-specific aaRSs from numerous organisms have been determined, many of which are in complex with ATP, their cognate amino acids, or their analogs. These structures reveal that the active sites of these enzymes bind the ATP and target amino acid in optimal positions for in-line nucleophilic displacement (Section 16-2B) during amino acid

**Figure 32-16** Experimentally observed identity elements of tRNAs. The tRNA backbone is cyan and each of its nucleotides is represented by a yellow circle whose diameter is proportional to the fraction of the 20 tRNA acceptor types for which the nucleotide is an observed determinant. [Courtesy of William McClain, University of Wisconsin.]

activation and that the specificity of an aaRS for its target amino acid is determined by idiosyncratic contacts with the side chain of the amino acid.

The X-ray structures of 16 different aaRSs in their complexes with their cognate tRNAs (all but those of Gly, Ala, Lys, and His) have so far been reported. The first of them to be elucidated, that of *E. coli* GlnRS, a Class I synthetase, in its complex with tRNA<sup>Gln</sup> and ATP (Fig. 32-17), was determined by Thomas Steitz. The tRNA<sup>Gln</sup> assumes an L-shaped conformation that resembles those of tRNAs of known structures (e.g., Fig. 32-11*b*). GlnRS, a 553-residue monomeric protein that consists of four domains arranged to form an elongated molecule, interacts with the tRNA along the entire inside face of the L such that the anticodon is bound near one end of the protein and the acceptor stem is bound near its other end.

Genetic and biochemical data indicate that the identity elements of tRNA<sup>Gln</sup> are largely clustered in its anticodon loop and acceptor stem (Fig. 32-14*c*). The anticodon loop of tRNA<sup>Gln</sup> is extended by two novel non-Watson–Crick base

pairs (2'-*O*-methyl-U32 ·  $\psi$ 38 and U33 · m<sup>2</sup>A37), thereby causing the bases of the anticodon to unstack and splay outward in different directions so as to bind in separate recognition pockets of GlnRS. These structural features suggest that GlnRS uses all seven bases of the anticodon loop to discriminate among tRNAs. Indeed, changes to any one of the bases of residues C34 through  $\psi$ 38 yield tRNAs with decreases in  $k_{\text{cat}}/K_M$  for aminoacylation by GlnRS by factors ranging from 70 to 28,000.

The GCCA at the 3' end of the tRNA<sup>Gln</sup> makes a hair-pin turn toward the inside of the L rather than continuing helically onward (as does the ACCA at the 3' end in the X-ray structure of tRNA<sup>Phe</sup>; Fig. 32-11*b*). This conformation change is facilitated by the insinuation of a Leu side chain between the 5' and 3' ends of the tRNA so as to disrupt the first base pair of the acceptor stem (U1 · A72). The GlnRS reaction is therefore relatively insensitive to base changes in these latter two positions except when base pairing is strengthened by their conversion to G1 · C72. The GCCA end of the tRNA<sup>Gln</sup> plunges deeply into a protein pocket

(a)

**Figure 32-17** X-ray structure of *E. coli* GlnRS · tRNA<sup>Gln</sup> · ATP. (a) The tRNA is drawn in stick form colored as the ATP but with the C atoms of the anticodon (UCG) and the 3'-CCA end yellow. An orange rod links its successive P atoms. The ATP bound in the protein's active site is drawn in space-filling form with C green, N blue, O red, and P orange. The protein is represented by a semitransparent light blue surface diagram that reveals the buried portions of the tRNA and ATP. Note that both the 3' end of the tRNA (*top right*) and its anticodon bases

(b)

(*bottom*) are inserted into deep pockets in the protein. (b) The complex viewed as in Part a. The tRNA's sugar–phosphate backbone is represented by an orange worm and the bases forming its identity elements (Fig. 32-14*c*) are drawn in stick form colored according to atom type with C magenta, N blue, and O red. The ATP is drawn as in Part a. The protein is shown in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). [Based on an X-ray structure by Thomas Steitz, Yale University. PDBid 1GTR.]  See Kinemage Exercise 20

that also binds the enzyme's ATP and glutamine substrates. Three protein "fingers" are inserted into the minor groove of the acceptor stem to make sequence-specific interactions with base pairs G2 · C71 and G3 · C70 [recall that double helical RNA has an A-DNA-like structure (Section 29-1Bc) whose wide minor groove readily admits protein but whose major groove is normally too narrow to do so].

The GlnRS domain that binds glutamine, ATP, and the GCCA end of tRNA<sup>Gln</sup>, the so-called catalytic domain, contains, as we previously discussed, a dinucleotide-binding fold. Much of this domain is nearly superimposable with and thus evolutionarily related to the corresponding domains of other Class I aaRSs.

#### d. The X-Ray Structure of AspRS · tRNA<sup>Asp</sup>, a Class II Complex

Yeast AspRS, a Class II synthetase, is an  $\alpha_2$  dimer of 557-residue subunits. Its X-ray structure in complex with tRNA<sup>Asp</sup>, determined by Moras, reveals that the protein symmetrically binds two tRNA molecules (Fig. 32-18). Like GlnRS, AspRS principally contacts its bound tRNA both at the end of its acceptor stem and in its anticodon region. The contacts in these two enzymes are, nevertheless, quite different in character (Fig. 32-19): Although both tRNAs approach their cognate synthetases along the inside of their L shapes, tRNA<sup>Gln</sup> does so toward the direction of the minor groove of its acceptor stem, whereas tRNA<sup>Asp</sup> does so toward the direction of its major groove. The GCCA at the 3' end of tRNA<sup>Asp</sup> thereby continues its helical track as it plunges into AspRS's catalytic site, whereas, as we saw, the GCCA end of tRNA<sup>Gln</sup> bends backward into a hairpin

turn that opens up the first base pair (U1 · A72) of its acceptor stem. Although the deep major groove of an A-RNA helix is normally too narrow to admit groups larger than water molecules (Section 29-1Bc), the major groove at the end of the acceptor stem in AspRS · tRNA<sup>Asp</sup> is sufficiently widened for its base pairs to interact with a protein loop.

The anticodon arm of tRNA<sup>Asp</sup> is bent by as much as 20 Å toward the inside of the L relative to that in the X-ray structure of uncomplexed tRNA<sup>Asp</sup> and its anticodon bases are unstacked. The hinge point for this bend is a G30 · U40 base pair in the anticodon stem which, in nearly all other species of tRNA, is a Watson–Crick base pair. The anticodon bases of tRNA<sup>Gln</sup> are also unstacked in contacting GlnRS but with a backbone conformation that differs from that in tRNA<sup>Asp</sup>. Evidently, the conformation of a tRNA in complex with its cognate synthetase appears to be dictated more by its interactions with the protein (induced fit) than by its sequence.

Structural analyses of complexes of AspRS · tRNA<sup>Asp</sup> with ATP and aspartic acid, and of GlnRS · tRNA<sup>Gln</sup> with ATP, have permitted models of the aminoacyl–AMP complexes of these enzymes to be independently formulated. Comparison of these models reveals that the 3'-terminal A residues of tRNA<sup>Gln</sup> and tRNA<sup>Asp</sup> (to which the aminoacyl groups are appended; Fig. 32-13) are positioned on opposite sides of the enzyme-bound aminoacyl–AMP intermediate (Fig. 32-20). The 3'-terminal ribose residues are puckered C2'-endo for tRNA<sup>Asp</sup> and C3'-endo for tRNA<sup>Gln</sup> (see Fig. 29-8) such that the 2'-hydroxyl group of tRNA<sup>Gln</sup> (Class I) is stereochemically positioned to attack the

**Figure 32-18** X-ray structure of yeast AspRS · tRNA<sup>Asp</sup> · ATP. (a) The homodimeric enzyme with its two symmetrically bound tRNAs is viewed with its 2-fold axis approximately vertical. The tRNAs are drawn in skeletal form colored according to atom type with the C atoms of the anticodon (GUC) and the 3'-CCA end yellow, the remaining C atoms green, N blue, O red, and P orange. An orange rod connects its successive P atoms. The two protein subunits are represented by semitransparent pink and light blue surface diagrams that reveal the buried portions of

the tRNAs. (b) A ribbon diagram of the AspRS · tRNA<sup>Asp</sup> protomer. The tRNA's sugar–phosphate backbone is represented by an orange worm and the bases forming its identity elements (Fig. 32-14b) are drawn in stick form colored according to atom type with C magenta, N blue, and O red. The protein is shown in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). [Based on an X-ray structure by Dino Moras, CNRS/INSERM/ULP, Illkirch Cédex, France. PDBid 1ASY.]

**Figure 32-19** Comparison of the modes by which GlnRS and AspRS bind their cognate tRNAs. The proteins and tRNAs are represented by blue and red spheres centered on their  $C_{\alpha}$  and P atom positions. Note how GlnRS (a), a Class I synthetase, binds  $tRNA^{Gln}$  from the minor groove side of its acceptor stem so as to bend its 3' end into a hairpin conformation. In contrast, AspRS

(b), a Class II synthetase, binds  $tRNA^{Asp}$  from the major groove side of its acceptor stem so that its 3' end continues its helical path on entering the active site. [After drawings by Dino Moras, CNRS/INSERM/ULP, Illkirch Cédex, France. PDBids 1GTR abd 1ASY.]

aminoacyl-AMP's carboxyl group, whereas for  $tRNA^{Asp}$  (Class II), only the 3'-hydroxyl group is situated to do so. This clearly explains the different aminoacylation specificities of the Class I and Class II aaRSs.

**Figure 32-20** Comparison of the stereochemistries of aminoacylation by Class I and Class II aaRSs. The positions of the 3' terminal adenosine residues (A76) of AspRS (Class II, left) and GlnRS (Class I, right) are drawn relative to that of the enzyme-bound aminoacyl-AMP (below; only the carbonyl group of its aminoacyl residue is shown). Note how only  $O3'$  of  $tRNA^{Asp}$  and  $O2'$  of  $tRNA^{Gln}$  are suitably positioned to attack the aminoacyl residue's carbonyl group and thereby transfer the aminoacyl residue to the tRNA. [After Cavarelli, J., Eriani, G., Rees, B., Ruff, M., Boeglin, M., Mitschler, A., Martin, F., Gangloff, J., Thierry, J.-C., and Moras, D., *EMBO J.* **13**, 335 (1994).]

### e. Proofreading Enhances the Fidelity of Amino Acid Attachment to tRNA

The charging of a tRNA with its cognate amino acid is a remarkably accurate process: aaRSs display an overall error rate of about 1 in 10,000. We have seen that aaRSs bind only their cognate tRNAs through an intricate series of specific contacts. But how do they discriminate among the various amino acids, some of which are quite similar?

Experimental measurements indicate, for example, that IleRS transfers as many as 40,000 isoleucines to  $tRNA^{Ile}$  for every valine it so transfers. Yet, as Linus Pauling first pointed out, *there are insufficient structural differences between Val and Ile to permit such a high degree of discrimination in the direct generation of aminoacyl-tRNAs*. The X-ray structure of *Thermus thermophilus* IleRS, a monomeric

Class I aaRS, in complex with isoleucine, determined by Shigeyuki Yokoyama and Schimmel, indicates that isoleucine fits snugly into its binding site in the enzyme's Rossmann fold domain and hence that this binding site would sterically exclude leucine as well as larger amino acids. However, valine, which differs from isoleucine by only the lack of a single methylene group, fits into this isoleucine-binding site. The binding free energy of a methylene group is estimated to be  $\sim 12 \text{ kJ} \cdot \text{mol}^{-1}$ . Equation [3.17] indicates that the ratio  $f$  of the equilibrium constants,  $K_1$  and  $K_2$ , with which two substances bind to a given binding site is given by

$$f = \frac{K_1}{K_2} = \frac{e^{-\Delta G_1^{\circ'}/RT}}{e^{-\Delta G_2^{\circ'}/RT}} = e^{-\Delta\Delta G^{\circ'}/RT} \quad [32.1]$$

where  $\Delta\Delta G^{\circ'} = \Delta G_1^{\circ'} - \Delta G_2^{\circ'}$  is the difference between the free energies of binding of the two substances. It is therefore estimated that isoleucyl-tRNA synthetase could discriminate between isoleucine and valine by no more than a factor of  $\sim 100$ .

Berg resolved this apparent paradox by demonstrating that, in the presence of tRNA<sup>Ile</sup>, IleRS catalyzes the nearly quantitative hydrolysis of valyl-adenylate to valine + AMP rather than forming Val-tRNA<sup>Ile</sup>. Moreover, the few Val-tRNA<sup>Ile</sup> molecules that do form are hydrolyzed to valine + tRNA<sup>Ile</sup>. Thus, *IleRS* subjects both aminoacyl-adenylate and aminoacyl-tRNA<sup>Ile</sup> to a **proofreading or editing step that occurs at a separate catalytic site**. This site binds Val residues but excludes the larger Ile residues. *The enzyme's overall selectivity is therefore the product of the selectivities of its synthesis and proofreading steps, thereby accounting for the high fidelity of aminoacylation. Note that in this so-called double-sieve mechanism, editing occurs at the expense of ATP hydrolysis, the thermodynamic price of high fidelity (increased order).*

The X-ray structure of *Staphylococcus aureus* IleRS in complex with tRNA<sup>Ile</sup> and the clinically useful antibiotic **mupirocin**

(a product of *Pseudomonas fluorescens* that acts by specifically binding to bacterial IleRS so as to inhibit bacterial protein synthesis), determined by Steitz, suggests how IleRS carries out its editing process. The X-ray structure (Fig. 32-21) reveals that this complex resembles the GlnRS · tRNA<sup>Gln</sup> · ATP complex (Fig. 32-17) but with IleRS having an additional editing domain (also called CP1 for connective peptide 1) inserted in its Rossmann fold domain. The two 3' terminal residues of the tRNA<sup>Ile</sup>, C75 and A76, are disordered but, when modeled so as to continue the acceptor stem's stacked A-form helix, extend into a cleft in the editing domain that has been implicated as its hydrolytic site (Fig. 32-22a, left). Thus, this IleRS complex ap-

**Figure 32-21** X-ray structure of *S. Aureus* isoleucyl-tRNA synthetase in complex with tRNA<sup>Ile</sup> and mupirocin. The tRNA is white, the protein is colored by domain, and the mupirocin is shown in stick form in pink. [Courtesy of Thomas Steitz, Yale University. PDBid 1QU2.]

pears to resemble an “editing complex” instead of a “transfer complex” as seen in the GlnRS structure. However, a transfer complex would form if the 3' ending segment of the tRNA<sup>Ile</sup> assumes a hairpin conformation (Fig. 32-22a, right) similar to that in the GlnRS structure (Figs. 32-17b and 32-19a; recall that IleRS and GlnRS are both Class I aaRSs). Steitz has therefore postulated that the aminoacyl group is shuttled between the IleRS's aminoacylation site and its editing site by such a conformational change (Fig. 32-22b). This process functionally resembles the way in which DNA polymerase I edits its newly synthesized strand (Section 30-2Ag), which Steitz also elucidated.

**ValRS** is a monomeric Class I aaRS that resembles IleRS. The X-ray structure of the complex of *T. thermophilus* ValRS, tRNA<sup>Val</sup>, and the nonhydrolyzable valyl-adenylate analog **5'-O-[N-(L-valyl)sulfamoyl]adenosine (Val-AMS)**,

**5'-O-[N-(L-Valyl)sulfamoyl]adenosine (Val-AMS)**

(a)

**Figure 32-22 Comparison of the putative aminoacylation and editing modes of IleRS · tRNA<sup>Ile</sup>.** (a) The superposition of tRNA<sup>Ile</sup> in these two binding modes on the solvent-accessible surface of IleRS (green). The acceptor strand of tRNA<sup>Ile</sup> in the editing mode observed in the X-ray structure of IleRS · tRNA<sup>Ile</sup> · mupirocin (Fig. 32-21) is drawn in ribbon form in white with the modeled positions of C75 and A76 in red. This places the tRNA's 3' end in the editing site. In contrast, the three 3' terminal residues of tRNA<sup>Ile</sup>, as positioned through homology modeling based on the X-ray structure of GlnRS · tRNA<sup>Gln</sup> · ATP (Fig. 32-17) and drawn in ball-and-stick form with C yellow, N blue, O red, and P magenta, places the tRNA's 3' end in the synthetic (aminoacylation) site, 34 Å distant from its position in the editing site. Note that there is a cleft running between the editing and synthetic sites and that the 3' end of the tRNA continues its A-form helical path in the editing mode but assumes a hairpin conformation in the synthetic mode. (b) A cartoon comparing the positions of the 3' end of tRNA<sup>Ile</sup> in its complex with IleRS in its synthetic mode (left) and in its editing mode (right). (b)

Valyl-adenylate

determined by Yokoyama, reveals that the Val-AMS is bound in the aminoacylation pocket in the Rossmann fold domain, which accommodates the isosteric Val and Thr moieties but sterically excludes Ile. Modeling studies based on the IleRS · tRNA<sup>Ile</sup> · mupirocin structure indicate that

the Thr side chain would fit into the ValRS editing pocket with its side chain hydroxyl group hydrogen bonded to the side chain of Asp 279 of ValRS, which protrudes into the pocket in contrast to the corresponding Asp 328 of IleRS, which does not. Consequently, a Val side chain would be excluded from the ValRS editing pocket because it cannot form such a hydrogen bond, thereby explaining why this editing pocket hydrolyzes **threonyl-adenylate** and Thr-tRNA<sup>Val</sup> but not the corresponding Val derivatives. The ValRS · tRNA<sup>Val</sup> structure also indicates that ValRS and tRNA<sup>Val</sup> together form a tunnel connecting the ValRS's aminoacylation pocket with its editing pocket. Improperly formed threonyl-adenylate is proposed to be channeled through this tunnel for hydrolysis in the editing pocket, thereby explaining why tRNA<sup>Val</sup> must be bound to ValRS for this pretransfer editing reaction to occur. Valyl-adenylate is presumably channeled through the similar IleRS · tRNA<sup>Ile</sup> complex for its hydrolysis.

**ThrRS**, a Class II homodimer, has the opposite problem of ValRS: It must synthesize **Thr-tRNA<sup>Thr</sup>** but not Val-tRNA<sup>Thr</sup>. The X-ray structure of *E. coli* ThrRS that lacks its N-terminal domain but remains catalytically active in a complex with either threonine or the threonyl-adenylate analog **Thr-AMS**, determined by Moras, reveals that ThrRS's aminoacylation pocket contains a Zn<sup>2+</sup> ion that is coordinated by the side chain hydroxyl and amino groups of the threonyl group as well as by three protein side chains. The isosteric valine could not coordinate the Zn<sup>2+</sup> ion in this way and hence does not undergo adenylation by ThrRS. However, what prevents ThrRS from synthesizing Ser-tRNA<sup>Thr</sup>? In fact, the truncated ThrRS synthesizes Ser-tRNA<sup>Thr</sup> at more than half the rate it synthesizes Thr-tRNA<sup>Thr</sup>, thereby indicating that the N-terminal domain of wild-type ThrRS contains the enzyme's editing site. Mutational analysis of ThrRS has localized this editing site to a cleft in the N-terminal domain of wild-type ThrRS, whose X-ray structure in complex with tRNA<sup>Thr</sup> was also determined by Moras. In this latter structure, the tRNA's 3' end follows a regular helical path similar to that seen in the X-ray structure of AspRS · tRNA<sup>Asp</sup> · ATP (Fig. 32-18) so as to enter the aminoacylation site. However, if the 3' end of the bound tRNA<sup>Thr</sup> assumed a hairpin conformation similar to that seen in X-ray structure of tRNA<sup>Gln</sup> in complex with the Class I enzyme GlnRS and ATP (Fig. 32-17), its covalently linked aminoacyl group would enter the editing site. This indicates an intriguing "mirror symmetry" (Fig. 32-23): In Class I aaRSs that mediate a double-sieve editing mechanism, the 3' end of the bound cognate tRNA assumes a hairpin conformation when it enters the aminoacylation site and a helical conformation when it enters the editing site, whereas the converse holds for Class II aaRSs. Finally, ThrRS does not appear to mediate pretransfer editing (does not hydrolyze **seryl-adenylate**), and, in fact, the ThrRS · tRNA<sup>Thr</sup> complex lacks a channel connecting its aminoacylation and editing sites such as is seen in the ValRS · tRNA<sup>Val</sup> complex.

Synthetases that have adequate selectivity for their corresponding amino acid lack editing functions. Thus, for example, the TyrRS aminoadenylation site discriminates between tyrosine and phenylalanine through hydrogen bonding with the tyrosine —OH group. The cell's other amino acids, standard as well as nonstandard, have even less resemblance to tyrosine, which rationalizes why TyrRS lacks an editing site.

#### f. Gln-tRNA<sup>Gln</sup> May Be Formed via an Alternative Pathway

Although it was long believed that each of the 20 standard amino acids is covalently linked to a tRNA by its corresponding aaRS, it is now clear that gram-positive bacteria, archaeobacteria, cyanobacteria, mitochondria, and chloroplasts all lack GlnRS. Rather glutamate is linked to tRNA<sup>Gln</sup> by the same GluRS that synthesizes **Glu-tRNA<sup>Gln</sup>**. The resulting **Glu-tRNA<sup>Gln</sup>** is then transamidated to Gln-tRNA<sup>Gln</sup> by the enzyme **Glu-tRNA<sup>Gln</sup> amidotransferase (Glu-AdT)** in an ATP-requiring reaction in which glutamine is the

**Figure 32-23** Schematic diagram of the aminoacylation and editing mechanisms of Class I and Class II aaRSs emphasizing the "mirror symmetry" of their overall mechanisms. With Class I aaRSs (left; e.g., IleRS), the 3' end of the bound tRNA's acceptor stem assumes a hairpin conformation in the synthetic mode and a helical conformation in the editing mode, whereas the converse occurs with Class II aaRSs (right; e.g., ThrRS). [Courtesy of Dino Moras, CNRS/INSERM/ULP, Illkirch Cedex, France.]

amide donor. Some microorganisms use a similar transamidation pathway for the synthesis of Asn-tRNA<sup>Asn</sup> from **Asp-tRNA<sup>Asn</sup>**.

The overall reaction catalyzed by Glu-AdT occurs in three stages (Fig. 32-24): (1) Glutamine is hydrolyzed to glutamate and the resulting NH<sub>3</sub> sequestered; (2) ATP reacts with the Glu side chain of Glu-tRNA<sup>Gln</sup> to yield an activated acylphosphate intermediate and ADP; and (3) the acylphosphate intermediate reacts with the NH<sub>3</sub> to yield Gln-tRNA<sup>Gln</sup> + P<sub>i</sub>. Glu-AdT from *Bacillus subtilis*, which was characterized by Dieter Söll, is a heterotrimeric protein, none of whose subunits exhibit significant sequence similarity to GlnRS. The genes encoding these subunits, *gatA*, *gatB*, and *gatC*, form a single operon whose disruption is lethal, thereby demonstrating that *B. subtilis* has no alternative pathway for Gln-tRNA<sup>Gln</sup> production. The **GatA** subunit of Glu-AdT appears to catalyze the activation of the side chain carboxyl of glutamic acid via a reaction resembling that catalyzed by carbamoyl phosphate synthetase (Section 26-2A). Nevertheless, GatA exhibits no sequence similarity with other known glutamine amidotransferases (members of the triad or Ntn families; Section 26-5Aa). The **GatB** subunit may be used to select the correct tRNA substrate. The role of the **GatC** subunit is unclear, although the observation that its presence is necessary for the expression of GatA in *E. coli* suggests that it participates in the modification, folding, and/or stabilization of GatA.

Since Glu is not misincorporated into *B. subtilis* proteins in place of Gln, the Glu-tRNA<sup>Gln</sup> product of the above aminoacylation reaction must not be transported to the ribosome in the same way as Gln-tRNA<sup>Gln</sup>. It is likely that this occurs because, as has been shown in chloroplasts, **EF-Tu**, the elongation factor that binds and transports most bacterial aminoacyl-tRNAs to the ribosome in a GTP-dependent process (Section 32-3D), does not bind Glu-tRNA<sup>Gln</sup>. It is unclear why two independent routes have evolved for the synthesis of Gln-tRNA<sup>Gln</sup>.

**Figure 32-24** The Glu-AdT-mediated synthesis of Gln-tRNA<sup>Gln</sup> from Glu-tRNA<sup>Gln</sup>. The reaction involves the ATP-activated transfer of a glutamine-derived NH<sub>3</sub> to the glutamate moiety of Glu-tRNA<sup>Gln</sup>.

### g. Some Archaeobacteria Lack a Separate CysRS

The genomes of certain archaeobacteria such as *M. jannaschii* lack an identifiable gene for CysRS. This is because the enzyme responsible for synthesizing **Pro-tRNA<sup>Pro</sup>** in these organisms also synthesizes **Cys-tRNA<sup>Cys</sup>**. Interestingly, this enzyme, which is named **ProCysRS**, does not synthesize Pro-tRNA<sup>Cys</sup> or Cys-tRNA<sup>Pro</sup>. Although ProCysRS synthesizes **cysteinyl-adenylate** only in the presence of tRNA<sup>Cys</sup>, it synthesizes **prolyl-adenylate** in the absence of tRNA<sup>Pro</sup>. The binding of tRNA<sup>Cys</sup> to ProCysRS blocks the activation of proline so that only cysteine can be activated. Conversely, the activation of proline facilitates the binding of tRNA<sup>Pro</sup> while preventing the binding of tRNA<sup>Cys</sup>. However, the mechanism through which ProCysRS carries out these mutually exclusive syntheses is unknown. In any case, it appears that some organisms can get by with as few as 17 different aaRSs; they may lack GlnRS, AspRS, and a separate CysRS.

### D. Codon-Anticodon Interactions

In protein synthesis, the proper tRNA is selected only through codon-anticodon interactions; the aminoacyl group does not participate in this process. This phenomenon was demonstrated as follows. Cys-tRNA<sup>Cys</sup>, in which the Cys

residue was <sup>14</sup>C labeled, was reductively desulfurized with Raney nickel so as to convert the Cys residue to Ala:

The resulting <sup>14</sup>C-labeled hybrid, Ala-tRNA<sup>Cys</sup>, was added to a cell-free protein synthesizing system extracted from rabbit reticulocytes. The product hemoglobin α chain's only radioactive tryptic peptide was the one that normally contains the subunit's only Cys. No radioactivity was found in the peptides that normally contain Ala but no Cys.

Evidently, *only the anticodons of aminoacyl-tRNAs participate in codon recognition.*

**a. Genetic Code Degeneracy Is Largely Due to Variable Third Position Codon–Anticodon Interactions**

One might naively guess that each of the 61 codons specifying an amino acid would be read by a different tRNA. Yet, even though most cells contain several groups of isoaccepting tRNAs, *many tRNAs bind to two or three of the codons specifying their cognate amino acids.* For example, yeast tRNA<sup>Phe</sup>, which has the anticodon GmAA, recognizes the codons UUC and UUU (remember that the anticodon pairs with the codon in an antiparallel fashion),

and yeast tRNA<sup>Ala</sup>, which has the anticodon IGC, recognizes the codons GCU, GCC, and GCA.

It therefore seems that non-Watson–Crick base pairing can occur at the third codon–anticodon position (the anticodon’s first position is defined as its 3’ nucleotide), the site of most codon degeneracy (Table 32-2). Note also that the third (5’) anticodon position commonly contains a modified base such as Gm or I.

**b. The Wobble Hypothesis Structurally Accounts for Codon Degeneracy**

By combining structural insight with logical deduction, Crick proposed, in what he named the **wobble hypothesis**, how a tRNA can recognize several degenerate codons. He assumed that the first two codon–anticodon pairings have normal Watson–Crick geometry. The structural constraints that this places on the third codon–anticodon pairing ensure that its conformation does not drastically differ from that of a Watson–Crick pair. Crick then proposed that there could be a small amount of play or “wobble” in the third codon position which allows limited conformational adjustments in its pairing geometry. This permits the formation of several non-Watson–Crick pairs such as U · G and I · A (Fig. 32-25a). The allowed “wobble” pairings are indicated in Fig. 32-25b. Then, by analyzing the known pattern of codon–anticodon pairing, Crick deduced the most plausible sets of pairing combinations in the third codon–anticodon position (Table 32-5). Thus, an anticodon

**Figure 32-25 Wobble pairing.** (a) U · G and I · A wobble pairs. Both have been observed in X-ray structures. (b) The geometry of wobble pairing. The spheres and their attached bonds represent the positions of ribose C1' atoms with their accompanying glycosidic bonds. X (*left*) designates the nucleoside at the 5' end of the anticodon (tRNA). The positions on the right are those of the 3' nucleoside of the codon (mRNA) in the indicated wobble pairings. [After Crick, F.H.C., *J. Mol. Biol.* **19**, 552 (1966).]

with C or A in its third position can only pair with its Watson–Crick complementary codon. If U, G, or I occupies the third anticodon position, two, two, or three codons are recognized, respectively.

**Table 32-5 Allowed Wobble Pairing Combinations in the Third Codon–Anticodon Position**

5'-Anticodon Base	3'-Codon Base
C	G
A	U
U	A or G
G	U or C
I	U, C, or A

(Section 4-3B), Pyl is directly incorporated into proteins during translation. Pyl is specified by the codon UAG (normally the *amber* Stop codon). Pyl is carried to the ribosome by **tRNA<sup>Pyl</sup>**, which contains a CUA anticodon and differs from typical tRNAs in having a D loop with five rather than eight residues, an anticodon stem with six rather than five base pairs, and a T $\psi$ C loop that lacks the sequence T $\psi$ C. A specific aminoacyl-tRNA synthetase, **PylRS**, that differs from known LysRSs, charges tRNA<sup>Pyl</sup> with pyrrolysine in an ATP-dependent reaction, the first known example in nature of the direct aminoacylation of a tRNA with a “nonstandard” amino acid. Unlike the case for Ser-tRNA<sup>Sec</sup>, Pyl-tRNA<sup>Pyl</sup> is delivered to the ribosome by EF-Tu. This suggests that the mRNA contains a signal that causes UAG to be read as a Pyl codon rather than as a Stop codon. A conserved stem-loop structure located on the 3' side of UAG codons specifying Pyl may comprise this signal. Alternatively, a Pyl-tRNA<sup>Pyl</sup> may occasionally read a UAG codon and is therefore a type of nonsense suppressor (see below).

### E. Nonsense Suppression

Nonsense mutations are usually lethal when they prematurely terminate the synthesis of an essential protein. An organism with such a mutation may nevertheless be “rescued” by a second mutation on another part of the genome. For many years after their discovery, the existence of such **intergenic suppressors** was quite puzzling. It is now known, however, that they usually arise from mutations in a tRNA gene that causes the tRNA to recognize a nonsense codon. Such a **nonsense suppressor** tRNA appends its amino acid (which is the same as that carried by the corresponding wild-type tRNA) to a growing polypeptide in response to the recognized Stop codon, thereby preventing chain termination. For example, the *E. coli* amber suppressor known as **su3** is a tRNA<sup>Tyr</sup> whose anticodon has mutated from the wild-type GUA (which reads the Tyr codons UAU and UAC) to CUA (which recognizes the amber Stop codon UAG). An *su3*<sup>+</sup> *E. coli* with an otherwise lethal *amber* mutation in a gene coding for an essential protein would be viable if the replacement of the wild-type amino acid residue by Tyr does not inactivate the protein.

There are several well-characterized examples of *amber* (UAG), *ochre* (UAA), and *opal* (UGA) suppressors in *E. coli* (Table 32-6). Most of them, as expected, have mutated anticodons. **UGA-1** tRNA, however, differs from the wild type only by a G  $\rightarrow$  A mutation in its D stem, which changes a G  $\cdot$  U pair to a stronger A  $\cdot$  U pair. This mutation apparently alters the conformation of the tRNA's CCA anticodon so that it can form an unusual wobble pairing with UGA as well as with its normal codon, UGG. Nonsense suppressors also occur in yeast.

#### a. Suppressor tRNAs Are Mutants of Minor tRNAs

How do cells tolerate a mutation that both eliminates a normal tRNA and prevents the termination of polypeptide synthesis? They survive because the mutated tRNA is usually a minor member of a set of isoaccepting tRNAs and be-

**Table 32-6** Some *E. coli* Nonsense Suppressors

Name	Codon Suppressed	Amino Acid Inserted
<i>su1</i>	UAG	Ser
<i>su2</i>	UAG	Gln
<i>su3</i>	UAG	Tyr
<i>su4</i>	UAA, UAG	Tyr
<i>su5</i>	UAA, UAG	Lys
<i>su6</i>	UAA	Leu
<i>su7</i>	UAA	Gln
UGA-1	UGA	Trp
UGA-2	UGA	Trp

cause nonsense suppressor tRNAs must compete for Stop codons with the protein factors that mediate the termination of polypeptide synthesis (Section 32-3F). Consequently, the rate of suppressor-mediated synthesis of active proteins with either UAG or UGA nonsense mutations rarely exceeds 50% of the wild-type rate, whereas mutants with UAA, the most common termination codon, have suppression efficiencies of <5%. Many mRNAs, moreover, have two tandem Stop codons so that even if their first Stop codon were suppressed, termination could occur at the second. Nevertheless, many suppressor-rescued mutants grow relatively slowly because they cannot make an otherwise prematurely terminated protein as efficiently as do wild-type cells.

Other types of suppressor tRNAs are also known. **Mis-sense suppressors** act similarly to nonsense suppressors but substitute one amino acid in place of another. **Frameshift suppressors** have eight nucleotides in their anticodon loops rather than the normal seven. They read a four-base codon beyond a base insertion thereby restoring the wild-type reading frame.

## 3 RIBOSOMES AND POLYPEPTIDE SYNTHESIS

Ribosomes were first seen in cellular homogenates by dark-field microscopy in the late 1930s by Albert Claude who referred to them as “microsomes.” It was not until the mid-1950s, however, that George Palade observed them in cells by electron microscopy, thereby disposing of the contention that they were merely artifacts of cell disruption. The name ribosome derives from the fact that these particles in *E. coli* consist of approximately two-thirds RNA and one-third protein. (**Microsomes** are now defined as the artifactual vesicles formed by the endoplasmic reticulum on cell disruption. They are easily isolated by differential centrifugation and are rich in ribosomes.) The correlation between the amount of RNA in a cell and the rate at which it synthesizes protein led to the suspicion that ribosomes are the site of protein synthesis. This hypothesis was confirmed in 1955 by Paul Zamecnik, who demonstrated that <sup>14</sup>C-labeled amino acids are transiently associated with

**Table 32-7** Components of *E. coli* Ribosomes

	Ribosome	Small Subunit	Large Subunit
Sedimentation coefficient	70S	30S	50S
Mass (kD)	2520	930	1590
RNA			
Major		16S, 1542 nucleotides	23S, 2904 nucleotides
Minor			5S, 120 nucleotides

Proportion of mass	34%	40%	30%

ribosomes before they appear in free proteins. Further research showed that ribosomal polypeptide synthesis has three distinct phases: (1) chain initiation, (2) chain elongation, and (3) chain termination.

In this section we examine the structure of the ribosome and then outline the ribosomal mechanism of polypeptide synthesis. In doing so we shall compare the properties of ribosomes from prokaryotes with those of eukaryotes.

### A. Ribosome Structure

The *E. coli* ribosome, which has a particle mass of  $\sim 2.5 \times 10^6$  D and a sedimentation coefficient of 70S, is a spheroidal particle that is  $\sim 250$  Å across in its largest dimension. It may be dissociated, as James Watson discovered, into two unequal subunits (Table 32-7). The small (30S) subunit consists of a 16S rRNA molecule and 21 different polypeptides, whereas the large (50S) subunit contains a 5S and a 23S rRNA together with 31 different polypeptides. The up to 20,000 ribosomes in an *E. coli* cell account for  $\sim 80\%$  of its RNA content and  $\sim 10\%$  of its protein.

Structural studies of the ribosome through electron microscopy began soon after its discovery. Three-dimensional (3D) structures of the ribosome and its subunits at low ( $\sim 50$  Å) resolution first became available in the 1970s through image reconstruction techniques, pioneered by Klug, in which electron micrographs of a single particle or ordered sheets of particles taken from several directions are combined to yield its 3D image. The small subunit is a roughly mitten-shaped particle, whereas the large subunit is spheroidal with three protuberances on one side (Fig. 32-26).

**Figure 32-26** A low resolution model of the *E. coli* ribosome.

The small subunit (*top; red*) associates with the large subunit (*middle; green*) to form the intact ribosome (*bottom*). Two perpendicular views of each particle are provided. These models are based on transmission electron micrographs of negatively stained particles (in which the particle being imaged is embedded in electron-absorbing heavy metal salts, thereby providing contrast between the relatively electron-transparent particle and the background).

**Figure 32-27 Secondary structures of the *E. coli* ribosomal RNAs.** (a) 16S RNA and (b) 23S and 5S RNAs. The rRNAs are colored by domain with short lines spanning a stem representing Watson–Crick base pairs, small dots representing G · U base pairs, and large dots representing other non-Watson–Crick base

#### a. Ribosomal RNAs Have Complicated Secondary Structures

The *E. coli* 16S rRNA, which was sequenced by Harry Noller, consists of 1542 nucleotides. A computerized search of this sequence for stable double helical segments yielded many plausible but often mutually exclusive secondary structures. However, the comparison of the sequences of 16S rRNAs from several prokaryotes, under the assumption that their structures have been evolutionarily conserved, led to the flowerlike secondary structure for 16S rRNA seen in Fig. 32-27a. This four-domain structure is 54% base paired. Its double helical stems tend to be short (<8 bp) and many of them are imperfect. Intriguingly, electron micrographs of the 16S rRNA resemble those of the complete 30S subunit, thereby suggesting that the 30S subunit's overall shape is largely determined by the 16S rRNA. The large ribosomal subunit's 5S and 23S rRNAs, which consist of 120 and 2904 nucleotides, respectively, have also been sequenced. As with the 16S rRNA, they have extensive secondary structures (Fig. 32-27b).

#### b. Ribosomal Proteins Have Been Partially Characterized

Ribosomal proteins are difficult to separate because most of them are insoluble in ordinary buffers. By convention, ribosomal proteins from the small and large subunits are designated with the prefixes S and L, respectively, followed by a number indicating their position, from upper left to lower right, on a two-dimensional gel electrophoretogram (roughly in order of decreasing molecular mass; Fig. 32-28). Only protein S20/L26 appears to be common to both subunits. One of the large subunit proteins is partially acetylated at its N-terminus so that it gives rise to two elec-

trophoretic spots (L7/L12). Four copies of this protein, a dimer of dimers, are present in the large subunit. Moreover, these four copies of L7/L12 aggregate with L10 to form a stable complex that was initially thought to be a unique protein, “L8.” All the other ribosomal proteins occur in only one copy per subunit.

**Figure 32-28 Two-dimensional gel electrophoretogram of *E. coli* small ribosomal subunit proteins.** First dimension (vertical): 8% acrylamide, pH 8.6; second dimension (horizontal): 18% acrylamide, pH 4.6. [From Kaltschmidt, E. and Wittmann, H.G., *Proc. Natl. Acad. Sci.* **67**, 1277 (1970).]

The amino acid sequences of all 52 *E. coli* ribosomal proteins were elucidated, mainly by Heinz-Günter Wittmann and Brigitte Wittmann-Liebold. They range in size from 46 residues for L34 to 557 residues for S1. Most of these proteins, which exhibit little sequence similarity with one another, are rich in the basic amino acids Lys and Arg and contain few aromatic residues as is expected for proteins that are closely associated with polyanionic RNA molecules.

The X-ray and NMR structures of around half of the ribosomal proteins or their fragments have been independently determined. These proteins have a wide variety of structural motifs although most of their folds occur in other proteins of known structure. Around one-third of these ribosomal proteins contain the **RNA-recognition motif (RRM; Section 31-4Ab)**, which occurs in >200 RNA-binding proteins including rho factor (the transcriptional termination protein, which contains four such motifs; Section 31-2Db), poly(A) polymerase, poly(A)-binding protein (PABP), several proteins involved in gene splicing (Section 31-4A), and the translational initiation factor **eIF4B** (Section 32-3Cd). All of these proteins presumably evolved from an ancient RNA-binding protein.

### c. Ribosomal Subunits Are Self-Assembling

Ribosomal subunits form, under proper conditions, from mixtures of their numerous macromolecular components. *Ribosomal subunits are therefore self-assembling entities.* Masayasu Nomura determined the order in which this occurs through partial reconstitution experiments. If one macromolecular component is left out of an otherwise

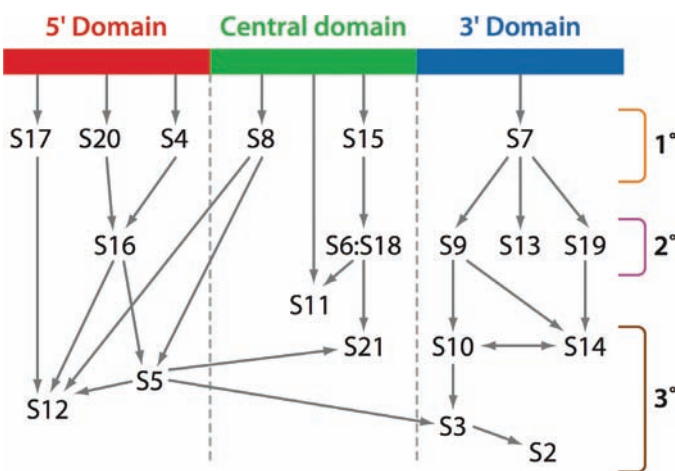

self-assembling mixture of proteins and RNA, the other components that fail to bind to the resulting partially assembled subunit must somehow interact with the omitted component. Through the analysis of a series of such partial reconstitution experiments, Nomura constructed an assembly map of the small (30S) subunit (Fig. 32-29). This map indicates that the initial steps in small subunit assembly are the independent binding to naked 16S rRNA of six so-called primary ( $1^\circ$ ) binding proteins (S4, S7, S8, S15, S17, and S20). The resulting assembly intermediates provide the molecular scaffolding for binding secondary ( $2^\circ$ ) binding proteins, which after a significant conformational change, form the attachment sites for tertiary ( $3^\circ$ ) binding proteins. An analogous assembly map for the large subunit was elucidated by Knud Nierhaus. The observation that similar assembly intermediates occur *in vivo* and *in vitro* suggests that *in vivo* and *in vitro* assembly processes are much alike.

In the cell, the 16S RNA folds in an ordered manner such that each domain is folded before the next domain is transcribed. The assembly of the small ribosomal subunit is then facilitated by a variety of **assembly factors**, proteins that bind to immature complexes but not to mature subunits. Many assembly factors associate with segments of the 16S RNA that change conformation during the latter stages of assembly. Presumably, the assembly of the large ribosomal subunit follows a similar course.

### d. The Atomic Structure of the Prokaryotic Ribosome Has Been Long in Coming

The elucidation of the ribosome's atomic structure was a tortuous affair extending over four decades in which slow incremental improvements were occasionally punctuated by significant technical gains. The process began in the 1960s with shadowy transmission electron micrographs that provided only rough 2D shapes. This was followed in the 1970s by image reconstruction techniques that generated 3D models although still at low resolution (Fig. 32-26). Later in the 1970s, the sites of many of the ribosome's proteins were determined by James Lake and Georg Stöffler through **immune electron microscopy**, a technique in which antibodies raised against a particular ribosomal protein are used to mark its position in electron micrographs of the antibody complexed to a ribosomal subunit. These results were improved and extended in the 1980s by neutron scattering experiments conducted by Donald Engelman and Peter Moore on the 30S subunit, which indicated the distances between the centers of mass of its component proteins and hence their three-dimensional distribution. These structural studies were supplemented by a variety of chemical cross-linking and fluorescence transfer studies that demonstrated the proximity of various ribosomal components.

The molecular structure of the prokaryotic ribosome began to come into focus in the mid-1990s through the development of **cryoelectron microscopy (cryo-EM)**. In this technique, the sample is cooled to near liquid  $N_2$  temperatures ( $-196^\circ C$ ) so rapidly (in a few milliseconds) that the water in the sample does not have time to crystallize but,

**Figure 32-29** Assembly map of the *E. coli* small subunit. The map is organized according to the domains of the 16S rRNA (Fig. 32-27) with arrows indicating the facilitation of binding. For example, the arrow from the 5' domain of the 16S rRNA to S20 indicates that S20 binds directly to the 16S rRNA in the absence of other proteins and is therefore a primary ( $1^\circ$ ) binding protein; the arrow from S20 to S16 indicates that S20 facilitates the binding of S16, which is therefore a secondary ( $2^\circ$ ) binding protein; and the arrows from S16 to S5 and S12 indicate that S5 and S12 are tertiary ( $3^\circ$ ) binding proteins. [Courtesy of James Williamson, The Scripps Research Institute, La Jolla, California.]

**Figure 32-30** Cryoelectron microscopy–based image of the *E. coli* ribosome. The 30S subunit (yellow) is on the left and the 50S subunit (blue) is on the right. The tRNAs that occupy the A, P, and E sites (Section 32-3B) are colored magenta, green, and brown. A portion of the 50S subunit has been cut away to reveal the polypeptide exit tunnel. A segment of mRNA (5' end brown and 3' end lavender) and the nascent polypeptide chain (yellow) have been modeled into the structure. [Courtesy of Joachim Frank, State University of New York at Albany.]

rather, assumes a vitreous (glasslike) state. Consequently, the sample remains hydrated and hence retains its native shape to a greater extent than in conventional electron microscopy (in which the sample is vacuum dried). Studies, carried out in large part by Joachim Frank, revealed the positions where tRNAs and mRNA as well as various soluble protein factors bind to the ribosome (Fig. 32-30). The highest resolution achieved by cryo-EM of ribosomes has gradually improved over the years to  $\sim 8$  Å.

Ribosomal subunits were first crystallized by Ada Yonath in 1980 although they diffracted X-rays poorly. Over the course of several years, however, the quality of these crystals were incrementally improved until, in 1991, Yonath reported crystals of the 50S subunit that diffracted X-rays to 3-Å resolution. It was not until later in the 1990s, however, that technology was up to the task of determining the X-ray structures of these gargantuan molecular complexes. In 2000, the *annus mirabilis* (miracle year) of ribosomology, Moore and Steitz reported the X-ray structure of the 50S ribosomal subunit of the halophilic (salt-loving) bacterium *Haloarcula marismortui* at atomic (2.4-Å) resolution and Venki Ramakrishnan and Yonath independently reported the X-ray structure of the 30S subunit of *T. thermophilus* at  $\sim 3$ -Å resolution. In 2001, Noller reported the 5.5-Å resolution structure of the entire *T. thermophilus* ribosome, which was gradually improved to 2.8 Å. In addition, the structures of the *E. coli* ribosome, by Jamie Cate, and the large subunit from *Deinococcus radiodurans*, by Yonath, have been determined. In the following paragraphs we discuss the properties of these groundbreaking structures. We consider their functional implications starting in Section 32-3C.

#### e. Ribosomal Architecture

Several generalizations can be made about ribosomal architecture based on the structures of the 30S and 50S subunits:

- Both the 16S and 23S rRNAs are assemblies of coaxially stacked helical elements connected by loops, most of which are irregular extensions of helices (Fig. 32-31). These structures, which are in close accord with previous secondary structure predictions (Fig. 32-27), are stabilized by interactions between helices such as minor groove to minor groove packing, which also occur in the structures of the group I intron and RNase P (Sections 31-4Af and 31-4Ca; recall that A-form RNA has a very shallow minor groove); the insertion of a phosphate ridge into a minor groove; and adenines that are distant in sequence but often highly conserved that are inserted into minor grooves. The overall shapes of these subunits are relatively flat rather than globular with most regions having a thickness of two or three helical diameters [in contrast, other large ( $>100$  nt) RNAs of known structure, such as the group I intron, RNase P, and the RNA from the signal recognition particle (Section 12-4Bb), are only one helix thick]. Although the determination of the structures of the 30S and 50S ribosomal subunits increased the amount of RNA structure that was then known at atomic resolution by  $\sim 10$ -fold, nearly all of the secondary structural motifs seen in the ribosome also occur in smaller RNA structures. This suggests that the repertoire of RNA secondary structural motifs is limited.

- Each of the 16S RNA's four domains, which extend out from a central junction (Fig. 32-27a), forms a morphologically distinct portion of the 30S subunit (Fig. 32-31a): The 5' domain forms most of the body (Fig. 32-26), the central domain forms the platform, the 3' major domain forms the entire head, and the 3' minor domain, which consists of just two helices, is located at the interface between the 30S and 50S subunits. In contrast, the 23S RNA's six domains (Fig. 32-27b) are intricately intertwined in the 50S subunit (Fig. 32-31b). Since the ribosomal proteins are embedded in the RNA (see below), this suggests that the domains of the 30S subunit can move relative to one

**Figure 32-31** Tertiary structures of the ribosomal RNAs. (a) The 16S rRNA of *T. thermophilus*. (b) The 23S rRNA of *H. marismortui*. The rRNAs are colored according to domain as in Fig. 32-27. The interface view of a ribosomal subunit (*left*) is toward its surface that associates with the other subunit in the whole ribosome and the back view (*right*) is from the opposite (solvent-exposed) side. Note that the secondary structure

domains of the 16S rRNA fold as separate tertiary structure domains, whereas in the 23S rRNA the secondary structure domains are convoluted together. [Courtesy of Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K., and Peter Moore, Yale University. PDBids 1J5E and 1JJ2.]

another during protein synthesis, whereas the 50S subunit appears to be rigid.

3. The distribution of the proteins in the two ribosomal subunits is not uniform (Fig. 32-32). The vast majority of the ribosomal proteins are located on the back and sides of their subunits. In contrast, the face of each subunit that forms the interface between the two subunits, particularly those regions that bind the tRNAs and mRNA (see below), is largely devoid of proteins.

4. Most ribosomal proteins consist of a globular domain, which is, for the most part, located on a subunit sur-

face (Fig. 32-32), and a long segment that is largely devoid of secondary structure and unusually rich in basic residues that infiltrates between the RNA helices into the subunit interior (Fig. 32-33). Indeed, a few ribosomal proteins lack a globular domain altogether (e.g., L39e in Fig. 32-33b). Ribosomal proteins make far fewer base-specific interactions than do other known RNA-binding proteins. They tend to interact with the RNA through salt bridges between their positively charged side chains and the RNAs' negatively charged phosphate oxygen atoms, thereby neutralizing the repulsive charge-charge interactions between nearby RNA segments. This is consistent with the hypothesis that

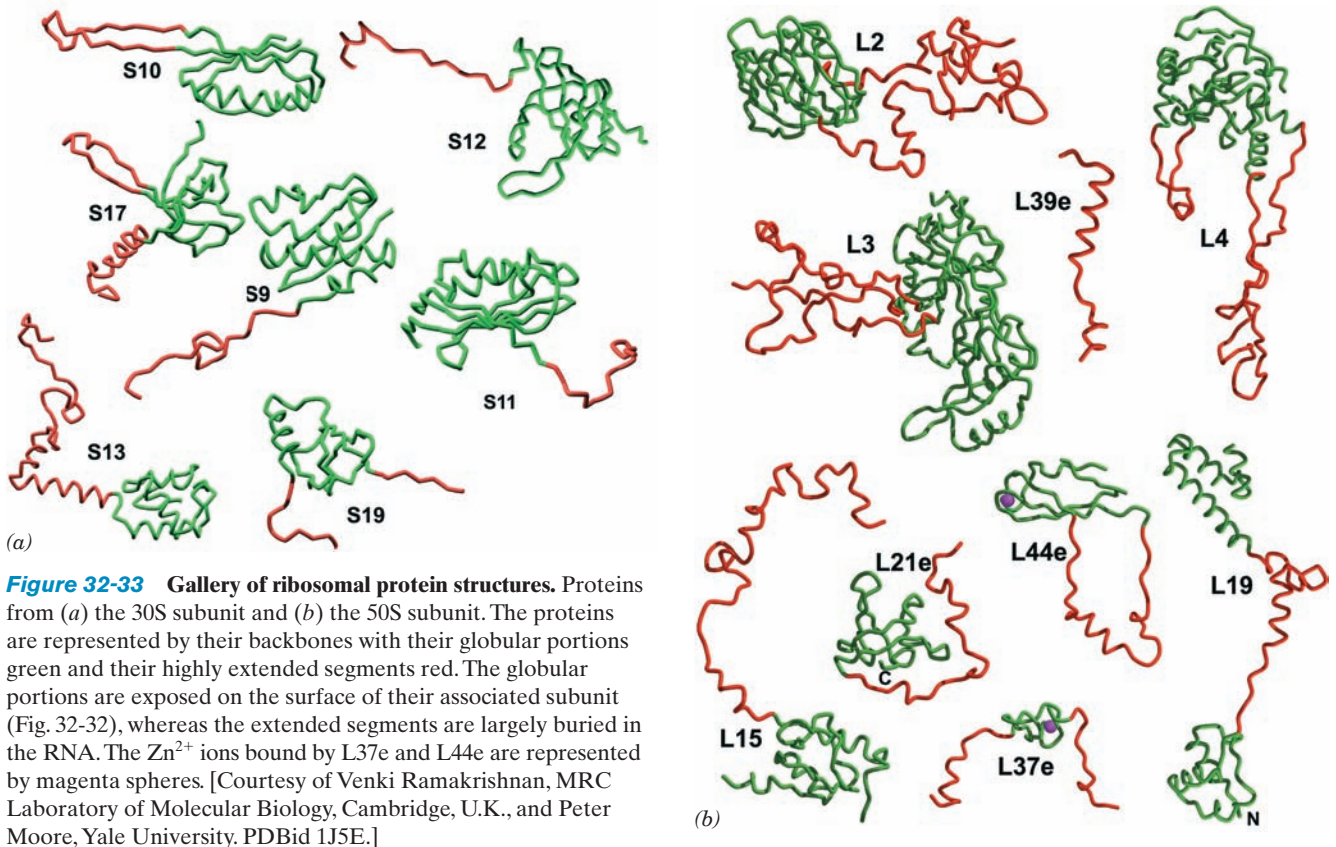

**Figure 32-32** Distribution of protein and RNA in the ribosomal subunits. (a) The 30S subunit of *T. thermophilus*. (b) The 50S subunit of *H. marismortui*. The subunits are drawn in space-filling form with their RNAs gray and their proteins in various colors. Note that the interface side of each subunit is largely free of protein, particularly in its regions that interact

with mRNA and tRNAs. [Part *a* based on an X-ray structure by Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. Part *b* based on an X-ray structure by Peter Moore and Thomas Steitz, Yale University. PDBids 1J5E and 1JJ2.]

the primordial ribosome consisted entirely of RNA (the RNA world) and that the proteins that were eventually acquired stabilized its structure and fine-tuned its function.

The X-ray structure of the entire *T. thermophilus* ribosome in complex with three tRNAs and a 11-nt mRNA segment was determined by Ramakrishnan (Fig. 32-34; ribosomes, as we shall see in Section 32-3B, have three functionally distinct tRNA-binding sites known as the A, P, and E sites). The structures of the 30S and 50S subunits in this enormous molecular machine closely resemble those of the isolated subunits although there are several regions at the subunit interface that exhibit significant conformational shifts, which suggests that these changes occur as a consequence of subunit association. In addition, several disordered portions of the isolated *H. marismortui* 50S subunit are ordered in the intact *T. thermophilus* ribosome, although this may be a consequence of the latter's greater thermal stability.

The ribosome binds all three tRNAs in a similar manner with their anticodon stem-loops bound to the 30S subunit and their remaining portions, the D stem, elbow, and acceptor stem, bound to the 50S subunit. These interactions, which mainly consist of RNA–RNA contacts, are made to the tRNAs' universally conserved segments, thereby permitting the ribosome to bind different species of tRNAs in the similar ways.

The small and large ribosomal subunits contact each other at 12 positions via RNA–RNA, protein–protein, and

RNA–protein bridges. These intersubunit bridges have a distinct distribution: The RNA–RNA bridges are centrally located adjacent to the three bound tRNAs, whereas the protein–protein and RNA–protein bridges are peripherally located away from the ribosome's functional sites. The RNA–RNA contacts consist mainly of minor groove–minor groove interactions although major groove, loop, and backbone contacts also occur. In the RNA–protein bridges, the proteins contact nearly all types of RNA features including major groove, minor groove, backbone, and loop elements.

We discuss the path of the mRNA and how it interacts with the tRNAs in Section 32-3D. There we shall see that *the large subunit is mainly involved in mediating biochemical tasks such as catalyzing the reactions of polypeptide elongation, whereas the small subunit is the major actor in ribosomal recognition processes such as mRNA and tRNA binding* (although, as we have seen, the large subunit also participates in tRNA binding). We shall also see that *rRNA has the major functional role in ribosomal processes* (recall that RNA has demonstrated catalytic properties; Sections 31-4Ae and 31-4Ca).

#### f. Eukaryotic Ribosomes Are Larger and More Complex than Prokaryotic Ribosomes

Although eukaryotic and prokaryotic ribosomes resemble one another in both structure and function, they differ in nearly all details. Eukaryotic ribosomes have particle masses in the range  $3.9$  to  $4.5 \times 10^6$  D and have a nominal

**Figure 32-34** X-ray structure of the *T. thermophilus* ribosome in complex with tRNA and mRNA at 3.5 Å resolution. The E site binds tRNA<sup>Phe</sup> and the A and P sites bind Phe-tRNA<sup>Phe</sup> (in which the O atom forming an ester linkage from Phe to O3' of the 3' terminal A has been replaced by an NH group to prevent the hydrolysis of the Phe-tRNA linkage). (a) The RNA components of the ribosomal complex (its proteins are omitted for clarity) drawn in cartoon form except for the 11-residue mRNA, which is shown in space-filling form. The 16S RNA is cyan, the 23S RNA is yellow, the 5S RNA is blue, the tRNAs in the A, P, and E sites are green, magenta, and red, and the mRNA, which is largely occluded by the 16S RNA, is colored according to atom type with C pink, N blue, O red, and P orange. (b) The 16S RNA in interface view with its bound tRNAs and mRNA, all

represented as in Part a. (c) The 23S RNA in interface view (rotated 180° about the vertical direction relative to Part b) with its bound tRNAs all represented as in Part a. (d) The interactions of the tRNAs with the mRNA. This assembly is drawn in cartoon form with A-site C green, P-site C magenta, E-site C red, mRNA C pink, N blue, and O red and with successive P atoms connected by orange rods. The Phe residues appended to the A- and P-site tRNAs are represented in space-filling form. Note the close approach of these Phe residues and that the tRNAs in the A and P sites, but not that in the E site, form based paired codon-anticodon interactions with the mRNA. [Based on an X-ray structure by Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBids 2WDK and 2WDL.]  See Interactive Exercise 44.

**Table 32-8** Components of Rat Liver Cytoplasmic Ribosomes

	Ribosome	Small Subunit	Large Subunit
Sedimentation coefficient	80S	40S	60S
Mass (kD)	4220	1400	2820
RNA			
Major		18S, 1874 nucleotides	28S, 4718 nucleotides
Minor			5.8S, 160 nucleotides 5S, 120 nucleotides
RNA mass (kD)	2520	700	1820
Proportion of mass	60%	50%	65%
Proteins			
		33 polypeptides	49 polypeptides
Protein mass (kD)	1700	700	1000
Proportion of mass	40%	50%	35%

sedimentation coefficient of 80S. They dissociate into two unequal subunits that have compositions that are distinctly different from those of prokaryotes (Table 32-8; compare with Table 32-7). The small (**40S**) subunit of the rat liver cytoplasmic ribosome, which together with the yeast ribosome is the most well-characterized eukaryotic ribosome, consists of 33 unique polypeptides and an **18S rRNA**. Its large (**60S**) subunit contains 49 different polypeptides and three rRNAs of **28S**, **5.8S**, and **5S**. The additional complexity of the eukaryotic ribosome relative to its prokaryotic counterpart is presumably due to the eukaryotic ribosome's additional functions: Its mechanism of translational initiation is more complex (Section 32-3Cd); it must be transported from the nucleus, where it is formed, to the cy-

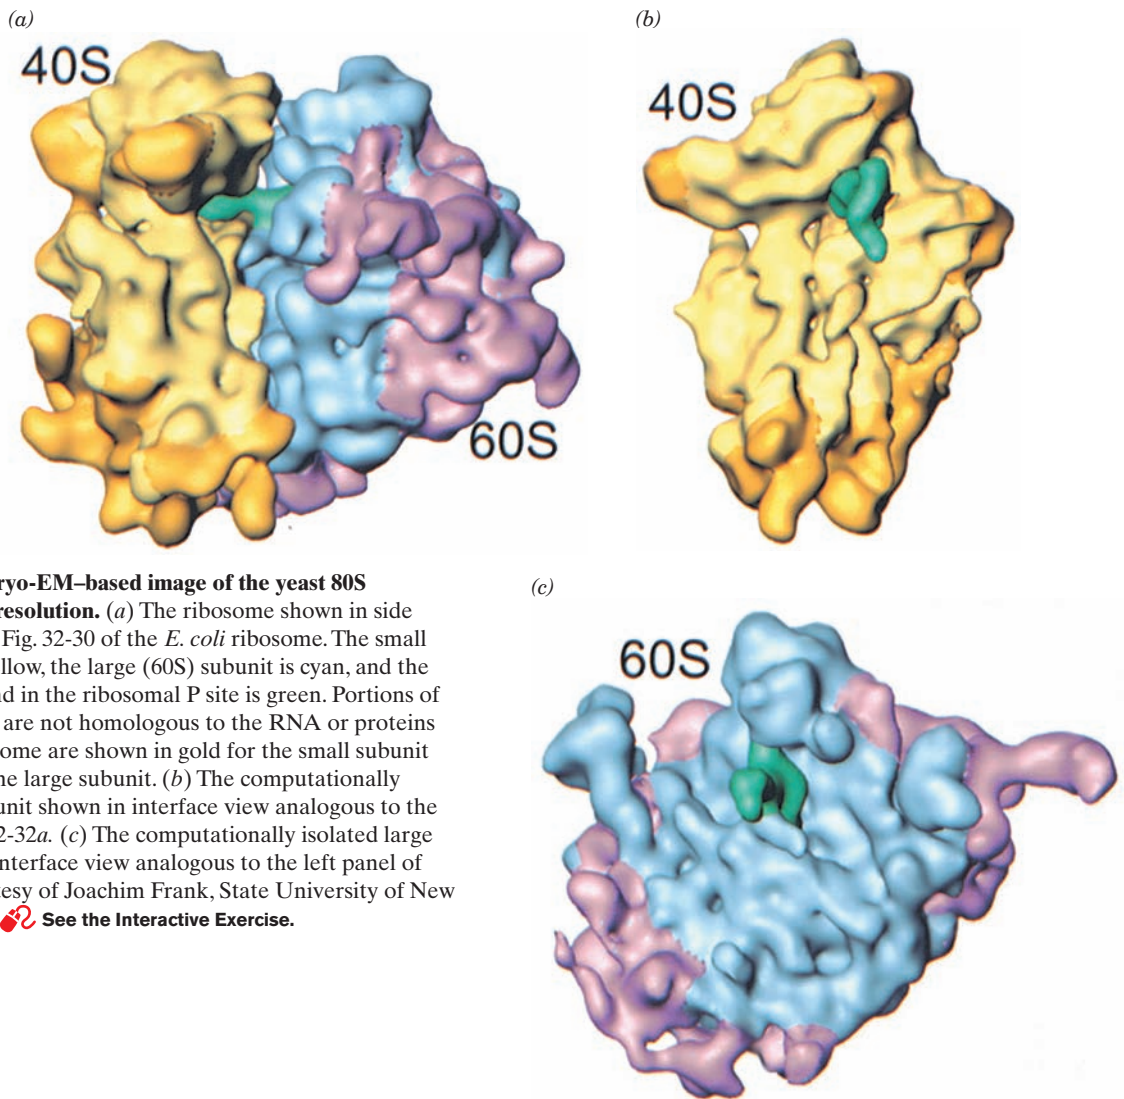

toplasm, where translation occurs; and the machinery with which it participates in the secretory pathway is more complicated (Section 12-4B).

Sequence comparisons of the corresponding rRNAs from various species indicates that evolution has conserved their secondary structures rather than their base sequences (Figs. 32-27a and 32-35). For example, a G · C in a base paired stem of *E. coli* 16S rRNA has been replaced by an A · U in the analogous stem of yeast 18S rRNA. The **5.8S rRNA**, which occurs in the large eukaryotic subunit in base paired complex with the **28S rRNA**, is homologous in sequence to the 5' end of prokaryotic 23S rRNA. Apparently 5.8S RNA arose through mutations that altered rRNA's post-transcriptional processing, producing a fourth rRNA.

**Figure 32-35** Predicted secondary structures of evolutionarily distant 16S-like rRNAs. (a) Archaeobacteria (*Halobacterium volcanii*), (b) eukaryotes (*S. cerevisiae*), and (c) mammalian mitochondria (bovine). Compare them with Fig. 32-27a, the secondary structure of 16S RNA from eubacteria (*E. coli*). Note the close similarities of these assemblies; they differ mostly by

insertions and deletions of stem-and-loop structures. The 23S-like rRNAs from a variety of species likewise have similar secondary structures. [After Gutell, R.R., Weiser, B., Woese, C.R., and Noller, H.F., *Prog. Nucleic Acid Res. Mol. Biol.* **32**, 183 (1985).]

**Figure 32-36** Cryo-EM-based image of the yeast 80S ribosome at 15 Å resolution. (a) The ribosome shown in side view analogous to Fig. 32-30 of the *E. coli* ribosome. The small (40S) subunit is yellow, the large (60S) subunit is cyan, and the tRNA that is bound in the ribosomal P site is green. Portions of this ribosome that are not homologous to the RNA or proteins of the *E. coli* ribosome are shown in gold for the small subunit and magenta for the large subunit. (b) The computationally isolated small subunit shown in interface view analogous to the left panel of Fig. 32-32a. (c) The computationally isolated large subunit shown in interface view analogous to the left panel of Fig. 32-32b. [Courtesy of Joachim Frank, State University of New York at Albany.]  See the Interactive Exercise.

The cryo-EM-based image of the yeast 80S ribosome (Fig. 32-36), determined at 15 Å resolution by Andrej Sali, Günter Blobel, and Frank, reveals that there is a high degree of structural conservation between eukaryotic and prokaryotic ribosomes. Although the yeast 40S subunit (which consists of a 1798-nt 18S rRNA and 32 proteins) contains an additional 256 nt of RNA and 11 proteins relative to the *E. coli* 30S subunit (Table 32-8; 15 of the *E. coli* proteins are homologous to those of yeast), both exhibit a similar division into head, neck, body, and platform (Fig. 32-36b vs Figs. 32-32a and 32-34b). Many of the differences between these two small ribosomal subunits are accounted for by the 40S subunit's additional RNA and proteins, although their homologous portions exhibit several distinct conformational differences. Similarly, the yeast 60S subunit (Fig. 32-35c; which consists of an aggregate of 3671 nt and 45 proteins) structurally resembles the considerably smaller (Table 32-7) prokaryotic 50S subunit (Fig. 32-32b). The yeast ribosome exhibits 16 intersubunit bridges, 12 of which match the 12 that were observed in the X-ray structure of the *T. thermophilus* ribosome, a remarkable evolu-

tionary conservation that indicates the importance of these bridges. Moreover, the tRNA that occupies the P site of the yeast ribosome has a conformation that more closely resembles that of the P-site tRNA in the *T. thermophilus* ribosome than that of free tRNA<sup>Phe</sup>.

## B. Polypeptide Synthesis: An Overview

Before we commence our detailed discussion of polypeptide synthesis, it will be helpful to outline some of its major features.

### a. Polypeptide Synthesis Proceeds from N-Terminus to C-Terminus

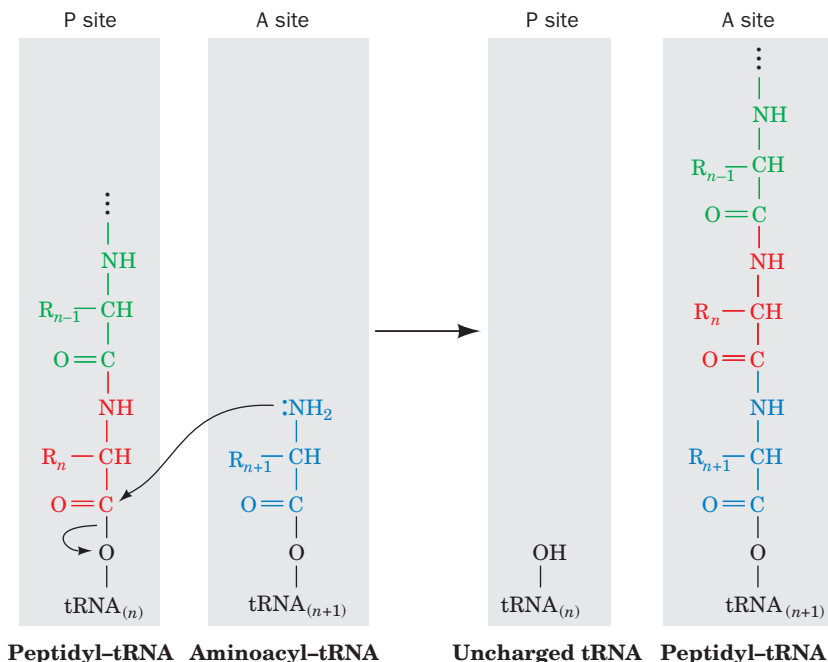

The direction of ribosomal polypeptide synthesis was established, in 1961 by Howard Dintzis, through radioactive labeling experiments. He exposed reticulocytes that were actively synthesizing hemoglobin to <sup>3</sup>H-labeled leucine for times less than that required to make an entire polypeptide. The extent to which the tryptic peptides from the soluble (completed) hemoglobin molecules were labeled increased

**Figure 32-38** Cryo-EM-based image of an *E. coli* polysome. The mRNA (which is mostly occluded) is represented by a red line, the small ribosomal subunits are yellow, the large subunits are blue-gray, and the red cones point to the polypeptide exit tunnel on each large subunit. The assembly shown has a pseudo-helical arrangement of ribosomes in which the center-to-center distance between adjacent ribosomes averages  $\sim 230$  Å. Polysomes with somewhat different although equally densely packed arrangements of ribosomes have also been observed. [Courtesy of Ulrich Hartl and Wolfgang Baumeister, Max Planck Institute of Biochemistry, Martinsreid, Germany.]

residue (Fig. 32-39). Apparently, the ribosome has at least two tRNA-binding sites: the so-called **peptidyl** or **P site**, which binds the peptidyl-tRNA, and the **aminoacyl** or **A site**, which binds the incoming aminoacyl-tRNA (Fig. 32-39). Consequently, after the formation of a peptide bond, the newly deacylated P-site tRNA must be released and replaced by the newly formed peptidyl-tRNA from the A site, thereby permitting a new round of peptide bond for-

**Figure 32-39** Ribosomal peptidyl transferase reaction forming a peptide bond. The ribosome catalyzes the nucleophilic attack of the amino group of the aminoacyl-tRNA in the A site on the peptidyl-tRNA ester in the P site, thereby forming a new peptide bond and transferring the nascent polypeptide to the A-site tRNA, while displacing the P-site tRNA.

mation. The finding by Knud Nierhaus that each ribosome can bind up to three deacylated tRNAs but only two aminoacyl-tRNAs indicates, however, that the ribosome has a third tRNA-binding site, the **exit** or **E site**, which transiently binds the outgoing deacylated tRNA. All three sites, as we have seen (Fig. 32-34), extend over both ribosomal subunits.

The details of the chain elongation process are discussed in Section 32-3D. Chain initiation and chain termination, which are special processes, are examined in Sections 32-3C and 32-3F, respectively. In all of these sections we shall first consider the process of interest in *E. coli* and then compare it with the analogous eukaryotic activity.

### C. Chain Initiation

#### a. fMet Is the N-Terminal Residue of Prokaryotic Polypeptides

The first indication that the initiation of translation requires a special codon, since identified as AUG (and, in prokaryotes, occasionally GUG), was the observation that almost half of the *E. coli* proteins begin with the otherwise uncommon amino acid Met. This was followed by the discovery of a peculiar form of Met-tRNA<sup>Met</sup> in which the Met residue is *N*-formylated:

**Figure 32-40** Nucleotide sequence of *E. coli* tRNA<sub>f</sub><sup>Met</sup> shown in cloverleaf form. The shaded boxes indicate the significant differences between this initiator tRNA and noninitiator tRNAs such as yeast tRNA<sup>Ala</sup> (Fig. 32-8). [After Woo, N.M., Roe, B.A., and Rich, A., *Nature* **286**, 346 (1980).]

The **N-formylmethionine** residue (**fMet**) already has an amide bond and can therefore only be the N-terminal residue of a polypeptide. In fact, polypeptides synthesized in an *E. coli*-derived cell-free protein synthesizing system always have a leading fMet residue. *fMet must therefore be E. coli's initiating residue.*

The tRNA that recognizes the initiation codon, tRNA<sub>f</sub><sup>Met</sup> (Fig. 32-40), differs from the tRNA that carries internal Met residues, tRNA<sub>m</sub><sup>Met</sup>, although they both recog-

nize the same codon. In *E. coli*, uncharged (deacylated) tRNA<sub>f</sub><sup>Met</sup> is first aminoacylated with methionine by the same MetRS that charges tRNA<sub>m</sub><sup>Met</sup>. The resulting **Met-tRNA<sub>f</sub><sup>Met</sup>** is specifically N-formylated to yield **fMet-tRNA<sub>f</sub><sup>Met</sup>** in an enzymatic reaction that employs N<sup>10</sup>-formyltetrahydrofolate (Section 26-4D) as its formyl donor. The formylation enzyme does not recognize Met-tRNA<sub>m</sub><sup>Met</sup>. The X-ray structures of *E. coli* tRNA<sub>f</sub><sup>Met</sup> and yeast tRNA<sup>Phe</sup> (Fig. 32-11b) are largely similar but differ conformationally in their acceptor stems and anticodon loops. Perhaps these structural differences permit tRNA<sub>f</sub><sup>Met</sup> to be distinguished from tRNA<sub>m</sub><sup>Met</sup> in the reactions of chain initiation and elongation (see Section 32-3D).

*E. coli* proteins are post-translationally modified by a **deformylase**, which hydrolytically deformylates their fMet residue, and, in many proteins, by the subsequent removal of the resulting N-terminal Met. This processing usually occurs on the nascent polypeptide, which accounts for the observation that mature *E. coli* proteins all lack fMet.

**b. Base Pairing between mRNA and the 16S rRNA Helps Select the Translational Initiation Site**

AUG codes for internal Met residues as well as the initiating Met residue of a polypeptide. Moreover, mRNAs usually contain many AUGs (and GUGs) in different reading frames. Clearly, *a translational initiation site must be specified by more than just an initiation codon.* This occurs in two ways: (1) the masking of AUGs that are not initiation codons by mRNA secondary structure; and (2) interactions between the mRNA and the 16S rRNA that select the initiating AUG as we now discuss.

The 16S rRNA contains a pyrimidine-rich sequence at its 3' end. This sequence, as John Shine and Lynn Dalgarno pointed out in 1974, is partially complementary to a purine-rich tract of 3 to 10 nucleotides, the **Shine-Dalgarno sequence**, that is centered ~10 nucleotides upstream from the start codon of nearly all known prokaryotic mRNAs (Fig. 32-41). *Base pairing interactions between an mRNA's*

**Figure 32-41** Some translational initiation sequences recognized by *E. coli* ribosomes. The mRNAs are aligned according to their initiation codons (blue shading). Their Shine-Dalgarno sequences (red shading) are complementary, counting G · U pairs, to a portion of the 16S rRNA's 3' end

(green shading; below). [After Steitz, J.A., in Chambliss, G., Craven, G.R., Davies, J., Davis, K., Kahan, L., and Nomura, M. (Eds.), *Ribosomes. Structure, Function and Genetics*, pp. 481-482, University Park Press (1979).]

*Shine–Dalgarno sequence and the 16S rRNA apparently permit the ribosome to select the proper initiation codon.* Thus ribosomes with mutationally altered anti-Shine–Dalgarno sequences often have greatly reduced ability to recognize natural mRNAs, although they efficiently translate mRNAs whose Shine–Dalgarno sequences have been made complementary to the altered anti-Shine–Dalgarno sequences. Moreover, treatment of ribosomes with the bactericidal protein **colicin E3** (produced by *E. coli* strains carrying the E3 plasmid), which specifically cleaves a 49-nucleotide fragment from the 3' terminus of 16S rRNA, yields ribosomes that cannot initiate new polypeptide synthesis but can complete the synthesis of a previously initiated chain.

The X-ray structure of the 70S ribosome reveals, in agreement with Fig. 32-30, that a 27-nt segment of the mRNA is wrapped in a groove that encircles the neck of the 30S subunit (Fig. 32-42). The mRNA codons in the A and P sites are exposed on the interface side of the 30S subunit (as in Fig. 32-34*b*), whereas its 5' and 3' ends are bound in tunnels composed of RNA and protein. The mRNA's

**Figure 32-42** Path of mRNA through the ribosomal 30S subunit as viewed from its interface side. The 16S rRNA is cyan, and the 27-nt mRNA is represented in worm form with its A- and P-site codons orange and red, the Shine–Dalgarno helix (which includes a segment of 16S rRNA) magenta, and its remaining segments yellow. The S3, S4, and S5 proteins are green, the S7, S11, and S12 proteins are purple, and the remaining ribosomal proteins have been omitted for clarity. The S3, S4, and S5 proteins, which in part form the tunnel through which the mRNA enters the ribosome, may function as a helicase to remove secondary structure from the mRNA that would otherwise interfere with tRNA binding. [Courtesy of Gloria Culver, Iowa State University. Based on an X-ray structure by Harry Noller, University of California at Santa Cruz. PDBid 1JGO.]

Shine–Dalgarno sequence, which is located near its 5' end, is base paired, as expected, with the 16S rRNA's anti-Shine–Dalgarno sequence, which is situated close to the E site. The resulting double helical segment is accommodated in a cleft formed by both RNA and protein elements of the 16S subunit's head, neck, and platform (Fig. 32-26).

### c. Prokaryotic Initiation Is a Three-Stage Process That Requires the Participation of Soluble Protein Initiation Factors

**See Guided Exploration 28: Translational initiation** Intact ribosomes do not directly bind mRNA so as to initiate polypeptide synthesis. Rather, *initiation is a complex process in which the two ribosomal subunits and fMet-tRNA<sup>fMet</sup> assemble on a properly aligned mRNA to form a complex that is competent to commence chain elongation.* This assembly process also requires the participation of protein **initiation factors** that are not permanently associated with the ribosome. Initiation in *E. coli* involves three initiation factors designated **IF-1**, **IF-2**, and **IF-3** (Table 32-9). Their existence was discovered when it was found that washing small ribosomal subunits with 1M ammonium chloride solution,

**Table 32-9** The Soluble Protein Factors of *E. coli* Protein Synthesis

Factor	Number of Residues <sup>a</sup>	Function
<b>Initiation Factors</b>		
IF-1	71	Assists IF-3 binding
IF-2	890	Binds initiator tRNA and GTP
IF-3	180	Releases mRNA and tRNA from recycled 30S subunit and aids new mRNA binding
<b>Elongation Factors</b>		
EF-Tu	393	Binds aminoacyl-tRNA and GTP
EF-Ts	282	Displaces GDP from EF-Tu
EF-G	703	Promotes translocation through GTP binding and hydrolysis
<b>Release Factors</b>		
RF-1	360	Recognizes UAA and UAG Stop codons
RF-2	365	Recognizes UAA and UGA Stop codons
RF-3	528	Stimulates RF-1/RF-2 release via GTP hydrolysis
RRF	185	Together with EF-G, induces ribosomal dissociation to small and large subunits

<sup>a</sup>All *E. coli* translational factors are monomeric proteins.

which removes the initiation factors but not the “permanent” ribosomal proteins, prevents initiation.

The initiation sequence in *E. coli* ribosomes has three stages (Fig. 32-43):

**1.** On completing a cycle of polypeptide synthesis, the 30S and 50S subunits are separated (Section 32-3Fa). IF-3 then binds to the 30S subunit so as to prevent the reassociation of the 50S subunit. The X-ray structure of the 30S subunit in complex with the C-terminal domain of IF-3 (which by itself prevents the association of the 30S and 50S subunits), determined by Yonath and François Franceschi, indi-

cates that IF-3 binds to the upper end of the platform (Fig. 32-26) on its solvent (back) side. Hence IF-3 does not function by physically blocking the binding of the 50S subunit.

**2.** mRNA and IF-2 in a ternary complex with GTP and fMet-tRNA<sub>f</sub><sup>Met</sup> that is accompanied by IF-1 subsequently bind to the 30S subunit in either order. Hence, fMet-tRNA<sub>f</sub><sup>Met</sup> recognition must not be mediated by a codon-anticodon interaction. This interaction, nevertheless, helps bind fMet-tRNA<sub>f</sub><sup>Met</sup> to the ribosome. IF-1 binds in the A site where it may function to prevent the inappropriate or premature binding of a tRNA. IF-3 also functions in this stage of the initiation process: it destabilizes the binding of tRNAs that lack the three G · C pairs in the anticodon stem of RNA<sub>f</sub><sup>Met</sup> (Fig. 32-40) and helps discriminate between matched and mismatched codon-anticodon interactions.

**3.** Last, in a process that is preceded by IF-1 and IF-3 release, the 50S subunit joins the 30S initiation complex in a manner that stimulates IF-2 to hydrolyze its bound GTP to GDP + P<sub>i</sub>. This irreversible reaction conformationally rearranges the 30S subunit and releases IF-2 for participation in further initiation reactions.

IF-2 is a member of the superfamily of regulatory GTPases such as Ras and hence is a **G protein** (Section 19-2A). The 30S initiation complex therefore functions as its **GAP** (GTPase-activating protein; Section 19-2Ca).

Initiation results in the formation of an fMet-tRNA<sub>f</sub><sup>Met</sup> · mRNA · ribosome complex in which the fMet-tRNA<sub>f</sub><sup>Met</sup> occupies the ribosome's P site while its A site is poised to accept an incoming aminoacyl-tRNA (an arrangement similar to that at the conclusion of a round of elongation; Section 32-3D). In fact, tRNA<sub>f</sub><sup>Met</sup> is the only tRNA that directly enters the P site. All other tRNAs must do so via the A site during chain elongation (Section 32-3D). This arrangement was established through the use of the antibiotic puromycin as is discussed in Section 32-3Df.

#### d. Eukaryotic Initiation Is Far More Complicated than That of Prokaryotes

Although translational initiation in eukaryotes superficially resembles that in prokaryotes, it is, in fact, a far more complicated process. Whereas prokaryotic initiation only requires the assistance of three monomeric initiation factors, that in eukaryotes involves the participation of at least 12 initiation factors (designated eIF<sub>n</sub>; “e” for eukaryotic) that consist of at least 26 polypeptide chains. Eukaryotic initiation occurs as follows (Fig. 32-44):

**1.** The process begins with the binding of **eIF3** (which in mammals consists of 13 different subunits) and **eIF1A** (a monomer and homolog of bacterial IF-1) to the 40S subunit in the inactive 80S ribosome (which had terminated elongation in its previous elongation cycle) so that it releases the 60S subunit.

**2.** The ternary complex of **eIF2** (a heterotrimer), GTP, and **Met-tRNA<sub>f</sub><sup>Met</sup>** binds to the 40S ribosomal subunit accompanied by **eIF1** (a monomer) to form the so-called **43S**

**Figure 32-43** Translational initiation pathway in *E. coli*. The E site, which is unoccupied during this process, has been omitted for clarity.

**Figure 32-44 Translational initiation pathway in eukaryotes.** Initiation factors are represented by colored rectangles where they are first implicated in the pathway and by circles of the same color thereafter. The higher order complexes are hypothetical. Several of the initiation factors (4A, 4B, 4E, 4G, and 4H) have been left out of the 48S preinitiation complex for clarity. [Based on a drawing by Hershey, J.W.B. and Merrick, W.C., in Sonenberg, N., Hershey, J.W.B., and Mathews, M.B. (Eds.), *Translational Control of Gene Expression*, Cold Spring Harbor Laboratory Press (2000).]

**preinitiation complex.** Here the subscript “i” on  $\text{tRNA}_{\text{Met}}^{\text{i}}$  distinguishes this eukaryotic initiator tRNA, whose appended Met residue is never *N*-formylated, from that of prokaryotes; both species are, nevertheless, readily interchangeable *in vitro*.

**3.** Eukaryotic mRNAs lack the complementary sequences to bind to the 18S rRNA in the Shine–Dalgarno manner. Rather, they have an entirely different mechanism for recognizing the mRNA’s initiating AUG codon. *Eukaryotic mRNAs, nearly all of which have an  $\text{m}^7\text{G}$  cap and a poly(A) tail (Section 31-4Ab), are invariably monocistronic and almost always initiate translation at their leading AUG.* This AUG, which occurs at the end of a 5′-untranslated region of 50 to 70 nt, is embedded in the consensus sequence GCCRCCAUGG, with changes in the purine (R) 3 nt before the AUG and the G immediately following it reducing translational efficiency by  $\sim 10$ -fold each and with other changes having much smaller effects. In addition, secondary structure (stem-loops) in the mRNA upstream of the initiation site may affect initiation efficiency.

The recognition of the initiation site begins by the binding of **eIF4F** to the  $\text{m}^7\text{G}$  cap. eIF4F is a heterotrimeric complex of **eIF4E**, **eIF4G**, and **eIF4A** (all monomers), in

which **eIF4E (cap-binding protein)** recognizes the mRNA’s  $\text{m}^7\text{G}$  cap and eIF4G serves as a scaffold to join eIF4E with eIF4A. Both the X-ray and NMR structures of eIF4E in complex with  **$\text{m}^7\text{GDP}$** , determined by Nahum Sonenberg and Stephen Burley and by Sonenberg and Gerhard Wagner, reveal that the protein binds the  $\text{m}^7\text{G}$  base by intercalating it between two highly conserved Trp residues (Fig. 32-45a) in a region that is adjacent to a positively charged cleft that forms the putative mRNA-binding site (Fig. 32-45b). The  $\text{m}^7\text{G}$  base is specifically recognized by hydrogen bonding to protein side chains in a manner reminiscent of G · C base pairing. eIF4G also binds poly(A)-binding protein (PABP; Section 31-4Ab) bound to the mRNA’s poly(A) tail, thereby circularizing the mRNA (not shown in Fig. 32-44). Although this explains the synergism between an mRNA’s  $\text{m}^7\text{A}$  cap and its poly(A) tail in stimulating translational initiation, the function of this circle is unclear. However, an attractive hypothesis is that it enables a ribosome that has finished translating the mRNA to reinitiate translation without having to disassemble and then reassemble. Another possibility is that it prevents the translation of incomplete (broken) mRNAs. This circularization, as we have seen in Section 31-4Av, also protects the mRNA from degradation

**Figure 32-45** X-ray structure of murine eIF4E in complex with the  $\text{m}^7\text{G}$  cap analog  $\text{m}^7\text{GDP}$ . (a) The  $\text{m}^7\text{GDP}$ -binding site with the  $\text{m}^7\text{GDP}$  and the side chains that bind it drawn in ball-and-stick form with the atoms of the  $\text{m}^7\text{GDP}$  colored according to type (C green, N dark yellow, O red, and P bright yellow) and the protein side chains with which the  $\text{m}^7\text{GDP}$  interacts drawn in various colors. Hydrogen bonds, salt bridges, and van der Waals interactions are represented by dashed lines and bridging water molecules are drawn as black spheres. The  $\text{m}^7\text{G}$  base is intercalated between the indole rings of Trp 56 and Trp 102, where it specifically interacts with protein side chains through

hydrogen bonds and van der Waals interactions. The GDP’s phosphate groups interact directly and indirectly with three basic side chains. (b) The solvent-accessible surface of eIF4E colored according to its electrostatic potential (red negative, blue positive, and white neutral) and viewed approximately as in Part a. The  $\text{m}^7\text{GDP}$  is drawn in ball-and-stick form colored as in Part a. The mRNA presumably binds in the positively charged cleft (yellow arrow) that is adjacent to the  $\text{m}^7\text{G}$  binding site and which passes between Lys 159 and Ser 209. [Courtesy of Nahum Sonenberg, McGill University, Montréal, Québec, Canada. PDBid 1EJ1.]

by preventing the action of decapping enzyme until the mRNA's poly(A) tail has been shortened to the point that it can no longer bind PABP.

**4. eIF4B** (an RRM-containing homodimer) and **eIF4H** (a monomer) join the eIF4F–mRNA complex where they stimulate the RNA helicase activity of eIF4A to unwind the mRNA's helical segments in an ATP-dependent process. This presumably also strips away the proteins that are bound to the mRNA (Section 31-4Au). eIF4A is the prototype of the so-called **DEAD-box family** of proteins (also known as DExD/H family proteins; Section 31-4Au), which is named after one of the sequence motifs shared by the diverse members of this family, all of which have NTPase activity.

**5.** The eIF4F–mRNA–eIF4B–eIF4H complex joins the 43S preinitiation complex through a protein–protein interaction between eIF4G and the 40S subunit-bound eIF3. This differs substantially from the corresponding prokaryotic process (Fig. 32-43) in which the mRNA is bound to the 30S ribosomal subunit via associations between RNA molecules (involving the Shine–Dalgarno sequence and the codon–anticodon interaction).

**6. eIF5** (a monomer) joins the growing assembly. The 43S preinitiation complex then translocates along the mRNA, an ATP-dependent process called **scanning**, until it encounters the mRNA's AUG initiation codon, which is optimally in the sequence GCC(A/G)CCAUGG. This yields the **48S preinitiation complex**. The recognition of the AUG occurs mainly through base pairing with the CUA anticodon on the bound Met–tRNA<sub>i</sub><sup>Met</sup>, as was demonstrated by the observation that mutating this anticodon results in the recognition of the new cognate codon instead of AUG. This explains why the initiator tRNA must bind to the small subunit before the mRNA.

**7.** The formation of the 48S preinitiation complex induces eIF2 to hydrolyze its bound GTP to GDP + P<sub>i</sub>, which results in the release of all the initiation factors, thereby leaving the Met–tRNA<sub>i</sub><sup>Met</sup> in the small subunit's P site. The hydrolysis reaction is stimulated by eIF5, acting as a GAP (Section 19-2Ca).

**8.** The 60S subunit then joins the mRNA-bound Met–tRNA<sub>i</sub><sup>Met</sup>–40S subunit complex in a GTPase reaction mediated by **eIF5B** (a monomer and homolog of bacterial IF-2), thereby yielding the 80S ribosomal initiation complex. Thus eukaryotic translation initiation consumes two GTPs versus one for prokaryotic initiation (Fig. 32-43).

**9.** What remains is to recycle the eIF2 · GDP complex by exchanging its GDP for GTP. This reaction is mediated by **eIF2B** (a heteropentamer), which therefore functions as eIF2's **GEF** (guanine nucleotide exchange factor; Section 19-2Ca).

Many eukaryotic initiation factors are subject to phosphorylation/dephosphorylation and are therefore likely to par-

ticipate in the control of eukaryotic translation, a subject we discuss in Section 32-4.

Although the initiation sites on most eukaryotic mRNAs are identified by the above-described scanning mechanism, a few mRNAs have an **internal ribosome entry site (IRES)** to which the 40S subunit can directly bind in a process reminiscent of prokaryotic initiation. However, little is yet known about the mechanism of IRES-based initiation. Indeed, IRESs lack clearly identifiable consensus sequences.

## D. Chain Elongation

 **See Guided Exploration 29: Translational elongation** *Ribosomes elongate polypeptide chains in a three-stage reaction cycle that adds amino acid residues to a growing polypeptide's C-terminus (Fig. 32-46):*

**1. Decoding**, in which the ribosome selects and binds an aminoacyl–tRNA, whose anticodon is complementary to the mRNA codon in the A site.

**2. Transpeptidation**, in which the peptidyl group on the P-site tRNA is transferred to the aminoacyl group in the A site through the formation of a peptide bond (Fig. 32-39).

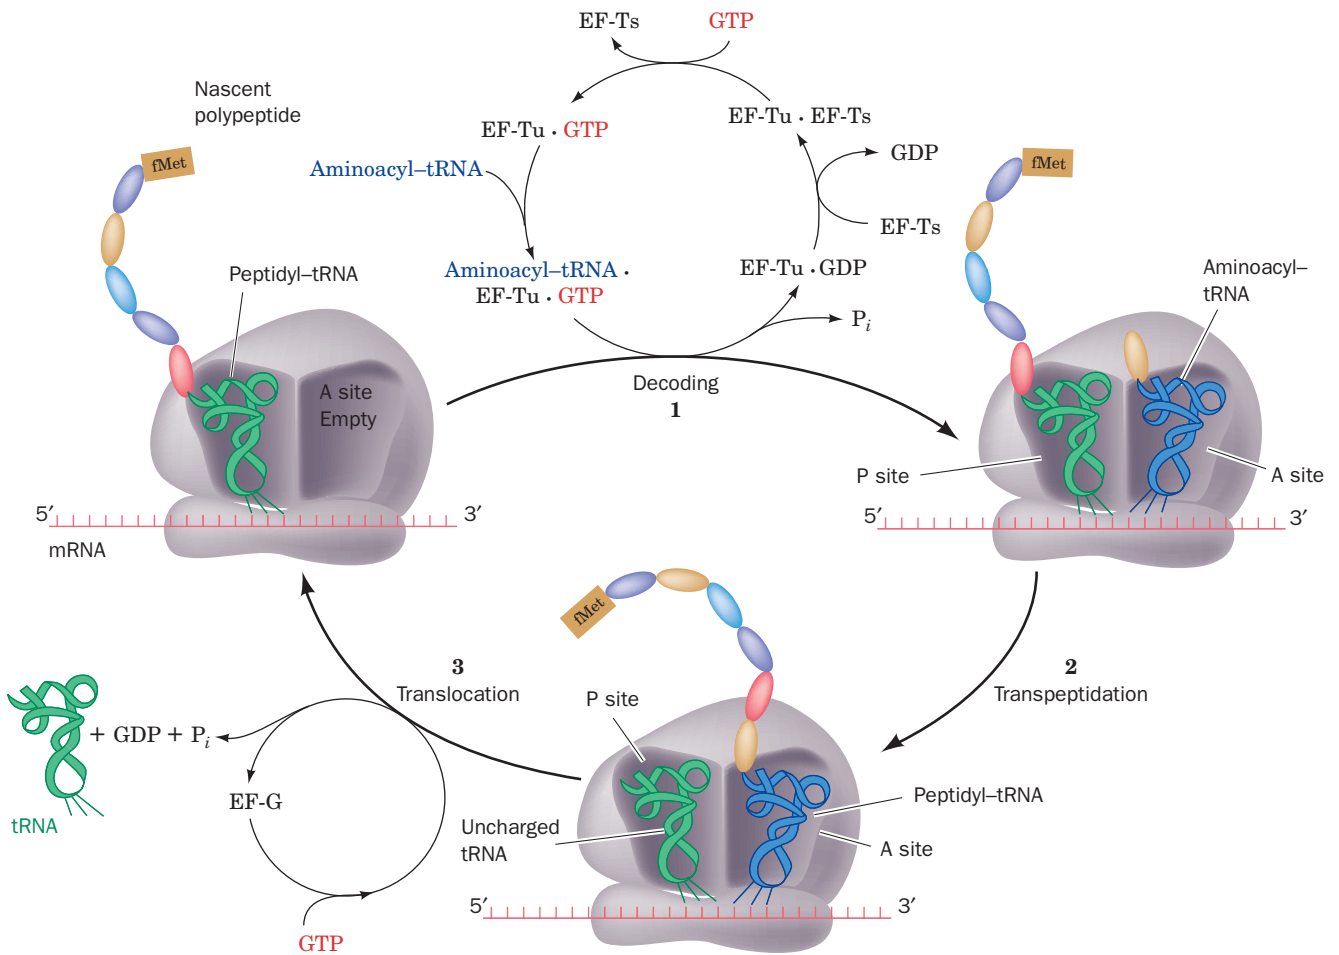

**3. Translocation**, in which A-site and P-site tRNAs are respectively transferred to the P site and E site accompanied by their bound mRNA; that is, the mRNA, together with its base paired tRNAs, is ratcheted through the ribosome by one codon.

Translational elongation, which occurs at a rate of 10 to 20 residues/s, involves the participation of several nonribosomal proteins known as **elongation factors** (Table 32-9). We describe these processes in the following paragraphs.

### a. Decoding

In the decoding stage of the *E. coli* elongation cycle, a binary complex of GTP with the elongation factor **EF-Tu** (also called **EF1A**) combines with an aminoacyl–tRNA. The resulting ternary complex binds to the ribosome, and, in a reaction that hydrolyzes the GTP to GDP + P<sub>i</sub>, the aminoacyl–tRNA is bound in a codon–anticodon complex to the ribosomal A site and EF-Tu · GDP + P<sub>i</sub> is released. In the remainder of this stage, the bound GDP is replaced by GTP in a reaction mediated the elongation factor **EF-Ts** (also called **EF1B**). EF-Tu, as are several other GTP-binding ribosomal factors, is a G-protein, and hence the ribosome functions as its GAP and EF-Ts is its GEF.

Aminoacyl–tRNAs can bind to the ribosomal A site without the mediation of EF-Tu but at a rate too slow to support cell growth. The importance of EF-Tu is indicated by the fact that it is the most abundant *E. coli* protein; it is present in ~100,000 copies per cell (>5% of the cell's protein), which is approximately the number of tRNA molecules in the cell. Consequently, *the cell's entire complement of aminoacyl–tRNAs is essentially sequestered by EF-Tu.*

**Figure 32-46** Elongation cycle in *E. coli* ribosomes. The E site, to which discharged tRNAs are transferred before being released to solution, is not shown. Eukaryotic elongation follows

a similar cycle but EF-Tu and EF-Ts are replaced by a single multisubunit protein, eEF1, and EF-G is replaced by eEF2.

### b. EF-Tu Is Sterically Prevented from Binding Initiator tRNA

The X-ray structure of the Phe-tRNA<sup>Phe</sup> · EF-Tu · GMPPNP ternary complex (GMPPNP is a nonhydrolyzable GTP analog; Section 19-3Ch), determined by Brian Clark and Jens Nyborg, reveals that these two macromolecules associate to form a corkscrew-shaped complex in which the EF-Tu and the tRNA's acceptor stem form a knoblike handle and the tRNA's anticodon helix forms the screw (Fig. 32-47). The conformation of the tRNA<sup>Phe</sup> closely resembles that of the uncomplexed molecule (Fig. 32-11b). The EF-Tu folds into three distinct domains that are connected by flexible peptides, rather like beads on a string. The N-terminal domain 1, which binds guanine nucleotides and catalyzes GTP hydrolysis, structurally resembles other known G-proteins.

The two macromolecules associate rather tenuously via three major regions: (1) the CCA—Phe segment at the 3' end of the Phe-tRNA<sup>Phe</sup> binds in a cleft between EF-Tu's domains 1 and 2 (the blue and green mainly helical domain

and the yellow  $\beta$  sheet domain in Fig. 32-47) that ends in a pocket large enough to accommodate all amino acid residues; (2) the 5'-phosphate of the tRNA binds in a depression at the junction of EF-Tu's three domains; and (3) one side of the tRNA's T $\psi$ C stem contacts the exposed main chain and side chains of EF-Tu's C-terminal domain 3 (the orange and red  $\beta$  barrel-containing domain in Fig. 32-47). The tight association of the aminoacyl group with EF-Tu appears to greatly increase the affinity of EF-Tu for the otherwise loosely bound tRNA, which explains why EF-Tu does not bind uncharged elongator tRNAs.

EF-Tu binds neither formylated aminoacyl-tRNAs nor unformylated Met-tRNA<sup>Met</sup>, which is why the initiator tRNA never reads internal AUG or GUG codons. The first base pair of tRNA<sup>Met</sup> is mismatched (C · A; Fig. 32-40) and hence this initiator tRNA has a 3' overhang of 5 nt vs 4 nt for an elongator tRNA. It seems likely that this mismatch, together with the formyl group, prevents fMet-tRNA<sup>Met</sup> from binding to EF-Tu. Indeed, EF-Tu binds to *E. coli* tRNA<sup>Met</sup> whose 5'-terminal C residue has been deaminated

**Figure 32-47** X-ray structure of the ternary complex of yeast Phe-tRNA<sup>Phe</sup>, *Thermus aquaticus* EF-Tu, and GMPPNP. The EF-Tu is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The tRNA is shown in stick form colored according to atom type with C green, N blue, O red, and P orange and with orange rods linking successive P atoms. The tRNA's appended aminoacyl-Phe residue and the GMPPNP that is bound to the EF-Tu are drawn in space-filling form with C atoms cyan and yellow, respectively. Two bound Mg<sup>2+</sup> ions are represented by magenta spheres. [Based on an X-ray structure by Jens Nyborg, University of Aarhus, Århus, Denmark. PDBid 1TTT.]

by bisulfite treatment (Section 30-7b), which reestablishes the “missing” base pair as U · A. Similarly, Sec-tRNA<sup>Sec</sup>, which is also not bound by EF-Tu (but rather by SELB; Section 32-2De), has 8 bp in its acceptor stem vs 7 bp in those of other elongator tRNAs. However, initiator tRNAs from several sources have fully base paired acceptor stems, and the U1 · A72 base pair of tRNA<sup>Gln</sup> is opened up on binding to GlnRS (Section 32-2Cc).

### c. EF-Tu Undergoes a Major Conformational Change on Hydrolyzing GTP

Morten Kjeldgaard and Nyborg determined the X-ray structures of *T. aquaticus* EF-Tu (405 residues) in com-

**Figure 32-48** Comparison of the X-ray structures of EF-Tu in its complexes with GDP and GMPPNP. The protein is represented by its C<sub>α</sub> backbone with domain 1, its GTP-binding domain, purple in the GDP complex and red in the GMPPNP complex. Domain 2 and domain 3, which have the same orientation in both complexes, are green and cyan. The bound GDP and GMPPNP are shown in stick form with C yellow, N blue, O red, and P green. [Courtesy of Morten Kjeldgaard and Jens Nyborg, University of Aarhus, Århus, Denmark. PDBid 1EFT.]  See Interactive Exercise 45

plex with GMPPNP and the 70% identical *E. coli* EF-Tu (393 residues) in complex with GDP (Fig. 32-48). The conformation of EF-Tu in its complex with only GMPPNP closely resembles that in its ternary complex with Phe-tRNA<sup>Phe</sup> and GMPPNP (Fig. 32-47). However, comparison of the GMPPNP and GDP complexes indicates that, on hydrolyzing its bound GTP, EF-Tu undergoes a major structural reorganization. Its greatest local conformational changes occur in the Switch I and Switch II regions of domain 1, which in all G-proteins signal the state of the bound nucleotide to interacting partners (Section 19-2Cb; here domains 2 and 3): Switch I converts from a β hairpin to a short α helix and the α helix of Switch II shifts toward the C-terminus by 4 residues. As a consequence, this latter helix reorients by 42°, which results in domain 1 rigidly changing its orientation with respect to domains 2 and 3 by a dramatic 91° rotation. The tRNA binding site is thereby eliminated.

### d. EF-Ts Disrupts the Binding of GDP to EF-Tu

EF-Tu has a 100-fold higher affinity for GDP than GTP. Hence, replacement of the EF-Tu-bound GDP by GTP must be facilitated by the interaction of EF-Tu with EF-Ts (Fig. 32-46, top). The X-ray structure of the EF-Tu · EF-Ts complex, determined by Stephen Cusack and Reuben

**Figure 32-49** X-ray structure of the *E. coli* EF-Tu · EF-Ts complex. Domains 1, 2, and 3 of EF-Tu are magenta, green, and cyan, respectively, and EF-Ts is orange. [Based on an X-ray structure by Stephen Cusack and Reuben Leberman, EMBL, Grenoble Cedex, France. PDBid 1EFU.]

Leberman, reveals that the EF-Tu has a conformation resembling that of its GDP complex (Fig. 32-49) but with its domains 2 and 3 swung away from domain 1 by  $\sim 18^\circ$ . EF-Ts is an elongated molecule that binds along the right side of EF-Tu as shown in Fig. 32-49, where it contacts EF-Tu's domains 1 and 3. The intrusive interactions of EF-Ts side chains with the GDP binding pocket on EF-Tu domain 1 disrupts the  $Mg^{2+}$  ion binding site. This reduces the affinity of EF-Tu for GDP, thereby facilitating its exchange for GTP (after EF-Ts has dissociated), which has a 10-fold higher concentration in the cell than does GDP (the GEF-containing segment of Sos similarly interferes with  $Mg^{2+}$  binding and hence guanine nucleotide binding by Ras; Sec-

tion 19-3Cf). EF-Tu's subsequent binding of a charged elongator tRNA increases its affinity for GTP.

#### e. Transpeptidation

In the transpeptidation stage of the elongation cycle (Fig. 32-46), the peptide bond is formed through the nucleophilic displacement of the P-site tRNA by the amino group of the 3'-linked aminoacyl-tRNA in the A site (Fig. 32-39). The nascent polypeptide chain is thereby lengthened at its C-terminus by one residue and transferred to the A-site tRNA. The reaction occurs without the need of activating cofactors such as ATP because the ester linkage between the nascent polypeptide and the P-site tRNA is a "high-energy" bond. The **peptidyl transferase** center that catalyzes peptide bond formation is located entirely on the large subunit as is demonstrated by the observation that in high concentrations of organic solvents such as ethanol, the large subunit alone catalyzes peptide bond formation. The organic solvent apparently distorts the large subunit in a way that mimics the effect of small subunit binding.

#### f. Puromycin Is an Aminoacyl-tRNA Analog

The ribosomal elongation cycle was originally characterized through the use of the antibiotic **puromycin** (Fig. 32-50). This product of *Streptomyces alboniger*, which resembles the 3' end of Tyr-tRNA, causes the premature termination of polypeptide chain synthesis. Puromycin, in competition with the mRNA-specified aminoacyl-tRNA but without the need of elongation factors, binds to the ribosomal A site which, in turn, catalyzes a normal transpeptidation reaction to form peptidyl-puromycin. Yet, the ribosome cannot catalyze the transpeptidation reaction in the next elongation cycle because puromycin's "amino acid residue" is linked to its "tRNA" via an amide rather than an ester bond. Polypeptide synthesis is therefore aborted and the peptidyl-puromycin is released.

In the absence of the elongation factor EF-G (see below), an active ribosome cannot bind puromycin because its A site is at least partially occupied by a peptidyl-tRNA. A newly initiated ribosome, however, violates this rule; it

**Figure 32-50** Puromycin. This antibiotic (*left*) resembles the 3'-terminus of tyrosyl-tRNA (*right*).

catalyzes fMet–puromycin formation. *These observations demonstrated the functional existence of the ribosomal P and A sites and established that fMet–tRNA<sup>fMet</sup> binds directly to the P site, whereas other aminoacyl–tRNAs must first enter the A site.*

### g. Transpeptidation: The Ribosome Is a Ribozyme

What is the nature of the peptidyl transferase center, that is, does it consist of RNA, protein, or both? Since all proteins, including those associated with ribosomes, are ribosomally synthesized, the primordial ribosome must have preceded the primordial proteins and hence consisted entirely of RNA. Despite this (in hindsight) obvious evolutionary argument, the idea that rRNA functions catalytically was not seriously entertained until after it had been discovered that RNA can, in fact, act as a catalyst (Section 31-4Ae). Several other observations further indicate that the ribosome is a ribozyme:

1. The absence from the 50S subunit of any one of its proteins but L2, L3, and L4 does not abolish its peptidyl transferase function.
2. rRNAs are more highly conserved throughout evolution than are ribosomal proteins.
3. Most mutations that confer resistance to antibiotics that inhibit protein synthesis occur in genes encoding rRNAs rather than ribosomal proteins.

Nevertheless, the unambiguous demonstration that rRNA functions catalytically in polypeptide synthesis proved to be

surprisingly elusive. Noller succeeded in showing that the *T. thermophilus* large ribosomal subunit from which ~95% of the protein had been removed by treatment with SDS and **proteinase K** followed by phenol extraction (which denatures proteins; Section 6-6A) maintained >80% of its peptidyl transferase activity in a model reaction. Moreover, this activity was abolished by RNase treatment. However, since the remaining protein was due to several intact ribosomal proteins (which are presumably sequestered within the 23S RNA), it could be argued that these proteins are essential for ribosomal catalytic function, a reasonable expectation in light of the >3.5 billion years over which ribosomal proteins and RNAs have coevolved.

Steitz and Moore unequivocally determined the nature of the peptidyl transferase center through its identification in the X-ray structure of the 50S subunit. Peptide bond formation presumably resembles the reverse of peptide bond hydrolysis such as that catalyzed by serine proteases (Section 15-3C). The ribosomal reaction's tetrahedral intermediate (Fig. 32-51a) is mimicked by a compound synthesized by Michael Yarus that consists of the trinucleotide CCdA linked to puromycin via a phosphoramidite group (Fig. 32-51b). This compound, which is named **CCdA-p-Puro**, binds tightly to the ribosome so as to inhibit its peptidyl transferase activity. The X-ray structure of the 50S subunit in complex with CCdA-p-Puro reveals that the inhibitor binds to domain V of the 23S RNA (Fig. 32-27b) at the entrance to the ~100-Å-long polypeptide exit tunnel that runs through to the back of the subunit (Figs. 32-30 and 32-34c). There, *the inhibitor is completely enveloped in RNA*

**Figure 32-51** Ribosomal tetrahedral intermediate and its analog. (a) The chemical structure of the tetrahedral intermediate (red C) in ribosomally mediated peptide bond formation in which the A-site aminoacyl residue is Tyr. (b) CCdA-p-Puro, the

transition state analog of the tetrahedral intermediate in Part a produced by linking the 3'-OH group of CCdA to the amino group of puromycin's *O*-methyltyrosine residue via a phosphoryl group.

with no protein side chain approaching closer than  $\sim 18 \text{ \AA}$  to the inhibitor's phosphoramidite group and with the nearest  $Mg^{2+}$  ion  $8.5 \text{ \AA}$  away—both too far away to participate in catalysis. Moreover, all the nucleotides that contact the CCdA-p-Puro are  $>95\%$  conserved among all three kingdoms of life. Clearly, the ribosomal transpeptidase reaction is catalyzed by RNA.

Despite the foregoing, the X-ray structure of the *T. thermophilus* ribosome in complex with tRNA and mRNA (Fig. 32-34) reveals that the N-terminal tail of L27 interacts with the phosphate group of residue C75 of the A-site tRNA. Moreover, L16 interacts with the elbow region of the A-site tRNA via interactions between conserved Arg residues and phosphate and 2'-OH groups in the elbow region of the tRNA. These observations confirm previous mutational studies indicating that L16 and L27 help stabilize the binding of the A-site tRNA. However, some organisms lack L27, which indicates that its binding to A-site tRNA is not part of an evolutionarily conserved mechanism.

#### h. Peptide Bond Formation Does Not Occur via Acid-Base Catalysis

The ribosomal peptidyl transferase reaction occurs  $\sim 10^7$ -fold faster than the uncatalyzed reaction. How does the ribosome catalyze this reaction? Peptide bond formation is naively expected to proceed via the nucleophilic attack of the amino group on the carbonyl group of an ester to form a tetrahedral intermediate that collapses to an amide and an alcohol (Fig. 32-39). However, in the physiological pH range, the attacking amino group is predominantly in its ammonium form ( $RNH_3^+$ ), and hence lacks the lone pair necessary to undertake a nucleophilic attack. This suggests that the peptidyl transferase reaction is catalyzed in part by a general base that abstracts a proton from the ammonium group to generate the required free amino group ( $RNH_2$ ).

Inspection of the peptidyl transferase center in *H. marismortui* reveals that the only basic group within  $5 \text{ \AA}$  of the inferred position of the attacking amino group is atom N3 of the invariant rRNA base A2486 (A2451 in *E. coli*). It is  $\sim 3 \text{ \AA}$  from and hence hydrogen bonded to the attacking amino group (Fig. 32-52). This further suggests that the protonated A2486-N3 electrostatically stabilizes the oxyanion of the tetrahedral reaction intermediate and then donates the proton to the leaving group of the P-site tRNA to yield a 3'-OH group (general acid catalysis). However, in order for A2486-N3 to act as a general base in abstracting the proton from an ammonium group (whose  $pK$  is  $\sim 10$ ), it must have a  $pK$  of at least 7 (recall that proton transfers between hydrogen-bonded groups occur at physiologically significant rates only when the  $pK$  of the proton donor is no more than 2 or 3 pH units greater than that of the proton acceptor; Section 15-3Dd). Yet, the  $pK$  of N3 in AMP is  $<3.5$ . Moreover, several lines of evidence indicate that A2486 does not function as an acid-base catalyst including (1) the model displayed in Fig. 32-52 indicates that the tetrahedral intermediate's oxyanion would point away from and hence could not be stabilized by protonated

**Figure 32-52** Model of the substrate complex of the 50S ribosomal subunit. Atoms are colored according to type with the A-site substrate C and P purple, P-site substrate C and P green, 23S rRNA C and P orange, N blue, and O red. The attacking amino group of the A-site aminoacyl residue is held in position for nucleophilic attack (cyan arrow) on the carbonyl C of the P-site aminoacyl ester through hydrogen bonds (dashed black lines) to A2486-N3 and the 2'-O of the P-site A76. [Courtesy of Peter Moore and Thomas Steitz, Yale University.]

A2486-N3; and (2) mutagenic replacement of A2486 by any other base does not greatly alter the ribosome's catalytic rate.

#### i. The Ribosome Is an Entropy Trap

If the peptidyl transfer reaction does not involve acid-base catalysis, what is the origin of the ribosome's catalytic power? Marina Rodnina and Richard Wolfenden noted that the uncatalyzed reaction of esters with amines to form amides occurs quite readily in aqueous solution. They therefore measured the rates of both uncatalyzed peptide bond formation by model compounds and peptidyl transfer by the ribosome at several different temperatures. This provided values of  $\Delta\Delta H_{\text{cat}}^\ddagger$  and  $\Delta\Delta S_{\text{cat}}^\ddagger$ , the reaction's change in the enthalpy and entropy of activation by the ribosome relative to the uncatalyzed reaction. Here  $\Delta\Delta H_{\text{cat}}^\ddagger - T\Delta\Delta S_{\text{cat}}^\ddagger = \Delta\Delta G_{\text{cat}}^\ddagger = \Delta G_{\text{cat}}^\ddagger(\text{uncat}) - \Delta G_{\text{cat}}^\ddagger(\text{cat})$ , where  $\Delta\Delta G_{\text{cat}}^\ddagger$  is the change in the reaction's free energy of activation by the ribosome,  $\Delta G_{\text{cat}}^\ddagger(\text{cat})$ , relative to that of the uncatalyzed reaction,  $\Delta G_{\text{cat}}^\ddagger(\text{uncat})$  (Section 14-1C). The measured value of  $\Delta\Delta H_{\text{cat}}^\ddagger$  is  $-19 \text{ kJ} \cdot \text{mol}^{-1}$ , a quantity that would be positive, not negative, if the ribosomal reaction had a significant component of chemical catalysis such as acid-base catalysis and/or the formation of new hydrogen bonds. In contrast, the value of  $T\Delta\Delta S_{\text{cat}}^\ddagger$  is  $52 \text{ kJ} \cdot \text{mol}^{-1}$ , which indicates that the Michaelis complex in the ribosomal reaction is significantly more ordered relative to the transition state than is the uncatalyzed reaction. This value of  $T\Delta\Delta S_{\text{cat}}^\ddagger$  largely accounts for the observed  $\sim 10^7$ -fold rate enhancement of the ribosomal reaction relative to

**Figure 32-53** The mechanism of ribosome-catalyzed peptidyl transfer. The nucleophilic attack of the  $\alpha$ -amino group of the aminoacyl-tRNA (red) on the carbonyl C of the peptidyl-tRNA (blue) occurs in concert with a proton shuttle that involves the O3' and 2'-OH of the P-site A76 together with the  $\alpha$ -amino

group of the aminoacyl-tRNA. The reaction proceeds through a transition state (center; enclosed by square brackets) that contains a six-membered ring of partially bonded atoms and which collapses to the reaction products drawn on the right.

the uncatalyzed reaction (the rate enhancement by the ribosome is given by  $e^{\Delta\Delta G_{\text{cat}}^{\ddagger}/RT}$ ; Section 14-1Cd). Evidently, the ribosome enhances the rate of peptide bond formation by properly positioning and orienting its substrates and/or excluding water from the preorganized electrostatic environment of the active site (a form of reactant ordering) rather than by chemical catalysis.

The X-ray structures of the large ribosomal subunit in complex with aminoacyl-tRNA and peptidyl-tRNA indicate that the ribosome uses an induced fit mechanism, as occurs in enzymes such as hexokinase (Section 17-2Aa). Conformational changes in the 23S rRNA, presumably triggered by proper binding of the aminoacyl-tRNA in the A site, orient the ester group of the peptidyl-tRNA for nucleophilic attack. The hydrogen bond between the 2'-OH of the P-site A76 and the attacking amino group (Fig. 32-52) is crucial in doing so. In fact, replacing this 2'-OH group with H or F reduces the reaction rate by at least  $10^6$ . This suggests that the peptidyl transferase reaction occurs via the substrate-assisted proton shuttle mechanism diagrammed in Fig. 32-53. Although the peptidyl transferase reaction is relatively sluggish compared to the reactions catalyzed by many protein enzymes, it is sufficiently fast to keep up with the other ribosomal processes (which collectively link together 10–20 residues/s). Apparently, the ribosome's peptidyl transferase function is a molecular fossil from the RNA world.

In the absence of a tRNA in the A site, the ester bond linking the peptidyl group to the P-site tRNA is shielded by U2585 of the 23S RNA from nucleophilic attack by water, which would otherwise release the peptidyl group from the ribosome.

#### j. Translocation: The Ribosome Moves to the Next Codon

In the translocation stage of the elongation cycle, the now uncharged P-site tRNA (at first  $tRNA_f^{\text{Met}}$  but subsequently an elongator tRNA) is transferred to the E site (not shown in Fig. 32-46), its former occupant having been previously expelled (see below). Simultaneously, the peptidyl-tRNA in the A site, together with its bound mRNA, is moved to the P site. This prepares the ribosome for the next elongation cycle. The maintenance of the peptidyl-tRNA's codon-anticodon association is no longer necessary for amino acid specification. Rather, it acts as a place-keeper that permits the ribosome to precisely step off the three nucleotides along the mRNA required to preserve the reading frame. Indeed, the observation that frameshift suppressor tRNAs induce a four-nucleotide translocation (Section 32-2Ea) indicates that mRNA movement is directly coupled to tRNA movement. An  $Mg^{2+}$ -stabilized kink in the mRNA between the A and P codons apparently helps prevent slippage.

#### k. EF-G Structurally Mimics the EF-Ts · tRNA Complex

The translocation process requires the participation of elongation factor **EF-G** (also called **EF2**), which binds to the ribosome together with GTP and is only released on hydrolysis of the GTP to GDP +  $P_i$  (Fig. 32-46). EF-G release is a prerequisite for beginning the next elongation cycle because EF-G and EF-Tu bind to the same site of the ribosome and hence their binding is mutually exclusive.

The X-ray structure of *T. thermophilus* EF-G · GMPPNP, determined by Anders Liljas and Derek Logan, reveals a tadpole-shaped monomeric protein that consists of five

**Figure 32-54** X-ray structure of EF-G from *T. thermophilus* in complex with GMPPNP. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The GMPPNP is drawn in space-filling form colored according to atom type with C yellow, N blue, O red, and P orange. An  $Mg^{2+}$  ion that is bound to the GMPPNP is represented by a magenta sphere. Portions of the structure are not visible. Note the remarkable resemblance in shape between this structure and that of Phe-tRNA<sup>Phe</sup> · EF-Tu · GMPPNP (Fig. 32-47). [Based on an X-ray structure by Anders Liljas and Derek Logan, Lund University, Lund, Sweden. PDBid 2BV3.]

domains (Fig. 32-54). The first two domains closely resemble those in EF-Tu · GMPPNP rather than those in EF-Tu · GDP (Fig. 32-48). This, it is argued, is because the two elongation factors have reciprocal functions with EF-Tu · GTP facilitating the conversion of the ribosome from its post- to its pre-translocational state and EF-G · GTP promoting the reverse transition. This idea is supported by the intriguing observation that the Phe-tRNA<sup>Phe</sup> · EF-Tu · GMPPNP and EF-G · GMPPNP complexes are almost identical in appearance: EF-G's three C-terminal domains (yellow through red in Fig. 32-54), which have no counterparts in EF-Tu, closely resemble the EF-Tu-bound tRNA in shape, a remarkable case of **macromolecular mimicry**. Indeed, EF-G occupies the same ribosomal site as does EF-Tu (Fig. 32-55).

EF-G is unusual among G-proteins in that it has no corresponding GEF. However, its N-terminal guanine nu-

**Figure 32-55** X-ray structure of the *T. thermophilus* ribosome in its complexes with (a) EF-G and (b) EF-Tu. The ribosome is drawn in ribbon form with its 23S RNA orange, its 50S subunit proteins brown, its 16S RNA cyan, and its 30S proteins blue. Its bound tRNAs, mRNA, EF-G, and EF-Tu are represented by their surface diagrams with E-site tRNA yellow, P-site tRNA green, A-site tRNA magenta, mRNA black, and both EF-G and EF-Tu red. In Part b, the A-site tRNA bound to EF-Tu is in the A/T conformation (see below). The positions of the decoding center (DC) and the peptidyl transferase center (PTC) are indicated. cleotide-binding domain contains a unique  $\alpha$  helical insert (green in Fig. 32-54) that contacts the domain's conserved core at sites analogous to those in EF-Tu that interact with EF-Ts. This suggests that this subdomain acts as an internal GEF.

### I. Translocation Occurs via Intermediate States

Chemical footprinting studies (Section 31-2Ab) by Noller revealed that certain bases in the 16S rRNA are protected by tRNAs bound in the ribosomal A and P sites and that certain bases in the 23S rRNA are protected by tRNAs in the A, P, and E sites. Almost all of these protected bases are absolutely conserved in evolution and many of them have been implicated in ribosomal function through biochemical or genetic studies.

Variations in chemical footprinting patterns during the elongation cycle together with the more recently determined X-ray and cryo-EM structures indicate that the translocation of tRNA occurs in several discrete steps (Fig. 32-56):

1. Let us start with the ribosome in its **post-translocational state**: a deacylated tRNA bound to the E subunits of both the 30S and 50S subunits (the E/E binding state), a peptidyl-tRNA bound in the P subunits of both subunits

**Figure 32-56** Ribosomal binding states in the elongation cycle.

Note how this scheme elaborates the classic elongation cycle diagrammed in Fig. 32-46. The drawings are accompanied by 17-Å-resolution cryo-EM-based images of the *E. coli* 70S ribosome in the corresponding binding states in which the 30S subunit is transparent yellow, the 50S subunit is transparent blue,

and the tRNAs and elongation factors are colored as in the drawing they accompany. [Cryo-EM images courtesy of Knud Nierhaus, Max-Planck-Institut für Molekulare Genetik, Berlin, Germany, and Joachim Frank, Wadsworth Center, State University of New York at Albany.]

(the P/P state), and the A site empty. An aminoacyl-tRNA (aa-tRNA) in ternary complex with EF-Tu and GTP binds to the A site accompanied by the release of the E-site tRNA (but see below). This yields a complex in which the incoming aa-tRNA is bound in the 30S subunit's A subsite via a codon-anticodon interaction (recall that the mRNA is bound to the 30S subunit) but with the EF-Tu preventing the entry of the tRNA's aminoacyl end into the 50S subunit's A subsite, an arrangement termed the A/T state (T for EF-Tu).

2. EF-Tu hydrolyzes its bound GTP to GDP + P<sub>i</sub> and is released from the ribosome. This permits the aa-tRNA to fully bind to the A site (the A/A state), a process called **accommodation** in which the 3' end of the tRNA swings around by nearly 70 Å.

3. The peptidyl transferase reaction occurs, yielding the **pre-translocational state**.

4. The acceptor end of the new peptidyl-tRNA shifts from the A subsite of the 50S subunit to its P-subsite, while the tRNA's anticodon end remains associated with the A subsite of the 30S subunit (yielding the A/P hybrid binding state). The acceptor end of the newly deacylated tRNA simultaneously moves from the P subsite to the E subsite of the 50S subunit while its anticodon end remains associated with the P subsite of the 30S subunit (the P/E state).

5. The ribosomal binding of the EF-G · GTP complex and the subsequent GTP hydrolysis impel the anticodon ends of these tRNAs, together with their bound mRNA, to move relative to the small ribosomal subunit such that the peptidyl-tRNA assumes the P/P state and the deacylated tRNA assumes the E/E state (the post-translocational state), thereby completing the elongation cycle.

The binding of tRNA to the A and E sites, as Nierhaus has shown, exhibits negative allosteric cooperativity. In the pre-translocational state, the E site binds the newly deacylated tRNA with high affinity (the E site is sterically unable to bind an aminoacyl-tRNA), whereas the empty A site has low affinity for aminoacyl-tRNA. However, in the post-translocational state, the ribosome has undergone a conformational change that converts the A site to a high-affinity state and the E site to a low-affinity state, which consequently releases the deacylated tRNA when aa-tRNA · EF-Tu · GTP binds to the A site. Thus, the E site is not simply a passive holding site for spent tRNAs but performs an essential function in the translation process. The GTP hydrolysis by the elongation factors EF-Tu and EF-G as well as the peptidyl transferase reaction apparently function to reduce the activation barriers between these conformational states. The unidirectional A → P → E flow of tRNAs through the ribosome is thereby facilitated.

Certain aspects of the foregoing mechanism are not fully resolved. For example, X-ray studies of the 70S ribosome in complex with three tRNAs (e.g., Fig. 32-34) suggest that the E-site tRNA is not released from the ribosome until Step 2 of Fig. 32-56. However, Nierhaus and Frank argue that these complexes were crystallized in the presence of unphysiologically high tRNA concentrations.

Whatever the case, it is clear that the changes in binding states result in large-scale tRNA movements, in some instances >50 Å. Moreover, cryo-EM studies indicate that on binding EF-G · GDP(CH<sub>2</sub>)P (like GMPPNP but with a CH<sub>2</sub> group rather than an NH group bridging its β and γ phosphates), the 30S subunit rotates with respect to the 50S subunit by 6° clockwise when viewed from the 30S subunit's solvent side, which results in a maximum displacement of ~19 Å at the periphery of the ribosome. This rotation is accompanied by many smaller conformational changes in both subunits, particularly in the regions about the entrance and exit to the mRNA channel. Clearly, we are far from fully understanding how the ribosome works at the molecular level.

### m. The Eukaryotic Elongation Cycle Resembles That of Prokaryotes

*The eukaryotic elongation cycle closely resembles that of prokaryotes.* In eukaryotes, the functions of EF-Tu and EF-Ts are respectively assumed by the eukaryotic elongation factors **eEF1A** and **eEF1B**, with yeast eEF1B consisting of two subunits: **eEF1Bα**, which catalyzes nucleotide exchange, and **eEF1Bγ**, which has unknown function (in higher eukaryotes, eEF1B contains a third subunit, **eEF1Bβ**, that possesses a nucleotide exchange activity similar to that of eEF1Bα). Likewise, **eEF2** functions in a manner analogous to EF-G. However, the corresponding eukaryotic and prokaryotic elongation factors are not interchangeable.

The X-ray structure of yeast eEF1A · eEF1Bα (Fig. 32-57), determined by Kjeldgaard and Nyborg, reveals that eEF1A structurally resembles the homologous EF-Tu (Fig. 32-49), whereas eEF1Bα exhibits no resemblance to EF-Ts, either in sequence or in structure. Nevertheless, eEF1Bα functionally interacts with eEF1A much as EF-Ts interacts with EF-Tu: Both GEFs associate with their corresponding G-protein so as to disrupt the Mg<sup>2+</sup> binding site associated with its bound guanine nucleotide.

### E. Translational Accuracy

The genetic code is normally expressed with remarkable fidelity. We have already seen that transcription and tRNA aminoacylation both proceed with high accuracy (Sections 31-2Ec and 32-2Ce). The accuracy of ribosomal mRNA decoding was estimated from the rate of misincorporation of [<sup>35</sup>S]Cys into highly purified **flagellin**, an *E. coli* protein (Section 35-3I) that normally lacks Cys. These measurements indicated that the mistranslation rate is ~10<sup>-4</sup> errors per codon. This rate is greatly increased in the presence of **streptomycin**, an antibiotic that increases the rate of ribosomal misreading (Section 32-3Ga). From the types of reading errors that streptomycin is known to induce, it was deduced that the mistranslation arose almost entirely from the confusion of the Arg codons CGU and CGC for the Cys codons UGU and UGC. The above error rate is therefore largely caused by mistakes in ribosomal decoding.

An aminoacyl-tRNA is selected by the ribosome only according to its anticodon. Yet the binding energy loss

**Figure 32-57** X-ray structure of yeast eEF1A · eEF1B $\alpha$ . Domains 1, 2, and 3 of eEF1A are magenta, green, and cyan, respectively, and eEF1B $\alpha$  is orange. The complex is oriented so as to emphasize the structural resemblance between eEF1A and the similarly colored EF-Tu in its complex with EF-Ts (Fig. 32-49). Note the lack of resemblance between eEF1B $\alpha$  and EF-Ts. [Based on an X-ray structure by Morten Kjeldgaard and Jens Nyborg, University of Aarhus, Århus, Denmark. PDBid 1F60.]

arising from a single base mismatch in a codon–anticodon interaction is estimated to be  $\sim 12 \text{ kJ} \cdot \text{mol}^{-1}$ , which, according to Eq. [32.1], cannot account for a ribosomal decoding accuracy of less than  $\sim 10^{-2}$  errors per codon. Moreover, the base pairing interaction between the UUU codon for Phe and the GAA anticodon of tRNA<sup>Phe</sup> would be naively expected to be less stable than the incorrect pairing be-

tween the UGC codon for Ser and the GCG anticodon of tRNA<sup>Arg</sup>. This is because both interactions have one G · U base pair and the former correct interaction's remaining two A · U base pairs are weaker than the latter incorrect interaction's remaining two G · C base pairs. Evidently, the ribosome has some sort of proofreading mechanism that increases its overall decoding accuracy.

#### a. The Ribosome Monitors the Formation of a Correct Codon–Anticodon Complex

As we have seen (Figs. 32-55*b* and 32-56), the aminoacyl-tRNA · EF-Tu · GTP ternary complex initially binds to the ribosome with the tRNA in the A/T binding state. The tRNA only assumes the fully bound A/A state (accommodation) after the GTP has been hydrolyzed and the EF-Tu · GDP complex has been released from the ribosome. These two states presumably permit the ribosome to double-check (proofread) the codon–anticodon complex that the mRNA makes with the incoming tRNA.

The X-ray structure of the *T. thermophilus* 30S subunit in complex with a U<sub>6</sub> hexanucleotide mRNA and a 17-nt RNA consisting of the tRNA<sup>Phe</sup> anticodon stem–loop (Fig. 32-11, although its nucleotides are unmodified), determined by Ramakrishnan, revealed how an mRNA-specified tRNA initially binds to the ribosome. The codon–anticodon association is stabilized by its interactions with three universally conserved ribosomal bases, A1492, A1493, and G530 (Fig. 32-58):

1. The first codon–anticodon base pair, that between mRNA U1 and tRNA A36, is stabilized by the binding of the rRNA A1493 base in the base pair's minor groove (Fig. 32-58*a*).
2. The second codon–anticodon base pair, that between U2 and A35, is bolstered by A1492 and G530, which both bind in this base pair's minor groove (Fig. 32-58*b*).
3. The third codon–anticodon base pair (the wobble pair; Section 32-2*Db*), that between U3 and G34, is reinforced through minor groove binding by G530 (Fig. 32-58*c*).

**Figure 32-58** Codon–anticodon interactions in the ribosome. The (a) first, (b) second, and (c) third codon–anticodon base pairs as seen in the X-ray structure of the *T. thermophilus* 30S subunit in complex with U<sub>6</sub> (a model mRNA) and the 17-nt anticodon stem–loop of tRNA<sup>Phe</sup> (whose anticodon is GAA). The structures are drawn in ball-and-stick form embedded in

their semitransparent van der Waals surfaces. Codons are purple, anticodons are yellow, and rRNA is brown or gray with non-C atoms colored according to type (N blue, O red, and P green). Protein C atoms are gray and Mg<sup>2+</sup> ions are represented by magenta spheres. [Courtesy of Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1IBM.]

**Figure 32-59** Ribosomal decoding site. The X-ray structures of *T. thermophilus* 30S subunit (a) alone and (b) in its complex with U<sub>6</sub> and the 17-nt anticodon stem-loop of tRNA<sup>Phe</sup>. The RNAs are drawn as ribbons with their nucleotides in paddle form with tRNA gold, A-site mRNA purple, rRNA gray, and

nucleotides that undergo conformational changes red. Protein S12 is tan and Mg<sup>2+</sup> ions are represented by red spheres. Compare Part b with Fig. 32-58. [Courtesy of Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBids (a) 1FJF and (b) 1IBM.]

This latter interaction appears to be less stringent than those in the first and second codon–anticodon positions, which is consistent with the need for the third codon–anticodon pairing to tolerate non-Watson–Crick base pairs (Section 32-2D).

Comparison of this structure with that of the 30S subunit alone reveals that the foregoing rRNA nucleotides undergo conformational changes on the formation of a codon–anticodon complex (Fig. 32-59). In the absence of tRNA, the bases of A1492 and A1493 stack in the interior of an RNA loop but flip out of this loop to form the codon–anticodon complex, whereas the G530 base switches from the syn to the anti conformation (Section 29-2Aa). These interactions enable the ribosome to monitor whether an incoming tRNA is cognate to the codon in the A site; a non-Watson–Crick base pair could not bind these ribosomal bases in the same way. Indeed, any mutation of A1492 or A1493 is lethal because pyrimidines in these positions could not reach far enough to interact with the codon–anticodon complex or G530 and because a G in either position would be unable to form the required hydrogen bonds and its N2 would be subjected to steric collisions. An incorrect codon–anticodon provides insufficient free energy to bind the tRNA to the ribosome and it therefore dissociates from it, still in its ternary complex with EF-Tu and GTP.

#### b. GTP Hydrolysis by EF-Tu Is a Thermodynamic Prerequisite to Ribosomal Proofreading

*A proofreading step must be entirely independent of the initial selection step.* Only then can the overall probability of error be equal to the product of the probabilities of error of the individual selection steps. We have seen that DNA polymerases and aminoacyl-tRNA synthetases maintain the independence of their two selection steps by carrying them out at separate active sites (Sections 30-2Ac and 32-2Ce). Yet the ribosome only recognizes the incoming aminoacyl-tRNA according to its anticodon's complementarity to the codon in the A site. Consequently, the ribosome must somehow examine this codon–anticodon interaction in two separate ways.

The formation of a correct codon–anticodon complex induces EF-Tu to hydrolyze its bound GTP, although how this occurs is unclear (note that EF-Tu's GTPase domain is bound in the 50S subunit which, together with the observation that GTP hydrolysis requires an intact tRNA, suggests that the hydrolysis signal is at least in part transmitted through the tRNA). The resulting conformational change in EF-Tu (Fig. 32-48) swings its bound tRNA into the A/A state (accommodation), a process that moves the 3' end of the tRNA by nearly 70 Å. This, it is hypothesized, subjects the codon–anticodon interaction to a strain that only a correct pairing can withstand. The codon–anticodon interaction is thereby subjected to a second screening that only

permits a cognate aminoacyl-tRNA to enter the peptidyl transferase center. The irreversible GTPase reaction must precede this proofreading step because otherwise the dissociation of a noncognate tRNA (the release of its anticodon from the codon) would simply be the reverse of the initial binding step, that is, it would be part of the initial selection step rather than proofreading. *GTP hydrolysis therefore provides the second context necessary for proofreading; it is the entropic price the system must pay for accurate tRNA selection.*

## F. Chain Termination

Polypeptide synthesis under the direction of synthetic mRNAs such as poly(U) terminates with a peptidyl-tRNA in association with the ribosome. However, *the translation of natural mRNAs, which contain the Stop codons UAA, UGA, or UAG, results in the release of free polypeptides.*

Accurate termination is essential, not only because it prevents the wasteful synthesis of nonfunctional polypeptides, but also because prematurely terminated polypeptides may be toxic.

### a. Prokaryotic Termination

In *E. coli*, chain termination has several stages (Fig. 32-60):

**1.** The termination codons, the only codons that normally have no corresponding tRNAs, are recognized by class I **release factors** (Table 32-9): **RF-1** recognizes UAA and UAG, whereas the 39% identical **RF-2** recognizes UAA and UGA. Swapping a conserved PXT tripeptide in RF-1 with a conserved SPF tripeptide in RF-2 interchanges their Stop codon specificities, which suggests that these tripeptides mimic anticodons.

**2.** On binding to their corresponding Stop codon, RF-1 and RF-2 induce the transfer of the peptidyl group from

**Figure 32-60** Termination pathway in *E. coli* ribosomes. RF-1 recognizes the Stop codons UAA and UAG, whereas RF-2 (not shown) recognizes UAA and UGA. Eukaryotic termination

follows an analogous pathway but requires only a single class I release factor, eRF1, that recognizes all three Stop codons.

**Figure 32-61** Ribosome-catalyzed hydrolysis of peptidyl-tRNA to form a polypeptide and free tRNA.

tRNA to water rather than to an aminoacyl-tRNA, thereby releasing the completed polypeptide (Fig 32-61). This occurs with an error rate of  $10^{-5}$  without proofreading. The class I release factors act at the ribosomal A site as is indicated by the observations that they compete with suppressor tRNAs for termination codons and that they cannot bind to the ribosome simultaneously with EF-G. A GGQ tripeptide that is universally conserved in all class I release factors is implicated in catalyzing the hydrolysis of the peptidyl-tRNA ester linkage (see below).

3. Once the newly synthesized polypeptide has been released from the ribosome, the class II release factor **RF-3**, in its complex with GDP, binds to the ribosome at the same site as do EF-Tu and EF-G. In fact, the X-ray structure of RF-3 · GDP resembles that of EF-Tu · GMPPNP (Fig. 32-47). Free RF-3 has a greater affinity for GDP than GTP but on binding to the ribosome–RF-1/2 complex, it exchanges its bound GDP for GTP. The resulting change in the conformation of RF-3, as seen in cryo-EM studies, causes it to bind more tightly to the ribosome and expel the RF-1/2. RF-3 is not required for cell viability although it is necessary for maximum growth rate; RF-3 only accelerates the dissociation of RF-1/2 from the ribosome by ~5-fold.

4. The interaction of RF-3 · GTP with the ribosome stimulates it to hydrolyze its bound GTP, much as occurs with EF-Tu · GTP and EF-G · GTP. The resulting RF-3 · GDP then dissociates from the ribosome. Subsequently, **ribosomal recycling factor (RRF)** binds in the ribosomal A site followed by EF-G · GTP. RRF, which was discovered by Akira Kaji, is essential for cell viability.

5. EF-G hydrolyzes its bound GTP, which causes RRF to be translocated to the P site and the tRNAs previously in the P and E sites (the latter not shown in Fig. 32-60) to be released. Finally, the small and large ribosomal subunits

separate, a process that is facilitated by the binding of IF-3 (Section 32-3Cc), and RRF, EF-G · GDP, and mRNA are released. The ribosomal subunits can then participate in a new round of initiation (Fig. 32-43).

### b. Eukaryotic Termination

Chain termination in eukaryotes resembles that in prokaryotes, but it has only one class I release factor, **eRF1**, that recognizes all three Stop codons. It is unrelated in sequence to RF-1 and RF-2. However, the eukaryotic class II release factor, **eRF3**, resembles RF-3 in both sequence and function. Nevertheless, eRF3 is essential for eukaryotic cell viability.

### c. The Ribosome Binds RF-1 and RF-2 in a Conformation That Catalyzes Peptide Release

The X-ray structures of the *T. thermophilus* ribosome with RF-1, an mRNA containing a UAA Stop codon, and deacylated tRNAs in its P and E sites was determined by Noller (Fig. 32-62a), and the closely similar structures containing the tRNAs, RF-2, and an mRNA with a UAA or a UGA Stop codon, were respectively determined by Noller and Ramakrishnan. These are all product complexes since they lack peptidyl groups on their P-site tRNAs. The structurally similar RF-1 (Fig. 32-62b) and RF-2 each consist of four domains with domains 2 and 4 occupying the ribosome's decoding center (DC), where they contact the mRNA's Stop codon, and with domain 3 occupying the peptidyl transferase center (PTC), where it interacts with the ribose residue of the P-site tRNA's A76 to which a peptidyl group would be linked in a substrate complex. The deletion of domain 1 does not affect peptide release activity but is required for the RF-3-facilitated dissociation of RF-1/2 from the ribosome (see below).

**Figure 32-62** X-ray structure of the *T. thermophilus* ribosome in complex with RF-1, a UAA Stop codon-containing mRNA, and deacylated tRNAs in its P and E sites. (a) The overall structure with proteins shown in ribbon form and all RNAs shown in ladder form but the mRNA, which is drawn in worm form in green. The ribosome is semitransparent with its 23S RNA gray, its 5S RNA light blue, its 16S RNA cyan, the 50S subunit's proteins magenta, and the 30S subunit's proteins purple. The tRNAs occupying the P and E sites are orange and red, and the RF-1, which in part occupies the ribosomal A site, is yellow. (b) Close-up of the interactions between the P-site tRNA, mRNA,

and RF-1. The ribosome, tRNA, and mRNA are drawn as in Part a and the RF-1 is colored with its domains 1, 2, 3, and 4 green, yellow, blue, and magenta, respectively. The so-called switch-loop, which connects domains 3 and 4 and undergoes a major conformational rearrangement between the free and ribosome-bound RF-1, is orange. The PVT tripeptide implicated in Stop codon recognition and the GGQ tripeptide implicated in catalyzing the ester hydrolysis reaction are drawn in stick form in red. [Courtesy of Harry Noller, University of California at Santa Cruz. PDBids 3D5A and 3D5B.]

The binding of RF-1 or RF-2 in the DC causes A530 and A1492 of the 16S RNA to flip out from their resting state (Fig. 32-59a) as occurs with the binding of a tRNA to its cognate codon (Fig. 32-59b). However, A1493 does not flip out because in doing so it would clash with domain 2 of either release factor. Instead, it stacks on A1913 of the 23S RNA. The Stop codons are recognized by hydrogen bonding and van der Waals interactions with the similarly located PXT and SPF tripeptides on domain 2 of RF-1 and RF-2. However, the observation that mutations in RF-2 distant from its SQF motif result in altered specificity suggests that Stop codon recognition arises from a subtle balance of binding energy and conformational changes as we have seen to be the case for codon recognition by tRNA (Section 32-3Ea).

In the PTC, the GGQ tripeptide on domain 3 of both RF-1 and RF-2 contacts the 3'-terminal ribose residue (A76) of the deacylated P-site tRNA. Both Gly residues adopt backbone conformations that are forbidden for other amino acid residues, which accounts for the observations that the mutation of either residue results in an up to  $10^4$ -fold reduction in the rate of peptide release. The main chain NH group of the Gln residue is hydrogen bonded to the 3'-OH group of A76, which, it is hypothesized, positions it to also hydrogen bond to and thereby stabilize the tran-

sition state oxyanion in the hydrolysis reaction. In agreement with this hypothesis, the mutation of the Gln residue to Pro, which lacks a main chain NH group, abolishes the hydrolysis reaction. The side chain of the Gln residue is pointed away from the ribose (top of Fig. 32-62b) where, it is proposed, it helps position a water molecule for an in-line nucleophilic attack on the scissile ester bond. In addition, the observation that peptide release is nearly abolished by the removal of the 2'-OH from the P-site tRNA's 3' terminal residue suggests that peptide release utilizes a substrate-assisted proton shuttle mechanism similar to that of peptide bond formation (Section 32-3Di). Finally, the binding of RF-1/2 shifts U2585 so as to expose the otherwise protected scissile ester bond to nucleophilic attack (Section 32-3Di). Nevertheless, the formulation of a definitive mechanism for peptide release must await the X-ray structure of a ribosome in complex with both a release factor and a peptidyl-tRNA, that is, a substrate complex.

How does the binding of a release factor to a Stop codon in the DC induce the  $\sim 75$ -Å distant PTC to hydrolyze the scissile ester bond? In the X-ray structures of RF-1 or RF-2 alone, their PXT/SPF and GGQ motifs are only  $\sim 23$  Å apart due to a change in conformation of their switch-loop segments (Fig. 32-62b) relative to that in the ribosomal complexes. The conformation of the

switch-loop observed in the ribosomal complexes is only possible when a Stop codon is recognized. This is because the flipping out of A1493, which only occurs when a tRNA binds its cognate codon in the DC (Fig. 32-59), or the failure of A1913 to stack on A1493, alters the binding pocket for the ribosomally bound switch-loop. Noller has therefore proposed that the binding of a Stop codon by its corresponding release factor and the consequent rearrangement of both its switch-loop and the DC cooperatively permit the GGQ motif to bind to the PTC in a way that catalyzes peptide release.

#### d. RRF Binds in the Ribosomal A Site

The X-ray structure of *T. thermophilus* ribosomal recycling factor (RRF), determined by Yoshikazu Nakamura, reveals it to be a two-domain structure that resembles tRNA in its overall shape (Fig. 32-63). The comparison of this structure with those of several other bacterial RRFs indicates that the two linkers connecting the RRF domains are flexible such that domain II can rotate about the axis of the three-helix bundle forming domain I.

The X-ray structure of the *T. thermophilus* ribosome in complex with RRF in its A site, the anticodon stem-loop (ASL) of tRNA<sup>Phe</sup> in its P site, tRNA<sub>f</sub><sup>Met</sup> in its E site, and an mRNA with a UAG Stop codon in the A site was determined by Ramakrishnan (Fig. 32-64). Domain I of the RRF spans the A and P sites of the 50S ribosome, a position in which the tip of its domain I would clash with a tRNA in the P site (and which rationalizes why a ribosomal complex of RRF and a tRNA in the P site has not been crystallized). This suggests that RRF binding forces a tRNA bound in the P site into the P/E hybrid binding state (Section 32-3DI). Previous structural studies suggested that RRF binding induced changes in the bridges connecting the small and large subunits (Section 32-3Ae). However, no such changes are observed in the above structure. Perhaps they occur in the P/E hybrid state.

**Figure 32-63** X-ray structure of *T. thermophilus* RRF. This monomeric protein is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). [Based on an X-ray structure by Yoshikazu Nakamura, The University of Tokyo, Japan. PDBid 1EH1.]

#### e. GTP Hydrolysis Speeds Up Ribosomal Processes

What is the role of the GTP hydrolysis reactions mediated by the various ribosomally associated G proteins (IF-2, EF-Tu, EF-G, and RF-3 in bacteria)? Translation occurs in the absence of GTP, albeit slowly, so that the free energy of the peptidyl transferase reaction is sufficient to drive the entire translational process. Moreover, none of the GTP

**Figure 32-64** X-ray structure of the *T. thermophilus* ribosome in complex with RRF in its A site, the anticodon stem-loop (ASL) of tRNA<sup>Phe</sup> in its P site, tRNA<sub>f</sub><sup>Met</sup> in its E site, and an mRNA with a UAG Stop codon in the A site. The ribosomal RNAs are shown as semitransparent surface diagrams with 23S RNA light blue, 5S RNA blue-green, and 16S RNA yellow. The ribosomal proteins are drawn in ribbon form with 50S subunit proteins blue and 30S subunit proteins tan. The RRF, tRNAs, and mRNA are represented by their surface diagrams with domains I and II of RRF red and blue, the mRNA magenta, the P-site ASL purple, and the E-site tRNA<sub>f</sub><sup>Met</sup> gray. [Courtesy of Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBids 2V46 and 2V47.]

hydrolysis reactions yields a “high-energy” covalent intermediate as does, say, ATP hydrolysis in numerous biosynthetic reactions. Instead, the ribosomal binding of a G-protein induces it to hydrolyze its bound GTP to GDP resulting a conformational change that causes the ribosome to carry out a particular process (fMet-tRNA<sub>f</sub><sup>Met</sup> binding for IF-2, accommodation for EF-Tu, translocation for EF-G, and RF-1/2 release for RF-3) and release the resulting G-protein · GDP complex. *The high rate and irreversibility of the GTP hydrolysis reaction ensures that the various complex ribosomal processes to which it is coupled, initiation, elongation, and termination, will themselves be fast and irreversible.* In essence, G-protein · GTP complexes act as Maxwell’s demons to trap the ribosome in functionally productive conformations. Hence, as we saw to be the case for ribosomal proofreading (Section 32-3Eb), the ribosome utilizes the free energy of GTP hydrolysis to gain a more ordered (lower entropy) state rather than a higher energy state as often occurs in ATP-dependent processes.

### G. Protein Synthesis Inhibitors: Antibiotics

*Antibiotics are bacterially, fungally, or synthetically produced substances that inhibit the growth of microorganisms.* Antibiotics are known to inhibit a variety of essential biological processes, including DNA replication (e.g., ciprofloxacin; Section 29-3Cd), transcription (e.g., rifamycin B; Section 31-2Bb), and bacterial cell wall synthesis (e.g., penicillin; Section 11-3Bb). However, *the majority of known antibiotics, including a great variety of medically useful substances, block translation.* This situation is presumably a consequence of the translational machinery’s enormous complexity, which makes it vulnerable to disruption in many ways. Antibiotics have also been useful in an-

alyzing ribosomal mechanisms because, as we have seen for puromycin (Section 32-3Df), the blockade of a specific function often permits its biochemical dissection into its component steps. Table 32-10 and Fig. 32-65 present several medically significant and/or biochemically useful translational inhibitors. We study the mechanisms of a few of the best characterized of them below.

#### a. Streptomycin

**Streptomycin**, which was discovered in 1944 by Selman Waksman, is a medically important member of a family of antibiotics known as **aminoglycosides** that inhibit prokaryotic ribosomes in a variety of ways. At low concentrations, streptomycin induces the ribosome to characteristically misread mRNA: One pyrimidine may be mistaken for the other in the first and second codon positions and either pyrimidine may be mistaken for adenine in the first position. This inhibits the growth of susceptible cells but does not kill them. At higher concentrations, however, streptomycin prevents proper chain initiation and thereby causes cell death.

Certain streptomycin-resistant mutants (*str<sup>R</sup>*) have ribosomes with an altered protein S12 compared with streptomycin-sensitive bacteria (*str<sup>S</sup>*). Intriguingly, a change in base C912 of 16S rRNA (which lies in its central domain; Fig. 32-27a) also confers streptomycin resistance. (Some mutant bacteria are not only resistant to streptomycin but dependent on it; they require it for growth.) In partial diploid bacteria that are heterozygous for streptomycin resistance (*str<sup>R</sup>/str<sup>S</sup>*), streptomycin sensitivity is dominant. This puzzling observation is explained by the finding that, in the presence of streptomycin, *str<sup>S</sup>* ribosomes remain bound to initiation sites, thereby excluding *str<sup>R</sup>* ribosomes from these sites. Moreover, the mRNAs in these blocked complexes are degraded after a few

**Table 32-10** Some Ribosomal Inhibitors

Inhibitor	Action
Chloramphenicol	Inhibits peptidyl transferase on the prokaryotic large subunit
Cycloheximide	Inhibits peptidyl transferase on the eukaryotic large subunit
Erythromycin	Inhibits translocation by the prokaryotic large subunit
Fusidic acid	Inhibits elongation in prokaryotes by binding to EF-G · GDP in a way that prevents its dissociation from the large subunit
Paromomycin	Increases the ribosomal error rate
Puromycin	An aminoacyl-tRNA analog that causes premature chain termination in prokaryotes and eukaryotes
Streptomycin	Causes mRNA misreading and inhibits chain initiation in prokaryotes
Tetracycline	Inhibits the binding of aminoacyl-tRNAs to the prokaryotic small subunit
Diphtheria toxin	Catalytically inactivates eEF2 by ADP-ribosylation
Ricin/abrin/α-sarcin	<b>Ricin</b> and <b>abrin</b> are poisonous plant glycosidases that catalytically inactivate the eukaryotic large subunit by hydrolytically depurinating a specific highly conserved A residue of the 28S RNA, which is located on the so-called <b>sarcin-ricin loop</b> that forms a critical part of the ribosomal factor-binding center; <b>α-sarcin</b> is a fungal protein that cleaves a specific phosphodiester bond in the sarcin-ricin loop

minutes, which allows the *str*<sup>S</sup> ribosomes to bind to newly synthesized mRNAs as well.

#### b. Chloramphenicol

**Chloramphenicol**, the first of the “broad-spectrum” antibiotics, inhibits the peptidyl transferase activity on the large subunit of prokaryotic ribosomes. However, its clinical uses are limited to only severe infections because of its toxic side effects, which are caused, at least in part, by the chloramphenicol sensitivity of mitochondrial ribosomes. The 23S RNA is implicated in chloramphenicol binding by the observation that some of its mutants are chloramphenicol resistant. Indeed, X-ray studies indicate that chloramphenicol binds in the large subunit’s polypeptide exit tunnel in the vicinity of the A site. This explains why chloramphenicol competes for binding with the 3’ end of aminoacyl-tRNAs as well as with puromycin (whose ribosomal binding site overlaps that of chloramphenicol) but not with peptidyl-tRNAs. These observations suggest that chloramphenicol inhibits peptidyl transfer by interfering with the interactions of ribosomes with A site-bound aminoacyl-tRNAs.

#### c. Paromomycin

**Paromomycin**, a clinically useful aminoglycoside antibiotic, increases the ribosomal error rate. The X-ray structure of the 30S subunit in complex with paromomycin (Fig. 32-66) reveals that it binds to the interior of the RNA loop in which the bases of A1492 and A1493 are normally stacked (Fig. 32-59a). This causes these bases to flip out of the loop and assume a conformation resembling that in the codon-anticodon-30S subunit complex (Fig. 32-59b). Indeed, this codon-anticodon-30S subunit complex is not significantly disturbed by the binding of paromomycin. As we have seen in Section 32-3Ea, the 30S subunit employs A1492 and A1493 to ascertain whether the first two codon-anticodon base pairs are Watson-Crick base pairs, that is, whether the incoming tRNA is cognate to the codon in the A site. Noncognate tRNAs normally have insufficient codon-anticodon binding energy to flip A1492 and A1493 out of the loop and consequently are rejected by the ribosome. However, the binding of paromomycin to the 30S subunit pays the energetic price of these base flips. This facilitates the ribosomal acceptance (stabilizes the binding) of near-cognate aminoacyl-tRNAs and hence the erroneous incorporation of their amino acid residues into the polypeptide being synthesized.

#### d. Tetracycline

**Tetracycline** and its derivatives are broad-spectrum antibiotics that bind to the small subunit of prokaryotic ribosomes, where they inhibit aminoacyl-tRNA binding. An X-ray structure of tetracycline in complex with the 30S subunit reveals that tetracycline mainly binds in a crevice comprised of only the 3’ major domain of 16S RNA (Fig. 32-27a) and which is located in the neck of the 30S subunit just above its A site. This permits the initial screening of the aminoacyl-tRNA to proceed but physically blocks its accommodation into the peptidyl transferase (A/A) site after

**Figure 32-66** X-ray structure of the 30S ribosome in complex with the antibiotic paromomycin. The view and coloring are the same as those in Fig. 32-59 with the paromomycin (PAR) drawn in stick form in yellow-green. [Courtesy of Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1IBK.]

EF-Tu-catalyzed GTP hydrolysis has occurred, resulting in the release of the tRNA. Hence, in addition to preventing protein synthesis, tetracycline binding causes the unproductive hydrolysis of GTP which, since this occurs every time a cognate aminoacyl-tRNA binds to the ribosome, poses an enormous energetic drain on the cell. The nucleotides forming the tetracycline binding site are poorly conserved in eukaryotic ribosomes, thereby accounting for tetracycline’s bacterial specificity.

Tetracycline also blocks the stringent response (Section 31-3I) by inhibiting (p)ppGpp synthesis. This indicates that deacylated tRNA must bind to the A site in order to activate stringent factor.

Tetracycline-resistant bacterial strains have become quite common, thereby precipitating a serious clinical problem. Resistance is often conferred by a decrease in bacterial cell membrane permeability to tetracycline rather than any alteration of ribosomal components.

#### e. Diphtheria Toxin

**Diphtheria** is a disease resulting from bacterial infection by *Corynebacterium diphtheriae* that harbor the bacteriophage **corynephage β**. Diphtheria was a leading cause of childhood death until the late 1920s when immunization became prevalent. Although the bacterial infection is usually confined to the upper respiratory tract, the bacteria secrete a phage-encoded protein, known as **diphtheria toxin (DT)**, which is responsible for the disease’s lethal effects. *Diphtheria toxin specifically inactivates the eukaryotic elongation factor eEF2, thereby inhibiting eukaryotic protein synthesis.*

The pathogenic effects of diphtheria are prevented, as was discovered in the 1880s, by immunization with **toxoid** (formaldehyde-inactivated toxin). Individuals who have contracted diphtheria are treated with antitoxin from horse serum, which binds to and thereby inactivates DT, as well as with antibiotics to combat the bacterial infection.

DT is a member of the family of bacterial toxins that includes cholera toxin (CT) and pertussis toxin (PT; Section 19-2Ce). It is a monomeric 535-residue protein that is readily cleaved past its Arg residues 190, 192, and 193 by trypsin and trypsinlike enzymes. This hydrolysis occurs around the time diphtheria toxin encounters its target cell, yielding two fragments, A and B, which, nevertheless, remain linked by a disulfide bond. The B fragment's C-terminal domain binds to a specific receptor on the plasma membrane of susceptible cells, thereby inducing DT's uptake into the endosome (Fig. 12-91) via receptor-mediated endocytosis (Section 12-5Bc; free fragment A is devoid of toxic activity). The endosome's low pH of 5 triggers a conformational change in the B fragment's N-terminal domain, which then inserts into the endosomal membrane so as to facilitate the entry of the A fragment into the cytoplasm. The disulfide bond linking the A and B subunits is then cleaved by the cytoplasm's reducing environment.

Within the cytosol, the A fragment catalyzes the **ADP-ribosylation** of eEF2 by  $\text{NAD}^+$ ,

thereby inactivating this elongation factor. Since the A fragment acts catalytically, *one molecule is sufficient to ADP-ribosylate all of a cell's eEF2s, which halts protein synthesis and kills the cell.* Only a few micrograms of diphtheria toxin are therefore sufficient to kill an unimmunized individual.

Diphtheria toxin specifically ADP-ribosylates a modified His residue on eEF2 known as **diphthamide**:

Diphthamide occurs only in eEF2 (not even in its bacterial counterpart, EF-G), which accounts for the specificity of diphtheria toxin in exclusively modifying eEF2 (recall that CT ADP-ribosylates a specific Arg residue on  $G_{\text{sa}}$  and PT ADP-ribosylates a specific Cys residue on  $G_{1a}$ ; Section 19-2C). Since diphthamide occurs in all eukaryotic eEF2s, it probably is essential to eEF2 activity. Yet, certain mutant cultured animal cells, which have unimpaired capacity to synthesize proteins, lack the enzymes that post-translationally modify His to diphthamide (although mutating the diphthamide His to Asp, Lys, or Arg inactivates translation). Perhaps the diphthamide residue has a control function.

#### 4 CONTROL OF EUKARYOTIC TRANSLATION

The rates of ribosomal initiation on prokaryotic mRNAs differ by factors of up to 100, a variation that is largely a consequence of their different Shine–Dalgarno sequences. Moreover, the genes forming an operon are often expressed in decreasing molar amounts from the operon's 5' end to its 3' end. For example, the proteins specified by the *E. coli lac* operon (Section 31-1Ab),  $\beta$ -galactosidase, galactose permease, and thiogalactoside transacetylase, are produced in molar ratios of 10:5:2. Such **polarity** may arise when the initiation codon of a gene that lacks a Shine–Dalgarno sequence is very near the Stop codon of its upstream gene, a situation that occurs most often when the Stop codon overlaps the initiation codon as in the sequence AUGA. The translation of the upstream gene will then be required for the translation of the downstream gene, a phenomenon termed **translational coupling**. The polarity arises because a ribosome often dissociates from the mRNA on encountering the upstream gene's Stop codon. Alternatively, an mRNA may fold in a way that masks an internal Shine–Dalgarno sequence, for example, by the base pairing of a segment adjacent to the Shine–Dalgarno sequence to a downstream element of the preceding gene. Such Shine–Dalgarno sequences only become available when a ribosome that is translating the preceding gene disrupts the folded structure.

*Genetic expression in prokaryotes is largely transcriptionally controlled (Section 31-3).* This is apparently because prokaryotic mRNAs have lifetimes of only a few minutes and, hence, it is a more efficient use of resources to control their transcription. Nevertheless, the expression of certain prokaryotic genes is translationally controlled, most notably those encoding the ribosomal proteins (which comprise 10% of cellular proteins), which must be produced in equimolar amounts. The production of ribosomal proteins is controlled, in part, through a process in which a ribosomal protein binds to the mRNA of the operon encoding it in the vicinity of a translational start site located near the mRNA's 5' end so as to inhibit its translational initiation. However, each such protein binds

more tightly to an rRNA in forming the ribosome. Consequently, only when there is an excess of that protein will it inhibit its own translation as well as those of other proteins encoded by its operon.

Eukaryotic cells, whose mRNAs have lifetimes of hours or days, respond to many of their needs through translational control. In this section, we examine how eukaryotic translation is regulated via the phosphorylation/dephosphorylation of eIF2 and eIF4E. We then consider translational control by mRNA masking and cytoplasmic polyadenylation and end by discussing the uses of antisense oligonucleotides.

### A. Regulation of eIF2

Four important pathways for the regulation of translation in eukaryotes involve the phosphorylation of the conserved Ser 51 on the  $\alpha$  subunit of eIF2 (**eIF2 $\alpha$** ; recall that eIF2 is an  $\alpha\beta\gamma$  trimer that conducts Met-tRNA<sub>i</sub><sup>Met</sup> to the 40S ribosomal subunit, and the resulting complex scans the bound mRNA for the initiating AUG codon to form the 48S preinitiation complex; Section 32-3Cd). The so-called **eIF2 $\alpha$  kinases** that do so share a conserved kinase domain but have unique regulatory domains.

#### a. Heme Availability Controls Globin Translation

Reticulocytes synthesize protein, almost exclusively hemoglobin, at an exceedingly high rate and are therefore a favorite subject for the study of eukaryotic translation. Hemoglobin synthesis in fresh reticulocyte lysates proceeds normally for several minutes but then abruptly stops because of the inhibition of translational initiation and the consequent polysome disaggregation. This process is prevented by the addition of heme [a mitochondrial product (Section 26-4A) that this *in vitro* system cannot synthesize], thereby indicating that *globin synthesis is regulated by heme availability*. The inhibition of globin translational initiation is also reversed by the addition of the eukaryotic initiation factor eIF2 and by high levels of GTP.

In the absence of heme, reticulocyte lysates accumulate an eIF2 $\alpha$  kinase named **heme-regulated inhibitor [HRI]**; also called heme-controlled repressor (**HCR**). HRI is a homodimer whose 629-residue subunits each contain two heme-binding sites. When heme is plentiful, both of these sites are occupied and the protein, which is autophosphorylated at several Ser and Thr residues, is inactive. However, when heme is scarce, one of these sites loses its bound heme, thereby activating HRI to autophosphorylate itself at several additional sites and to phosphorylate Ser 51 of eIF2 $\alpha$ .

Phosphorylated eIF2 can participate in the ribosomal initiation process in much the same way as unphosphorylated eIF2. This puzzling observation was clarified by the discovery that GDP does not dissociate from phosphorylated eIF2 at the completion of the initiation process as it normally does through a process facilitated by eIF2B acting as a GEF (Fig. 32-44). This is because phosphorylated eIF2 forms a much tighter complex with eIF2B than does unphosphorylated eIF2. This sequesters eIF2B (Fig. 32-

**Figure 32-67** Model for heme-controlled protein synthesis in reticulocytes.

67), which is present in lesser amounts than eIF2, thereby preventing the regeneration of the eIF2 · GTP required for translational initiation. The presence of heme reverses this process by inhibiting HRI, whereon the phosphorylated eIF2 molecules are reactivated through the action of **eIF2 phosphatase**, which is unaffected by heme. The reticulocyte thereby coordinates its synthesis of globin and heme.

#### b. Interferons Protect against Viral Infection

**Interferons** are cytokines that are secreted by virus-infected vertebrate cells. On binding to surface receptors of other cells, interferons convert them to an antiviral state, which inhibits the replication of a wide variety of RNA and DNA viruses. Indeed, the discovery of interferons in the 1950s arose from the observation that virus-infected individuals are resistant to infection by a second type of virus.

There are three families of interferons: **type  $\alpha$**  or **leukocyte interferon** (165 residues; leukocytes are white blood cells), the related **type  $\beta$**  or **fibroblast interferon** (166 residues; fibroblasts are connective tissue cells), and **type  $\gamma$**  or **lymphocyte interferon** (146 residues; lymphocytes are immune system cells). *Interferon synthesis is induced by the double-stranded RNA (dsRNA) that is generated during infection by both DNA and RNA viruses, as well as by the synthetic dsRNA poly(I) · poly(C)*. Interferons are effective antiviral agents in concentrations as low as  $3 \times 10^{-14}$  M, which makes them among the most potent biological substances known. Moreover, they have far wider specificities than antibodies raised against a particular virus. They have therefore elicited great medical interest, particularly since some cancers are virally induced (Section 19-3B). Indeed, they are in clinical use against certain tumors and viral infections. These treatments are made possible by the production of large quantities of these otherwise quite scarce proteins through recombinant DNA techniques (Section 5-5G).

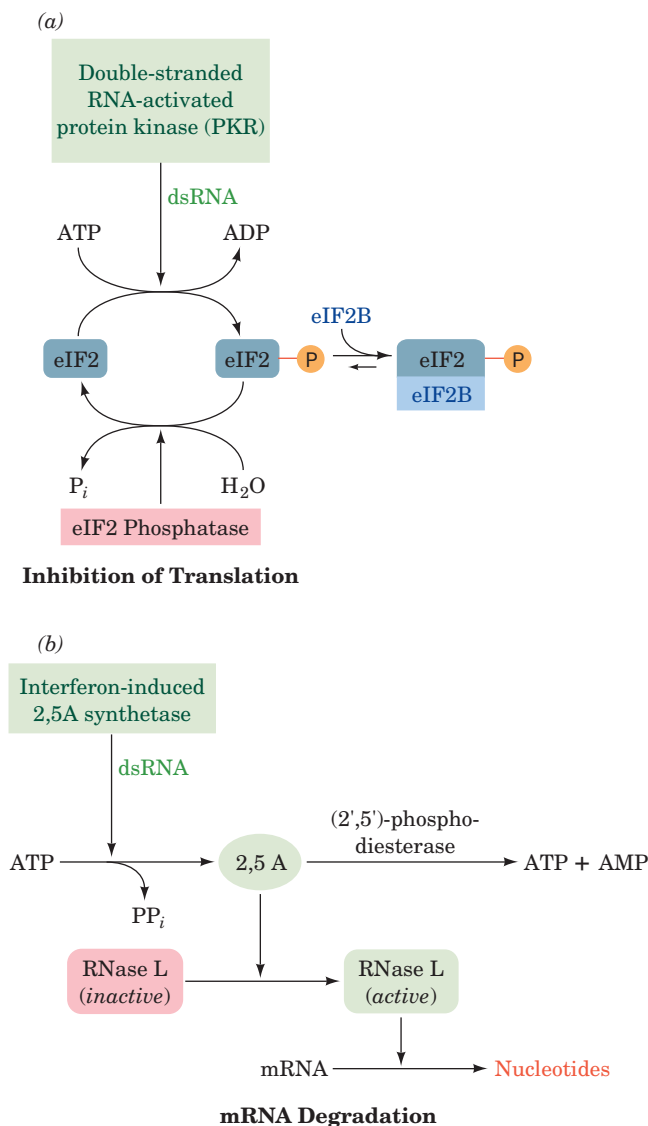

*Interferons prevent viral proliferation largely by inhibiting protein synthesis in infected cells* (lymphocyte interferon

also modulates the immune response). They do so in two independent ways (Fig. 32-68):

**1. Interferons induce the production of an eIF2 $\alpha$  kinase, double-stranded RNA-activated protein kinase [PKR; also known as double-stranded RNA-activated inhibitor (DAI); 551 residues], which on binding dsRNA, dimerizes and autophosphorylates itself. This activates PKR to phosphorylate eIF2 $\alpha$  at its Ser 51, thereby inhibiting ribosomal initiation and hence the proliferation of viruses in virus-infected cells. The importance of PKR to cellular antiviral defense is indicated by the observation that many viruses express inhibitors of PKR.**

**2. Interferons also induce the synthesis of (2',5')-oligoadenylate synthetase (2,5A synthetase).** In the presence of dsRNA, this enzyme catalyzes the synthesis from ATP of the unusual oligonucleotide pppA(2'p5'A)<sub>n</sub>, where  $n = 1$  to 10. This compound, 2,5-A, activates a preexisting endonuclease, RNase L, to degrade mRNA, thereby inhibiting protein synthesis. 2,5-A is itself rapidly degraded by an enzyme named (2',5')-phosphodiesterase so that it must be continually synthesized to maintain its effect.

The independence of the 2,5-A and PKR systems is demonstrated by the observation that the effect of 2,5-A on protein synthesis is reversed by added mRNA but not by added eIF2. [Recall that RNA interference (RNAi; Section 31-4At) constitutes an alternative dsRNA-based antiviral defense.]

**Figure 32-68 The action of interferon.** In interferon-treated cells, the presence of dsRNA, which normally results from a viral infection, causes (a) the inhibition of translational initiation and (b) the degradation of mRNA, thereby blocking translation and preventing virus replication.

### c. PERK Prevents the Buildup of Unfolded Proteins in the ER

**PKR-like endoplasmic reticulum kinase (PERK)**, a 1087-residue transmembrane protein, resides in the endoplasmic reticulum (ER) membrane of all multicellular eukaryotes. It is repressed by its binding to the ER-resident chaperone BiP (Section 12-4Bf). When the ER contains an excessive amount of unfolded proteins (caused by various forms of stress such as high temperatures), BiP dissociates from PERK, thereby activating PERK to phosphorylate eIF2 $\alpha$  at its Ser 51 and hence inhibit translation. Thus PERK functions to protect the cell from the irreversible damage caused by the accumulation of unfolded proteins in the ER.

**Wolcott-Rallison syndrome** is a genetic disease characterized mainly by insulin-dependent (type I) diabetes that develops in early infancy (type I diabetes usually first appears in childhood; Section 27-4B). It is caused by mutations in the catalytic domain of PERK. This results in the death of pancreatic  $\beta$  cells, in which PERK is particularly abundant. Multiple systemic disorders subsequently occur including **osteoporosis** (reduction in the quantity of bone) and growth retardation.

### d. GCN2 Regulates Amino Acid Biosynthesis

**GCN2** (1590 residues), the sole eIF2 $\alpha$  kinase in yeast, is a transcriptional activator of the gene encoding **GCN4**, a transcriptional activator of numerous yeast genes, many of which encode enzymes that participate in amino acid biosynthetic pathways. The C-terminal domain of GCN2, which resembles histidyl-tRNA synthetase (HisRS), preferentially binds uncharged tRNAs (whose presence is indicative of an insufficient supply of amino acids). The binding of an uncharged tRNA to this HisRS-like domain activates the adjacent eIF2 $\alpha$  kinase domain and thereby inhibits translational initiation, although at only a modest level.

Despite this inhibition of yeast protein synthesis, activated GCN2 induces the expression of GCN4. This seemingly paradoxical property of GCN2, as Alan Hinnebusch explained, arises from the fact that GCN4 mRNA contains four short so-called **upstream open reading frames**

(**uORFs**), uORF1 to uORF4, in its 5' leader that precedes the sequence encoding GCN4. Under the normal nutrient conditions in which GCN2 is inactive, the ribosome binds to the mRNA near its 5' cap and scans for the nearest AUG initiation codon (which is in uORF1), where it forms the 48S preinitiation complex (Fig. 32-44) and commences the translation of uORF1 (Section 32-3Cd). On terminating translation at uORF1's Stop codon, the presence of the surrounding A + U-rich sequences causes the ribosome to resume scanning for the next AUG codon, where it initiates the translation of uORF2. This process repeats until the ribosome terminates at the end of uORF4, where its Stop codon's surrounding G + C-rich sequences induce the ribosome to disengage from the mRNA. Hence GCN4 is only expressed at a low basal level. However, under the low nutrient conditions in which GCN2 phosphorylates eIF2 $\alpha$  at its Ser 51, the resulting reduced level of the eIF2 · Met-tRNA<sup>Met</sup> · GTP ternary complex causes the 40S subunit to scan longer distances before it can form the 48S preinitiation complex. Consequently, ~50% of the ribosomes scan past uORF2, uORF3, and uORF4 and only initiate translation at the *GCN4* AUG codon, which is therefore translated at a high level (uORF2 and uORF3 can be mutationally eliminated without significantly affecting translational control).

Mammalian homologs of GCN2 are activated under conditions of amino acid starvation. This suggests that the foregoing process has been conserved throughout eukaryotic evolution.

### B. Regulation of eIF4E

eIF4E (cap-binding protein) binds to the m<sup>7</sup>G cap of eukaryotic mRNAs and thereby participates in translational initiation by helping to identify the initiating AUG codon (Section 32-3Cd). When mammalian cells are treated with hormones, cytokines, **mitogens** (substances that induce mitosis), and/or growth factors, Ser 209 of human eIF4E is phosphorylated via a Ras-activated MAP kinase cascade (Sections 19-3C and 19-3D), thereby increasing eIF4E's affinity for capped mRNA and hence stimulating translational initiation. Ser 209 occupies a surface position on eIF4E adjacent to the binding site for the  $\beta$  phosphate group of the m<sup>7</sup>GDP and flanking the putative binding cleft for mRNA (Fig. 32-45b). The structure of eIF4E suggests that the phosphoryl group of phosphorylated Ser 209 forms a salt bridge with Lys 159, which occupies the other side of the putative mRNA-binding cleft, so as to form a clamp that would help stabilize the bound mRNA. The importance of regulating eIF4E activity is indicated by the observations that the overexpression of eIF4E causes the malignant transformation of rodent cell lines and that eIF4E expression is elevated in several human cancers.

The homologous ~120-residue proteins known as **4E-BP1**, **4E-BP2**, and **4E-BP3** (BP for *binding protein*; the first two are also known as **PHAS-I** and **PHAS-II**) inhibit cap-dependent translation. They do so by binding on the

opposite side of eIF4E from its mRNA-binding site, presumably to a patch of seven highly conserved surface residues, and hence do not prevent eIF4E from binding the m<sup>7</sup>G cap. Rather, they block eIF4E from binding to eIF4G and thereby interfere with the formation of the eIF4F complex that positions the 40S ribosomal subunit-bound Met-tRNA<sup>Met</sup> on the mRNA's initiating AUG codon (Section 32-3Cd). In fact, the 4E-BPs and eIF4G all possess the sequence motif YXXXXL $\phi$  (where  $\phi$  is an aliphatic residue, most often L but also M or F) through which they bind to eIF4E.

The treatment of responsive cells with insulin or any of several protein growth factors causes the 4E-BPs to dissociate from eIF4E. This is because the presence of these hormones induces the phosphorylation of the 4E-BPs at six Ser/Thr residues via the signal transduction pathway involving PI3K, PKB, and mTOR (Fig. 19-67). Evidently, the phosphorylation of eIF4E and the 4E-BPs have similar if not synergistic effects in the hormonal regulation of translation in eukaryotes.

### C. mRNA Masking and Cytoplasmic Polyadenylation

It has been known since the nineteenth century that early embryonic development in animals such as sea urchins, insects, and frogs is governed almost entirely by information present in the oocyte (egg) before fertilization. Indeed, sea urchin embryos exposed to sufficient actinomycin D (Section 31-2Cc) to inhibit RNA synthesis without blocking DNA replication develop normally through their early stages without a change in their protein synthesis program. This is in part because an unfertilized egg contains large quantities of mRNA that is "masked" by associated proteins to form ribonucleoprotein particles, thereby preventing the mRNAs' association with the ribosomes that are also present. On fertilization, this mRNA is "unmasked" in a controlled fashion, quite possibly by the dephosphorylation of the associated proteins, and commences directing protein synthesis. Development of the embryo can therefore start immediately on fertilization rather than wait for the synthesis of paternally specified mRNAs. Thus, gene expression in the early stages of development is entirely translationally controlled; transcriptional control only becomes important when transcription is initiated.

#### a. Cytoplasmic Polyadenylation

Another mechanism of translational control in oocytes and early embryos involves the polyadenylation of mRNAs in the cytoplasm (polyadenylation usually occurs in the nucleus, following which the mRNA is exported to the cytoplasm; Section 31-4Ab). A substantial number of maternally supplied mRNAs in oocytes have relatively short poly(A) tails (20–40 nt versus a usual length of ~250 nt). The 3' untranslated region of these mRNAs contains both the AAUAAA polyadenylation signal (which is required for polyadenylation in the nucleus; Section 31-4Ab)

together with a so-called **cytoplasmic polyadenylation element (CPE)**, which has the consensus sequence UUUUUUAU. The CPE is recognized by **CPE-binding protein (CPEB)**, which contains two RNA recognition motifs (RRMs) as well as a **zinc finger** motif (Section 34-3BI) that contribute to its binding to the mRNA. Joel Richter discovered that CPEB recruits a 931-residue protein named **maskin** which, in turn, binds the eIF4E (cap-binding protein) that is bound to the mRNA's 5' cap (Fig. 32-69a). Maskin contains the same YXXXXL $\phi$  motif through which the 4E-BPs and eIF4G bind to eIF4E (Section 32-4B), thereby blocking the binding of eIF4G to eIF4E and hence preventing the formation of the 48S preinitiation complex (Fig. 32-44).

In the maturation of *Xenopus laevis* oocytes, a process that precedes fertilization and is stimulated by the steroid hormone progesterone (Section 19-1Gb), a variety of mRNAs, including those encoding several cyclins (which participate in cell cycle control; Section 34-4Da) are translationally activated. Soon after exposure to progesterone, a protein kinase named **aurora** phosphorylates the mRNA-bound CPEB at its Ser 174. This increases CPEB's affinity for cleavage and polyadenylation specificity factor (CPSF; Section 31-4Ab), which then binds to the mRNA's AAUAAA sequence, where it recruits poly(A) polymerase (PAP) to lengthen the mRNA's poly(A) tail (Fig. 32-69b).

Translational initiation and cytoplasmic polyadenylation occur simultaneously, which suggests that these processes are linked. Indeed, Richter has shown that this occurs through the binding to poly(A) of poly(A)-binding protein (PABP; Section 31-4Ab), which as we saw (Section 32-3Cd), also binds to eIF4G to circularize the mRNA. The eIF4G in this complex displaces maskin from eIF4E, thereby permitting the formation of the 48S preinitiation complex and hence the mRNA's translation (Fig. 32-69b).

Mammalian cells also exhibit cell cycle-dependent cytoplasmic polyadenylation of mRNAs. This suggests that translational control by polyadenylation is a general feature in animal cells.

#### D. Antisense Oligonucleotides

Since ribosomes cannot translate double-stranded RNA or DNA–RNA hybrid helices, the translation of a given mRNA can be inhibited by a segment of its complementary RNA or DNA, that is, an **antisense RNA** or an **antisense oligodeoxynucleotide**, which are collectively known as **antisense oligonucleotides**. Moreover, endogenous RNase H's (enzymes that cleave the RNA strand of an RNA–DNA duplex; Section 31-4C) cleave an mRNA–oligodeoxynucleotide duplex on its mRNA strand, leaving the antisense oligodeoxynucleotide intact for binding to another mRNA.

Since the human genome consists of ~3 billion bp, an ~15-nt oligonucleotide (which is easily synthesized; Section 7-6Aa) should ideally be able to target any segment of the human genome. This exquisite specificity provides the delivery of an antisense oligonucleotide to, or its expression in, a selected tissue or organism with enormous biomedical and biotechnological potential. However, care must be taken that an antisense oligonucleotide does not also eliminate nontarget mRNAs.

Methods for the delivery of a therapeutically useful antisense oligonucleotide to a target tissue are as yet in their infancy. This is in large part because oligonucleotides are readily degraded by the many nucleases present in an organism and because they do not readily pass through cell membranes. Moreover, a target mRNA is likely to be associated with cellular proteins and hence not available for binding to other molecules. The nuclease resistance of oligonucleotides can be increased by derivatizing them, for example, by replacing a nonbridging oxygen at each phosphate group with a methyl group or an S atom so as to yield **methylphosphonate** or **phosphorothioate oligonucleotides**, although this reduces their antisense activity. The expression of antisense oligonucleotides in the specified tissues would, of course, circumvent the delivery problem but has all the difficulties associated with gene therapy (Section 5-5H).

**Figure 32-69 CPEB-mediated translational control.** (a) In immature *Xenopus* oocytes, an mRNA containing the CPE (UUUUUUAU) is bound by CPEB, which binds maskin, which then binds eIF4E so as to prevent it from binding eIF4G, thereby maintaining the mRNA in a translationally dormant (masked) state. (b) In the maturation process, CPEB is phosphorylated by an aurora protein kinase. The phosphorylated CPEB binds CPSF,

which recruits PAP to extend the mRNA's heretofore short poly(A) tail. PABP binds to the newly lengthened poly(A) tail and simultaneously binds to eIF4G so as to displace maskin. This permits the 48S preinitiation complex to assemble and hence the translation of the mRNA to proceed. [Based on a drawing by Mendez, R. and Richer, J.D., *Nature Rev. Mol. Cell Biol.* **2**, 521 (2001).]

Despite the foregoing, antisense technology is beginning to show success. **Fomivirsen** (trade name **Vitravene**), a 21-nt phosphorothioate oligonucleotide that is complementary to an mRNA expressed by **cytomegalovirus (CMV)**, is effective in the treatment of retinitis (inflammation of the retina) caused by CMV infection in individuals with AIDS (CMV is an opportunistic pathogen that rarely infects individuals with normally functioning immune systems). It was approved for human use in 1998 by the FDA, the first antisense drug so approved. A number of antisense oligonucleotides that are mainly targeted against genes that are overexpressed in specific cancers and autoimmune diseases as well as other viral infections are in clinical trials (Section 15-4Bb), although additional antisense drugs have not yet been approved for human use.

Antisense technology has also had some success in the arena of biotechnology. For example, in tomatoes and other fruits, the enzyme **polygalacturonase (PG)**, which is expressed during ripening, depolymerizes the pectin (mainly polygalacturonic acid) in the cell wall. This results in a softening of tomatoes to the point that vine-ripened (and hence better tasting) tomatoes are unable to withstand the rigors of shipping and hence must be picked before they are ripe. The introduction into a tomato, via genetic engineering techniques, of a gene expressing antisense PG RNA yielded the so-called Flavr Savr tomato that had substantially reduced PG expression and hence remained firm after vine ripening.

## 5 POST-TRANSLATIONAL MODIFICATION

To become mature proteins, polypeptides must fold to their native conformations, their disulfide bonds, if any, must form, and, in the case of multisubunit proteins, the subunits must properly combine. Moreover, as we have seen throughout this text, many proteins are modified in enzymatic reactions that proteolytically cleave certain peptide bonds and/or derivatize specific residues. In this section we shall review some of these **post-translational modifications**.

### A. Proteolytic Cleavage

Proteolytic cleavage is the most common type of post-translational modification. Probably all mature proteins have been so modified, if by nothing else than the proteolytic removal of their leading Met (or fMet) residue shortly after it emerges from the ribosome. Many proteins, which are involved in a wide variety of biological processes, are synthesized as inactive precursors that are activated under proper conditions by limited proteolysis. Some examples of this phenomenon that we have encountered are the conversion of trypsinogen and chymotrypsinogen to their active forms by tryptic cleavages

of specific peptide bonds (Section 15-3E), and the formation of active insulin from the 84-residue proinsulin by the excision of its internal 33-residue C chain (Section 9-1Aa). Inactive proteins that are activated by removal of polypeptides are called **proproteins**, whereas the excised polypeptides are termed **propeptides**.

### a. Propeptides Direct Collagen Assembly

Collagen biosynthesis is illustrative of many facets of post-translational modification. Recall that collagen, a major extracellular component of connective tissue, is a fibrous triple-helical protein whose polypeptides each contain the amino acid sequence  $(\text{Gly-X-Y})_n$  where X is often Pro, Y is often 4-hydroxyproline (Hyp), and  $n \approx 340$  (Section 8-2B). The polypeptides of **procollagen** (Fig. 32-70) differ from those of the mature protein by the presence of both N-terminal and C-terminal propeptides of  $\sim 100$  residues whose sequences, for the most part, are unlike those of mature collagen. The procollagen polypeptides rapidly assemble, *in vitro* as well as *in vivo*, to form a collagen triple helix. In contrast, polypeptides extracted from mature collagen will reassemble only over a period of days, if at all. *The collagen propeptides are apparently necessary for proper procollagen folding.*

The N- and C-terminal propeptides of procollagen are respectively removed by **amino-** and **carboxyprocollagen**

**Figure 32-70** Electron micrograph of procollagen aggregates that have been secreted by fibroblasts into the extracellular medium. [Courtesy of Jerome Gross, Massachusetts General Hospital, Harvard Medical School.]

**Figure 32-71 Schematic representation of the procollagen molecule.** Gal, Glc, GlcNAc, and Man, respectively, denote galactose, glucose, *N*-acetylglucosamine, and mannose residues. Note that the N-terminal propeptide has intrachain disulfide

bonds while the C-terminal propeptide has both intrachain and interchain disulfide bonds. [After Prockop, D.J., Kivirikko, K.I., Tuderman, L., and Guzman, N.A., *New Engl. J. Med.* **301**, 16 (1979).]

**peptidases** (Fig. 32-71), which may also be specific for the different collagen types. An inherited defect of aminoprocollagen peptidase in cattle and sheep results in a bizarre condition, **dermatosparaxis**, that is characterized by extremely fragile skin. An analogous disease in humans, **Ehlers–Danlos syndrome VII**, is caused by a mutation in one of the procollagen polypeptides that inhibits the enzymatic removal of its aminopropeptide. Collagen molecules normally spontaneously aggregate to form collagen fibrils (Figs. 8-31 and 8-32). However, electron micrographs of dermatosparaxic skin show sparse and disorganized collagen fibrils. *The retention of collagen's aminopropeptides apparently interferes with proper fibril formation.* (The dermatosparaxis gene was bred into some cattle herds because heterozygotes produce tender meat.)

#### b. Signal Peptides Are Removed from Nascent Proteins by a Signal Peptidase

Many transmembrane proteins or proteins that are destined to be secreted are synthesized with an N-terminal **signal peptide** of 13 to 36 predominantly hydrophobic residues. As we saw in our discussion of the **secretory pathway** (Section 12-4B), a signal peptide is recognized by a **signal recognition particle (SRP)**. The SRP binds a ribosome synthesizing a signal peptide to a protein pore known as the **translocon** that is embedded in the membrane [the rough endoplasmic reticulum (RER) in eukaryotes and the plasma membrane in bacteria] and conducts the signal peptide and its following nascent polypeptide through the translocon.

Proteins bearing a signal peptide are known as **preproteins** or, if they also contain propeptides, as **preproproteins**.

Once the signal peptide has passed through the membrane, it is specifically cleaved from the nascent polypeptide by a membrane-bound **signal peptidase**. Both insulin and collagen are secreted proteins and are therefore synthesized with leading signal peptides in the form of **preproinsulin** and **preprocollagen**. These and many other proteins are therefore subject to three sets of sequential proteolytic cleavages: (1) the deletion of their initiating Met residue, (2) the removal of their signal peptides, and (3) the excision of their propeptides.

#### c. Polyproteins

Some proteins are synthesized as segments of **polyproteins**, polypeptides that contain the sequences of two or more proteins. Examples include many polypeptide hormones (Section 34-3C); the proteins synthesized by many viruses, including those causing polio (Section 33-2C) and AIDS (Section 15-4Cb); and **ubiquitin**, a highly conserved eukaryotic protein involved in protein degradation (Section 32-6Bb). Specific proteases post-translationally cleave polyproteins to their component proteins, presumably through the recognition of the cleavage site sequences. Some of these proteases are conserved over remarkable evolutionary distances. For instance, ubiquitin is synthesized as several tandem repeats (**polyubiquitin**) that *E. coli* properly cleave even though prokaryotes lack ubiquitin. Other proteases have more idiosyncratic cleavage sequences. This has allowed medicinal chemists to design inhibitors of **HIV protease** (which catalyzes an essential step in the viral life cycle) that have been highly effective in attenuating if not preventing the progression of AIDS (Section 15-4Cd).

## B. Covalent Modification

Proteins are subject to specific chemical derivatizations, both at the functional groups of their side chains and at their terminal amino and carboxyl groups. Over 150 different types of side chain modifications, involving all side chains but those of Ala, Gly, Ile, Leu, Met, and Val, are known (Section 4-3A). These include acetylations, glycosylations, hydroxylations, methylations, nucleotidylations, phosphorylations, and ADP-ribosylations as well as numerous “miscellaneous” modifications.

Some protein modifications, such as the phosphorylation of glycogen phosphorylase (Section 18-1A) and the ADP-ribosylation of eEF2 (Section 32-3Ge), modulate protein activity. Several side chain modifications covalently bond cofactors to enzymes, presumably to increase their catalytic efficiency. Examples of linked cofactors that we have encountered are  $N^{\epsilon}$ -lipoyllysine in dihydrolipoyl transacetylase (Section 21-2Ac) and  $8\alpha$ -histidylflavin in succinate dehydrogenase (Section 21-3F). The attachment of complex carbohydrates, which occur in almost infinite variety, alter the structural properties of proteins and form recognition markers in various types of targeting and cell–cell interactions (Sections 11-3C, 12-3E, and 23-3B). Modifications that cross-link proteins, such as occur in collagen (Section 8-2Bc), stabilize supramolecular aggregates. The functions of most side chain modifications, however, remain enigmatic.

### a. Collagen Assembly Requires Chemical Modification

Collagen biosynthesis (Fig. 32-72) is illustrative of protein maturation through chemical modification. As the nascent procollagen polypeptides pass into the RER of the fibroblasts that synthesized them, the Pro and Lys residues are hydroxylated to Hyp, 3-hydroxy-Pro, and 5-hydroxy-Lys

(Hyl). The enzymes that do so are sequence specific: **Prolyl 4-hydroxylase** and **lysyl hydroxylase** act only on the Y residues of the Gly-X-Y sequences, whereas **prolyl 3-hydroxylase** acts on the X residues but only if Y is Hyp. Glycosylation, which also occurs in the RER, subsequently attaches sugar residues to Hyl residues (Section 8-2Bb). The folding of three polypeptides into the collagen triple helix must follow hydroxylation and glycosylation because the hydroxylases and glycosyl transferases do not act on helical substrates. Moreover, the collagen triple helix denatures below physiological temperatures unless stabilized by hydrogen bonding interactions involving Hyp residues (Section 8-2B). Folding is also preceded by the formation of specific interchain disulfide bonds between the carboxypropeptides. This observation bolsters the previously discussed conclusion that collagen propeptides help select and align the three collagen polypeptides for proper folding.

The procollagen molecules pass into the Golgi apparatus where they are packaged into **secretory vesicles** (Sections 12-4C and 12-4D) and secreted into the extracellular spaces of connective tissue. The aminopropeptides are excised just after procollagen leaves the cell and the carboxypropeptides are removed sometime later. The collagen molecules then spontaneously assemble into fibrils, which suggests that an important propeptide function is to prevent intracellular fibril formation. Finally, after the action of the extracellular enzyme lysyl oxidase, the collagen molecules in the fibrils spontaneously cross-link (Fig. 8-33).

## C. Protein Splicing: Inteins and Exteins

**Protein splicing** is a post-translational modification process in which an *internal protein segment* (an **intein**) excises itself from a surrounding *external protein*, which it ligates to form the mature **extein**. The portions of the unspliced

**Figure 32-72** Schematic representation of procollagen biosynthesis. Saccharides are represented as in Fig. 32-71. The diagram does not indicate the removal of signal peptides. [After

Prockop, D.J., Kivirikko, K.I., Tuderman, L., and Guzman, N.A., *New Engl. J. Med.* **301**, 18 (1979).]

**Figure 32-73** Series of reactions catalyzed by inteins to splice themselves out of a polypeptide chain. See the text for details.

extein on the N- and C-terminal sides of the intein are called the **N-extein** and the **C-extein**. Over 500 putative inteins, ranging in length from 100 to 1650 residues, have so far been identified in archaeobacteria, eubacteria, single-celled eukaryotes, and viruses (and are registered in the InteIn Database at <http://www.neb.com/neb/inteins.html>). The various exteins in which these inteins are embedded exhibit no significant sequence similarity and, in fact, can be replaced by other polypeptides, thereby indicating that exteins do not contain the catalytic elements that mediate protein splicing. In contrast, the ~130-residue splicing elements of inteins exhibit significant sequence similarity. All of them have four conserved splice-junction residues: (1) a Ser/Thr/Cys at the intein's N-terminus; and (2 and 3) a His–Asn/Gln dipeptide at the intein's C-terminus; which is immediately followed by (4) a Ser/Thr/Cys at the N-terminus of the C-extein.

Protein splicing occurs via a reaction sequence that involves four successive nucleophilic displacements, the first three of which are mediated by the intein (Fig. 32-73):

1. Attack by the N-terminal intein residue (Ser, Thr, or Cys; shown in Fig. 32-73 as Ser) on its preceding carbonyl group, yielding a linear (thio)ester intermediate.

2. A transesterification reaction in which the —OH or —SH group on the C-extein's N-terminal residue (shown in Fig. 32-73 as Ser) attacks the above (thio)ester linkage, thereby yielding a branched intermediate in which the N-extein has been transferred to the C-extein.

3. Cleavage of the amide linkage connecting the intein to the C-extein by cyclization of the intein's C-terminal Asn or Gln (shown in Fig. 32-73 as Asn). The succinimide ring of the excised intein then spontaneously hydrolyzes to regenerate Asn (or iso-Asn).

4. Spontaneous rearrangement of the (thio)ester linkage between the ligated exteins to yield the more stable peptide bond.

The X-ray structure of the 198-residue **GyrA intein** from *Mycobacterium xenopi*, determined by James Sacchetini, indicates how this intein catalyzes the foregoing splicing reactions. This intein's N-terminal residue, Cys 1, was replaced by an Ala–Ser dipeptide with the expectation that the mutant protein would resemble the intein's pre-splicing state (the new N-terminal residue, Ala 0, presumably represents the C-terminal residue of the N-extein). The X-ray structure reveals that this monomeric protein consists primarily of  $\beta$  strands, two of which curve about the periphery of the entire protein to give it the shape of a flattened horseshoe (Fig. 32-74). The intein's catalytic site is located at the bottom of a broad and shallow cleft near the center of this so-called  **$\beta$ -horseshoe**, where the intein's N-terminal and C-terminal residues are in close proximity. The Ala 0–Ser 1 peptide bond, the bond cleaved in Reaction 1 of the protein splicing process (Fig. 32-73) assumes the cis conformation (Fig. 8-2), a rare high-energy conformation (except when the peptide bond is followed by Pro) that destabilizes this bond. Its amide nitrogen atom is hydrogen bonded to the side chain of the highly conserved

**Figure 32-74** X-ray structure of the *M. xenopi* Gyr A intein in which Cys 1 was replaced by an Ala 0–Ser 1 dipeptide. The protein is drawn in ribbon form with its N-terminal Ala 0–Ser 1 dipeptide and its C-terminal His 197–Asn 198 dipeptide as well as the side chains of residues 72 through 75 drawn in stick form colored according to atom type (C of residues 0–1 magenta, C of residues 72–75 green, C of residues 197–198 cyan, N blue, and O red). Hydrogen bonds are represented by thin gray bonds. [Based on an X-ray structure by James Sacchetini, Texas A&M University. PDBid 1AM2.]

His 75. Hence His 75 is well positioned to donate a proton that would promote the breakdown of the tetrahedral intermediate in Reaction 1. The side chains of Thr 72 and Asn 74 appear well positioned to stabilize this tetrahedral intermediate in a manner resembling that of the oxyanion hole in serine proteases (Section 15-3Db). The position of Ser 1 and a modeled Thr at the intein's C-terminus is consistent with Reaction 2 of the splicing process. The side chain of the invariant His 197 is hydrogen bonded to the carboxylate of the C-terminal Asn 198 and hence is positioned to protonate the peptide bond cleaved in Reaction 3.

#### a. Most Inteins Encode a Homing Endonuclease

What is the biological function of inteins? Nearly all inteins contain polypeptide inserts forming so-called **homing endonucleases**. These are site-specific endonucleases that make a double-strand break in genes that are homologous to their corresponding extein but which lack inteins. The break initiates the double-strand break repair of the DNA via recombination (Section 30-6Ag). Since the intein-containing gene is likely to be the only other gene in the cell containing extein-like sequences, the intein gene is copied into the break. Thus, most inteins mediate a highly specific transposition or “homing” of the genes that insert them in similar sites. The intein's protease and endonuclease activities appear to have a symbiotic relationship: The protease activity excises the intein from the host protein, thereby preventing deleterious effects on the host, whereas the endonuclease

activity assures the mobility of the intein gene. Thus intein genes appear to be molecular parasites (junk DNA) that only function to propagate themselves. Indeed, homing endonucleases are also encoded by certain types of introns.

## 6 PROTEIN DEGRADATION

The pioneering work of Henry Borsook and Rudolf Schoenheimer around 1940 demonstrated that the components of living cells are constantly turning over. For example, adult humans normally turn over ~2% of their proteins per day. Proteins have lifetimes that range from as short as a few minutes to weeks or more. In any case, *cells continuously synthesize proteins from and degrade them to their component amino acids*. The function of this seemingly wasteful process is 2-fold: (1) to eliminate abnormal proteins whose accumulation would be harmful to the cell, and (2) to permit the regulation of cellular metabolism by eliminating superfluous enzymes and regulatory proteins. Indeed, since the level of an enzyme depends on its rate of degradation as well as its rate of synthesis, *controlling a protein's rate of degradation is as important to the cellular economy as is controlling its rate of synthesis*. In this section we consider the processes of intracellular protein degradation and their consequences.

### A. Degradation Specificity

*Cells selectively degrade abnormal proteins*. For example, hemoglobin that has been synthesized with the valine analog  $\alpha$ -amino- $\beta$ -chlorobutyrate

has a half-life in reticulocytes of ~10 min, whereas normal hemoglobin lasts the 120-day lifetime of the red cell (which makes it perhaps the longest lived cytoplasmic protein). Likewise, unstable mutant hemoglobins are degraded soon after their synthesis, which, for reasons explained in Section 10-3A, results in the hemolytic anemia characteristic of these molecular disease agents. Bacteria also selectively degrade abnormal proteins. For instance, *amber* and *ochre* mutants of  $\beta$ -galactosidase have half-lives in *E. coli* of only a few minutes, whereas the wild-type enzyme is almost indefinitely stable. Most abnormal proteins, however, probably arise from the chemical modification and/or spontaneous denaturation of these fragile molecules in the cell's reactive environment rather than by mutations or the rare errors in transcription or translation. *The ability to eliminate damaged proteins selectively is therefore an essential recycling mechanism that prevents the buildup of substances that would otherwise interfere with cellular processes*.

Normal intracellular proteins are eliminated at rates that depend on their identities. A given protein is elimi-

**Table 32-11** Half-Lives of Some Rat Liver Enzymes

Enzyme	Half-Life (h)
<b>Short-Lived Enzymes</b>	
Ornithine decarboxylase	0.2
RNA polymerase I	1.3
Tyrosine aminotransferase	2.0
Serine dehydratase	4.0
PEP carboxylase	5.0
<b>Long-Lived Enzymes</b>	
Aldolase	118
GAPDH	130
Cytochrome <i>b</i>	130
LDH	130
Cytochrome <i>c</i>	150

Source: Dice, J.F. and Goldberg, A.L., *Arch. Biochem. Biophys.* **170**, 214 (1975).

nated with first-order kinetics, indicating that the molecules being degraded are chosen at random rather than according to their age. The half-lives of different enzymes in a given tissue vary substantially as is indicated for rat liver in Table 32-11. Remarkably, *the most rapidly degraded enzymes all occupy important metabolic control points, whereas the relatively stable enzymes have nearly constant catalytic activities under all physiological conditions. The susceptibilities of enzymes to degradation have evidently evolved together with their catalytic and allosteric properties so that cells can efficiently respond to environmental changes and metabolic requirements*. The criteria through which native proteins are selected for degradation are considered in Section 32-6B.

The rate of protein degradation in a cell also varies with its nutritional and hormonal state. Under conditions of nutritional deprivation, cells increase their rate of protein degradation so as to provide the necessary nutrients for indispensable metabolic processes. The mechanism that increases degradative rates in *E. coli* is the stringent response (Section 31-3I). A similar mechanism may be operative in eukaryotes since, as happens in *E. coli*, increased rates of degradation are prevented by antibiotics that block protein synthesis.

### B. Degradation Mechanisms

*Eukaryotic cells have dual systems for protein degradation: lysosomal mechanisms and ATP-dependent cytosolically based mechanisms*. We consider both mechanisms below.

#### a. Lysosomes Mostly Degrade Proteins Nonselectively

Lysosomes are membrane-encapsulated organelles (Section 1-2Ad) that contain ~50 hydrolytic enzymes, including a variety of proteases known as **cathepsins**. The lysosome maintains an internal pH of ~5 and its enzymes have acidic pH optima. This situation presumably protects

the cell against accidental lysosomal leakage since lysosomal enzymes are largely inactive at cytosolic pH's.

Lysosomes recycle intracellular constituents by fusing with membrane-enclosed bits of cytoplasm known as **autophagic vacuoles** and subsequently breaking down their contents. They similarly degrade extracellular substances that the cell takes up via endocytosis (Section 12-5Bc). The existence of these processes has been demonstrated through the use of lysosomal inhibitors. For example, the antimalarial drug **chloroquine**

**Chloroquine**

is a weak base that, in uncharged form, freely penetrates the lysosome where it accumulates in charged form, thereby increasing the intralysosomal pH and inhibiting lysosomal function. The treatment of cells with chloroquine reduces their rate of protein degradation. Similar effects arise from treatment of cells with cathepsin inhibitors such as the polypeptide antibiotic **antipain**.

**Antipain**

*Lysosomal protein degradation in well-nourished cells appears to be nonselective.* Lysosomal inhibitors do not affect the rapid degradation of abnormal proteins or short-lived enzymes. Rather, they prevent the acceleration of nonselective protein breakdown on starvation. However, the continued nonselective degradation of proteins in starving cells would rapidly lead to an intolerable depletion of essential enzymes and regulatory proteins. Lysosomes therefore also have a selective pathway, which is activated only after a prolonged fast, that takes up and degrades proteins containing the pentapeptide Lys-Phe-Glu-Arg-Gln (KFERQ) or a closely related sequence. Such KFERQ proteins are selectively lost in fasting animals from tissues that atrophy in response to fasting (e.g., liver and kidney) but not from tissues that do not do so (e.g., brain and testes). KFERQ proteins are specifically bound in the cytosol and delivered to the lysosome by a 73-kD **peptide recognition protein (prp73)**, a member of the 70-kD heat shock protein (Hsp70) family (Section 9-2C).

Both normal and pathological processes are associated with increased lysosomal activity. **Diabetes mellitus** (Section 27-4B) stimulates the lysosomal breakdown of proteins. Similarly, muscle wastage caused by disuse, denervation, or traumatic injury arises from increased lysosomal activity. The regression of the uterus after childbirth, in which this muscular organ reduces its mass from 2 kg to

50 g in 9 days, is a striking example of this process. Many chronic inflammatory diseases, such as **rheumatoid arthritis**, involve the extracellular release of lysosomal enzymes that break down the surrounding tissues.

### b. Ubiquitin Marks Proteins Selected for Degradation

It was initially assumed that protein degradation in eukaryotic cells is primarily a lysosomal process. Yet, reticulocytes, which lack lysosomes, selectively degrade abnormal proteins. The observation that protein breakdown is inhibited under anaerobic conditions led to the discovery of a cytosolically based ATP-dependent proteolytic system that is independent of the lysosomal system. This phenomenon was thermodynamically unexpected since peptide hydrolysis is an exergonic process.

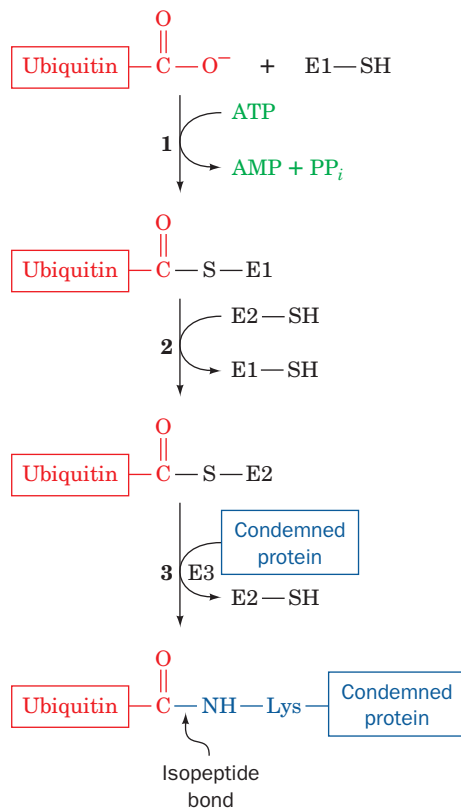

The analysis of a cell-free rabbit reticulocyte system demonstrated that **ubiquitin** (Fig. 32-75) is required for ATP-dependent protein degradation. *This 76-residue monomeric protein, so named because it is ubiquitous as well as abundant in eukaryotes, is the most highly conserved protein known:* It is identical in such diverse organisms as humans, toad, trout, and *Drosophila* and differs in only three residues between humans and yeast. Evidently, ubiquitin is all but uniquely suited to an essential cellular function.

*Proteins that are selected for degradation are so marked by covalently linking them to ubiquitin.* This process, which is reminiscent of amino acid activation (Section 32-2C),

**Figure 32-75** X-ray structure of human ubiquitin. The polypeptide is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*) with the side chain of Lys 48 shown in stick form with C green and N blue. This  $\alpha + \beta$  architecture is known as a  **$\beta$ -Grasp** fold because its  $\beta$  sheets appear to grasp its  $\alpha$  helix. [Based on an X-ray structure by Charles Bugg, University of Alabama at Birmingham. PDBid 1UBQ.]  See Interactive Exercise 46.

**Figure 32-76 Reactions involved in the attachment of ubiquitin to a protein.** In the first part of the process, ubiquitin's terminal carboxyl group is joined, via a thioester linkage, to E1 in a reaction driven by ATP hydrolysis. The activated ubiquitin is subsequently transferred to a sulfhydryl group of an E2 and then, in a reaction catalyzed by an E3, to a Lys  $\epsilon$ -amino group on a condemned protein, thereby flagging the protein for proteolytic degradation by the 26S proteasome.

occurs in a three-step pathway that was elucidated notably by Avram Hershko, Aaron Ciechanover, and Irwin Rose (Fig. 32-76):

**1.** In an ATP-requiring reaction, ubiquitin's terminal carboxyl group is conjugated, via a thioester bond, to **ubiquitin-activating enzyme (E1)**, a homodimer of  $\sim 1050$ -residue subunits. In this process, the substrate protein's terminal carboxyl group is initially adenylylated and then transferred to the E1 Cys—SH group with the elimination of AMP. Most organisms, including yeast and humans, have only one type of E1.

**2.** The ubiquitin is then transferred to a specific Cys sulfhydryl group on one of numerous proteins named **ubiquitin-conjugating enzymes (E2s)**; 11 in yeast and over 20 in mammals). The various E2's are characterized by  $\sim 150$ -residue catalytic cores containing the active site Cys that exhibit at least 25% sequence identities and which mainly vary by the presence or absence of N- and/or C-terminal extensions that exhibit little sequence identity to each other. The X-ray and NMR structures of several species of E2 reveal that their catalytic cores all assume closely similar  $\alpha/\beta$  structures (e.g., Fig. 32-77) in which

**Figure 32-77 X-ray structure of an E2 protein from *Arabidopsis thaliana*.** The protein is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The side chain of Cys 88, to which ubiquitin is covalently linked, is shown in ball-and-stick form with C green and S yellow. [Based on an X-ray structure by William Cook, University of Alabama at Birmingham. PDBid 2AAK.]

most of the identical residues are clustered on one surface near the ubiquitin-accepting Cys residue, where they presumably interact with ubiquitin and E1.

**3. Ubiquitin-protein ligase (E3) transfers the activated ubiquitin from E2 to a Lys  $\epsilon$ -amino group of its target protein, thereby forming an isopeptide bond.** Each of the many E3s present in eukaryotic cells mediates the ubiquitination (alternatively, ubiquitylation) of a specific set of proteins and thereby marks them for degradation. Each E3 is served by one or a few specific E2s. Most E3s are members of two unrelated families, those containing a **HECT** domain (HECT for *homologous to E6AP C-terminus*) and those containing a so-called **RING** domain (also called a **RING-finger** domain; RING for *really interesting new gene*), although some E2s react well with members of both families. The human genome contains 28 HECT genes and 616 RING genes, more than its number of protein kinase genes (518), which is indicative of the specialized and varied functions of E3s (although not all RING domain-containing proteins are E3s). HECT domain E3s are modularly constructed with a unique N-terminal domain that interacts with its target proteins via their so-called **ubiquitination signals** (usually short polypeptide segments; see below) and an  $\sim 350$ -residue HECT domain that mediates E2 binding and catalyzes the ubiquitination reaction. RING domains, which are implicated in recognizing a substrate protein's ubiquitination signal, are 40- to 60-residue motifs that each bind two structurally but not catalytically implicated  $\text{Zn}^{2+}$  ions via a total of 8 Cys and His residues in a characteristic consensus sequence (much like the zinc finger motifs in certain DNA-binding proteins, Section 34-3B1). RING domain-containing E3s may consist of a single subunit or may be multisubunit proteins in which the RING domain is contained in one subunit. HECT E3-mediated ubiquitination occurs via the transfer of ubiquitin from E2 to a conserved Cys residue on the HECT domain followed by its transfer to the substrate protein Lys side chain. In contrast, RING domain E3s act

**Figure 32-78** X-ray structure of human tetraubiquitin. (a) A ribbon drawing in which the isopeptide bonds connecting successive ubiquitin molecules, together with the Lys side chains making them, are drawn in stick form with C green, N blue, and O red. However, since the C-terminal three residues of ubiquitin 2 are disordered, the isopeptide bond connecting it to ubiquitin 3 is represented by a thin gray bond (this isopeptide bond nevertheless exists, as was demonstrated by SDS-PAGE of dissolved crystals). The monomer units in a multiubiquitin chain of any length are likely to be arranged with the repeating symmetry of the tetraubiquitin structure, although the weak interactions between adjacent ubiquitin units suggests that this chain is conformationally flexible. (b) A surface diagram, viewed as in Part a, in which basic residues (Arg, Lys, His) are blue, acidic residues (Asp, Glu) are red, uncharged polar residues (Gly, Ser, Thr, Asn, Gln) are purple, and hydrophobic residues (Ile, Leu, Val, Ala, Met, Phe, Tyr, Pro) are tan (ubiquitin lacks Cys and Trp residues). Note the unusually large solvent-exposed surface occupied by the hydrophobic residues. [Based on an X-ray structure by William Cook, University of Alabama at Birmingham, and Cecile Pickart, Johns Hopkins University. PDBid 1TBE.]

as adapters that position the reactive E2–ubiquitin thioester bond for the direct transfer of the ubiquitin to the substrate protein Lys side chain.

In order for a target protein to be efficiently degraded, it must be linked to a chain of at least four tandemly linked ubiquitin molecules in which Lys 48 of each ubiquitin forms an isopeptide bond with the C-terminal carboxyl group of the succeeding ubiquitin (Fig. 32-78). These **polyubiquitin (polyUb)** chains, which can reach lengths of 50 or more ubiquitin molecules, are generated by the E3s, although how they switch from transferring a ubiquitin to the target protein to processively synthesizing a polyubiquitin chain is unknown.

### c. Ubiquitinated Proteins Are Hydrolyzed in the Proteasome

A ubiquitinated protein is proteolytically degraded to short peptides in an ATP-dependent process mediated by a large (2000 kD, 26S) multisubunit protein complex named the **26S proteasome** (sometimes spelled “proteasome”) that electron micrographic studies reveal has the shape of a bi-capped hollow barrel (Fig. 32-79). Proteolysis occurs inside the barrel, which permits this process to be extensive and processive, while preventing nonspecific proteolytic damage to other cellular components. PolyUb chains are the signals that target a protein to the proteasome; the identity of the target protein has little effect on the efficiency with which it is degraded by the proteasome. Nevertheless, the proteasome does not degrade ubiquitin molecules; they are returned to the cell. The size and functional complexity of this entire proteolytic system, which occurs in the nucleus as well as the cytosol, rivals that of the ribosome (Section 32-3) and the spliceosome (Section 31-4A) and hence is

**Figure 32-79** Electron microscopy-based image of the *Drosophila melanogaster* 26S proteasome. The complex is around  $450 \times 190 \text{ \AA}$ . The central portion of this 2-fold symmetric multiprotein complex (yellow), the **20S proteasome**, consists of four stacked 7-membered rings of subunits that form a hollow barrel in which the proteolysis of ubiquitin-linked proteins occurs. The **19S caps** (cyan), which may attach to one or both ends of the 20S proteasome, control the access of condemned proteins to the 20S proteasome (see below). [Courtesy of Wolfgang Baumeister, Max Planck Institute of Biochemistry, Martinsreid, Germany.]

indicative of the importance of properly managing protein degradation. Indeed, ~5% of the proteins expressed by yeast participate in protein degradation. We discuss the structure and function of the 26S proteasome below.

#### d. Many E3s Have Elaborate Modular Structures

The proto-oncogene product **c-Cbl** (906 residues) is a single-subunit, RING domain-containing E3 that functions to ubiquitinate certain activated receptor tyrosine kinases (RTKs; Section 19-3A), thereby terminating their signaling. Nikola Pavletich determined the X-ray structure of the N-terminal half of c-Cbl (residues 47–447) in its ternary complex with the E2 protein **UbcH7** (which consists of little more than the ~150-residue E2 catalytic core) and a 9-residue peptide containing the ubiquitination signal from a nonreceptor tyrosine kinase (NRTK) named **ZAP-70** (Fig. 19-44). The structure (Fig. 32-80) reveals that UbcH7 and c-Cbl's RING domain and SH2-containing tyrosine kinase-binding (TKB) domains interact with one another across multiple interfaces to form a compact and apparently rigid structure. The RING domain consists of a 3-stranded  $\beta$  sheet, an  $\alpha$  helix, and two large loops that are held together by two tetrahedrally coordinated  $Zn^{2+}$  ions. UbcH7 adopts the characteristic  $\alpha/\beta$  fold of other E2s of known structure (e.g., Fig. 32-77). The ZAP-70 peptide is bound on the opposite side of the TKB domain from the UbcH7 active site Cys residue (Cys 86) and is ~60 Å distant from it.

**Figure 32-80** X-ray structure of the human c-Cbl-UbcH7-ZAP-70 peptide ternary complex drawn in tube-and-arrow form.

UbcH7, an E2 that consists almost entirely of the E2 catalytic core, is colored orange with the side chain of its active site Cys 86 shown in stick form with C green and S yellow. c-Cbl (residues 47–447 of the 903-residue protein), a monomeric RING E3, is colored according to domain with its TKB domain green, its RING domain red, and the linker joining them yellow. The RING domain's two bound  $Zn^{2+}$  ions are represented by cyan spheres. The 9-residue ubiquitination site of the RTK ZAP-70, whose fourth residue is phospho-Tyr, is drawn in stick form with C magenta, N blue, and O red, and P orange. [Based on an X-ray structure by Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1FBV.]

**SCF complexes** are multisubunit RING E3s that consist of **Cul1** (a member of the **cullin** family; 776 residues), **Rbx1** (which contains the complex's RING domain; 108 residues), **Skp1** (163 residues), and a member of the **F-box protein** family (~430 to >1000 residues; SCF for Skp1-cullin-F-box protein). Rbx1 and Cul1 form the complex's catalytic core that binds E2; F-box proteins consist of an ~40-residue **F-box** that binds Skp1 followed by protein-protein interaction modules such as **leucine-rich repeats (LRRs)** or WD40 repeats (Section 19-2C) that bind substrate protein; and Skp1 functions as an adapter that links the F-box to Cul1. Cells contain numerous different F-box proteins (at least 38 in humans) that presumably permit the specific ubiquitination of a diverse variety of protein substrates (see below).

Pavletich has also determined the X-ray structures of two segments of the **SCF<sup>Skp2</sup>** complex (where the superscript identifies the complex's F-box protein, here **Skp2**, 436 residues). The structure of the Skp1-Skp2 complex (Fig. 32-81) reveals that it has the shape of a sickle with the Skp1 and the 3-helix F-box of Skp2 forming the handle and its 10 LRRs (~26 residues each) forming the curved blade. The structure of the Cul1-Rbx1-Skp1-F-box<sup>Skp2</sup> quaternary complex (Fig. 32-82) shows that Cul1 is an elongated protein that consists of a long stalk formed by three repeats of a novel five-helix motif known as a cullin repeat followed by a globular domain that binds Rbx1. Apparently Cul1 acts like a rigid scaffold that organizes the Skp1-F-box<sup>Skp2</sup> complex and Rbx1 so as to hold them over 100 Å

**Figure 32-81** X-ray structure of the human Skp1-Skp2 complex.

Skp1 and Skp2 are drawn in tube-and-arrow form in blue and magenta. Skp2 consists of an N-terminal F-box that forms three helices, followed by 3 noncanonical so-called linker leucine-rich repeats (LRRs) that are contiguous with 7 LRRs that were predicted from their amino acid sequences for a total of 10 LRRs. After the tenth LRR, Skp2's ~30-residue C-terminal tail extends back past the first LRR by packing under the concave surface of the LRR domain. [Based on an X-ray structure by Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1FQV.]

**Figure 32-82** X-ray structure of the human **Cul1-Rbx1-Skp1-F-box<sup>Skp2</sup>** quaternary complex. Cul1, Rbx1, Skp1, and the Skp2 F-box are drawn in tube-and-arrow form and respectively colored green, red, blue, and magenta. The three cullin repeats of Cul1 are indicated. The three  $Zn^{2+}$  ions bound to Rbx1 are represented by cyan spheres. [Based on an X-ray structure by Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1LDK.]

apart. The Rbx1 RING domain contains a 20-residue insert that forms the binding site for a third tetrahedrally liganded  $Zn^{2+}$  ion.

The apparent rigidity of the foregoing three structures has enabled Pavletich to construct a model of the intact SCF<sup>Skp2</sup>-E2 complex by superimposing Skp1-Skp2 on Cul1-Rbx1-Skp1-F-box<sup>Skp2</sup> and docking the E2 UbcH7 onto the Rbx1 RING domain based on the c-Cbl-UbcH7 structure (Fig. 32-83). The model indicates that E2 and the LRR-containing domain of Skp2 are on the same side of the SCF complex but separated by a distance of  $\sim 50$  Å.

**Figure 32-83** Model of the SCF<sup>Skp2</sup>-E2 complex. This model, which is based on the X-ray structures in Figs. 32-80, 32-81, and 32-82, is colored and viewed as in Fig. 32-82. E2 is yellow with its active site Cys residue, to which ubiquitin would be covalently linked, drawn in space-filling form in cyan. The  $Zn^{2+}$  ions associated with the Rbx1 RING domain are represented by yellow spheres. The gray arrow indicates the 50-Å gap between the tip of the Skp2 LRR domain and the E2 active site. [Courtesy of Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York.]

This suggests that Cul1's long stalk functions to separate the complex's substrate-binding and catalytic sites so that substrates with different sizes and various distances between their ubiquitinated Lys residues and their ubiquitination signals can be accommodated.

### e. The Ubiquitin System Has Both Housekeeping and Regulatory Functions

Until the mid-1990s, it appeared that the ubiquitin system functioned mainly in a “housekeeping” capacity to maintain the proper balance among metabolic proteins and to eliminate damaged proteins. Indeed, as Alexander Varshavsky discovered, *the half-lives of many cytoplasmic proteins vary with the identities of their N-terminal residues* (Table 32-12). Thus, in a selection of 208 cytoplasmic proteins known to be long lived, all have a “stabilizing” residue, Met, Ser, Ala, Thr, Val, or Gly, at their N-termini. This so-called **N-end rule** is true for both eukaryotes and prokaryotes, which suggests the system that selects proteins for degradation is conserved in eukaryotes and prokaryotes, even though prokaryotes lack ubiquitin. The N-end rule results from the actions of the single-subunit, RING E3 named **E3 $\alpha$**  ( $\sim 1950$  residues; also known as **Ubr1**) whose ubiquitination signals are the destabilizing N-terminal residues in Table 32-12.

Similarly, it has long been known that proteins with segments rich in Pro (P), Glu (E), Ser (S), and Thr (T), the so-called **PEST proteins**, are rapidly degraded. This is because these PEST elements often contain phosphorylation sites that target their proteins for ubiquitination.

**Table 32-12** Half-Lives of Cytoplasmic Enzymes as a Function of Their N-Terminal Residues

N-Terminal Residue	Half-Life
<b>Stabilizing</b>	
Met	>20 h
Ser

Asp	
Lys	
Arg	$\sim 2$ min

Source: Bachmair, A., Finley, D., and Varshavsky, A., *Science* **234**, 180 (1986).

It is now clear, however, that the ubiquitin system is far more sophisticated than a simple garbage disposal system. Thus, the known E3s each respond to certain ubiquitination signals that often occur on a quite limited range of target proteins, many of which have regulatory functions. For example, *the ubiquitination system has an essential function in cell cycle progression*. The cell cycle, as we have seen in Section 30-4Aa and will further discuss in Section 34-4D, is regulated by a series of proteins known as cyclins. A given cyclin, which is expressed immediately preceding and/or during a specific phase of the cell cycle, binds to a corresponding **cyclin-dependent protein kinase (Cdk)**, which then phosphorylates its target proteins so as to activate them to carry out the processes of that phase of the cell cycle. Moreover, many cyclins also inhibit the transition to the subsequent phase of the cell cycle (e.g., DNA replication or mitosis). Consequently, for a cell to progress from one phase of the cell cycle to the next, the cyclin(s) governing that phase must be eliminated. This occurs via the specific ubiquitination of the cyclin, thereby condemning it to be destroyed by the proteasome. The E3s responsible for this process are the SCF complexes containing F-box proteins targeted to a corresponding cyclin and a multisubunit complex known as the **anaphase-promoting complex (APC; alternatively the cyclosome; Section 34-4Da)**. APC, an ~1500-kD RING domain-containing particle that in yeast consists of 11 subunits, specifically ubiquitinates proteins that contain the 9-residue consensus sequence RTALGDIGN, the so-called **destruction box**, near their N-termini.

The transcription factor **NF- $\kappa$ B**, which plays a central role in immune and inflammatory responses (Section 34-3Bs), is maintained in an inactive state in the cytosol through its binding to the inhibitor **I $\kappa$ B $\alpha$**  in a way that occludes the short internal basic sequence that directs NF- $\kappa$ B's import into the nucleus (its **nuclear localization signal; NLS**). However, the stimulation of cell-surface receptors by proinflammatory cytokines such as **tumor necrosis factor- $\alpha$  (TNF $\alpha$ ; Section 19-3Db)** and **interleukin-1 (IL-1; Section 19-3Eb)** initiate a signal transduction pathway (Section 19-3D) that phosphorylates I $\kappa$ B $\alpha$  bound to NF- $\kappa$ B at both Ser residues in the sequence DSGLDS. This phosphorylated sequence is the ubiquitination signal for the SCF complex containing the F-box protein  **$\beta$ -TrCP** (605 residues), which mediates the ubiquitination of the phosphorylated I $\kappa$ B $\alpha$ . The consequent destruction of I $\kappa$ B $\alpha$  exposes the NLS of NF- $\kappa$ B, which is then translocated to the nucleus where it activates the transcription of its target genes (Section 34-3Bs).

Some viruses usurp the ubiquitin system. Oncogenic forms of **human papillomavirus (HPV)**, the cause of nearly all cervical cancers (a leading cause of death of women in developing countries), encode the ~150-residue **E6 protein**, which combines with the 875-residue cellular protein named **E6-associated protein (E6AP; the first E3 known to contain a HECT domain)** to ubiquitinate **p53**, thereby marking it for destruction. This latter protein is a transcription factor that monitors genome integrity and

hence is important in preventing malignant transformation and the proliferation of cancer cells (Section 34-4Ca), that is, it is a **tumor suppressor** (a protein whose loss of function is a cause of cancer). Consequently, HPV provokes the uncontrolled growth of the cells it infects and hence its own proliferation. E6AP normally functions to ubiquitinate certain members of the Src family of protein tyrosine kinases (Section 19-3Ba), including Src itself. The deletion of the segment of chromosome 15 that contains the E6AP gene causes Angelman syndrome, which as we have seen (Section 30-7d) is characterized by severe mental retardation and is exclusively maternally inherited due to genomic imprinting.

The foregoing are only a few examples of the numerous cellular processes that are regulated by the ubiquitin-mediated proteolysis system. Not surprisingly, therefore, many pathological conditions in humans, including inflammatory, neurodegenerative, and muscle-wasting diseases, are attributable to malfunctioning ubiquitination systems.

#### f. The 20S Proteasome Catalyzes Proteolysis Inside a Hollow Barrel

The 26S proteasome (Fig. 32-79) is an ~2100-kD multi-subunit protein that catalyzes the ATP-dependent hydrolysis of ubiquitin-linked proteins. This yields oligopeptides with lengths of 4 to 25 residues and averaging 7 to 9 residues that are subsequently degraded to their component amino acids by cytosolic exopeptidases. The 26S proteasome consists of a **20S proteasome** (~670 kD), the barrel-shaped catalytic core of the 26S proteasome, and its **19S caps** (~700 kD; also known as **PA700** and the **19S regulator**), which associate with the ends of the 20S proteasome and stimulate its activity (PA for *proteasome activator*). The 20S proteasome only hydrolyzes unfolded proteins in an ATP-independent manner; the 19S caps function to identify and unfold the ubiquitinated protein substrates.

The 20S proteasome occurs in the nuclei and cytosol of all eukaryotic cells and in all archaeobacteria yet examined. However, the only eubacteria in which it occurs are those of the class Actinobacteria, which suggests that they obtained it via horizontal gene transfer from some other organism.

The 20S proteasome of *Thermoplasma acidophilum* (an archaeobacterium) consists of 14 copies each of  $\alpha$  and  $\beta$  subunits (233 and 203 residues) that electron microscopy studies revealed form a 150-Å long and 110-Å-diameter barrel in which the subunits are arranged in four stacked rings (as is evident in the central portion of the 26S proteasome seen in Fig. 32-79). The  $\alpha$  and  $\beta$  subunits are 26% identical in sequence except for an ~35-residue N-terminal tail of the  $\alpha$  subunit, which the  $\beta$  subunit lacks. Eukaryotic 20S proteasomes are more complex in that they consist of 7 different  $\alpha$ -like and 7 different  $\beta$ -like subunits versus only one of each type for the *T. acidophilum* 20S proteasome.

The X-ray structure of the *T. acidophilum* 20S proteasome, determined by Baumeister and Robert Huber, reveals that its two inner rings each consist of 7  $\beta$  subunits and its two outer rings each consist of 7  $\alpha$  subunits, all arranged with  $D_7$  symmetry (Fig. 32-84). Thus the overall

(a)

**Figure 32-84 X-ray structure of the *T. acidophilum* 20S proteasome.** (a) Ribbon diagram, viewed with its 7-fold axis tipped toward the viewer by 20°, in which the  $\alpha$  subunits are pink and the  $\beta$  subunits are light blue except for one  $\alpha$  subunit (*left*) and a similarly oriented  $\beta$  subunit (*middle*), which are both colored in rainbow order from their N-termini (*blue*) to their C-termini (*red*). Note their close structural resemblance. (b) Diagram, viewed as in Part a, in which the subunits are represented by equal-sized spheres with  $\alpha$  subunits pink and  $\beta$  subunits light blue. (c) Surface diagram, viewed along a 2-fold axis, with the subunits nearest the viewer removed to expose the proteasome's triple-chambered internal cavity, which is maximally  $\sim 100$  Å long and  $\sim 60$  Å in diameter. The active sites on the  $\beta$  subunits are marked by the bound inhibitor, LLnL, which is drawn in stick form in yellow. [Part a based on an X-ray structure by and Part c courtesy of Robert Huber, Max-Planck-Institut für Biochemie, Martinsried, Germany. PDBid 1PMA.]

(b)

(c)

structure of the 20S proteasome superficially resembles that of the unrelated molecular chaperone GroEL (Section 9-2Ca). The structures of the  $\alpha$  and  $\beta$  subunits are remarkably similar (Fig. 32-84a) except, of course, for the  $\alpha$  subunit's N-terminal tail (blue in Fig. 32-84a), which extends radially inward to contact the N-terminal tail of a neighboring  $\alpha$  subunit. This accounts for the observation that  $\alpha$  subunits alone spontaneously assemble into 7-membered rings (a capacity that is abolished by the deletion of their N-terminal 35 residues), whereas  $\beta$  subunits alone remain monomeric.

The central cavity of the *T. acidophilum* 20S proteasome consists of three large chambers (Fig. 32-84c): Two are located at the interfaces between adjoining rings of  $\alpha$  and  $\beta$  subunits, with the third, larger chamber centrally located between the two rings of  $\beta$  subunits. Unfolded polypeptide substrates enter the central chamber of the barrel (where the proteasome's active sites are located; see below) through  $\sim 13$ -Å-diameter axially located apertures in the  $\alpha$  rings that are lined with hydrophobic residues. This allows only unfolded

proteins to enter the central chamber, thereby protecting properly folded proteins from indiscriminate degradation by this omnivorous protein-dismantling machine.

The X-ray structure of the yeast 20S proteasome, determined by Huber, demonstrates that its outer and inner rings respectively consist of seven different  $\alpha$ -type subunits and seven different  $\beta$ -type subunits, all of which are uniquely arranged (Fig. 32-85). The  $\alpha$ -like subunits have folds that are similar to one another as well as to that of the *T. acidophilum* 20S proteasome and likewise for the  $\beta$ -like subunits. Consequently, this 28-subunit, 6182-residue protein complex has exact 2-fold rotational symmetry relating its two pairs of rings but only pseudo-7-fold rotational symmetry relating the subunits within each ring. The narrow axial apertures in the  $\alpha$  rings through which unfolded polypeptides enter the hydrolytic chamber (Fig. 32-85d) are occluded in the closed state (Fig. 32-85c) by a plug formed by the interdigitation of its  $\alpha$  subunits' N-terminal tails. This indicates that the 19S caps of the 26S proteasome, which have been shown to activate the 20S proteasome,

**Figure 32-85** (Opposite) **X-ray structure of the yeast 20S proteasome.** (a) Surface diagram viewed along the 28-mer's 2-fold axis. Each pair of identical subunits has the same color except for  $\beta 1$  and the symmetry related  $\beta 1'$ , which are colored differently. (b) Cutaway surface diagram sliced along the complex's pseudo-7-fold axis. The slice surface is green and the active sites of the  $\beta 1$ ,  $\beta 2$ , and  $\beta 5'$  subunits are marked in red. The brackets indicate the approximate positions of the channel entry ports as seen in the open state. (c) End view of the 20S proteasome showing its  $\alpha$ -ring in its closed state represented as in Part a. The pockets where PA26 binds (see below) are highlighted in blue. (d) The open state represented as in Part c and with the C-termini of its bound PA26 subunits shown in worm form in yellow. [Courtesy of Daniel Finley, Harvard Medical School. control the access to it by inducing conformational changes in its  $\alpha$  rings (see below). The X-ray structure of the bovine 20S proteasome, determined by Tomitake Tsukihara, reveals that its arrangement of seven  $\alpha$ -type and seven  $\beta$ -type subunits is similar to that in yeast.

### g. The Proteasome Catalyzes Peptide Hydrolysis via a Novel Mechanism

The X-ray structure of the *T. acidophilum* 20S proteasome in complex with the aldehyde inhibitor **acetyl-Leu-Leu-norleucinal (LLnL)**

**Acetyl-Leu-Leu-norleucinal (LLnL)**

reveals that its active sites are on the inner surfaces of its rings of  $\beta$  subunits, with the aldehyde function of the LLnL close to the side chain of the highly conserved Thr  $1\beta$ . Deletion of this Thr or its mutation to Ala yields properly assembled 20S proteasomes that are completely inactive. Evidently, 20S proteasomes catalyze peptide hydrolysis by a novel mechanism in which the hydroxyl group of its Thr  $1\beta$  is the attacking nucleophile. This, as yet, poorly understood mechanism, in which the amino group at the N-terminus and possibly a bound water molecule act to nucleophilically activate the hydroxyl side chain, is now known to be employed by other hydrolases (e.g., glutamate synthase; Section 26-5Aa), which are collectively known as the **N-terminal nucleophile (Ntn)** family of hydrolases. The *T. acidophilum*  $\beta$  subunits preferably cleave polypeptides after hydrophobic residues. However, in the yeast and the bovine 20S proteasomes, only subunits  $\beta 1$ ,  $\beta 2$ , and  $\beta 5$  are catalytically active. Their respective preferences for cleavage after acidic (caspase-like), basic (trypsin-like), and hydrophobic (chymotrypsin-like) residues are explained by

the respective basic, acidic, and nonpolar characters of their pockets that bind the side chain of the residue preceding the scissile peptide bond, although this specificity is relatively low. The functions of the four different catalytically inactive  $\beta$  subunits are unknown, although mutagenically modifying an inactive  $\beta$  subunit can abolish the catalytic activity of an active  $\beta$  subunit.

### h. The 19S Caps Control the Access of Ubiquitinated Proteins to the 20S Proteasome

The 20S proteasome probably does not exist alone *in vivo*; it is most often in complex with two 19S caps that function to recognize ubiquitinated proteins, unfold them, and feed them into the 20S proteasome in an ATP-dependent manner (it may also associate with other regulatory complexes; see below). The 19S cap, which consists of  $\sim 18$  different subunits, is poorly characterized due in large part to its low intrinsic stability. Its so-called base complex consists of 9 different subunits, 6 of which are ATPases that form a ring that abuts the  $\alpha$  ring of the 20S proteasome (Fig. 32-79). Each of these ATPases contains an  $\sim 230$ -residue ATPase module that is a member of the AAA+ family (Section 30-2Ca). Cecile Pickart demonstrated via cross-linking experiments that one of these ATPases, named **S6'** (alternatively **Rpt5**), contacts the polyUb signal that targets a condemned protein to the 26S proteasome. This suggests that the recognition of the polyUb chain as well as substrate protein unfolding are ATP-driven processes. Moreover, the ring of ATPases must function to open (gate) the otherwise closed axial aperture of the 20S proteasome so as to permit the entry of the unfolded substrate protein.

Eight additional subunits form the so-called lid complex, the portion of the 19S cap that is more distal to (distant from) the 20S proteasome. The functions of the lid subunits are largely unknown, although a truncated 26S proteasome that lacks the lid subunits is unable to degrade polyubiquitinated substrates. Several other subunits may be transiently associated with the 19S cap and/or with the 20S proteasome.

### i. Deubiquitinating Enzymes Have Several Functions

The enzymes that hydrolytically cleave the isopeptide bonds linking successive ubiquitin units in polyUb are known as **deubiquitinating enzymes (DUBs)**. Cells contain a surprisingly large number of DUBs (at least 17 in yeast and  $\sim 100$  in humans). Nearly all known DUBs are **cysteine proteases**, enzymes whose catalytic mechanism resembles that of serine proteases (Section 15-3C) but whose attacking nucleophile is Cys—S<sup>-</sup> rather than Ser—OH.

DUBs may release entire polyUb chains from a condemned protein or sequentially release ubiquitin units from the chain terminus. It has been proposed that this latter process functions as a clock to time the protein degradation process. If a polyUb chain is trimmed to less than four ubiquitin units before degradation begins, then its attached protein is likely to escape destruction. This would spare proteins that had been inappropriately tagged with only short polyUb chains.

The mammalian 19S lid subunit known as **POH1** (**Rpn11** for the 65% identical yeast subunit) appears to be responsible for the deubiquitination of target proteins prior to their degradation; its inactivation prevents target protein degradation. Curiously, this DUB is a  $Zn^{2+}$ -dependent protease (as is carboxypeptidase A; Fig. 15-42) rather than a cysteine protease.

Certain DUBs function to dismember polyUb chains that have been released from substrate proteins by sequentially removing ubiquitin units from the end of the chain that is nearest to the substrate protein (that with a free C-terminus). Consequently, these DUBs cannot remove ubiquitin units from polyUb chains that are still attached to substrate proteins, thereby preventing their premature removal.

Cells express ubiquitin as polyproteins containing several ubiquitin units (Section 32-5Ac) or with ubiquitin fused to certain ribosomal subunits (there is no gene that encodes a single ubiquitin unit). These polyproteins are rapidly processed by certain DUBs to yield free ubiquitin.

#### j. The 11S Activator Forms a Heptameric Barrel That Opens the 20S Proteasome

Higher eukaryotes contain an **11S activator** (alternatively, **11S regulator**) that functions to open the channel

into the 20S proteasome in an ATP-independent manner so as to permit the entrance of polypeptides (but not folded proteins). The mammalian 11S activator, which functions in the generation of peptides for presentation to the immune system (Section 35-2E), is named **REG** (alternatively **PA28**). It is a heteroheptameric complex of two  $\sim 245$ -residue subunits, **REG $\alpha$**  and **REG $\beta$** , that exhibit  $\sim 50\%$  sequence identity except for a highly variable internal 18-residue segment that is thought to confer subunit-specific properties. Indeed **REG $\alpha$**  alone forms a heptamer whose biochemical properties are similar to that of **REG** (although both subunits must be present *in vivo*).

The trypanosome *Trypanosoma brucei*, which lacks 19S caps, expresses a homoheptameric 11S activator named **PA26** that is only 14% identical to human **REG $\alpha$** . Nevertheless, the various 11S activators activate 20S proteasomes from widely divergent species. Thus, rat 20S proteasome is activated by PA26 and the yeast 20S proteasome is activated by human **REG $\alpha$**  despite the fact that yeast lacks 11S activators.

(a)

**Figure 32-86** X-ray structure of *T. brucei* PA26 in complex with the yeast 20S proteasome. (a) The PA26 heptamer in ribbon form viewed with its 7-fold axis vertical. Each of its subunits are differently colored with that closest to the viewer colored in rainbow order from its N-terminus (blue) to its C-terminus (red). (b) Cutaway diagram of the entire complex drawn in worm form and viewed with its 7-fold axis vertical. The PA26 is yellow, the  $\alpha$  and  $\beta$  subunits of the 20S proteasome are magenta and blue, its  $\alpha$ -annulus is green, and its N-terminal segments that are ordered and partially disordered are red and pink. [Part a based on an X-ray structure by and Part b courtesy of Christopher Hill, University of Utah. PDBid 1FNT.]

(b)

The X-ray structure of PA26 in complex with the yeast 20S proteasome, determined by Christopher Hill, reveals that each PA26 monomer consists of an up–down–up–down 4-helix bundle. These monomers form a 7-fold symmetric heptameric barrel that is 90 Å in diameter, 70 Å long, and has a 33-Å-diameter central pore (Fig. 32-86*a*) and which closely resembles the previously determined X-ray structure of human REG $\alpha$ . Two PA26 barrels associate coaxially with the 20S proteasome, one at each end (Fig. 32-86*b*). The conformation of the 20S proteasome in this complex, for the most part, is closely similar to that of the 20S proteasome alone (Fig. 32-85). However, the C-terminal tails of the PA26 subunits insert into pockets on the 20S proteasome's  $\alpha$  subunits in a way that induces conformational changes in its N-terminal tails that clear the 20S proteasome's otherwise blocked central aperture (Fig. 32-85*c,d*), thus permitting unfolded polypeptides to enter the proteasome's central chamber.

#### k. Bacteria Contain a Variety of Self-Compartmentalized Proteases

Nearly all eubacteria lack 20S proteasomes. Nevertheless they have ATP-dependent proteolytic assemblies that share the same barrel-shaped architecture and carry out similar functions. For example, in *E. coli*, two proteins known as **Lon** and **Clp** mediate up to 80% of the bacterium's protein degradation, with additional contributions from at least three other proteins including **heat shock locus UV (HslUV)**. Thus, *all cells appear to contain proteases*

*whose active sites are only available from the inner cavity of a hollow particle to which access is controlled.* These so-called **self-compartmentalized proteases** appear to have arisen early in the history of cellular life, before the advent of eukaryotic membrane-bound organelles such as the lysosome, which similarly carry out degradative processes in a way that protects the cell contents from indiscriminate destruction.

Clp protease consists of two components, the proteolytically active **ClpP** and one of several ATPases, which in *E. coli* are **ClpA** and **ClpX**. The X-ray structure of ClpP, determined by John Flanagan, reveals that it oligomerizes to form an  $\sim$ 90-Å-long and -wide hollow barrel that consists of two back-to-back 7-fold symmetric rings of 193-residue subunits (Fig. 32-87) and thereby has the same  $D_7$  symmetry as does the 20S proteasome. Nevertheless, the ClpP subunit has a novel fold that is different from that of the 20S proteasome's homologous  $\alpha$  and  $\beta$  subunits. The ClpP active site, which is only exposed on the inside of the barrel, contains a catalytic triad composed of Ser 97, His 122, and Asp 171, and hence is a serine protease (Section 15-3Ab).

HslUV protease appears to be a hybrid of Clp and the 26S proteasome. Its **HslV** subunits in *Haemophilus influenzae* (174 residues) are 18% identical to the  $\beta$  subunits of the *T. acidophilum* 20S proteasome, whereas its regulatory **HslU** caps (444 residues) have ATPase activity and are homologous to *E. coli* ClpX. The X-ray structure of *H. influenzae* HslUV, determined by David McKay, indicates that HslV forms a dimer of hexameric rather than

**Figure 32-87** X-ray structure of *E. coli* ClpP. (a) View of the heptameric complex along its 7-fold axis, drawn in ribbon form in which the lower ring is pale cyan and the upper ring is pink with one subunit colored in rainbow order from its N-terminus (blue)

to its C-terminus (red). (b) View along the complex's 2-fold axis (rotated 90° about a horizontal axis with respect to Part a). [Based on an X-ray structure by John Flanagan, Brookhaven National Laboratory, Upton, New York. PDBid 1TYF.]

**Figure 32-88** X-ray structure of *H. influenzae* HslVU in complex with ATP. The 821-kD complex is drawn in ribbon form viewed along a 2-fold axis with its 6-fold axis vertical. The  $D_6$  symmetric dodecamer of HslV subunits is coaxially bound at both ends by  $C_6$  symmetric HslU hexamers to yield a complex with overall  $D_6$  symmetry. The subunits of the lower HslU hexamer are alternately orange and cyan, whereas those of the upper HslU hexamer are pale orange except for one subunit, which is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The subunits of the lower HslV hexamer are alternately green and magenta, whereas those of the upper hexamer are pale blue except for one subunit, which is colored in rainbow order. The ATPs, which are bound at the interfaces between neighboring HslU subunits, are drawn in space-filling form with C green, N blue, O red, and P orange. [Based on an X-ray structure by David McKay, Stanford University School of Medicine. PDBid 1G3I.]

heptameric rings (Fig. 32-88). A hexameric ring of HslU subunits binds to both ends of the HslV dodecamer to form a 24-subunit assembly with  $D_6$  symmetry, rather than the  $D_7$  symmetry of the 26S proteasome. Nevertheless, both the fold and the intersubunit contacts of the HslV subunits are

closely similar to those of the 20S proteasome  $\beta$  subunits. In addition, both have N-terminal Thr residues. Thus, HslV can be regarded as the eubacterial homolog of archaeobacterial and eukaryotic 20S proteasomes.

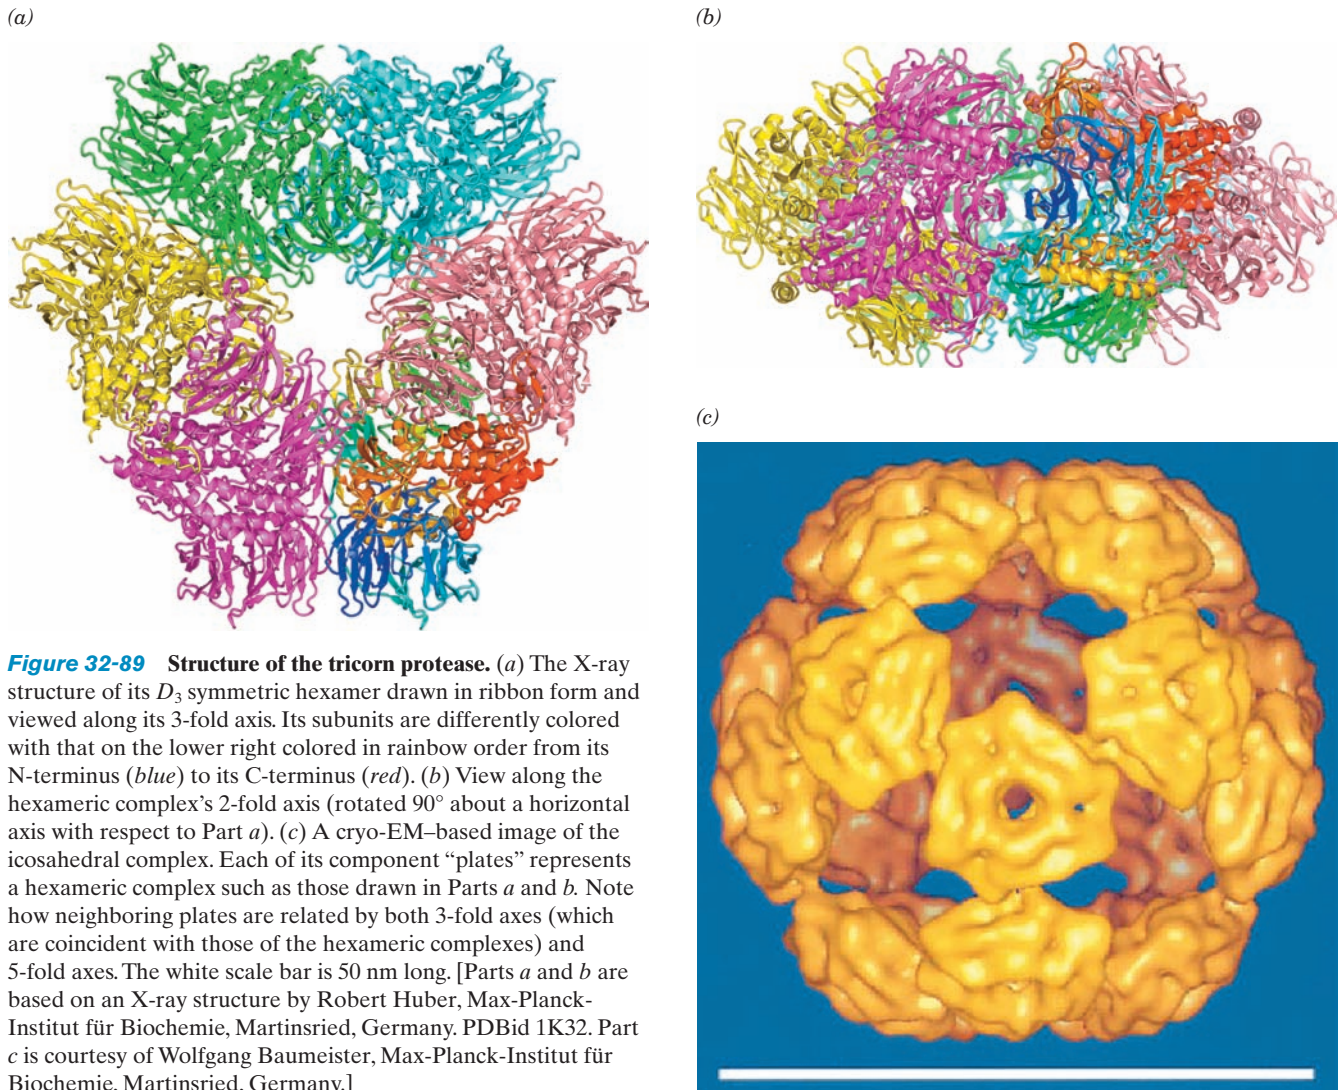

*Thermoplasma acidophilum* contains another large proteolytic complex, which is unrelated to the proteasome. The X-ray structure of this protease (Fig. 32-89), determined by Huber, indicates that it forms a 730-kD toroidal hexameric ring with  $D_3$  symmetry that has a peculiar triangular shape reminiscent of a tricorn (a hat whose brim is turned up on three sides) and hence was named **tricorn protease**. Cryo-EM studies indicate that 20 of these tricorn hexamers associate to form a 14,600-kD hollow icosahedron (Fig. 32-89c; an icosahedron is shown in Fig. 8-65c), making it by far the largest homooligomeric enzyme complex known (it is even larger than some virus particles, many of which also have icosahedral symmetry; Section 33-2Aa).

### I. Ubiquitination Has Multiple Proteasome-Independent Functions

Proteins may be monoubiquitinated or polyubiquitinated or even monoubiquitinated on more than one Lys residue. Moreover, ubiquitin has seven Lys residues so that seven types of polyubiquitin chains are possible.

Many types of ubiquitination mediate processes other than directing their associated proteins to the proteasome. This occurs through mechanisms reminiscent of protein phosphorylation, but instead of being recognized by specialized phosphoprotein-binding motifs such as SH2 (Section 19-3Cb), ubiquitinated proteins are recognized by conserved **ubiquitin-binding domains (UBDs)**. Moreover, whereas protein phosphorylation is reversible through the action of protein phosphatases (Section 19-3F), ubiquitination is reversible through the agency of DUBs.

Ubiquitination participates in regulating such diverse cellular processes as endocytosis, protein trafficking, DNA repair, intracellular signaling, and transcription. For example, during S phase of the cell cycle, the monoubiquitination of PCNA (the sliding clamp associated with the eukaryotic DNA replication fork; Section 30-4Ba) at its Lys 164 recruits an error-prone translesion DNA polymerase to the replication fork at a DNA damage site, whereas the polyubiquitination of the same site with a Lys 63-linked chain recruits DNA polymerases that mediate error-free lesion repair. In another example, in the signal transduction pathway that activates NF- $\kappa$ B (Section 32-6Be), I $\kappa$ B $\alpha$  is phosphorylated by **I $\kappa$ B kinase (IKK)**, which has a regulatory subunit named **NEMO** (for NF- $\kappa$ B essential modulator). The binding of cytokines such as TNF $\alpha$  and IL-1 to their transmembrane receptors in this pathway activates the receptor to Lys 63-linked polyubiquitinate NEMO, which in turn activates IKK to phosphorylate I $\kappa$ B $\alpha$ . This, as we saw, induces the formation of the Lys 48-linked polyubiquitination signal that leads to the destruction of I $\kappa$ B $\alpha$  and hence the translocation of NF- $\kappa$ B to the nucleus. *Yersinia pestis*, the bacterium that causes bubonic plague (Section 19-3Fc), produces a virulence factor named **YopJ**, which functions as a DUB that prevents the activation of NF- $\kappa$ B (which is an

important immune system activator). We shall see in Section 34-3Bff that the monoubiquitination of certain histones functions to regulate transcription.

### m. Ubiquitinlike Modifiers Participate in a Variety of Regulatory Processes

Eukaryotic cells express several proteins that have the same  $\beta$ -Grasp fold as ubiquitin and are similarly conjugated to other proteins, although their surface residues and charge distributions differ significantly. These **ubiquitinlike modifiers (Ubls)**, which participate in a variety of fundamental cellular processes, each have a corresponding activating enzyme (E1), at least one conjugating enzyme (E2), and one or more ligases (E3s), that function to link the Ubl to its target protein(s) in a manner closely resembling that of ubiquitin.

Two of the most extensively studied Ubls are **SUMO** (small ubiquitin-related modifier; 18% identical to ubiquitin) and **RUB1** (related-to-ubiquitin 1; called **NEDD8** in

vertebrates; 50% identical to ubiquitin), proteins that are highly conserved from yeast to humans. The sumoylation of PCNA at the same Lys residue at which it is ubiquitinated promotes normal DNA replication during S phase. The sumoylation of  $I\kappa B\alpha$  at the same residue (Lys 21) at which it is ubiquitinated blocks its ubiquitination and subsequent degradation and thereby prevents the translocation of  $NF-\kappa B$  to the nucleus. Evidently, there is a complex regulatory interplay between the ubiquitination and sumoylation of both PCNA and  $I\kappa B\alpha$ . SUMO also modifies two mammalian glucose transporters, GLUT1 and GLUT4 (Section 20-2Eb), and in doing so, increases the availability of GLUT4 but decreases that of GLUT1.

All known RUB1 targets are cullins, all of which are subunits of SCF complexes, the multisubunit RING E3s (Section 32-6Bd). In fact,  $\beta$ -TrCP, the E3 that directs the ubiquitination of  $I\kappa B\alpha$ , must be conjugated to RUB1 before it can do so, thereby adding further complexity to the control of  $NF-\kappa B$ .

## CHAPTER SUMMARY

**1 The Genetic Code** Point mutations are caused by either base analogs that mispair during DNA replication or by substances that react with bases to form products that mispair. Insertion/deletion (frameshift) mutations arise from the association of DNA with intercalating agents that distort the DNA structure. The analysis of a series of frameshift mutations that suppress one another established that the genetic code is an unpunctuated triplet code. In a cell-free protein synthesizing system, poly(U) directs the synthesis of poly(Phe), thereby demonstrating that UUU is the codon specifying Phe. The genetic code was elucidated through the use of polynucleotides of known composition but random sequence, by the ability of defined triplets to promote the ribosomal binding of tRNAs bearing specific amino acids, and through the use of synthetic mRNAs of known alternating sequences. The latter investigations have also demonstrated that the 5' end of mRNA corresponds to the N-terminus of the polypeptide it specifies and have established the sequences of the Stop codons. Degenerate codons differ mostly in the identities of their third base. Small single-stranded DNA phages such as  $\phi$ X174 contain overlapping genes in different reading frames. The genetic code used by mitochondria differs in several codons from the “standard” genetic code.

**2 Transfer RNA and Its Aminoacylation** Transfer RNAs consist of 54 to 100 nucleotides that can be arranged in the cloverleaf secondary structure. As many as 10% of a tRNA's bases may be modified. Yeast tRNA<sup>Phe</sup> forms a narrow, L-shaped, three-dimensional structure that resembles that of other tRNAs. Most of the bases are involved in stacking and base pairing associations including nine tertiary interactions that appear to be essential for maintaining the molecule's native conformation. Amino acids are appended to their cognate tRNAs in a two-stage reaction catalyzed by the corresponding aminoacyl-tRNA synthetase (aaRS). There are two classes of aaRSs, each containing 10 members. Class I aaRSs have two conserved sequence motifs that occur in the Rossmann fold common to the catalytic domain of these enzymes. Class II aaRSs have three conserved sequence motifs that occur in the 7-stranded antiparallel  $\beta$  sheet-containing fold that forms the core of their catalytic domains. In binding only their cognate tRNAs, aaRSs recognize only an idiosyncratic but limited number of bases (identity elements) that are, most often, located at the anticodon and in the acceptor stem. The great accuracy of tRNA charging arises from the proofreading of the bound amino acid by certain aminoacyl-tRNA synthetases via a double-sieve mechanism and at the expense of ATP hydrolysis.

Many organisms and organelles lack a GlnRS and instead synthesize Gln-tRNA<sup>Gln</sup> by the GluRS-catalyzed charging of tRNA<sup>Gln</sup> with glutamate followed by its transamidation using glutamine as the amido group source in a reaction mediated by Glu-tRNA<sup>Gln</sup> amidotransferase (Glu-AdT). Ribosomes select tRNAs solely on the basis of their anticodons. Sets of degenerate codons are read by a single tRNA through wobble pairing. The UGA codon, which is normally the *opal* Stop codon may, depending on its context in mRNA, specify a selenoCys (Sec) residue, which is carried by a specific tRNA (tRNA<sup>Sec</sup>), thereby forming a selenoprotein. Nonsense mutations may be suppressed by tRNAs whose anticodons have mutated to recognize a Stop codon.

**3 Ribosomes and Polypeptide Synthesis** The ribosome consists of a small and a large subunit whose complex shapes have been revealed by cryoelectron microscopy and X-ray crystallography. The three RNAs and 52 proteins comprising the *E. coli* ribosome self-assemble under proper conditions. Both ribosomal subunits consist of an RNA core in which the proteins are embedded, mainly as globular domains on the back and sides of the particle, with long basic polypeptide segments that infiltrate between the RNA helices so as to neutralize their anionic charges. Eukaryotic ribosomes are larger and more complex than those of prokaryotes.

Ribosomal polypeptide synthesis proceeds by the addition of amino acid residues to the C-terminal end of the nascent polypeptide. The mRNAs are read in the 5'  $\rightarrow$  3' direction. mRNAs are usually simultaneously translated by several ribosomes in the form of polysomes. The ribosome has three tRNA-binding sites: the A site, which binds the incoming aminoacyl-tRNA; the P site, which binds the peptidyl-tRNA; and the E site, which transiently binds the outgoing deacylated tRNA. During polypeptide synthesis, the nascent polypeptide is transferred to the aminoacyl-tRNA, thereby lengthening the nascent polypeptide by one residue. The newly deacylated tRNA is translocated to the E site and the new peptidyl-tRNA, with its associated codon, is translocated to the P site. In prokaryotes, the initiation sites on mRNA are recognized through their Shine-Dalgarno sequences and by their initiating codon. Prokaryotic initiating codons specify fMet-tRNA<sub>f</sub><sup>Met</sup>. Initiation involves the participation of three initiation factors that induce the assembly of the ribosomal subunits with fMet-tRNA<sub>f</sub><sup>Met</sup> in the P site and mRNA. Eukaryotic initiation is a far more complicated process that requires the participation of at least 11 initiation factors. The system binds the mRNA's 5' cap and scans along the mRNA until it finds its AUG initiation codon, usually the mRNA's first AUG, through codon-anticodon interactions with the initiating tRNA, Met-tRNA<sub>i</sub><sup>Met</sup>.

Polypeptides are elongated in a three-part cycle, consisting of aminoacyl-tRNA decoding, transpeptidation, and translocation, that requires the participation of elongation factors and is vectorially driven by GTP hydrolysis. EF-Tu, which functions to escort aminoacyl-tRNAs into the ribosomal A site, undergoes a major conformational change on hydrolyzing its bound GTP. The X-ray structure of the 50S subunit clearly shows that the ribosomal peptidyl transferase center is distant from any protein and hence that the ribosome is a ribozyme. Peptide bond formation is catalyzed by a substrate-assisted mechanism in which the ribosome functions as an entropy trap. Translocation is motivated through the EF-G-catalyzed hydrolysis of GTP. EF-G  $\cdot$  GDP, which binds to the same ribosomal site as aminoacyl-tRNA  $\cdot$  EF-Tu  $\cdot$  GTP, is a macromolecular mimic of this complex. Translocation occurs via intermediate states, the A/P and P/E states, in which the newly formed peptidyl-tRNA and the newly deacylated tRNA are respectively bound to the A and P subsites of the 30S subunit and to the P and E subsites of the 50S subunit, following which EF-G hydrolyzes its bound GTP and shifts these tRNAs to the P/P and E/E states. The ribosome initially selects an aminoacyl-tRNA whose anticodon is cognate to its A-site-bound codon through interactions involving three universally con-

served 30S subunit bases while the tRNA is in the A/T binding state. The codon–anticodon interaction is then proofread in an independent process that follows the hydrolysis of the EF-Tu–bound GTP and which occurs when the tRNA has shifted to the A/A binding state, a process called accommodation.

Termination codons bind release factors that induce the hydrolysis of the peptidyl–tRNA bond. Eukaryotic elongation and termination resemble those of prokaryotes. Ribosomal inhibitors, many of which are antibiotics, are medically important and biochemically useful in elucidating ribosomal function. Streptomycin causes mRNA misreading and inhibits prokaryotic chain initiation, chloramphenicol inhibits prokaryotic peptidyl transferase, paromomycin causes codon misreading, tetracycline inhibits aminoacyl–tRNA binding to the prokaryotic 30S subunit, and diphtheria toxin ADP-ribosylates eEF2.

**4 Control of Eukaryotic Translation** Several mechanisms of translational control have been elucidated in eukaryotes. eIF2 $\alpha$  kinases catalyze the phosphorylation of eIF2 $\alpha$ , which then tightly binds eIF2B so as to prevent it from exchanging eIF2-bound GDP for GTP and hence inhibits translational initiation. These eIF2 $\alpha$  kinases include heme-regulated inhibitor (HRI), which functions to coordinate globin synthesis with heme availability; double-stranded RNA-activated protein kinase (PKR), an interferon-induced protein that functions to inhibit viral proliferation; and PKR-like endoplasmic reticulum kinase (PERK), which functions to protect the cell from the irreversible damage caused by the accumulation of unfolded proteins in the ER. GCN2, in contrast, is an eIF2 $\alpha$  kinase that, when amino acids are scarce, stimulates the translation of the transcriptional activator GCN4 by causing the 40S ribosomal subunit to scan across four upstream open reading frames (uORFs) in the *GCN4* mRNA, thereby permitting the ribosome to initiate translation at the GCN4 coding sequence. The phosphorylation of eIF4E (cap-binding protein) by a MAP kinase cascade increases eIF4E's affinity for capped mRNA and thereby stimulates translational initiation. The binding of 4E-BPs to eIF4E blocks its binding of eIF4G and hence prevents initiation. However, the insulin-induced phosphorylation of the 4E-BPs causes them to dissociate from eIF4E. The mRNAs in certain animal oocytes are masked by the binding of proteins, which prevents their translation.

Many oocyte mRNAs have short poly(A) tails that are preceded by a cytoplasmic polyadenylation element (CPE) that is bound by CPE-binding protein (CPEB). CPEB binds maskin which binds eIF4E, thereby inhibiting translational initiation. However, when CPEB is phosphorylated, it recruits poly(A) polymerase (PAP), which extends the mRNA's poly(A) tail such that it is bound by poly(A)-binding protein (PABP). PABP then binds to eIF4G, which in turn displaces maskin from eIF4E, thereby permitting the translation of the mRNA. Antisense oligonucleotides can be used to inhibit the translation of their complementary mRNAs. Although the delivery of antisense oligonucleotides to their sites of action has proved to be a difficult problem, their use is starting to show some medical and biotechnological successes.

**5 Post-Translational Modification** Proteins may be post-translationally modified in a variety of ways. Proteolytic cleavages, usually by specific peptidases, activate proproteins. The signal peptides of preproteins are removed by signal peptidases. Covalent modifications alter many types of side chains in a variety of ways that modulate the catalytic activities of enzymes, provide recognition markers, and stabilize protein structures.

Protein splicing occurs via the intein-catalyzed self-excision between an N-extein and a C-extein accompanied by the ligation of the N- and C-exteins via a peptide bond. Most inteins contain a homing endonuclease that makes a double-strand nick in a gene similar to that encoding the corresponding extein, thereby triggering a recombinational double-strand DNA repair process that copies the gene encoding the intein into the break. Inteins therefore appear to be molecular parasites.

**6 Protein Degradation** Proteins in living cells are continually turning over. This controls the level of regulatory enzymes and disposes of abnormal proteins that would otherwise interfere with cellular processes. Proteins are degraded by lysosomes via a nonspecific process as well via a process specific for KFERQ proteins that is stimulated during starvation. A cytosolically based ATP-dependent system degrades normal as well as abnormal proteins in a process that flags these proteins by the covalent attachment of Lys 48–linked polyubiquitin chains to their Lys residues. This process is mediated by three consecutively acting enzymes: ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzyme (E2), and ubiquitin–protein ligase (E3). Most cells have one species of E1, several species of E2, and numerous species of E3, each of which is served by one or a few E2s. The polyubiquitinated protein is proteolytically degraded in the 26S proteasome.

E3s can have complicated modular structures, each having different specificities for target proteins. SCF complexes, one of whose several subunits contains a RING domain, are particularly elaborate. The RING E3 known as E3 $\alpha$  functions to ubiquitinate proteins that satisfy the N-end rule. The transcription factor NF- $\kappa$ B is activated through the ubiquitination and subsequent destruction of its otherwise bound inhibitor I $\kappa$ B $\alpha$  by the SCF  $\beta$ -TrCP, which is activated through phosphorylation via a signal transduction cascade. Cyclins, which mediate the cell cycle, are destroyed in a programmed manner through ubiquitination by their cognate E3s, one of which is anaphase-promoting complex (APC).

The 26S proteasome consists of a hollow protein barrel formed by two rings of seven  $\alpha$  subunits flanking two rings of seven  $\beta$  subunits known as the 20S proteasome, which is bound at each end by 19S caps that each consist of  $\sim$ 18 subunits. The active sites of the  $\beta$  subunits, which are members of the N-terminal nucleophile (Ntn) family of hydrolases, are inside the barrel. Ubiquitinated proteins are selected by the 19S caps, which unfold them in an ATP-dependent manner and then feed them into the 20S proteasome via its axial channel.

The polyubiquitin (polyUb) chains are excised from the condemned protein by proteasome-associated deubiquitinating enzymes (DUBs), while other DUBs dismember the polyUb chains to their component ubiquitin units, thereby recycling them. The 11S activator is a heptameric complex that, on binding to one end of a 20S proteasome, opens its axial channel in an ATP-independent manner, thereby permitting polypeptides, but not folded proteins, to enter the 20S proteasome. Eubacteria, nearly all of which lack proteasomes, nevertheless express a variety of self-compartmentalized proteases, including ClpP, heat shock locus UV (HslUV), and tricorn protease, that function to proteolytically dispose of their cellular proteins. Monoubiquitination and polyubiquitination with chains linked through ubiquitin residues other than Lys 48 regulate a variety of cellular processes. Ubiquitinlike modifiers (Ubls), such as SUMO and RUB1, also participate in numerous regulatory processes.

## PROBLEMS

**1.** What is the product of the reaction of guanine with nitrous acid? Is the reaction mutagenic? Explain.

**2.** What is the polypeptide specified by the following DNA antisense strand? Assume translation starts at the first initiation codon.

5'-TCTGACTATTGAGCTCTCTGGCACATAGCA-3'

**\*3.** The fingerprint of a protein from a phenotypically revertant mutant of bacteriophage T4 indicates the presence of an altered tryptic peptide with respect to the wild type. The wild-type and mutant peptides have the following sequences:

Wild type	Cys-Glu-Asp-His- Val-Pro-Gln-Tyr-Arg
Mutant	Cys-Glu-Thr- Met-Ser- His-Ser- Tyr-Arg

Indicate how the mutant could have arisen and give the base sequences, as far as possible, of the mRNAs specifying the two peptides. Comment on the function of the peptide in the protein.

4. Explain why the various classes of mutations can reverse a mutation of the same class but not a different class.

5. Which amino acids are specified by codons that can be changed to an *amber* codon by a single point mutation?

6. The mRNA specifying the  $\alpha$  chain of human hemoglobin contains the base sequence

...UCCAAAUACCGUUAAGCUGGA...

The C-terminal tetrapeptide of the normal  $\alpha$  chain, which is specified by part of this sequence, is

-Ser-Lys-Tyr-Arg

In hemoglobin Constant Spring, the corresponding region of the  $\alpha$  chain has the sequence

-Ser-Lys-Tyr-Arg-Gln-Ala-Gly-...

Specify the mutation that causes hemoglobin Constant Spring.

7. Explain why a minimum of 32 tRNAs are required to translate the “standard” genetic code.

8. Draw the wobble pairings not in Fig. 32-25a.

9. A colleague of yours claims that by exposing *E. coli* to  $\text{HNO}_2$ , she has mutated a tRNA<sup>Gly</sup> to an *amber* suppressor. Do you believe this claim? Explain.

\*10. Deduce the anticodon sequences of all suppressors listed in Table 32-6 except UGA-1 and indicate the mutations that caused them.

11. How many different types of macromolecules must be minimally contained in a cell-free protein synthesizing system from *E. coli*? Count each type of ribosomal component as a different macromolecule.

12. Why do oligonucleotides containing Shine–Dalgarno sequences inhibit translation in prokaryotes? Why don't they do so in eukaryotes?

13. Why does  $m^7\text{GTP}$  inhibit translation in eukaryotes? Why doesn't it do so in prokaryotes?

14. What would be the distribution of radioactivity in the completed hemoglobin chains on exposing reticulocytes to  $^3\text{H}$ -labeled leucine for a short time followed by a chase with unlabeled leucine?

15. Design an mRNA with the necessary prokaryotic control sites that codes for the octapeptide Lys-Pro-Ala-Gly-Thr-Glu-Asn-Ser.

\*16. Indicate the translational control sites in and the amino acid sequence specified by the following prokaryotic mRNA.

5'-CUGAUAAGGAUUUAAAUAUGUGUCAACACGA-AUGCUAAUCGAGGCCUCCAUAUAACACUU CGAC-3'

17. What is the energetic cost, in ATP equivalents, for the *E. coli* synthesis of a polypeptide chain of 100 residues starting from amino acids and mRNA? Assume that no losses are incurred as a result of proofreading.

18. It has been suggested that Gly-tRNA synthetase does not require an editing mechanism. Why?

19. Explain why prokaryotic ribosomes can translate a circular mRNA molecule, whereas eukaryotic ribosomes normally cannot, even in the presence of the required cofactors.

20. EF-Tu binds all aminoacyl-tRNAs with approximately equal affinity so that it can deliver them to the ribosome with the same efficiency. Based on the experimentally determined binding constants for EF-Tu and correctly charged and mischarged aminoacyl-tRNAs (see table), explain how the tRNA-EF-Tu recognition system could prevent the incorporation of the wrong amino acid during translation.

Aminoacyl-tRNA	Dissociation Constant (nM)
Ala-tRNA <sup>Ala</sup>	6.2
Gln-tRNA <sup>Ala</sup>	0.05
Gln-tRNA <sup>Gln</sup>	4.4
Ala-tRNA <sup>Gln</sup>	260

Source: LaRiviere, F.J., Wolfson, A.D., and Uhlenbeck, O.C., *Science* **294**, 167 (2001).

21. All cells contain an enzyme called **peptidyl-tRNA hydrolase**, and cells that are deficient in this enzyme grow very slowly. What is the probable function of this enzyme and why is it necessary?

22. An antibiotic named fixmycin, which you have isolated from a fungus growing on ripe passion fruit, is effective in curing several types of sexually transmitted diseases. In characterizing fixmycin's mode of action, you have found that it is a bacterial translational inhibitor that binds exclusively to the large subunit of *E. coli* ribosomes. The initiation of protein synthesis in the presence of fixmycin results in the generation of dipeptides that remain associated with the ribosome. Suggest a mechanism of fixmycin action.

23. Heme inhibits protein degradation in reticulocytes by allosterically regulating ubiquitin-activating enzyme (E1). What physiological function might this serve?

24. Genbux Inc., a biotechnology firm, has cloned the gene encoding an industrially valuable enzyme into *E. coli* such that the enzyme is produced in large quantities. However, since the firm wishes to produce the enzyme in ton quantities, the expense of isolating it would be greatly reduced if the bacterium could be made to secrete it. As a high-priced consultant, what general advice would you offer to solve this problem?

# INDEX

Page references in **bold face** refer to a major discussion of the entry. Positional and configurational designations in chemical names (e.g., 3-,  $\alpha$ -, *N*-, *p*-, *trans*-, *D*-, *sn*-) are ignored in alphabetizing. Numbers and Greek letters are otherwise alphabetical as if they were spelled out.

Note: Chapters 33–35, which are only available on our book companion website, [www.wiley.com/college/voet](http://www.wiley.com/college/voet), are separately indexed at this website.

## One- and Three-Letter Symbols for the Amino Acids<sup>a</sup>

A	Ala	Alanine
B	Asx	Asparagine or aspartic acid
C	Cys	Cysteine
D	Asp	Aspartic acid
E	Glu	Glutamic acid
F	Phe	Phenylalanine
G	Gly	Glycine
H	His	Histidine
I	Ile	Isoleucine
K	Lys	Lysine
L	Leu	Leucine
M	Met	Methionine
N	Asn	Asparagine
P	Pro	Proline
Q	Gln	Glutamine
R	Arg	Arginine
S	Ser	Serine
T	Thr	Threonine
V	Val	Valine
W	Trp	Tryptophan
Y	Tyr	Tyrosine
Z	Glx	Glutamine or glutamic acid

<sup>a</sup>The one-letter symbol for an undetermined or nonstandard amino acid is X.

## Thermodynamic Constants and Conversion Factors

### Joule (J)

$$1 \text{ J} = 1 \text{ kg} \cdot \text{m}^2 \cdot \text{s}^{-2} \quad 1 \text{ J} = 1 \text{ C} \cdot \text{V} \text{ (coulomb volt)}$$

$$1 \text{ J} = 1 \text{ N} \cdot \text{m} \text{ (newton} \cdot \text{meter)}$$

### Calorie (cal)

$$1 \text{ cal heats } 1 \text{ g of H}_2\text{O from } 14.5 \text{ to } 15.5^\circ\text{C}$$

$$1 \text{ cal} = 4.184 \text{ J}$$

### Large calorie (Cal)

$$1 \text{ Cal} = 1 \text{ kcal} \quad 1 \text{ Cal} = 4184 \text{ J}$$

### Avogadro's number (N)

$$N = 6.0221 \times 10^{23} \text{ molecules} \cdot \text{mol}^{-1}$$

### Coulomb (C)

$$1 \text{ C} = 6.241 \times 10^{18} \text{ electron charges}$$

### Faraday (F)

$$1 \text{ F} = N \text{ electron charges}$$

$$1 \text{ F} = 96,485 \text{ C} \cdot \text{mol}^{-1} = 96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1}$$

### Kelvin temperature scale (K)

$$0 \text{ K} = \text{absolute zero} \quad 273.15 \text{ K} = 0^\circ\text{C}$$

### Boltzmann constant (k<sub>B</sub>)

$$k_B = 1.3807 \times 10^{-23} \text{ J} \cdot \text{K}^{-1}$$

### Gas constant (R)

$$R = Nk_B \quad R = 1.9872 \text{ cal} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$$

$$R = 8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1} \quad R = 0.08206 \text{ L} \cdot \text{atm} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$$

## The Standard Genetic Code

First Position (5' end)	Second Position				Third Position (3' end)
	U	C	A	G	
U	UUU Phe	UCU Ser	UAU Tyr	UGU Cys	U
	UUC Phe	UCC Ser	UAC Tyr	UGC Cys	C
	UUA Leu	UCA Ser	UAA Stop	UGA Stop	A
	UUG Leu	UCG Ser	UAG Stop	UGG Trp	G
C	CUU Leu	CCU Pro	CAU His	CGU Arg	U
	CUC Leu	CCC Pro	CAC His	CGC Arg	C
	CUA Leu	CCA Pro	CAA Gln	CGA Arg	A
	CUG Leu	CCG Pro	CAG Gln	CGG Arg	G
A	AUU Ile	ACU Thr	AAU Asn	AGU Ser	U
	AUC Ile	ACC Thr	AAC Asn	AGC Ser	C
	AUA Ile	ACA Thr	AAA Lys	AGA Arg	A
	AUG Met <sup>a</sup>	ACG Thr	AAG Lys	AGG Arg	G
G	GUU Val	GCU Ala	GAU Asp	GGU Gly	U
	GUC Val	GCC Ala	GAC Asp	GGC Gly	C
	GUA Val	GCA Ala	GAA Glu	GGA Gly	A
	GUG Val	GCG Ala	GAG Glu	GGG Gly	G

<sup>a</sup>AUG forms part of the initiation signal as well as coding for internal Met residues.

## Some Common Biochemical Abbreviations<sup>a</sup>

A	adenine	E4P	erythrose-4-phosphate
aa	amino acid	EPR	electron paramagnetic resonance
aaRS	aminoacyl-tRNA synthetase	ER	endoplasmic reticulum
ACAT	acyl-CoA:cholesterol acyltransferase	ESI	electrospray ionization
ACh	acetylcholine	EST	expressed sequence tag
AChE	acetylcholinesterase	ETF	electron-transfer flavoprotein
ACP	acyl-carrier protein	FAD	flavin adenine dinucleotide, oxidized form
ADA	adenosine deaminase	FADH·	flavin adenine dinucleotide, radical form
ADH	alcohol dehydrogenase	FADH <sub>2</sub>	flavin adenine dinucleotide, reduced form
AdoCbl	5'-deoxyadenosylcobalamin	FAS	fatty acid synthase
AdoMet	adenosylmethionine	FBP	fructose-1,6-bisphosphate
ADP	adenosine diphosphate	FBPase	fructose-1,6-bisphosphatase
ADPNP	adenosine-5'-(β,γ-imido)triphosphate	Fd	ferredoxin
AIDS	acquired immunodeficiency syndrome	FGF	fibroblast growth factor
AKAP	A-kinase anchoring protein	FH	familial hypercholesterolemia
ALA	δ-aminolevulinic acid	fMet	N-formylmethionine
AMP	adenosine monophosphate	FMN	flavin mononucleotide
AMPK	AMP-dependent protein kinase	FNR	ferredoxin-NADP <sup>+</sup> reductase
AMPPNP	adenosine-5'-(β,γ-imido)triphosphate	F1P	fructose-1-phosphate
ARS	autonomously replicating sequence	F2,6P	fructose-2,6-bisphosphate
ATCase	aspartate transcarbamoylase	F6P	fructose-6-phosphate
ATP	adenosine triphosphate	G	guanine
BAC	bacterial artificial chromosome	GABA	γ-aminobutyric acid
BChl	bacteriochlorophyll	Gal	galactose
BCKDH	branched chain α-keto acid dehydrogenase	GalNAc	N-acetylgalactosamine
BH <sub>4</sub>	5,6,7,8-tetrahydrobiopterin	GAP	glyceraldehyde-3-phosphate
bHLH	basic helix-loop-helix	GAP	GTPase activating protein
bp	base pair	GAPDH	glyceraldehyde-3-phosphate dehydrogenase
BPG	D-2,3-bisphosphoglycerate	GDH	glutamate dehydrogenase
BPheo	bacteriopheophytin	GDP	guanosine diphosphate
BPTI	bovine pancreatic trypsin inhibitor	GEF	guanine nucleotide exchange factor
C	cytosine	GK	glucokinase
CaM	calmodulin	Glc	glucose
CAM	crassulacean acid metabolism	GlcNAc	N-acetylglucosamine
cAMP	3',5'-cyclic AMP	GLUT	glucose transporter
CAP	catabolite gene activator protein	GMP	guanosine monophosphate
CCV	clathrin-coated vesicle	gp	gene product
CD	circular dichroism	G1P	glucose-1-phosphate
CDK	cyclin-dependent protein kinase	G6P	glucose-6-phosphate
cDNA	complementary DNA	G6PD	glucose-6-phosphate dehydrogenase
CDP	cytidine diphosphate	GPI	glycosylphosphatidylinositol
CDR	complementarity-determining region	gRNA	guide RNA
CE	capillary electrophoresis	GSH	glutathione
cGMP	3',5'-cyclic GMP	GSSG	glutathione disulfide
CGN	cis Golgi network	GTF	general transcription factor
Chl	chlorophyll	GTP	guanosine triphosphate
CM	carboxymethyl	HA	hemagglutinin
CMP	cytidine monophosphate	Hb	hemoglobin
CoA or CoASH	coenzyme A	HDL	high density lipoprotein
COP	coat protein	HGPRT	hypoxanthine-guanine phosphoribosyl transferase
CoQ	coenzyme Q (ubiquinone)	HIV	human immunodeficiency virus
COX	cyclooxygenase <i>or</i> cytochrome <i>c</i> oxidase	HMG-CoA	β-hydroxy-β-methylglutaryl-CoA
CPS	carbamoyl phosphate synthetase	hnRNA	heterogeneous nuclear RNA
CTD	C-terminal domain	HPETE	hydroperoxyeicosatetraenoic acid
CTP	cytidine triphosphate	HPLC	high-performance liquid chromatography
D	dalton	Hsp	heat shock protein
d	deoxy	HTH	helix-turn-helix
DAG	1,2-diacylglycerol	Hyl	5-hydroxylysine
dd	dideoxy	Hyp	4-hydroxyproline
DEAE	diethylaminoethyl	IDL	intermediate density lipoprotein
DG	<i>sn</i> -1,2-diacylglycerol	IF	initiation factor
DHAP	dihydroxyacetone phosphate	IgG	immunoglobulin G
DHF	dihydrofolate	IHP	inositol hexaphosphate
DHFR	dihydrofolate reductase	IMP	inosine monophosphate
DMF	<i>N,N</i> -dimethylformamide	IP <sub>3</sub>	inositol-1,4,5-trisphosphate
DMS	dimethyl sulfate	IP <sub>3</sub>	inositol-1,4,5-trisphosphate
DNA	deoxyribonucleic acid	IP <sub>3</sub>	inositol-1,4,5-trisphosphate
DNP	2,4-dinitrophenol	IR	infrared
dNTP	2'-deoxynucleotide triphosphate	IS	insertion sequence
Dol	dolichol	ISP	iron-sulfur protein
L-DOPA	L-3,4-dihydroxyphenylalanine	ITP	inosine triphosphate
dsDNA	double-stranded DNA	JAK	Janus kinase
DUB	deubiquitinating enzyme	K <sub>M</sub>	Michaelis constant
EF	elongation factor	kb	kilobase pair
EGF	epidermal growth factor	kD	kilodalton
ELISA	enzyme-linked immunosorbent assay	KF	Klenow fragment
EM	electron microscopy	LCAT	lecithin:cholesterol acyl transferase
emf	electromotive force	LDH	lactate dehydrogenase
		LDL	low density lipoprotein

<sup>a</sup>The three-letter and one-letter abbreviations for the "standard" amino acid residues are given in Table 4-1.

(table continued on following page)

LHC	light-harvesting complex	PtdIns	phosphatidylinositol
LT	leukotriene	PTK	protein tyrosine kinase
LX	lipoxin	PTP	protein tyrosine phosphatase
MALDI	matrix-assisted laser desorption/ionization	Q	ubiquinone (CoQ) or plastoquinone
Man	mannose	QH <sub>2</sub>	ubiquinol
MAPK	mitogen-activated protein kinase	QSAR	quantitative structure–activity relationship
Mb	myoglobin	r	ribo
MHC	major histocompatibility complex	RC	photosynthetic reaction center
miRNA	microRNA	RER	rough endoplasmic reticulum
MKK	MAP kinase kinase	RF	release factor <i>or</i> replicative form
mRNA	messenger RNA	RFLP	restriction-fragment length polymorphism
MS	mass spectrometry	RK	HMG-CoA reductase kinase
MurNAc	<i>N</i> -acetylmuramic acid	RNA	ribonucleic acid
NA	neuraminidase	RNAi	RNA interference
NAD <sup>+</sup>	nicotinamide adenine dinucleotide, oxidized form	RNAP	RNA polymerase
NADH	nicotinamide adenine dinucleotide, reduced form	RNR	ribonucleotide reductase
NADP <sup>+</sup>	nicotinamide adenine dinucleotide phosphate, oxidized form	R5P	ribose-5-phosphate
NADPH	nicotinamide adenine dinucleotide phosphate, reduced form	RPC	reverse phase chromatography
NAG	<i>N</i> -acetylglucosamine	RRM	RNA-recognition motif
NAM	<i>N</i> -acetylmuramic acid	rRNA	ribosomal RNA
NANA	<i>N</i> -acetylneuraminic (sialic) acid	RS	tRNA synthetase
NDP	nucleoside diphosphate	RSV	Rous sarcoma virus
NEM	<i>N</i> -ethylmaleimide	RT	reverse transcriptase
NER	nucleotide excision repair	RTK	receptor tyrosine kinase
NeuNAc	<i>N</i> -acetylneuraminic acid	RuBisCO	ribulose-1,5-bisphosphate carboxylase–oxygenase
NMN	nicotinamide mononucleotide	RuBP	ribulose-1,5-bisphosphate
NMR	nuclear magnetic resonance	Ru5P	ribulose-5-phosphate
NOESY	nuclear Overhauser effect spectroscopy	S	Svedberg unit
NOS	nitric oxide synthase	SAM	<i>S</i> -adenosylmethionine
NRK	nonreceptor tyrosine kinase	SAR	structure–activity relationship
NSAID	nonsteroidal anti-inflammatory drug	SCAP	SREPB cleavage-activating protein
NSF	NEM-sensitive fusion protein	SCID	severe combined immunodeficiency disease
NTP	nucleotide triphosphate	SDS	sodium dodecyl sulfate
OEC	oxygen-evolving complex	SH2	Src homology domain 2
OMP	orotidine monophosphate	SH3	Src homology domain 3
ORF	open reading frame	siRNA	small interfering RNA
P or p	phosphate	SNAP	soluble NSF attachment protein
P <sub>i</sub>	orthophosphate ion	SNARE	SNAP receptor
PAGE	polyacrylamide gel electrophoresis	snoRNA	small nucleolar RNA
PAP	poly(A) polymerase	snRNA	small nuclear RNA
PBG	porphobilinogen	snRNP	small nuclear ribonucleoprotein
PC	plastocyanin	SOD	superoxide dismutase
PCNA	proliferating cell nuclear antigen	S7P	sedoheptulose-7-phosphate
PCR	polymerase chain reaction	SR	SRP receptor
PDB	Protein Data Bank	SRE	sterol regulatory element
PDC	pyruvate dehydrogenase multienzyme complex	SREBP	SRE binding protein
PDE	phosphodiesterase	SRP	signal recognition particle
PDGF	platelet-derived growth factor	SSB	single-strand binding protein
PDI	protein disulfide isomerase	ssDNA	single-stranded DNA
PE	phosphatidylethanolamine	STAT	signal transducer and activator of transcription
PEP	phosphoenolpyruvate	STC	sequence-tagged connector
PEPCK	PEP carboxykinase	STS	sequence-tagged site
PFGE	pulsed-field gel electrophoresis	SV40	simian virus 40
PFK	phosphofructokinase	T	thymine
PG	prostaglandin	TAF	TBP-associated factor
2PG	2-phosphoglycerate	TBP	TATA box-binding protein
3PG	3-phosphoglycerate	TBSV	tomato bushy stunt virus
PGI	phosphoglucose isomerase	TCA	tricarboxylic acid
PGK	phosphoglycerate kinase	TGN	trans Golgi network
PGM	phosphoglycerate mutase	THF	tetrahydrofolate
PH	phenylalanine hydroxylase <i>or</i> pleckstrin homology	TIM	triose phosphate isomerase
Pheo	pheophytin	TLC	thin layer chromatography
PhK	phosphorylase kinase	TM	transmembrane
PIC	preinitiation complex	TMV	tobacco mosaic virus
PI3K	phosphoinositide 3-kinase	topo	topoisomerase
PIP <sub>2</sub>	phosphatidylinositol-4,5-bisphosphate	TPP	thiamine pyrophosphate
PK	pyruvate kinase	tRNA	transfer RNA
PKA	protein kinase A	TS	thymidylate synthase
PKB	protein kinase B	TTP	thymidine triphosphate
PKC	protein kinase C	U	uracil
PKU	phenylketonuria	UCP	uncoupling protein
PLC	phospholipase C	UDP	uridine diphosphate
PLP	pyridoxal-5'-phosphate	UDPG	uridine diphosphate glucose
pmf	protonmotive force	UMP	uridine monophosphate
PMP	pyridoxamine-5'-phosphate	UTP	uridine triphosphate
PNP	purine nucleotide phosphorylase	UV	ultraviolet
Pol	DNA polymerase	V <sub>max</sub>	maximal velocity
PP1	phosphoprotein phosphatase-1	VLDL	very low density lipoprotein
PP <sub>i</sub>	pyrophosphate ion	XMP	xanthosine monophosphate
PPI	peptidyl prolyl cis–trans isomerase	XP	xeroderma pigmentosum
PrP	prion protein	Xu5P	xylulose-5-phosphate
PRPP	5-phosphoribosyl- $\alpha$ -pyrophosphate	YAC	yeast artificial chromosome
PS	photosystem	YADH	yeast alcohol dehydrogenase
