WileyPLUS

WileyPLUS is a research-based online environment for effective teaching and learning.

WileyPLUS builds students' confidence because it takes the guesswork out of studying by providing students with a clear roadmap:

- **what to do**
- **how to do it**
- **if they did it right**

It offers interactive resources along with a complete digital textbook that help students learn more. With *WileyPLUS*, students take more initiative so you'll have greater impact on their achievement in the classroom and beyond.

For more information, visit www.wileyplus.com

This book was typeset in 10.5/12 Adobe Caslon at Aptara and printed and bound by QuadGraphics, Inc. The cover was printed by QuadGraphics, Inc.

Founded in 1807, John Wiley & Sons, Inc. has been a valued source of knowledge and understanding for more than 200 years, helping people around the world meet their needs and fulfill their aspirations. Our company is built on a foundation of principles that include responsibility to the communities we serve and where we live and work. In 2008, we launched a Corporate Citizenship Initiative, a global effort to address the environmental, social, economic, and ethical challenges we face in our business. Among the issues we are addressing are carbon impact, paper specifications and procurement, ethical conduct within our business and among our vendors, and community and charitable support. For more information, please visit our website: www.wiley.com/go/citizenship.

The paper in this book was manufactured by a mill whose forest management programs include sustained yield-harvesting of its timberlands. Sustained yield harvesting principles ensure that the number of trees cut each year does not exceed the amount of new growth.

This book is printed on acid-free paper.

About the Author

Gerald C. Karp received a bachelor's degree from UCLA and a Ph.D. from the University of Washington. He conducted postdoctoral research at the University of Colorado Medical Center before joining the faculty at the University of Florida. Gerry is the author of numerous research articles on the cell and molecular biology of early development. His interests have included the synthesis of RNA in early embryos, the movement of mesenchyme cells during gastrulation, and

cell determination in slime molds. For 13 years, he taught courses in molecular, cellular, and developmental biology at the University of Florida. During this period, Gerry coauthored a text in developmental biology with N. John Berrill and authored a text in cell and molecular biology. Finding it impossible to carry on life as both full-time professor and author, Gerry gave up his faculty position to concentrate on the revision of this textbook every three years.

About the Cover

The micrograph on the cover of the book shows human nerve cells that have developed (differentiated) in a culture dish from undifferentiated stem cells. The stem cells used in this experiment were pluripotent cells, that is, they were capable of developing into any one of the many different types of cells that make up the human body. In this experiment, the stem cells were driven to differentiate specifically into nerve cells by adding a number of neuron-specific factors to the medium in which the stem cells were growing. Normally, human pluripotent stem cells are only found within the very early stages of a human embryo, but the stem cells used in this experiment were not derived from an embryo but instead were generated experimentally. They were induced from a type of connective tissue cell called a fibroblast by forcing the fibroblast to express a number of genes that it would not normally express. Forcing adult fibroblasts (or other types of adult cells) to express these

“stem cell genes” causes them to lose their differentiated properties, such as the production of collagen, and become what has been termed *induced pluripotent stem cells* (or *iPS cells*). As discussed on page 22, iPS cells may one day play a key role in replacing the cells of diseased tissues and organs. The fibroblasts used in this experiment were not derived from a healthy person but from a person who had been diagnosed with schizophrenia. We don't understand the molecular basis of schizophrenia, but it is hoped that studying the differentiation of nerve cells from persons with this disease will provide important insights into the underlying basis of the disease. Such cells may also serve as a useful tool to screen potential drugs for their effectiveness in treating the disease being studied. Because of these features, such iPS cells have been referred to as “patients in a Petri dish.” (Courtesy Fred H. Gage and Kristen Brennand.)

Preface to the Seventh Edition

Before I began work on the *first* edition of this text, I drew up a number of basic guidelines regarding the type of book I planned to write.

- I wanted a text suited for an introductory course in cell and molecular biology that ran either a single semester or 1–2 quarters. I set out to draft a text of about 800 pages that would not overwhelm or discourage students at this level.
- I wanted a text that elaborated on fundamental concepts, such as the relationship between molecular structure and function, the dynamic character of cellular organelles, the use of chemical energy in running cellular activities and ensuring accurate macromolecular biosynthesis, the observed unity and diversity at the macromolecular and cellular levels, and the mechanisms that regulate cellular activities.
- I wanted a text that was grounded in the experimental approach. Cell and molecular biology is an experimental science and, like most instructors, I believe students should gain some knowledge of how we know what we know. With this in mind, I decided to approach the experimental nature of the subject in two ways. As I wrote each chapter, I included enough experimental evidence to justify many of the conclusions that were being made. Along the way, I described the salient features of key experimental approaches and research methodologies. Chapters 8 and 9, for example, contain introductory sections on techniques that have proven most important in the analysis of cytomembranes and the cytoskeleton, respectively. I included brief discussions of selected experiments of major importance in the body of the chapters to reinforce the experimental basis of our knowledge. I placed the more detailed aspects of methodologies in a final “techniques chapter” because (1) I did not want to interrupt the flow of discussion of a subject with a large tangential section on technology and (2) I realized that different instructors prefer to discuss a particular technology in connection with different subjects.

For students and instructors who wanted to explore the experimental approach in greater depth, I included an Experimental Pathways at the end of most chapters. Each of these narratives describes some of the key experimental findings that have led to our current understanding of a particular subject that is relevant to the chapter at hand. Because the scope of the narrative is limited, the design of the experiments can be considered in some detail. The figures and tables provided in these sections are often those that appeared in the original research article, which provides the reader an opportunity to examine original data and to realize that its analysis is not beyond their means. The Experimental Pathways also illustrate the stepwise nature of scientific discovery, showing how the result of one study raises questions that provide the basis for subsequent studies.

- I wanted a text that was interesting and readable. To make the text more relevant to undergraduate readers, particularly premedical students, I included The Human Perspective. These sections illustrate that virtually all human disorders can

be traced to disruption of activities at the cellular and molecular level. Furthermore, they reveal the importance of basic research as the pathway to understanding and eventually treating most disorders. In Chapter 11, for example, The Human Perspective describes how small synthetic siRNAs may prove to be an important new tool in the treatment of cancer and viral diseases, including AIDS. In this same chapter, the reader will learn how the action of such RNAs were first revealed in studies on plants and nematodes. It becomes evident that one can never predict the practical importance of basic research in cell and molecular biology. I have also tried to include relevant information about human biology and clinical applications throughout the body of the text.

- I wanted a high-quality illustration program that helped students visualize complex cellular and molecular processes. To meet this goal, many of the illustrations have been “stepped-out” so that information can be more easily broken down into manageable parts. Events occurring at each step are described in the figure legend and/or in the corresponding text. I also sought to include a large number of micrographs to enable students to see actual representations of most subjects being discussed. Included among the images are many fluorescence micrographs that illustrate either the dynamic properties of cells or provide a means to localize a specific protein or nucleic acid sequence. Wherever possible, I have tried to pair line art drawings with micrographs to help students compare idealized and actual versions of a structure.

The most important changes in the seventh edition can be delineated as follows:

- Each of the illustrations has been carefully scrutinized and a large number of drawings have been modified with the goal of achieving greater consistency and quality. Particular attention has been paid to the continuity of color and rendering style for each structure and element, as they are represented within each figure, and throughout the book.
- The illustration program for the seventh edition includes a new feature called Figure in Focus. The premise of this feature is to highlight one of the chapter’s key topics in a visually interesting way. Focusing attention on these figures, through the use of line art, 3D molecular models, and micrographs, provides a clear visual explanation of one of the chapter’s core concepts.
- The body of information in cell and molecular biology is continually changing, which provides much of the excitement we all feel about our selected field. Even though only three years have passed since the publication of the sixth edition, nearly every discussion in the text has been modified to a greater or lesser degree. This has been done without allowing the chapters to increase significantly in length.
- Altogether, the seventh edition contains more than 100 new micrographs and computer-derived images, all of which were provided by the original source.

This online teaching and learning environment integrates the **entire digital textbook** with the most effective instructor and student resources to fit every learning style.

With *WileyPLUS*:

- Students achieve concept mastery in a rich, structured environment that's available 24/7
- Instructors personalize and manage their course more effectively with assessment, assignments, grade tracking, and more.

WileyPLUS can complement your current textbook or replace the printed text altogether.

For Students

Personalize the learning experience

Different learning styles, different levels of proficiency, different levels of preparation—each of your students is unique. *WileyPLUS* empowers them to take advantage of their individual strengths:

- Students receive timely access to resources that address their demonstrated needs, and get immediate feedback and remediation when needed.
- Integrated, multi-media resources include
 -  Animations of key concepts based on the illustrations of the text.
 -  Video library of clips from leading journals which can now be assigned with accompanying questions by Anne Hemsley, Antelope Valley Community College.
- *WileyPLUS* includes many opportunities for self-assessment linked to the relevant portions of the text. Students can take control of their own learning and practice until they master the material.

For Instructors

Personalize the teaching experience

WileyPLUS empowers you with the tools and resources you need to make your teaching even more effective:

- You can customize your classroom presentation with a wealth of resources and functionality from PowerPoint slides to a database of rich visuals. You can even add your own materials to your *WileyPLUS* course.

- With *WileyPLUS* you can identify those students who are falling behind and intervene accordingly, without having to wait for them to come to office hours.
- *WileyPLUS* simplifies and automates such tasks as student performance assessment, making assignments, scoring student work, keeping grades, and more.
 - Pre and Post Lecture Assessment by Joel Piperberg, Millersville University.
 - Test Bank, Instructor's Manual, and "Clicker" Questions by Joel Piperberg, Millersville University.
 - **NEW** Lecture PowerPoint Presentations by Edmund B. Rucker, University of Kentucky.

Clinical and Experimental Focus!

- Clinical Case Studies and accompanying questions by Claire Walczak, Indiana University & Anthony Contento, SUNY Oswego.
- Clinical Connections Questions by Sarah VanVickle-Chavez, Washington University in St. Louis.
- Experimental Pathways Questions by Joel Piperberg, Millersville University.
- NEW Figure in Focus feature by Anthony Contento, SUNY Oswego, New podcasts & assessment questions accompany selected figures, highlighting important concepts & processes.

Book Companion Site (www.wiley.com/college/karp)

For the Student

- *Quizzes* for student self-testing.
- *Biology NewsFinder; Flash Cards; and Animations.*
- Answers to the end-of chapter Analytic Questions.
- Additional reading resources provide students with an extensive list of additional useful sources of information.
- Experimental Pathways for Chapters 5, 6, 7, 9, 12, 13, and 15.

For the Instructor

- Biology Visual Library; all images in jpg and PowerPoint formats.
- Instructor's Manual; Test Bank; Clicker Questions; Lecture PowerPoint Presentations.

Instructor Resources are password protected.

Acknowledgments

I am particularly grateful to James Patton of Vanderbilt University for providing a revised version of Chapter 12 on The Control of Gene Expression, which formed the basis of the current chapter in this text. There are many people at John Wiley & Sons who have made important contributions to this text. I continue to be grateful to Geraldine Osnato whose work and

support over two editions is not forgotten. Aply taking her place in this edition was Lauren Stauber, who served as the assistant editor on the project with the guidance of Kevin Witt. Thanks also go to Lauren Morris for directing the development of the diverse supplements that are offered with this text. I am particularly indebted to the Wiley production

staff, who are simply the best. Jeanine Furino, of Furino Production, served as the central nervous system, coordinating the information arriving from composers, copyeditors, proofreaders, illustrators, photo editors, designers, and dummies, as well as the constant barrage of text changes ordered by the author. Always calm, organized, and meticulous, she made sure everything was done correctly. Hilary Newman and Jennifer Atkins were responsible for obtaining all of the many new images that are found in this edition. Hilary and Jennifer are skillful and perseverant, and I have utmost confidence in their ability to obtain any image requested. The book has a complex illustration program and Kathy Naylor did a superb job in coordinating all of the many facets required

to guide it to completion. The elegant design of the book and cover is due to the efforts of Madelyn Lesure, whose talents are evident. A special thanks is owed Laura Ierardi who skillfully laid out the pages for each chapter.

I am especially thankful to the many biologists who have contributed micrographs for use in this book; more than any other element, these images bring the study of cell biology to life on the printed page. Finally, I would like to apologize in advance for any errors that may occur in the text, and express my heartfelt embarrassment. I am grateful for the constructive criticism and sound advice from the following reviewers of the most recent editions:

To the Student

At the time I began college, biology would have been at the bottom of a list of potential majors. I enrolled in a physical anthropology course to fulfill the life science requirement by the easiest possible route. During that course, I learned for the first time about chromosomes, mitosis, and genetic recombination, and I became fascinated by the intricate activities that could take place in such a small volume of cellular space. The next semester, I took Introductory Biology and began to seriously consider becoming a cell biologist. I am burdening you with this personal trivia so you will understand why I wrote this book and to warn you of possible repercussions.

Even though many years have passed, I still find cell biology the most fascinating subject to explore, and I still love spending the day reading about the latest findings by colleagues in the field. Thus, for me, writing a text on cell biology provides a reason and an opportunity to keep abreast with what is going on throughout the field. My primary goal in writing this text is to help generate an appreciation in students for the activities in which the giant molecules and minuscule structures that inhabit the cellular world of life are engaged. Another goal is to provide the reader with an insight into the types of questions that cell and molecular biologists ask and the experimental approaches they use to seek answers. As you read the text, think like a researcher; consider the evidence that is presented, think of alternate explanations, plan experiments that could lead to new hypotheses.

You might begin this approach by looking at one of the many electron micrographs that fill the pages of this text. To take this photograph, you would be sitting in a small, pitch-black room in front of a large metallic instrument whose column rises several meters above your head. You are looking through a pair of binoculars at a vivid, bright green screen. The parts of the cell you are examining appear dark and colorless against the bright green background. They are dark because they've been stained with heavy metal atoms that deflect a fraction of the electrons within a beam that is being focused on the viewing screen by large electromagnetic lenses in the wall of the column. The electrons that strike the screen are accelerated through the evacuated space of the column by a force of tens of thousands of volts. One of your hands may be gripping a knob that controls the magnifying power of the lenses. A simple turn of this knob can switch the image in front of your eyes from that of a whole field of cells to a tiny part of a cell, such as a few ribosomes or a small portion of a single membrane. By turning other knobs, you can watch different parts of the specimen glide across the screen, giving you the sensation that you're driving around inside a cell.

Because the study of cell function requires the use of considerable instrumentation, such as the electron microscope just described, the investigator is physically removed from the subject being studied. To a large degree, cells are like tiny black boxes. We have developed many ways to probe the

boxes, but we are always groping in an area that cannot be fully illuminated. A discovery is made or a new technique is developed and a new thin beam of light penetrates the box. With further work, our understanding of the structure or process is broadened, but we are always left with additional questions. We generate more complete and sophisticated constructions, but we can never be sure how closely our views approach reality. In this regard, the study of cell and molecular biology can be compared to the study of an elephant as conducted by six blind men in an old Indian fable. The six travel to a nearby palace to learn about the nature of elephants. When they arrive, each approaches the elephant and begins to touch it. The first blind man touches the side of the elephant and concludes that an elephant is smooth like a wall. The second touches the trunk and decides that an elephant is round like a snake. The other members of the group touch the tusk, leg, ear, and tail of the elephant, and each forms his impression of the animal based on his own limited experiences. Cell biologists are limited in a similar manner as to what they can learn by using a particular technique or experimental approach. Although each new piece of information adds to the preexisting body of knowledge to provide a better concept of the activity being studied, the total picture remains uncertain.

Before closing these introductory comments, let me take the liberty of offering the reader some advice: Don't accept everything you read as being true. There are several reasons for urging such skepticism. Undoubtedly, there are errors in this text that reflect the author's ignorance or misinterpretation of some aspect of the scientific literature. But, more importantly, we should consider the nature of biological research. Biology is an empirical science; nothing is ever proved. We compile data concerning a particular cell organelle, metabolic reaction, intracellular movement, etc., and draw some type of conclusion. Some conclusions rest on more solid evidence than others. Even if there is a consensus of agreement concerning the "facts" regarding a particular phenomenon, there are often several possible interpretations of the data. Hypotheses are put forth and generally stimulate further research, thereby leading to a reevaluation of the original proposal. Most hypotheses that remain valid undergo a sort of evolution and, when presented in the text, should not be considered wholly correct or incorrect.

Cell biology is a rapidly moving field and some of the best hypotheses often generate considerable controversy. Even though this is a textbook where one expects to find material that is well tested, there are many places where new ideas are presented. These ideas are often described as models. I've included such models because they convey the current thinking in the field, even if they are speculative. Moreover, they reinforce the idea that cell biologists operate at the frontier of science, a boundary between the unknown and known (or thought to be known). Remain skeptical.

Contents

1 Introduction to the Study of Cell and Molecular Biology 1

1.1 The Discovery of Cells 2

1.2 Basic Properties of Cells 3

- Cells Are Highly Complex and Organized 3
- Cells Possess a Generic Program and the Means to Use It 5
- Cells Are Capable of Producing More of Themselves 5
- Cells Acquire and Utilize Energy 5
- Cells Carry Out a Variety of Chemical Reactions 6
- Cells Engage in Mechanical Activities 6
- Cells Are Able to Respond to Stimuli 6
- Cells Are Capable of Self-Regulation 6
- Cells Evolve 7

1.3 Two Fundamentally Different Classes of Cells 7

- Characteristics That Distinguish Prokaryotic and Eukaryotic Cells 8
- Types of Prokaryotic Cells 14
- Types of Eukaryotic Cells: Cell Specialization 15
- The Sizes of Cells and Their Components 17
- Synthetic Biology 17
- **THE HUMAN PERSPECTIVE:** The Prospect of Cell Replacement Therapy 20

1.4 Viruses 23

- Viroids 26
- **EXPERIMENTAL PATHWAYS:** The Origin of Eukaryotic Cells 26

2 The Chemical Basis of Life 32

2.1 Covalent Bonds 33

- Polar and Nonpolar Molecules 34
- Ionization 34

2.2 Noncovalent Bonds 34

- **THE HUMAN PERSPECTIVE:** Free Radicals as a Cause of Aging 35
- Ionic Bonds: Attractions between Charged Atoms 35
- Hydrogen Bonds 36
- Hydrophobic Interactions and van der Waals Forces 36
- The Life-Supporting Properties of Water 37

2.3 Acids, Bases, and Buffers 39

2.4 The Nature of Biological Molecules 40

- Functional Groups 41
- A Classification of Biological Molecules by Function 41

2.5 Four Types of Biological Molecules 42

- Carbohydrates 43

Lipids 47

Proteins 50

- **THE HUMAN PERSPECTIVE:** Protein Misfolding Can Have Deadly Consequences 66

Nucleic Acids 77

2.6 The Formation of Complex Macromolecular Structures 79

The Assembly of Tobacco Mosaic Virus Particles and Ribosomal Subunits 79

- **EXPERIMENTAL PATHWAYS:** Chaperones: Helping Proteins Reach Their Proper Folded State 80

3 Bioenergetics, Enzymes, and Metabolism 86

3.1 Bioenergetics 87

The Laws of Thermodynamics and the Concept of Entropy 87

Free Energy 89

3.2 Enzymes as Biological Catalysts 94

The Properties of Enzymes 95

Overcoming the Activation Energy Barrier 96

The Active Site 97

Mechanisms of Enzyme Catalysis 99

Enzyme Kinetics 102

- **THE HUMAN PERSPECTIVE:** The Growing Problem of Antibiotic Resistance 106

3.3 Metabolism 108

An Overview of Metabolism 108

Oxidation and Reduction: A Matter of Electrons 109

The Capture and Utilization of Energy 110

Metabolic Regulation 115

4 The Structure and Function of the Plasma Membrane 120

4.1 An Overview of Membrane Functions 121

4.2 A Brief History of Studies on Plasma Membrane Structure 123

4.3 The Chemical Composition of Membranes 125

Membrane Lipids 125

The Asymmetry of Membrane Lipids 128

Membrane Carbohydrates 129

4.4 The Structure and Functions of Membrane Proteins 130

Integral Membrane Proteins 130

Studying the Structure and Properties of Integral Membrane Proteins 132

Peripheral Membrane Proteins 137
Lipid-Anchored Membrane Proteins 137

4.5 Membrane Lipids and Membrane Fluidity 138

The Importance of Membrane Fluidity 139
Maintaining Membrane Fluidity 139
Lipid Rafts 139

4.6 The Dynamic Nature of the Plasma Membrane 140

The Diffusion of Membrane Proteins after Cell Fusion 141
Restrictions on Protein and Lipid Mobility 142
The Red Blood Cell: An Example of Plasma Membrane Structure 145

4.7 The Movement of Substances Across Cell Membranes 147

The Energetics of Solute Movement 147
Diffusion of Substances through Membranes 149
Facilitated Diffusion 156
Active Transport 157

- **THE HUMAN PERSPECTIVE:** Defects in Ion Channels and Transporters as a Cause of Inherited Disease 162

4.8 Membrane Potentials and Nerve Impulses 164

The Resting Potential 164
The Action Potential 165
Propagation of Action Potentials as an Impulse 167
Neurotransmission: Jumping the Synaptic Cleft 168

- **EXPERIMENTAL PATHWAYS:** The Acetylcholine Receptor 171

5 Aerobic Respiration and the Mitochondrion 178

5.1 Mitochondrial Structure and Function 179

Mitochondrial Membranes 180
The Mitochondrial Matrix 182

5.2 Oxidative Metabolism in the Mitochondrion 183

The Tricarboxylic Acid (TCA) Cycle 185
The Importance of Reduced Coenzymes in the Formation of ATP 186

- **THE HUMAN PERSPECTIVE:** The Role of Anaerobic and Aerobic Metabolism in Exercise 188

5.3 The Role of Mitochondria in the Formation of ATP 189

Oxidation-Reduction Potentials 189
Electron Transport 190
Types of Electron Carriers 191

5.4 Translocation of Protons and the Establishment of a Proton-Motive Force 198

5.5 The Machinery for ATP Formation 199

The Structure of ATP Synthase 200
The Basis of ATP Formation According to the Binding Change Mechanism 201

Other Roles for the Proton-Motive Force in Addition to ATP Synthesis 205

5.6 Peroxisomes 206

- **THE HUMAN PERSPECTIVE:** Diseases that Result from Abnormal Mitochondrial or Peroxisomal Function 207

6 Photosynthesis and the Chloroplast 211

6.1 Chloroplast Structure and Function 213

6.2 An Overview of Photosynthetic Metabolism 214

6.3 The Absorption of Light 216

Photosynthetic Pigments 216

6.4 Photosynthetic Units and Reaction Centers 218

Oxygen Formation: Coordinating the Action of Two Different Photosynthetic Systems 218
Killing Weeds by Inhibiting Electron Transport 225

6.5 Photophosphorylation 225

Noncyclic Versus Cyclic Photophosphorylation 226

6.6 Carbon Dioxide Fixation and the Synthesis of Carbohydrate 226

Carbohydrate Synthesis in C₃ Plants 226
Carbohydrate Synthesis in C₄ Plants 231
Carbohydrate Synthesis in CAM Plants 232

7.1 The Extracellular Space 236

The Extracellular Matrix 236

7.2 Interactions of Cells with Extracellular Materials 244

Integrins 244
Focal Adhesions and Hemidesmosomes: Anchoring Cells to Their Substratum 247

7.3 Interactions of Cells with Other Cells 250

Selectins 251
The Immunoglobulin Superfamily 252
Cadherins 253

- **THE HUMAN PERSPECTIVE:** The Role of Cell Adhesion in Inflammation and Metastasis 255

Adherens Junctions and Desmosomes: Anchoring Cells to Other Cells 257
The Role of Cell-Adhesion Receptors in Transmembrane Signaling 259

7.4 Tight Junctions: Sealing The Extracellular Space 260

7.5 Gap Junctions and Plasmodesmata: Mediating Intercellular Communication 262

Plasmodesmata 265

7.6 Cell Walls 266

8 Cytoplasmic Membrane Systems: Structure, Function, and Membrane Trafficking 270

8.1 An Overview of the Endomembrane System 271

8.2 A Few Approaches to the Study of Endomembranes 273

Insights Gained from Autoradiography 273

Insights Gained from the Use of the Green Fluorescent Protein 273

Insights Gained from the Biochemical Analysis of Subcellular Fractions 275

Insights Gained from the Use of Cell-Free Systems 276

Insights Gained from the Study of Mutant Phenotypes 277

8.3 The Endoplasmic Reticulum 279

The Smooth Endoplasmic Reticulum 280

Functions of the Rough Endoplasmic Reticulum 280

From the ER to the Golgi Complex: The First Step in Vesicular Transport 289

8.4 The Golgi Complex 290

Glycosylation in the Golgi Complex 292

The Movement of Materials through the Golgi Complex 292

8.5 Types of Vesicle Transport and Their Functions 295

COPII-Coated Vesicles: Transporting Cargo from the ER to the Golgi Complex 296

COPI-Coated Vesicles: Transporting Escaped Proteins Back to the ER 298

Beyond the Golgi Complex: Sorting Proteins at the TGN 298

Targeting Vesicles to a Particular Compartment 300

8.6 Lysosomes 303

Autophagy 304

● **THE HUMAN PERSPECTIVE:** Disorders Resulting from Defects in Lysosomal Function 306

8.7 Plant Cell Vacuoles 307

8.8 The Endocytic Pathway: Moving Membrane and Materials into the Cell Interior 308

Endocytosis 308

Phagocytosis 315

8.9 Posttranslational Uptake of Proteins by Peroxisomes, Mitochondria, and Chloroplasts 316

Uptake of Proteins into Peroxisomes 316

Uptake of Proteins into Mitochondria 316

Uptake of Proteins into Chloroplasts 318

● **EXPERIMENTAL PATHWAYS:** Receptor-Mediated Endocytosis 319

9 The Cytoskeleton and Cell Motility 324

9.1 Overview of the Major Functions of the Cytoskeleton 325

9.2 The Study of the Cytoskeleton 326

The Use of Live-Cell Fluorescence Imaging 326

The Use of In Vitro and In Vivo Single-Molecule Assays 327

The Use of Fluorescence Imaging Techniques to Monitor the Dynamics of the Cytoskeleton 329

9.3 Microtubules 330

Structure and Composition 330

Microtubule-Associated Proteins 331

Microtubules as Structural Supports and Organizers 332

Microtubules as Agents of Intracellular Motility 333

Motor Proteins that Traverse the Microtubular Cytoskeleton 334

Microtubule-Organizing Centers (MTOCs) 339

The Dynamic Properties of Microtubules 341

Cilia and Flagella: Structure and Function 345

● **THE HUMAN PERSPECTIVE:** The Role of Cilia in Development and Disease 349

9.4 Intermediate Filaments 354

Intermediate Filament Assembly and Disassembly 354

Types and Functions of Intermediate Filaments 356

9.5 Microfilaments 356

Microfilament Assembly and Disassembly 358

Myosin: The Molecular Motor of Actin Filaments 360

9.6 Muscle Contractility 364

The Sliding Filament Model of Muscle Contraction 366

9.7 Nonmuscle Motility 371

Actin-Binding Proteins 372

Examples of Nonmuscle Motility and Contractility 374

10 The Nature of the Gene and the Genome 386

10.1 The Concept of a Gene as a Unit of Inheritance 387

10.2 Chromosomes: The Physical Carriers of the Genes 388

The Discovery of Chromosomes 388

Chromosomes as the Carriers of Genetic Information 389

Genetic Analysis in *Drosophila* 390

- 1.4 Viruses

THE HUMAN PERSPECTIVE: The Prospect of Cell Replacement Therapy

EXPERIMENTAL PATHWAYS: The Origin of Eukaryotic Cells

Cells, and the structures they comprise, are too small to be directly seen, heard, or touched. In spite of this tremendous handicap, cells are the subject of hundreds of thousands of publications each year, with virtually every aspect of their minuscule structure coming under scrutiny. In many ways, the study of cell and molecular biology stands as a tribute to human curiosity for seeking to discover, and to human creative intelligence for devising the complex instruments and elaborate techniques by which these discoveries can be made. This is not to imply that cell and molecular biologists have a monopoly on these noble traits. At one end of the scientific spectrum, astronomers are utilizing an orbiting telescope to capture images of primordial galaxies that are so far from earth they appear to us today as they existed more than 13 billion years ago, only a few hundred million years after the Big Bang. At the other end of the spectrum, nuclear physicists have recently forced protons to collide with one another at velocities approaching the speed of light, confirming the existence of a hypothesized particle—the Higgs boson—that is

An example of the role of technological innovation in the field of cell biology. This light micrograph shows a cell lying on a microscopic bed of synthetic posts. The flexible posts serve as sensors to measure mechanical forces exerted by the cell. The red-stained elements are bundles of actin filaments within the cell that generate forces during cell locomotion. When the cell moves, it pulls on the attached posts, which report the amount of strain they are experiencing. The cell nucleus is stained green. (FROM J. L. TAN ET AL., PROC. NAT'L. ACAD. SCI. U.S.A., 100 (4), © 2003 NATIONAL ACADEMY OF SCIENCES, U.S.A. COURTESY OF CHRISTOPHER S. CHEN, THE JOHNS HOPKINS UNIVERSITY.)

proposed to endow all other subatomic particles with mass. Clearly, our universe consists of worlds within worlds, all aspects of which make for fascinating study.

As will be apparent throughout this book, cell and molecular biology is *reductionist*; that is, it is based on the view that knowledge of the parts of the whole can explain the character of the

whole. When viewed in this way, our feeling for the wonder and mystery of life may be replaced by the need to explain everything in terms of the workings of the “machinery” of the living system. To the degree to which this occurs, it is hoped that this loss can be replaced by an equally strong appreciation for the beauty and complexity of the mechanisms underlying cellular activity.

1.1 | The Discovery of Cells

Because of their small size, cells can only be observed with the aid of a **microscope**, an instrument that provides a magnified image of a tiny object. We do not know when humans first discovered the remarkable ability of curved-glass surfaces to bend light and form images. Spectacles were first made in Europe in the thirteenth century, and the first compound (double-lens) light microscopes were constructed by the end of the sixteenth century. By the mid-1600s, a handful of pioneering scientists had used their handmade microscopes to uncover a world that would never have been revealed to the naked eye. The discovery of cells (Figure 1.1a) is generally credited to Robert Hooke, an English microscopist who, at age 27, was awarded the position of curator of the Royal Society of London, England’s foremost scientific academy. One of the many questions Hooke attempted to answer was why stoppers made of cork (part of the bark of trees) were so well suited to holding air in a bottle. As he wrote in 1665: “I took a good clear piece of cork, and with a Pen-knife sharpen’d as keen as a Razor, I cut a piece of it off, and . . . then examining it with a *Microscope*, me thought I could perceive it to appear a little porous . . . much like a Honeycomb.” Hooke called the pores *cells* because they reminded him of the cells inhabited by monks living in a monastery. In actual fact, Hooke had observed the empty cell walls of dead plant tissue, walls that had originally been produced by the living cells they surrounded.

Meanwhile, Anton van Leeuwenhoek, a Dutchman who earned a living selling clothes and buttons, was spending his spare time grinding lenses and constructing simple microscopes of remarkable quality (Figure 1.1b). For 50 years, Leeuwenhoek sent letters to the Royal Society of London describing his microscopic observations—along with a rambling discourse on his daily habits and the state of his health. Leeuwenhoek was the first to examine a drop of pond water under the microscope and, to his amazement, observe the teeming microscopic “animalcules” that darted back and forth before his eyes. He was also the first to describe various forms of bacteria, which he obtained from water in which pepper had been soaked and from scrapings of his teeth. His initial letters to the Royal Society describing this previously unseen world were met with such skepticism that the society dispatched its curator, Robert Hooke, to confirm the observations. Hooke did just that, and Leeuwenhoek was soon a worldwide celebrity, receiving visits in Holland from Peter the Great of Russia and the queen of England.

It wasn’t until the 1830s that the widespread importance of cells was realized. In 1838, Matthias Schleiden, a German lawyer turned botanist, concluded that, despite differences in

the structure of various tissues, plants were made of cells and that the plant embryo arose from a single cell. In 1839, Theodor Schwann, a German zoologist and colleague of Schleiden’s, published a comprehensive report on the cellular basis of animal life. Schwann concluded that the cells of plants

(a)

(b)

Figure 1.1 The discovery of cells. (a) One of Robert Hooke’s more ornate compound (double-lens) microscopes. (Inset) Hooke’s drawing of a thin slice of cork, showing the honeycomb-like network of “cells.” (b) Single-lens microscope used by Anton van Leeuwenhoek to observe bacteria and other microorganisms. The biconvex lens, which was capable of magnifying an object approximately 270 times and providing a resolution of approximately 1.35 μm , was held between two metal plates. (A: THE GRANGER COLLECTION, NEW YORK; INSET BIOPHOTO ASSOCIATES/GETTY IMAGES, INC.; B: © BETTMANN/CORBIS)

and animals are similar structures and proposed these two tenets of the **cell theory**:

- All organisms are composed of one or more cells.
- The cell is the structural unit of life.

Schleiden and Schwann's ideas on the *origin* of cells proved to be less insightful; both agreed that cells could arise from non-cellular materials. Given the prominence that these two scientists held in the scientific world, it took a number of years before observations by other biologists were accepted as demonstrating that cells did not arise in this manner any more than organisms arose by spontaneous generation. By 1855, Rudolf Virchow, a German pathologist, had made a convincing case for the third tenet of the cell theory:

- Cells can arise only by division from a preexisting cell.

1.2 | Basic Properties of Cells

Just as plants and animals are alive, so too are cells. Life, in fact, is the most basic property of cells, and cells are the smallest units to exhibit this property. Unlike the parts of a cell, which simply deteriorate if isolated, whole cells can be removed from a plant or animal and cultured in a laboratory where they will grow and reproduce for extended periods of time. If mistreated, they may die. Death can also be considered one of the most basic properties of life, because only a living entity faces this prospect. Remarkably, cells within the body generally die “by their own hand”—the victims of an internal program that causes cells that are no longer needed or cells that pose a risk of becoming cancerous to eliminate themselves.

The first culture of human cells was begun by George and Martha Gey of Johns Hopkins University in 1951. The cells were obtained from a malignant tumor and named HeLa cells after the donor, Henrietta Lacks. HeLa cells—descended by cell division from this first cell sample—are still being grown in laboratories around the world today (Figure 1.2). Because they are so much simpler to study than cells situated within the body, cells grown **in vitro** (i.e., in culture, outside the body) have become an essential tool of cell and molecular biologists. In fact, much of the information that will be discussed in this book has been obtained using cells grown in laboratory cultures.

We will begin our exploration of cells by examining a few of their most fundamental properties.

Cells Are Highly Complex and Organized

Complexity is a property that is evident when encountered, but difficult to describe. For the present, we can think of complexity in terms of order and consistency. The more complex a structure, the greater the number of parts that must be in their proper place, the less tolerance of errors in the nature and interactions of the parts, and the more regulation or control that must be exerted to maintain the system. Cellular activities can be remarkably precise. DNA duplication, for example, occurs

Figure 1.2 HeLa cells, such as the ones pictured here, were the first human cells to be kept in culture for long periods of time and are still in use today. Unlike normal cells, which have a finite lifetime in culture, these cancerous HeLa cells can be cultured indefinitely as long as conditions are favorable to support cell growth and division. (TORSTEN WITTMANN/PHOTO RESEARCHERS, INC.)

with an error rate of less than one mistake every ten million nucleotides incorporated—and most of these are quickly corrected by an elaborate repair mechanism that recognizes the defect.

During the course of this book, we will have occasion to consider the complexity of life at several different levels. We will discuss the organization of atoms into small-sized molecules; the organization of these molecules into giant polymers; and the organization of different types of polymeric molecules into complexes, which in turn are organized into subcellular organelles and finally into cells. As will be apparent, there is a great deal of consistency at every level. Each type of cell has a consistent appearance when viewed under a high-powered electron microscope; that is, its organelles have a particular shape and location, from one individual of a species to another. Similarly, each type of organelle has a consistent composition of macromolecules, which are arranged in a predictable pattern. Consider the cells lining your intestine that are responsible for removing nutrients from your digestive tract (Figure 1.3).

The epithelial cells that line the intestine are tightly connected to each other like bricks in a wall. The apical ends of these cells, which face the intestinal channel, have long processes (*microvilli*) that facilitate absorption of nutrients. The microvilli are able to project outward from the apical cell surface because they contain an internal skeleton made of filaments, which in turn are composed of protein (*actin*) monomers polymerized in a characteristic array. At their basal ends, intestinal cells have large numbers of mitochondria that provide the energy required to fuel various membrane transport processes. Each mitochondrion is composed of a defined pattern of internal membranes, which in turn are composed of

Figure 1.3 Levels of cellular and molecular organization. The brightly colored photograph of a stained section shows the microscopic structure of a villus of the wall of the small intestine, as seen through the light microscope. Inset 1 shows an electron micrograph of the epithelial layer of cells that lines the inner intestinal wall. The apical surface of each cell, which faces the channel of the intestine, contains a large number of microvilli involved in nutrient absorption. The basal region of each cell contains large numbers of mitochondria, where energy is made available to the cell. Inset 2 shows the apical microvilli; each microvillus contains a bundle of microfilaments. Inset 3 shows the actin protein subunits that make up each microfilament. Inset 4 shows an individual mitochondrion similar to those found in the basal region of the epithelial cells. Inset 5 shows a portion of an inner membrane of a mitochondrion including the stalked particles (upper arrow) that

project from the membrane and correspond to the sites where ATP is synthesized. Insets 6 and 7 show molecular models of the ATP-synthesizing machinery, which is discussed at length in Chapter 5. (LIGHT MICROGRAPH CECIL FOX/PHOTO RESEARCHERS; INSET 1 COURTESY OF SHAKTI P. KAPUR, GEORGETOWN UNIVERSITY MEDICAL CENTER; INSET 2 FROM MARK S. MOOSEKER AND LEWIS G. TILNEY, *J. CELL BIOL.* 67:729, 1975, REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS; INSET 3 COURTESY OF KENNETH C. HOLMES; INSET 4 KEITH R. PORTER/PHOTO RESEARCHERS; INSET 5 COURTESY OF HUMBERTO FERNANDEZ-MORAN; INSET 6 COURTESY OF RODERICK A. CAPALDI; INSET 7 COURTESY OF WOLFGANG JUNGE, HOLGER LILL, AND SIEGFRIED ENGELBRECHT, UNIVERSITY OF OSNABRÜCK, GERMANY.)

a consistent array of proteins, including an electrically powered ATP-synthesizing machine that projects from the inner membrane like a ball on a stick. Each of these various levels of organization is illustrated in the insets of Figure 1.3.

Fortunately for cell and molecular biologists, evolution has moved rather slowly at the levels of biological organization with which they are concerned. Whereas a human and a cat, for example, have very different anatomical features, the cells that make up their tissues, and the organelles that make up their cells, are very similar. The actin filament portrayed in Figure 1.3, Inset 3, and the ATP-synthesizing enzyme of Inset 6 are virtually identical to similar structures found in such diverse organisms as humans, snails, yeast, and redwood trees. Information obtained by studying cells from one type of organism often has direct application to other forms of life. Many of the most basic processes, such as the synthesis of proteins, the conservation of chemical energy, or the construction of a membrane, are remarkably similar in all living organisms.

Cells Possess a Genetic Program and the Means to Use It

Organisms are built according to information encoded in a collection of genes, which are constructed of DNA. The human genetic program contains enough information, if converted to words, to fill millions of pages of text. Remarkably, this vast amount of information is packaged into a set of chromosomes that occupies the space of a cell nucleus—hundreds of times smaller than the dot on this *i*.

Genes are more than storage lockers for information: they constitute the blueprints for constructing cellular structures, the directions for running cellular activities, and the program for making more of themselves. The molecular structure of genes allows for changes in genetic information (mutations) that lead to variation among individuals, which forms the basis of biological evolution. Discovering the mechanisms by which cells use and transmit their genetic information has been one of the greatest achievements of science in recent decades.

Cells Are Capable of Producing More of Themselves

Just as individual organisms are generated by reproduction, so too are individual cells. Cells reproduce by division, a process in which the contents of a “mother” cell are distributed into two “daughter” cells. Prior to division, the genetic material is faithfully duplicated, and each daughter cell receives a complete and equal share of genetic information. In most cases, the two daughter cells have approximately equal volume. In some cases, however, as occurs when a human oocyte undergoes division, one of the cells can retain nearly all of the cytoplasm, even though it receives only half of the genetic material (Figure 1.4).

Cells Acquire and Utilize Energy

Every biological process requires the input of energy. Virtually all of the energy utilized by life on the Earth’s surface arrives in the form of electromagnetic radiation from the sun. The

Figure 1.4 Cell reproduction. This mammalian oocyte has recently undergone a highly unequal cell division in which most of the cytoplasm has been retained within the large oocyte, which has the potential to be fertilized and develop into an embryo. The other cell is a nonfunctional remnant that consists almost totally of nuclear material (indicated by the blue-staining chromosomes, arrow). (COURTESY OF JONATHAN VAN BLERKOM.)

energy of light is trapped by light-absorbing pigments present in the membranes of photosynthetic cells (Figure 1.5). Light energy is converted by photosynthesis into chemical energy that is stored in energy-rich carbohydrates, such as sucrose or starch. For most animal cells, energy arrives prepackaged, often in the form of the sugar glucose. In humans, glucose is released by the liver into the blood where it circulates through the body delivering chemical energy to all the cells. Once in a cell, the glucose is disassembled in such a way that its energy content can be stored in a readily available form (usually as ATP) that is later put to use in running all of the cell’s myriad energy-requiring activities. Cells expend an enormous amount of energy simply breaking down and rebuilding the macromolecules and organelles of which they are made. This continual “turnover,” as it is called, maintains the integrity of cell components in the face of inevitable wear and tear and enables the cell to respond rapidly to changing conditions.

Figure 1.5 Acquiring energy. A living cell of the filamentous alga *Spirogyra*. The ribbon-like chloroplast, which is seen to zigzag through the cell, is the site where energy from sunlight is captured and converted to chemical energy during photosynthesis. (M. I. WALKER/PHOTO RESEARCHERS, INC.)

Cells Carry Out a Variety of Chemical Reactions

Cells function like miniaturized chemical plants. Even the simplest bacterial cell is capable of hundreds of different chemical transformations, none of which occurs at any significant rate in the inanimate world. Virtually all chemical changes that take place in cells require *enzymes*—molecules that greatly increase the rate at which a chemical reaction occurs. The sum total of the chemical reactions in a cell represents that cell's **metabolism**.

Cells Engage in Mechanical Activities

Cells are sites of bustling activity. Materials are transported from place to place, structures are assembled and then rapidly disassembled, and, in many cases, the entire cell moves itself from one site to another. These types of activities are based on dynamic, mechanical changes within cells, many of which are initiated by changes in the shape of “motor” proteins. Motor proteins are just one of many types of molecular “machines” employed by cells to carry out mechanical activities.

Cells Are Able to Respond to Stimuli

Some cells respond to stimuli in obvious ways; a single-celled protist, for example, moves away from an object in its path or moves toward a source of nutrients. Cells within a multicellular plant or animal respond to stimuli less obviously. Most cells are covered with *receptors* that interact with substances in the environment in highly specific ways. Cells possess receptors to hormones, growth factors, and extracellular materials, as well as to substances on the surfaces of other cells. A cell's receptors provide pathways through which external stimuli can evoke specific responses in target cells. Cells may respond to specific stimuli by altering their metabolic activities, moving from one place to another, or even committing suicide.

Cells Are Capable of Self-Regulation

In recent years, a new term has been used to describe cells: *robustness*. Cells are robust, that is, hearty or durable, because they are protected from dangerous fluctuations in composition and behavior. Should such fluctuations occur, specific feedback circuits are activated that serve to return the cell to the appropriate state. In addition to requiring energy, maintaining a complex, ordered state requires constant regulation. The importance of a cell's regulatory mechanisms becomes most evident when they break down. For example, failure of a cell to correct a mistake when it duplicates its DNA may result in a debilitating mutation, or a breakdown in a cell's growth-control safeguards can transform the cell into a cancer cell with the capability of destroying the entire organism. We are gradually learning how a cell controls its activities, but much more is left to discover.

Consider the following experiment conducted in 1891 by Hans Driesch, a German embryologist. Driesch found that he could completely separate the first two or four cells of a sea urchin embryo and each of the isolated cells would proceed to develop into a normal embryo (Figure 1.6). How can a cell that is normally destined to form only part of an embryo reg-

Figure 1.6 Self-regulation. The left panel depicts the normal development of a sea urchin in which a fertilized egg gives rise to a single embryo. The right panel depicts an experiment in which the cells of an early embryo are separated from one another after the first division, and each cell is allowed to develop in isolation. Rather than developing into half of an embryo, as it would if left undisturbed, each isolated cell recognizes the absence of its neighbor, regulating its development to form a complete (although smaller) embryo.

ulate its own activities and form an entire embryo? How does the isolated cell recognize the absence of its neighbors, and how does this recognition redirect the entire course of the cell's development? How can a part of an embryo have a sense of the whole? We are not able to answer these questions much better today than we were more than a hundred years ago when the experiment was performed.

Throughout this book we will be discussing processes that require a series of ordered steps, much like the assembly-line construction of an automobile in which workers add, remove, or make specific adjustments as the car moves along. In the cell, the information for product design resides in the nucleic acids, and the construction workers are primarily proteins. It is the presence of these two types of macromolecules that, more than any other factor, sets the chemistry of the cell apart from that of the nonliving world. In the cell, the workers must act without the benefit of conscious direction. Each step of a process must occur spontaneously in such a way that the next step is automatically triggered. In many ways, cells operate in a manner analogous to the orange-squeezing contraption discovered by “The Professor” and shown in Figure 1.7. Each type of cellular activity requires a unique set of highly complex molecular tools and machines—the products of eons of natural selection and biological evolution.

Orange Juice Squeezing Machine

Professor Butts steps into an open elevator shaft and when he lands at the bottom he finds a simple orange squeezing machine. Milkman takes empty milk bottle (A), pulling string (B) which causes sword (C) to sever cord (D) and allow guillotine blade (E) to drop and cut rope (F) which releases battering ram (G). Ram bumps against open door (H), causing it to close. Grass sickle (I) cuts a slice off end of orange (J)—at the same time spike (K) stabs “prune hawk” (L) he opens

his mouth to yell in agony, thereby releasing prune and allowing diver’s boot (M) to drop and step on sleeping octopus (N). Octopus awakens in a rage and, seeing diver’s face which is painted on orange, attacks it and crushes it with tentacles, thereby causing all the juice in the orange to run into glass (O).

Later on you can use the log to build a log cabin where you can raise your son to be President like Abraham Lincoln.

Figure 1.7 Cellular activities are often analogous to this “Rube Goldberg machine” in which one event “automatically” triggers the next event in a reaction sequence. (RUBE GOLDBERG IS THE ® AND © OF RUBE GOLDBERG, INC.)

A primary goal of biologists is to understand the molecular structure and role of each component involved in a particular activity, the means by which these components interact, and the mechanisms by which these interactions are regulated.

Cells Evolve

How did cells arise? Of all the major questions posed by biologists, this question may be the least likely ever to be answered. It is presumed that cells evolved from some type of precellular life form, which in turn evolved from nonliving organic materials that were present in the primordial seas. Whereas the origin of cells is shrouded in near-total mystery, the evolution of cells can be studied by examining organisms that are alive today. If you were to observe the features of a bacterial cell living in the human intestinal tract (see Figure 1.18a) and a cell that is part of the lining of that tract (Figure 1.3), you would be struck by the differences between the two cells. Yet both of these cells, as well as all other cells that are present in living organisms, share many features, including a common genetic code, a plasma membrane, and ribosomes. According to one of the tenets of modern biology, all living organisms have evolved from a single, common ancestral cell that lived more than three billion years ago. Because it gave rise to all the living organisms that we know of, this ancient cell is often referred to as the *last universal common ancestor* (or *LUCA*). We will examine some of the events that occurred during the evolution of cells in the Experimental Pathways at the end of the chapter. Keep in mind that evolution is not simply an event of the past, but an ongoing process that continues to modify the properties of cells that will be present in organisms that have yet to appear.

REVIEW

1. List the fundamental properties shared by all cells. Describe the importance of each of these properties.
2. Describe the features of cells that suggest that all living organisms are derived from a common ancestor.
3. What is the source of energy that supports life on Earth? How is this energy passed from one organism to the next?

1.3 | Two Fundamentally Different Classes of Cells

Once the electron microscope became widely available, biologists were able to examine the internal structure of a wide variety of cells. It became apparent from these studies that there were two basic classes of cells—prokaryotic and eukaryotic—distinguished by their size and the types of internal structures, or **organelles**, they contain (Figure 1.8). The existence of two distinct classes of cells, without any known intermediates, represents one of the most fundamental evolutionary divisions in the biological world. The structurally simpler **prokaryotic** cells include bacteria, whereas the structurally more complex **eukaryotic** cells include protists, fungi, plants, and animals.¹

We are not sure when prokaryotic cells first appeared on Earth. Evidence of prokaryotic life has been obtained from rocks approximately 2.7 billion years of age. Not only do these

¹Those interested in examining a proposal to do away with the concept of prokaryotic versus eukaryotic organisms can read a brief essay by N. R. Pace in *Nature* 441:289, 2006.

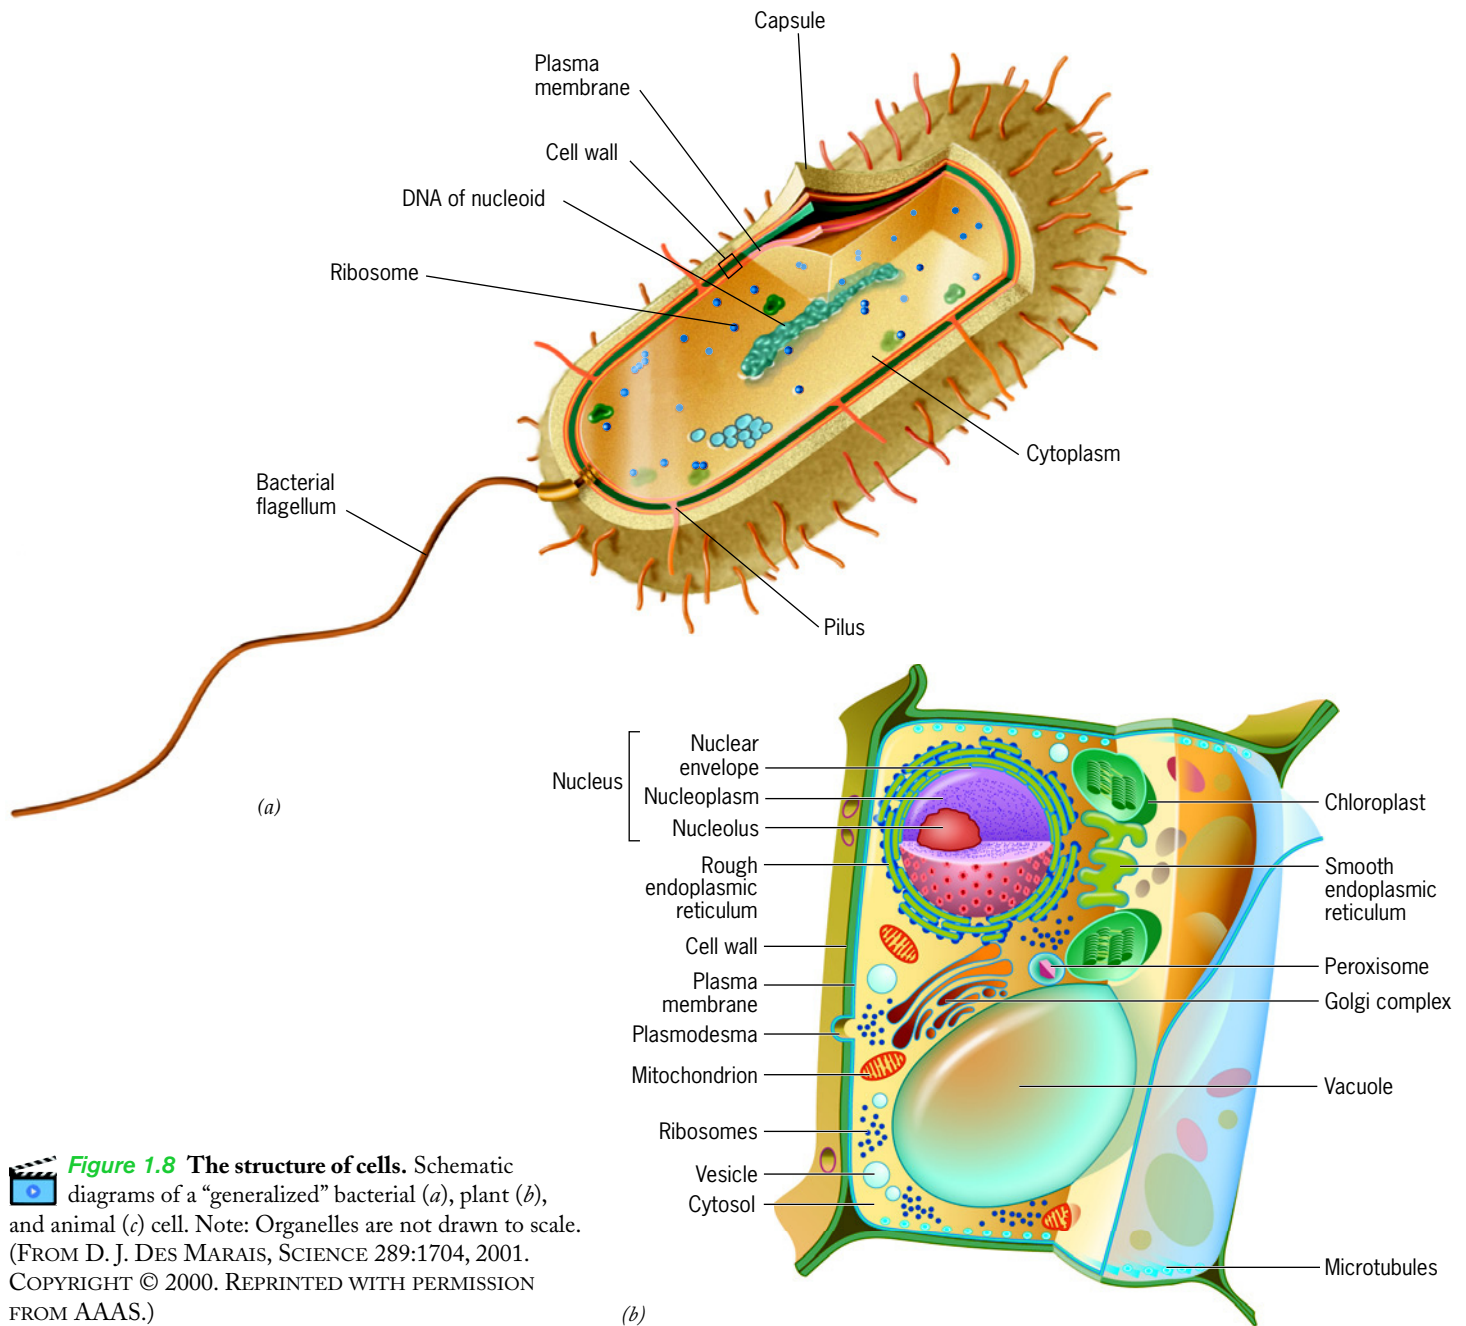

Figure 1.8 The structure of cells. Schematic diagrams of a “generalized” bacterial (a), plant (b), and animal (c) cell. Note: Organelles are not drawn to scale. (FROM D. J. DES MARAIS, SCIENCE 289:1704, 2001. COPYRIGHT © 2000. REPRINTED WITH PERMISSION FROM AAAS.)

rocks contain what appears to be fossilized microbes, they contain complex organic molecules that are characteristic of particular types of prokaryotic organisms, including cyanobacteria. It is unlikely that such molecules could have been synthesized abiotically, that is, without the involvement of living cells. Cyanobacteria almost certainly appeared by 2.4 billion years ago, because that is when the atmosphere became infused with molecular oxygen (O_2), which is a by-product of the photosynthetic activity of these prokaryotes. The dawn of the age of eukaryotic cells is also shrouded in uncertainty. Complex multicellular animals appear rather suddenly in the fossil record approximately 600 million years ago, but there is considerable evidence that simpler eukaryotic organisms were present on Earth more than one billion years

earlier. The estimated time of appearance on Earth of several major groups of organisms is depicted in Figure 1.9. Even a superficial examination of Figure 1.9 reveals how “quickly” life arose following the formation of Earth and cooling of its surface, and how long it took for the subsequent evolution of complex animals and plants.

Characteristics That Distinguish Prokaryotic and Eukaryotic Cells

The following brief comparison between prokaryotic and eukaryotic cells reveals many basic differences between the two types, as well as many similarities (see Figure 1.8). The similarities and differences between the two types of cells are

(c)

Figure 1.8 (continued)

listed in Table 1.1. The shared properties reflect the fact that eukaryotic cells almost certainly evolved from prokaryotic ancestors. Because of their common ancestry, both types of cells share an identical genetic language, a common set of metabolic pathways, and many common structural features. For example, both types of cells are bounded by plasma membranes of similar construction that serve as a selectively permeable barrier between the living and nonliving worlds. Both types of cells may be surrounded by a rigid, nonliving *cell wall* that protects the delicate life form within. Although the cell walls of prokaryotes and eukaryotes may have similar functions, their chemical composition is very different.

Figure 1.9 Earth's biogeologic clock. A portrait of the past five billion years of Earth's history showing a proposed time of appearance of major groups of organisms. Complex animals (shelly invertebrates) and vascular plants are relatively recent arrivals. The time indicated for the origin of life is speculative. In addition, photosynthetic bacteria may have arisen much earlier, hence the question mark. The geologic eras are indicated in the center of the illustration. (FROM D. J. DES MARAIS, SCIENCE 289:1704, 2001. COPYRIGHT © 2000. REPRINTED WITH PERMISSION FROM AAAS.)

Internally, eukaryotic cells are much more complex—both structurally and functionally—than prokaryotic cells (Figure 1.8). The difference in structural complexity is evident in

Table 1.1 A Comparison of Prokaryotic and Eukaryotic Cells

Features held in common by the two types of cells:

- Plasma membrane of similar construction
- Genetic information encoded in DNA using identical genetic code
- Similar mechanisms for transcription and translation of genetic information, including similar ribosomes
- Shared metabolic pathways (e.g., glycolysis and TCA cycle)
- Similar apparatus for conservation of chemical energy as ATP (located in the plasma membrane of prokaryotes and the mitochondrial membrane of eukaryotes)
- Similar mechanism of photosynthesis (between cyanobacteria and green plants)
- Similar mechanism for synthesizing and inserting membrane proteins
- Proteasomes (protein digesting structures) of similar construction (between archaeobacteria and eukaryotes)

Features of eukaryotic cells not found in prokaryotes:

- Division of cells into nucleus and cytoplasm, separated by a nuclear envelope containing complex pore structures
- Complex chromosomes composed of DNA and associated proteins that are capable of compacting into mitotic structures
- Complex membranous cytoplasmic organelles (includes endoplasmic reticulum, Golgi complex, lysosomes, endosomes, peroxisomes, and glyoxisomes)
- Specialized cytoplasmic organelles for aerobic respiration (mitochondria) and photosynthesis (chloroplasts)
- Complex cytoskeletal system (including microfilaments, intermediate filaments, and microtubules) and associated motor proteins
- Complex flagella and cilia
- Ability to ingest particulate material by enclosure within plasma membrane vesicles (phagocytosis)
- Cellulose-containing cell walls (in plants)
- Cell division using a microtubule-containing mitotic spindle that separates chromosomes
- Presence of two copies of genes per cell (diploidy), one from each parent
- Presence of three different RNA synthesizing enzymes (RNA polymerases)
- Sexual reproduction requiring meiosis and fertilization

the electron micrographs of a bacterial and an animal cell shown in Figures 1.18*a* and 1.10, respectively. Both contain a nuclear region, which houses the cell's genetic material, surrounded by cytoplasm. The genetic material of a prokaryotic cell is present in a **nucleoid**: a poorly demarcated region of the cell that lacks a boundary membrane to separate it from the surrounding cytoplasm. In contrast, eukaryotic cells possess a **nucleus**: a region bounded by a complex membranous structure called the *nuclear envelope*. This difference in nuclear structure is the basis for the terms *prokaryotic* (*pro* = before, *karyon* = nucleus) and *eukaryotic* (*eu* = true, *karyon* = nucleus). Prokaryotic cells contain relatively small amounts of DNA; the DNA content of bacteria ranges from about 600,000 base pairs to nearly 8 million base pairs and encodes between about 500 and several thousand proteins.² Although a “simple”

²Eight million base pairs is equivalent to a DNA molecule nearly 3 mm long.

baker's yeast cell has only slightly more DNA (12 million base pairs encoding about 6200 proteins) than the most complex prokaryotes, most eukaryotic cells contain considerably more genetic information. Both prokaryotic and eukaryotic cells have DNA-containing chromosomes. Eukaryotic cells possess a number of separate chromosomes, each containing a single linear molecule of DNA. In contrast, nearly all prokaryotes that have been studied contain a single, circular chromosome. More importantly, the chromosomal DNA of eukaryotes, unlike that of prokaryotes, is tightly associated with proteins to form a complex nucleoprotein material known as **chromatin**.

The cytoplasm of the two types of cells is also very different. The cytoplasm of a eukaryotic cell is filled with a great diversity of structures, as is readily apparent by examining an electron micrograph of nearly any plant or animal cell (Figure 1.10). Even yeast, the simplest eukaryote, is much more complex structurally than an average bacterium (compare Figures 1.18*a* and *b*), even though these two organisms have a similar number of genes. Eukaryotic cells contain an array of membrane-bound organelles. Eukaryotic organelles include mitochondria, where chemical energy is made available to fuel cellular activities; an endoplasmic reticulum, where many of a cell's proteins and lipids are manufactured; Golgi complexes, where materials are sorted, modified, and transported to specific cellular destinations; and a variety of simple membrane-bound vesicles of varying dimension. Plant cells contain additional membranous organelles, including chloroplasts, which are the sites of photosynthesis, and often a single large vacuole that can occupy most of the volume of the cell. Taken as a group, the membranes of the eukaryotic cell serve to divide the cytoplasm into compartments within which specialized activities can take place. In contrast, the cytoplasm of prokaryotic cells is essentially devoid of membranous structures. The complex photosynthetic membranes of the cyanobacteria are a major exception to this generalization (see Figure 1.15).

The cytoplasmic membranes of eukaryotic cells form a system of interconnecting channels and vesicles that function in the transport of substances from one part of a cell to another, as well as between the inside of the cell and its environment. Because of their small size, directed intracytoplasmic communication is less important in prokaryotic cells, where the necessary movement of materials can be accomplished by simple diffusion.

Eukaryotic cells also contain numerous structures lacking a surrounding membrane. Included in this group are the elongated tubules and filaments of the cytoskeleton, which participate in cell contractility, movement, and support. It was thought for many years that prokaryotic cells lacked any trace of a cytoskeleton, but primitive cytoskeletal filaments have been found in bacteria. It is still fair to say that the prokaryotic cytoskeleton is much simpler, both structurally and functionally, than that of eukaryotes. Both eukaryotic and prokaryotic cells possess ribosomes, which are nonmembranous particles that function as “workbenches” on which the proteins of the cell are manufactured. Even though ribosomes of prokaryotic and eukaryotic cells have considerably different dimensions (those of prokaryotes are smaller and

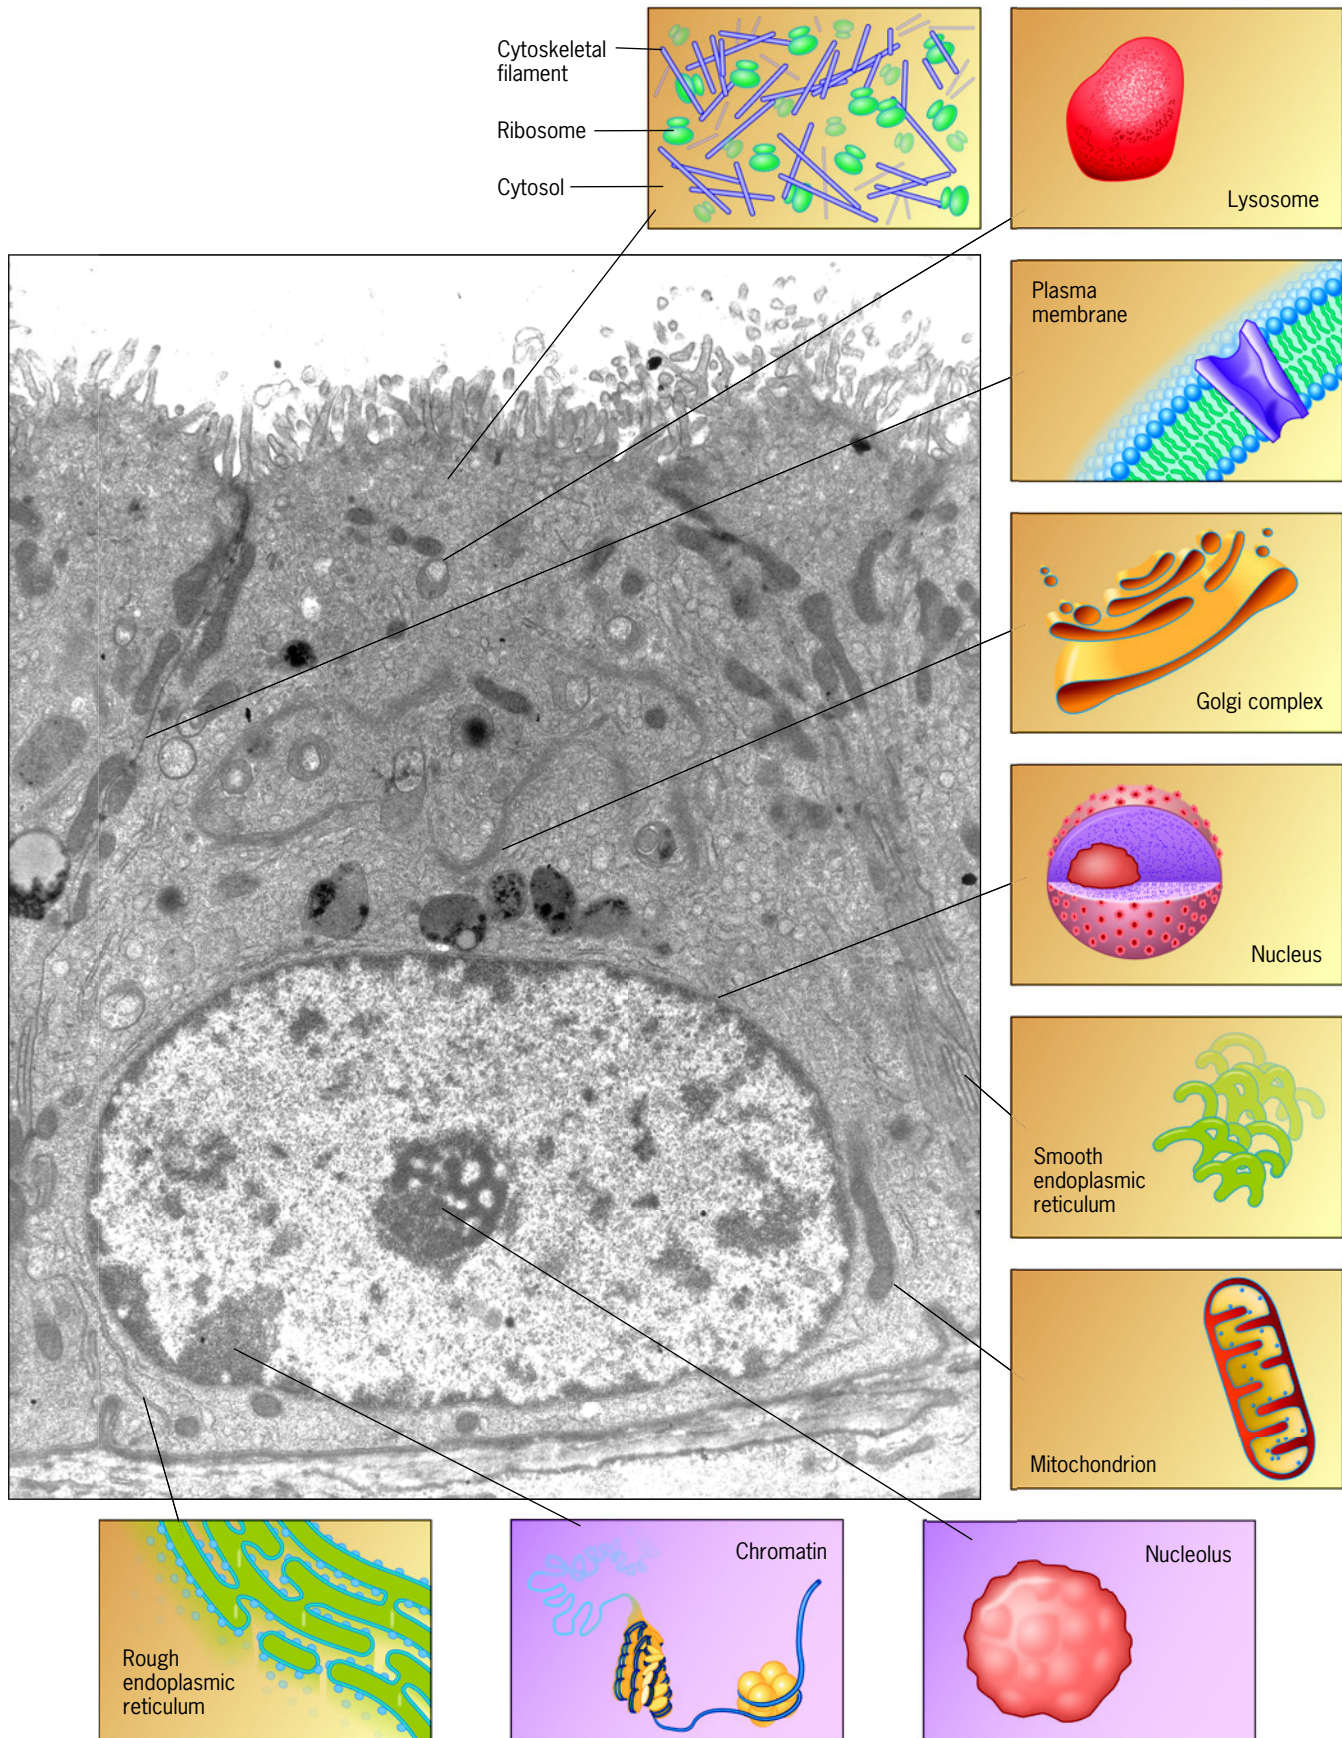

Figure 1.10 The structure of a eukaryotic cell. This epithelial cell lines the male reproductive tract in the rat. A number of different organelles are indicated and depicted in schematic diagrams around the border of the figure. (DAVID M. PHILLIPS/PHOTO RESEARCHERS, INC.)

Figure 1.11 The cytoplasm of a eukaryotic cell is a crowded compartment. This colorized electron micrographic image shows a small region near the edge of a single-celled eukaryotic organism that had been quickly frozen prior to microscopic examination. The three-dimensional appearance is made possible by capturing two-dimensional digital images of the specimen at different angles and merging the individual frames using a computer. Cytoskeletal filaments are shown in red, macromolecular complexes (primarily ribosomes) are green, and portions of cell membranes are blue. (FROM OHAD MEDALIA ET AL., SCIENCE 298:1211, 2002, FIGURE 3A. © 2002, REPRINTED WITH PERMISSION FROM AAAS. PHOTO PROVIDED COURTESY OF WOLFGANG BAUMEISTER.)

contain fewer components), these structures participate in the assembly of proteins by a similar mechanism in both types of cells. Figure 1.11 is a colorized electron micrograph of a portion of the cytoplasm near the thin edge of a single-celled eukaryotic organism. This is a region of the cell where membrane-bound organelles tend to be absent. The micrograph shows individual filaments of the cytoskeleton (red) and other large macromolecular complexes of the cytoplasm (green). Most of these complexes are ribosomes. It is evident from this type of image that the cytoplasm of a eukaryotic cell is extremely crowded, leaving very little space for the soluble phase of the cytoplasm, which is called the **cytosol**.

Other major differences between eukaryotic and prokaryotic cells can be noted. Eukaryotic cells divide by a complex process of mitosis in which duplicated chromosomes condense into compact structures that are segregated by an elaborate microtubule-containing apparatus (Figure 1.12). This apparatus, which is called a *mitotic spindle*, allows each daughter cell to receive an equivalent array of genetic material. In prokaryotes, there is no compaction of the chromosome and no mitotic spindle. The DNA is duplicated, and the two copies are separated accurately by the growth of an intervening cell membrane.

Figure 1.12 Cell division in eukaryotes requires the assembly of an elaborate chromosome-separating apparatus called the mitotic spindle, which is constructed primarily of microtubules. The microtubules in this micrograph appear green because they are bound by an antibody that is linked to a green fluorescent dye. The chromosomes, which were about to be separated into two daughter cells when this cell was fixed, are stained blue. (COURTESY OF CONLY L. RIEDER.)

For the most part, prokaryotes are nonsexual organisms. They contain only one copy of their single chromosome and have no processes comparable to meiosis, gamete formation, or true fertilization. Even though true sexual reproduction is lacking among prokaryotes, some are capable of *conjugation*, in which a piece of DNA is passed from one cell to another (Figure 1.13). However, the recipient almost never receives a whole chromosome from the donor, and the condition in which the recipient cell contains both its own and its partner's DNA is fleeting. The cell soon reverts back to possession of a single chromosome. Although prokaryotes may not be as efficient as eukaryotes in exchanging DNA with other members of their own species, they are more adept than eukaryotes at picking up and incorporating foreign DNA from their environment, which has had considerable impact on microbial evolution (page 29).

Eukaryotic cells possess a variety of complex locomotor mechanisms, whereas those of prokaryotes are relatively simple. The movement of a prokaryotic cell may be accomplished by a thin protein filament, called a *flagellum*, which protrudes from the cell and rotates (Figure 1.14a). The rotations of the flagellum, which can exceed 1000 times per second, exert pressure against the surrounding fluid, propelling the cell through the medium. Certain eukaryotic cells, including many protists and sperm cells, also possess flagella, but the eukaryotic versions are much more complex than the simple protein filaments of bacteria (Figure 1.14b), and they generate movement by a different mechanism.

In the preceding paragraphs, many of the most important differences between the prokaryotic and eukaryotic levels of cellular organization were mentioned. We will elaborate on many of these points in later chapters. Before you dismiss prokaryotes as inferior, keep in mind that these organisms have remained on Earth for more than three billion years, and at this very moment, trillions of them are clinging to the outer

Figure 1.13 Bacterial conjugation. Electron micrograph showing a conjugating pair of bacteria joined by a structure of the donor cell, termed the F pilus, through which DNA is thought to be passed. (COURTESY OF CHARLES C. BRINTON, JR., AND JUDITH CARNAHAN.)

surface of your body and feasting on the nutrients within your digestive tract. We think of these organisms as individual, solitary creatures, but recent insights have shown that they live in complex, multispecies communities called *biofilms*. The layer of plaque that grows on our teeth is an example of a biofilm. Different cells in a biofilm may carry out different specialized activities, not unlike the cells in a plant or an animal. Consider also that, metabolically, prokaryotes are very sophisticated, highly evolved organisms. For example, a bacterium, such as *Escherichia coli*, a common inhabitant of both the human digestive tract and the laboratory culture dish, has the ability to live and prosper in a medium containing one or two low-molecular-weight organic compounds and a few inorganic ions. Other bacteria are able to live on a diet consisting solely of inorganic substances. One species of bacteria has been found in wells more than a thousand meters below the Earth's surface living on basalt rock and molecular hydrogen (H_2) produced by inorganic reactions. In contrast, even the most metabolically talented cells in your body require a variety of organic compounds, including a number of vitamins and other essential substances they cannot make on their own. In fact, many of these essential dietary ingredients are produced by the bacteria that normally live in the large intestine.

(a)

(b)

Figure 1.14 The difference between prokaryotic and eukaryotic flagella. (a) The bacterium *Salmonella* with its numerous flagella. Inset shows a high-magnification view of a portion of a single bacterial flagellum, which consists largely of a single protein called flagellin. (b) Each of these human sperm cells is powered by the undulatory movements of a single flagellum. The inset shows a cross section of the central core of a mammalian sperm flagellum. The flagella of eukaryotic cells are so similar that this cross section could just as well have been taken of a flagellum from a protist or green alga. (A: FROM BERNARD R. GERBER, LEWIS M. DEPAMPHILIS; B: JUERGEN BERGER/PHOTO RESEARCHERS, INC.; INSET: DON W. FAWCETT/PHOTO RESEARCHERS, INC.)

Types of Prokaryotic Cells

The distinction between prokaryotic and eukaryotic cells is based on structural complexity (as detailed in Table 1.1) and not on phylogenetic relationship. Prokaryotes are divided into two major taxonomic groups, or domains: the Archaea (or archaeobacteria) and the Bacteria (or eubacteria). Members of the Archaea are more closely related to eukaryotes than they are to the other group of prokaryotes (the Bacteria). The experiments that led to the discovery that life is represented by three distinct branches are discussed in the Experimental Pathways at the end of the chapter.

The domain Archaea includes several groups of organisms whose evolutionary ties to one another are revealed by similarities in the nucleotide sequences of their nucleic acids. The best known Archaea are species that live in extremely inhospitable environments; they are often referred to as “extremophiles.” Included among the Archaea are the methanogens [prokaryotes capable of converting CO_2 and H_2 gases into methane (CH_4) gas]; the halophiles (prokaryotes that live in extremely salty environments, such as the Dead Sea or certain deep sea brine pools that possess a salinity equivalent to 5M MgCl_2); acidophiles (acid-loving prokaryotes that thrive at a pH as low as 0, such as that found in the drainage fluids of abandoned mine shafts); and thermophiles (prokaryotes that live at very high temperatures). Included in this last-named group are hyperthermophiles, which live in the hydrothermal vents of the ocean floor. The latest record holder among this group has been named “strain 121” because it is able to grow and divide in superheated water at a temperature of 121°C , which just happens to be the temperature used to sterilize surgical instruments in an autoclave. Recent analyses of soil and ocean microbes indicate that many members of the Archaea are also at home in habitats of normal temperature, pH, and salinity.

All other prokaryotes are classified in the domain Bacteria. This domain includes the smallest known cells, the mycoplasma ($0.2\ \mu\text{m}$ diameter), which are the only known prokaryotes to lack a cell wall and to contain a genome with

fewer than 500 genes. Bacteria are present in every conceivable habitat on Earth, from the permanent ice shelf of the Antarctic to the driest African deserts, to the internal confines of plants and animals. Bacteria have even been found living in rock layers situated several kilometers beneath the Earth’s surface. Some of these bacterial communities are thought to have been cut off from life on the surface for more than one hundred million years. The most complex prokaryotes are the cyanobacteria. Cyanobacteria contain elaborate arrays of cytoplasmic membranes, which serve as sites of photosynthesis (Figure 1.15*a*). The membranes of cyanobacteria are very similar to the photosynthetic membranes present within the chloroplasts of plant cells. As in eukaryotic plants, photosynthesis in cyanobacteria is accomplished by splitting water molecules, which releases molecular oxygen.

Many cyanobacteria are capable not only of photosynthesis, but also of **nitrogen fixation**, the conversion of nitrogen (N_2) gas into reduced forms of nitrogen (such as ammonia, NH_3) that can be used by cells in the synthesis of nitrogen-containing organic compounds, including amino acids and nucleotides. Those species capable of both photosynthesis and nitrogen fixation can survive on the barest of resources—light, N_2 , CO_2 , and H_2O . It is not surprising, therefore, that cyanobacteria are usually the first organisms to colonize the bare rocks rendered lifeless by a scorching volcanic eruption. Another unusual habitat occupied by cyanobacteria is illustrated in Figure 1.15*b*.

Prokaryotic Diversity For the most part, microbiologists are familiar only with those microorganisms they are able to grow in a culture medium. When a patient suffering from a respiratory or urinary tract infection sees his or her physician, one of the first steps often taken is to culture the pathogen. Once it has been cultured, the organism can be identified and the proper treatment prescribed. It has proven relatively easy to culture *most* disease-causing prokaryotes, but the same is not true for those living free in nature. The problem is compounded by the fact that prokaryotes are barely visible in a light microscope and their morphology is often not very distinctive. To date, roughly 6000 species of prokaryotes have

(a)

Figure 1.15 Cyanobacteria. (a) Electron micrograph of a cyanobacterium showing the cytoplasmic membranes that carry out photosynthesis. These concentric membranes are very similar to the thylakoid membranes present within the chloroplasts of plant cells, a reminder

(b)

that chloroplasts evolved from a symbiotic cyanobacterium. (b) Cyanobacteria living inside the hairs of these polar bears are responsible for the unusual greenish color of their coats. (A: COURTESY OF NORMA J. LANG; B: COURTESY ZOOLOGICAL SOCIETY OF SAN DIEGO.)

been identified by traditional techniques, which is less than one-tenth of 1 percent of the millions of prokaryotic species thought to exist on Earth! Our appreciation for the diversity of prokaryotic communities has increased dramatically in recent years with the use of molecular techniques that do not require the isolation of a particular organism.

Suppose one wanted to learn about the diversity of prokaryotes that live in the upper layers of the Pacific Ocean off the coast of California. Rather than trying to culture such organisms, which would prove largely futile, a researcher could concentrate the cells from a sample of ocean water, extract the DNA, and analyze certain DNA sequences present in the preparation. All organisms share certain genes, such as those that code for the RNAs present in ribosomes or the enzymes of certain metabolic pathways. Even though all organisms may share such genes, the sequences of the nucleotides that make up the genes vary considerably from one species to another. This is the basis of biological evolution. By using techniques that reveal the variety of DNA sequences of a particular gene in a particular habitat, one learns directly about the diversity of species that live in that habitat. Recent sequencing techniques have become so rapid and cost-efficient that virtually all of the genes present in the microbes of a given habitat can be sequenced, generating a collective genome, or *metagenome*. This approach can provide information about the types of proteins these organisms manufacture and thus about many of the metabolic activities in which they engage.

These same molecular strategies are being used to explore the remarkable diversity among the trillions of “unseen passengers” that live on or within our own bodies, in habitats such as the intestinal tract, mouth, vagina, and skin. This collection of microbes, which is known as the human *microbiome*, is the subject of several international research efforts aimed at identifying and characterizing these organisms in people of different age, diet, geography, and state of health. It has already been demonstrated, for example, that obese and lean humans have markedly different populations of bacteria in their digestive tracts. As obese individuals lose weight, their bacterial profile shifts toward that of the leaner individuals. One recent study of fecal samples taken from 124 people of varying weight revealed the presence within the collective population of more than 1000 different species of bacteria. Taken together, these microbes contained more than 3 million distinct genes—approximately 150 times as many as the number present in the human genome. Among the functions of proteins

encoded by these microbial genomes are the synthesis of vitamins, the breakdown of complex plant sugars, and the prevention of growth of pathogenic organisms.

By using sequence-based molecular techniques, biologists have found that most habitats on Earth are teeming with previously unrecognized prokaryotic life. One estimate of the sheer numbers of prokaryotes in the major habitats of the Earth is given in Table 1.2. It is noteworthy that more than 90 percent of these organisms are now thought to live in the subsurface sediments well beneath the oceans and upper soil layers. Nutrients can be so scarce in some of these deep sediments that microbes living there are thought to divide only once every several hundred years! Table 1.2 also provides an estimate of the amount of carbon that is sequestered in the world’s prokaryotic cells. To put this number into more familiar terms, it is roughly comparable to the total amount of carbon present in all of the world’s plant life.

Types of Eukaryotic Cells: Cell Specialization

In many regards, the most complex eukaryotic cells are not found inside of plants or animals, but rather among the single-celled (*unicellular*) protists, such as those pictured in Figure 1.16. All of the machinery required for the complex activities

Figure 1.16 Vorticella, a complex ciliated protist. A number of these unicellular organisms are seen here; most have withdrawn their “heads” due to shortening of the blue-stained contractile ribbon in the stalk. Each cell has a single large nucleus, called a macronucleus (arrow), which contains many copies of the genes. (CAROLINA BIOLOGICAL SUPPLY CO./PHOTOTAKE.)

Table 1.2 Number and Biomass of Prokaryotes in the World

Environment	No. of prokaryotic cells, $\times 10^{28}$	Pg of C in prokaryotes*
Aquatic habitats	12	2.2
Oceanic subsurface	355	303
Soil	26	26
Terrestrial subsurface	25–250	22–215
Total	415–640	353–546

in which this organism engages—sensing the environment, trapping food, expelling excess fluid, evading predators—is housed within the confines of a single cell.

Complex unicellular organisms represent one evolutionary pathway. An alternate pathway has led to the evolution of multicellular organisms in which different activities are conducted by different types of specialized cells. Specialized cells are formed by a process called **differentiation**. A fertilized human egg, for example, will progress through a course of embryonic development that leads to the formation of approximately 250 distinct types of differentiated cells. Some cells become part of a particular digestive gland, others part of a large skeletal muscle, others part of a bone, and so forth (Figure 1.17). The pathway of differentiation followed by each embryonic cell depends primarily on the signals it receives from the surrounding environment; these signals in turn depend on the position of that cell within the embryo. As discussed in the accompanying Human Perspective, researchers

are learning how to control the process of differentiation in the culture dish and applying this knowledge to the treatment of complex human diseases.

As a result of differentiation, different types of cells acquire a distinctive appearance and contain unique materials. Skeletal muscle cells contain a network of precisely aligned filaments composed of unique contractile proteins; cartilage cells become surrounded by a characteristic matrix containing polysaccharides and the protein collagen, which together provide mechanical support; red blood cells become disk-shaped sacks filled with a single protein, hemoglobin, which transports oxygen; and so forth. Despite their many differences, the various cells of a multicellular plant or animal are composed of similar organelles. Mitochondria, for example, are found in essentially all types of cells. In one type, however, they may have a rounded shape, whereas in another they may be highly elongated and thread-like. In each case, the number, appearance, and location of the various organelles can be

Figure 1.17 Pathways of cell differentiation. A few of the types of differentiated cells present in a human fetus. (MICROGRAPHS COURTESY OF MICHAEL ROSS, UNIVERSITY OF FLORIDA.)

correlated with the activities of the particular cell type. An analogy might be made to a variety of orchestral pieces: all are composed of the same notes, but varying arrangement gives each its unique character and beauty.

Model Organisms Living organisms are highly diverse, and the results obtained from a particular experimental analysis may depend on the particular organism being studied. As a result, cell and molecular biologists have focused considerable research activities on a small number of “representative” or **model organisms**. It is hoped that a comprehensive body of knowledge built on these studies will provide a framework to understand those basic processes that are shared by most organisms, especially humans. This is not to suggest that many other organisms are not widely used in the study of cell and molecular biology. Nevertheless, six model organisms—one prokaryote and five eukaryotes—have captured much of the attention: a bacterium, *E. coli*; a budding yeast, *Saccharomyces cerevisiae*; a flowering plant, *Arabidopsis thaliana*; a nematode, *Caenorhabditis elegans*; a fruit fly, *Drosophila melanogaster*; and a mouse, *Mus musculus*. Each of these organisms has specific advantages that make it particularly useful as a research subject for answering certain types of questions. Each of these organisms is pictured in Figure 1.18, and a few of their advantages as research systems are described in the accompanying legend. We will concentrate in this text on results obtained from studies on mammalian systems—mostly on the mouse and on cultured mammalian cells—because these findings are most applicable to humans. Even so, we will have many occasions to describe research carried out on the cells of other species. You may be surprised to discover how similar you are at the cell and molecular level to these much smaller and simpler organisms.

The Sizes of Cells and Their Components

Figure 1.19 shows the relative size of a number of structures of interest in cell biology. Two units of linear measure are most commonly used to describe structures within a cell: the **micrometer** (μm) and the **nanometer** (nm). One μm is equal to 10^{-6} meters, and one nm is equal to 10^{-9} meters. The **angstrom** (\AA), which is equal to one-tenth of a nm, is commonly employed by molecular biologists for atomic dimensions. One angstrom is roughly equivalent to the diameter of a hydrogen atom. Large biological molecules (i.e., macromolecules) are described in either angstroms or nanometers. Myoglobin, a typical globular protein, is approximately $4.5\text{ nm} \times 3.5\text{ nm} \times 2.5\text{ nm}$; highly elongated proteins (such as collagen or myosin) are over 100 nm in length; and DNA is approximately 2.0 nm in width. Complexes of macromolecules, such as ribosomes, microtubules, and microfilaments, are between 5 and 25 nm in diameter. Despite their tiny dimensions, these macromolecular complexes constitute remarkably sophisticated “nanomachines” capable of performing a diverse array of mechanical, chemical, and electrical activities.

Cells and their organelles are more easily defined in micrometers. Nuclei, for example, are approximately 5–10 μm in diameter, and mitochondria are approximately 2 μm in

length. Prokaryotic cells typically range in length from about 1 to 5 μm , eukaryotic cells from about 10 to 30 μm . There are a number of reasons most cells are so small. Consider the following.

- Most eukaryotic cells possess a single nucleus that contains only two copies of most genes. Because genes serve as templates for the production of information-carrying messenger RNAs, a cell can only produce a limited number of these messenger RNAs in a given amount of time. The greater a cell’s cytoplasmic volume, the longer it will take to synthesize the number of messages required by that cell.
- As a cell increases in size, the surface area/volume ratio decreases.³ The ability of a cell to exchange substances with its environment is proportional to its surface area. If a cell were to grow beyond a certain size, its surface would not be sufficient to take up the substances (e.g., oxygen, nutrients) needed to support its metabolic activities. Cells that are specialized for absorption of solutes, such as those of the intestinal epithelium, typically possess microvilli, which greatly increase the surface area available for exchange (see Figure 1.3). The interior of a large plant cell is typically filled by a large, fluid-filled vacuole rather than metabolically active cytoplasm (see Figure 8.36b).
- A cell depends to a large degree on the random movement of molecules (*diffusion*). Oxygen, for example, must diffuse from the cell’s surface through the cytoplasm to the interior of its mitochondria. The time required for diffusion is proportional to the square of the distance to be traversed. For example, O_2 requires only 100 microseconds to diffuse a distance of 1 μm , but requires 10^6 times as long to diffuse a distance of 1 mm. As a cell becomes larger and the distance from the surface to the interior becomes greater, the time required for diffusion to move substances in and out of a metabolically active cell becomes prohibitively long.

Synthetic Biology

A goal of one field of biological research, often referred to as *synthetic biology*, is to create some minimal type of living cell in the laboratory, essentially from “scratch,” as suggested by the cartoon in Figure 1.20. One motivation of these researchers is simply to accomplish the feat and, in the process, demonstrate that life at the cellular level emerges spontaneously when the proper constituents are brought together from chemically synthesized materials. At this point in time, biologists are nowhere near accomplishing this feat, and many members of society would argue that it would be unethical to do so. A more modest goal of synthetic biology is to develop novel life forms, using existing organisms as a starting point, that have a unique value in medicine and industry, or in cleaning up the environment.

³You can verify this statement by calculating the surface area and volume of a cube whose sides are 1 cm in length versus a cube whose sides are 10 cm in length. The surface area/volume ratio of the smaller cube is considerably greater than that of the larger cube.

(f)

Figure 1.18 Six model organisms. (a) *Escherichia coli* is a rod-shaped bacterium that lives in the digestive tract of humans and other mammals. Much of what we will discuss about the basic molecular biology of the cell, including the mechanisms of replication, transcription, and translation, was originally worked out on this one prokaryotic organism. The relatively simple organization of a prokaryotic cell is illustrated in this electron micrograph (compare to part *b* of a eukaryotic cell). (b) *Saccharomyces cerevisiae*, more commonly known as baker's yeast or brewer's yeast. It is the least complex of the eukaryotes commonly studied, yet it contains a surprising number of proteins that are homologous to proteins in human cells. Such proteins typically have a conserved function in the two organisms. The species has a small genome encoding about 6200 proteins; it can be grown in a haploid state (one copy of each gene per cell rather than two as in most eukaryotic cells); and it can be grown under either aerobic (O_2 -containing) or anaerobic (O_2 -lacking) conditions. It is ideal for the identification of genes through the use of mutants. (c) *Arabidopsis thaliana*, a weed (called the thale cress) that is related to mustard and cabbage, which has an unusually small genome (120 million base pairs) for a flowering plant, a rapid generation time, and large seed production, and it grows to a height of only a few inches. (d) *Caenorhabditis elegans*, a microscopic-sized nematode, consists of a defined number of cells (roughly 1000), each of which develops according to a precise pattern of cell divisions. The animal is easily cultured, can be kept alive in a

frozen state, has a transparent body wall, a short generation time, and facility for genetic analysis. This micrograph shows the larval nervous system, which has been labeled with the green fluorescent protein (GFP). The 2002 Nobel Prize was awarded to the researchers who pioneered its study. (e) *Drosophila melanogaster*, the fruit fly, is a small but complex eukaryote that is readily cultured in the lab, where it grows from an egg to an adult in a matter of days. *Drosophila* has been a favored animal for the study of genetics, the molecular biology of development, and the neurological basis of simple behavior. Certain larval cells have giant chromosomes, whose individual genes can be identified for studies of evolution and gene expression. In the mutant fly shown here, a leg has developed where an antenna would be located in a normal (wild type) fly. (f) *Mus musculus*, the common house mouse, is easily kept and bred in the laboratory. Thousands of different genetic strains have been developed, many of which are stored simply as frozen embryos due to lack of space to house the adult animals. The "nude mouse" pictured here develops without a thymus gland and, therefore, is able to accept human tissue grafts that are not rejected. (A&B: BIOPHOTO ASSOCIATES/PHOTO RESEARCHERS; C: JEAN CLAUDE REVY/PHOTOTAKE; D: COURTESY OF ERIK JORGENSEN, UNIVERSITY OF UTAH. FROM TRENDS GENETICS, VOL. 14, COVER #12, 1998, WITH PERMISSION FROM ELSEVIER. E: DAVID SCHARF/PHOTO RESEARCHERS, INC. F: TED SPIEGEL/© CORBIS IMAGES.)

If, as most biologists would argue, the properties and activities of a cell spring from the genetic blueprint of that cell, then it should be possible to create a new type of cell by introducing a new genetic blueprint into the cytoplasm of an exist-

ing cell. This feat was accomplished by J. Craig Venter and colleagues in 2007, when they replaced the genome of one bacterium with a genome isolated from a closely related species, effectively transforming one species into the other. By

Figure 1.19 Relative sizes of cells and cell components. These structures differ in size by more than seven orders of magnitude.

2010, after overcoming a number of stubborn technical roadblocks, the team was able to accomplish a similar feat using a copy of a bacterial genome that had been assembled (inside of a yeast cell) from fragments of DNA that had been chemically synthesized in the laboratory. The synthetic copy of the donor genome, which totaled approximately 1.1 million base pairs of DNA, contained a number of modifications introduced by the researchers. The modified copy of the genome (from *M. mycoides*) was transplanted into a cell of a closely related bacterial species (*M. capricolum*), where it replaced the host's original genome. Following genome transplantation, the recipient cell rapidly took on the characteristics of the species from which the donor DNA has been derived. In effect, these researchers have produced cells containing a “genetic skeleton” to which they can add combinations of new genes taken from other organisms.

Figure 1.20 The synthetic biologist's toolkit of the future? Such a toolkit would presumably contain nucleic acids, proteins, lipids, and many other types of biomolecules. (COURTESY OF JAKOB C. SCHWEIZER.)

Researchers around the world are attempting to genetically engineer organisms to possess metabolic pathways capable of producing pharmaceuticals, hydrocarbon-based fuel molecules, and other useful chemicals from cheap, simple precursors. At least one company has claimed to be growing genetically engineered cyanobacteria capable of producing diesel fuel from sunlight, water, and CO_2 . Researchers at another company have genetically engineered the common lab bacterium *E. coli* to ferment the complex polysaccharides present in seaweed into the biofuel ethanol. This feat required the introduction into *E. coli* of a combination of genes derived from three other bacterial species. Work has also begun on “rewriting” the yeast genome, signifying that eukaryotic cells have also become part of the effort to design genetically engineered biological manufacturing plants.

In principle, the work described in the Human Perspective, in which one type of cell is directed into the formation of an entirely different type of cell, is also a form of synthetic biology. As a result of these many efforts, biologists are no longer restricted to studying cells that are available in Nature, but can also turn their attention to cells that can become available through experimental manipulation.

REVIEW

1. Compare a prokaryotic and eukaryotic cell on the basis of structural, functional, and metabolic differences.
2. What is the importance of cell differentiation?
3. Why are cells almost always microscopic?
4. If a mitochondrion were $2 \mu\text{m}$ in length, how many angstroms would it be? How many nanometers? How many millimeters?

The Prospect of Cell Replacement Therapy

Many human diseases result from the deaths of specific types of cells. Type 1 diabetes, for example, results from the destruction of beta cells in the pancreas; Parkinson's disease occurs with the loss of dopamine-producing neurons in the brain; and heart failure can be traced to the death of cardiac muscle cells (cardiomyocytes) in the heart. Imagine the possibilities if we could isolate cells from a patient, convert them into the cells that are needed by that patient, and then infuse them back into the patient to restore the body's lost function. Recent studies have given researchers hope that one day this type of therapy will be commonplace. To better understand the concept of cell replacement therapy, we can consider a procedure used widely in current practice known as *bone marrow transplantation* in which cells are extracted from the pelvic bones of a donor and infused into the body of a recipient.

Bone marrow transplantation is used most often to treat lymphomas and leukemias, which are cancers that affect the nature and number of white blood cells. To carry out the procedure, the patient is exposed to a high level of radiation and/or toxic chemicals, which kills the cancer cells, but also kills all of the cells involved in the formation of red and white blood cells. This treatment has this effect because blood-forming cells are particularly sensitive to radiation and toxic chemicals. Once a person's blood-forming cells have been destroyed, they are replaced by bone marrow cells transplanted from a healthy donor. Bone marrow can regenerate the blood tissue of the transplant recipient because it contains a small percentage of cells that can proliferate and restock the patient's blood-forming bone marrow tissue.¹ These blood-forming cells in the bone marrow are termed **hematopoietic stem cells** (or **HSCs**), and they were discovered in the early 1960s by Ernest McCulloch and James Till at the University of Toronto. HSCs are responsible for replacing the millions of red and white blood cells that age and die every minute in our bodies (see Figure 17.6). Amazingly, a *single* HSC is capable of reconstituting the entire hematopoietic (blood-forming) system of an irradiated mouse. An increasing number of parents are saving the blood from the umbilical cord of their newborn baby as a type of "stem-cell insurance policy" in case that child should ever develop a disease that might be treated by administration of HSCs. Now that we have described one type of cell replacement therapy, we can consider several other types that have a much wider therapeutic potential. We will divide these potential therapies into four types.

Adult Stem Cells

Hematopoietic stem cells in the bone marrow are an example of an *adult stem cell*. **Stem cells** are defined as undifferentiated cells that (1) are capable of self-renewal, that is, production of more cells like themselves, and (2) are multipotent, that is, are capable of differentiating into two or more mature cell types. HSCs of the bone marrow are only one type of adult stem cell. Most, if not all, of the organs in a human adult contain stem cells that are capable of replacing the particular cells of the tissue in which they are found. Even the adult brain, which is not known for its ability to regenerate, contains stem cells that can generate new neurons and glial cells (the supportive cells of the brain). Figure 1a shows an isolated stem cell present in adult skeletal muscle;

¹Bone marrow transplantation can be contrasted to a simple blood transfusion where the recipient receives differentiated blood cells (especially red blood cells and platelets) present in the circulation.

Figure 1 An adult muscle stem cell. (a) A portion of a muscle fiber, with its many nuclei stained blue. A single stem cell (yellow) is seen to be lodged between the outer surface of the muscle fiber and an extracellular layer (or basement membrane), which is stained red. The undifferentiated stem cell exhibits this yellow color because it expresses a protein that is not present in the differentiated muscle fiber. (b) Adult stem cells undergoing differentiation into adipose (fat) cells in culture. Stem cells capable of this process are present in adult fat tissue and also bone marrow. (A: FROM CHARLOTTE A. COLLINS; ET AL., *CELL* 122:291, 2005; BY PERMISSION OF ELSEVIER; B: COURTESY OF THERMO FISHER SCIENTIFIC, FROM *NATURE* 451:855, 2008.)

these "satellite cells," as they are called, are thought to divide and differentiate as needed for the repair of injured muscle tissue. Figure 1b shows a culture of adipose (fat) cells that have differentiated in vitro from adult stem cells that are present within fat tissue.

The adult human heart contains stem cells that are capable of differentiating into the cells that form both the muscle tissue of the heart (the cardiomyocytes of the myocardium) and the heart's blood vessels. It had been hoped that these cardiac stem cells might have the potential to regenerate healthy heart tissue in a patient who had experienced a serious heart attack. This hope has apparently been realized based on the appearance of two landmark reports in late 2011 on the results from clinical trials of patients that had suffered significant heart-tissue damage following heart attacks. Stem cells were harvested from each of the patients during heart surgeries, expanded in number through in vitro culture, and then infused back into each patient's heart. Over the next few months, a majority of treated patients experienced significant replacement (e.g., 50 percent) of the damaged heart muscle by healthy tissue derived from the infused stem cells. This regeneration of heart tissue was accompanied by a clear improvement in quality of life compared to patients in the placebo group that did not receive stem cells. Adult stem cells are an ideal system for cell replacement therapies because they represent an *autologous* treatment; that is, the cells are taken from the same patient in which they are used. Consequently, these stem cells do not face the prospect of immune rejection. At the same time, however, adult stem cells are very scarce within the tissue in question, often difficult to isolate and work with, and are only likely to replace cells from the same tissue from which they are taken. These dramatic results with cardiac stem cells may have rekindled interest in adult stem cells, which had waned after a number of failed attempts to direct stem cells isolated from bone marrow to regenerate diseased tissues.

Embryonic Stem Cells

Much of the excitement that has been generated in the field over the past decade or two has come from studies on **embryonic stem (ES) cells**, which are a type of stem cell isolated from very young mammalian embryos (Figure 2a). These are the cells in the early embryo that give rise to all of the various structures of the mammalian fetus. Unlike adult stem cells, ES cells are *pluripotent*; that is, they are capable of differentiating into every type of cell in the body. In most cases, human ES cells have been isolated from embryos provided by in vitro fertilization clinics. Worldwide, dozens of genetically distinct human ES cell lines, each derived from a single embryo, are available for experimental investigation.

The long-range goal of clinical researchers is to learn how to coax ES cells to differentiate in culture into each of the many cell types that might be used for cell replacement therapy. Considerable progress has been made in this pursuit, and numerous studies have shown that transplants of differentiated, ES-derived cells can improve the condition of animals with diseased or damaged organs. The first trials in humans were begun in 2009 on patients who had experienced debilitating spinal cord injuries or were suffering from an eye disease called Stargardt's macular dystrophy. The trials to treat spinal cord injuries utilize cells, called oligodendrocytes, that produce the myelin sheaths that become wrapped around nerve cells (see Figure 4.5). The oligodendrocytes used in these trials were differentiated from human ES cells that were cultured in a medium containing insulin, thyroid hormone, and a combination of certain growth factors. This particular culture protocol had been found to direct the differentiation of ES cells into oligodendrocytes rather than any other cell type. At the time of this writing, no significant improvement had been reported in any of the treated patients, and the company conducting the trial has decided to cease further involvement in the effort. The primary risk with the therapeutic use of ES cells is the unnoticed presence of undifferentiated ES cells among the differentiated cell population. Undifferentiated ES

(b)

Figure 2 Embryonic stem cells; their isolation and potential use.

(a) Micrograph of a mammalian blastocyst, an early stage during embryonic development, showing the inner cell mass, which is composed of pluripotent ES cells. Once isolated, such cells are readily grown in culture. (b) A potential procedure for obtaining differentiated cells for use in cell replacement therapy. A small piece of tissue is taken from the patient, and one of the somatic cells is fused with a donor oocyte whose own nucleus had been previously removed. The resulting oocyte (egg), with the patient's cell nucleus, is allowed to develop into an early embryo, and the ES cells are harvested and grown in culture. A population of ES cells are induced to differentiate into the required cells,

cells are capable of forming a type of benign tumor, called a teratoma, which may contain a bizarre mass of various differentiated tissues, including hair and teeth. The formation of a teratoma within the central nervous system could have severe consequences. In addition, the culture of ES cells at the present time involves the use of non-human biological materials, which also poses potential risks.

The ES cells used in these early trials were derived from cell lines that had been isolated from human embryos unrelated to the patients who are being treated. Such cells face the prospect of immunologic rejection by the transplant recipient. It may be possible, however, to “customize” ES cells so that they possess the same genetic makeup of the individual who is being treated. This may be accomplished one day by a roundabout procedure called *somatic cell nuclear transfer (SCNT)*, shown in Figure 2b, that begins with an unfertilized egg—a cell that is obtained from the ovaries of an unrelated woman donor. In this approach, the nucleus of the unfertilized egg would be replaced by the nucleus of a cell from the patient to be treated, which would cause the egg to have the same chromosome composition as that of the patient. The egg would then be allowed to develop to an early embryonic stage, and the ES cells would be removed, cultured, and induced to differentiate into the type of cells needed by the patient. Because this procedure involves the formation of a human embryo that is used only as a source of ES cells, there are major ethical questions that must be settled before it could be routinely practiced. In addition, the process of SCNT is so expensive and technically demanding that it is highly improbable that it could ever be practiced as part of any routine medical treatment. It is more

which are subsequently transplanted into the patient to restore organ function. (At the present time, it has not been possible to obtain blastocyst stage embryos, that is, ones with ES cells, from any primate species by the procedure shown here, although it has been accomplished using an oocyte from which the nucleus is not first removed. The ES cells that are generated in such experiments are triploid; that is, they have three copies of each chromosome—one from the oocyte and two from the donor nucleus—rather than two, as would normally be the case. Regardless, these triploid ES cells are pluripotent and capable of transplantation.) (A: © PHANIE/SUPERSTOCK)

likely that, if ES cell-based therapy is ever practiced, it would depend on the use of a bank of hundreds or thousands of different ES cells. Such a bank could contain cells that are close enough as a tissue match to be suitable for use in the majority of patients.

Induced Pluripotent Stem Cells

It had long been thought that the process of cell differentiation in mammals was irreversible; once a cell had become a fibroblast, or white blood cell, or cartilage cell, it could never again revert to any other cell type. This concept was shattered in 2006 when Shinya Yamanaka and co-workers of Kyoto University announced a stunning discovery; his lab had succeeded in reprogramming a fully differentiated mouse cell—in this case a type of connective tissue fibroblast—into a pluripotent stem cell. They accomplished the feat by introducing, into the mouse fibroblast, the genes that encoded four key proteins that are characteristic of ES cells. These genes (*Oct4*, *Sox2*, *Klf4*, and *Myc*, known collectively as OSKM) are thought to play a key role in maintaining the cells in an undifferentiated state and allowing them to continue to self-renew. The genes were introduced into cultured fibroblasts using gene-carrying viruses, and those rare cells that became reprogrammed were selected from the others in the culture by specialized techniques. They called this new type of cells *induced pluripotent cells (iPS cells)* and demonstrated that they were indeed pluripotent by injecting them into a mouse blastocyst and finding that they participated in the differentiation of all the cells of the body, including eggs and sperm. Within the next year or so the same reprogramming feat had been accomplished in several labs with human cells. What this means is that researchers now have available to them an unlimited supply of pluripotent cells that can be directed to differentiate into various types of body cells using similar experimental protocols to those already developed for ES cells.

Indeed, iPS cells have already been used to correct certain disease conditions in experimental animals, including sickle cell anemia in mice as depicted in Figure 3. iPS cells have also been prepared from adult cells taken from patients with a multitude of genetic disorders. Researchers are then able to follow the differentiation of these iPS cells in culture into the specialized cell types that are affected by the particular disease. An example of this type of experiment is portrayed on the front cover of this book. It is hoped that such studies will reveal the mechanisms of disease formation as it unfolds in a culture dish just as it would normally occur in an unobserv-

able way deep within the body. These “diseased iPS cells” have been referred to as “patients in a Petri dish.” The clinical relevance of these cells can be illustrated by an example. iPS cells derived from patients with a heart disorder called long QT syndrome differentiate into cardiac muscle cells that exhibit irregular contractions (“beats”) in culture. This disease-specific phenotype seen in culture can be corrected by several medicines normally prescribed to treat this disorder. Moreover, when these cardiomyocytes that had differentiated from the diseased iPS cells were exposed to the drug cisapride, the irregularity of their contractions increased. Cisapride is a drug that was used to treat heartburn before it was pulled from the market in the United States after it was shown to cause heart arrhythmias in certain patients. Results of this type suggest that differentiated cells derived from diseased iPS cells will serve as valuable targets for screening potential drugs for their effectiveness in halting disease progression.

Unlike ES cells, the generation of iPS cells does not require the use of an embryo. This feature removes all of the ethical reservations that accompany work with ES cells and also makes it much easier to generate these cells in the lab. However, as research on iPS cells has increased, the therapeutic potential for these cells has become less clear. For the first several years of study, it was thought that iPS cells and ES cells were essentially indistinguishable. Recent studies, however, have shown that iPS cells lack the “high quality” characteristic of ES cells and that not all iPS cells are the same. For example, iPS cells exhibit certain genomic abnormalities that are not present in ES cells, including the presence of mutations and extra copies of random segments of the genome. In addition, the DNA-containing chromatin of iPS cells retains certain traces of the original cells from which they were derived, which means that they are not completely reprogrammed into ES-like, pluripotent cells. This residual memory of their origin makes it easier to direct iPS cells toward differentiation back into the cells from which they were derived than into other types of cells. It may be that these apparent deficiencies in iPS cells will not be a serious impediment in the use of these cells to treat diseases that affect adult tissues, but it has raised important questions. There are other issues with iPS cells as well. It will be important to develop efficient cell reprogramming techniques that do not use genome-integrating viruses because such cells carry the potential of developing into cancers. Progress has been made in this regard, but the efficiency of iPS cell formation typically drops when other procedures are used to introduce genes.

Like ES cells, undifferentiated iPS cells also give rise to teratomas, so it is essential that only fully differentiated cells are transplanted into

Figure 3 Steps taken to generate induced pluripotent stem (iPS) cells for use in correcting the inherited disease sickle cell anemia in mice. Skin cells are collected from the diseased animal, reprogrammed in culture by introducing the four required genes that are ferried into the cells by viruses, and allowed to develop into undifferentiated pluripotent iPS cells. The iPS cells are then treated so as to replace the defective (globin) gene with a normal copy, and the corrected iPS cells are caused to differentiate into normal blood stem cells in culture. These blood stem cells are then injected back into the diseased mouse, where they proliferate and differentiate into normal blood cells, thereby curing the disorder. (REPRINTED FROM AN ILLUSTRATION BY RUDOLF JAENISCH, CELL 132:5, 2008, WITH PERMISSION FROM ELSEVIER.)

human subjects. Also like ES cells, the iPS cells in current use have the same tissue antigens as the donors who originally provided them, so they would stimulate an immune attack if they were to be transplanted into other human recipients. Unlike the formation of ES cells, however, it will be much easier to generate personalized, tissue-compatible iPS cells, because they can be derived from a simple skin biopsy from each patient. Still, it does take considerable time, expense, and technical expertise to generate a population of iPS cells from a specific donor. Consequently, if iPS cells are ever developed for widespread therapeutic use, they would likely come from a large cell bank that could provide cells that are close tissue matches to most potential recipients. It may also be possible to remove all of the genes from iPS cells that normally prevent them from being transplanted into random recipients.

Direct Cell Reprogramming

In 2008 the field of cellular reprogramming took another unexpected turn with the announcement that one type of differentiated cell had been converted directly into another type of differentiated cell, a case of “transdifferentiation.” In this report, the acinar cells of the pancreas, which produce enzymes responsible for digestion of food in the intestine, were transformed into pancreatic beta cells, which synthesize and secrete the hormone insulin. The reprogramming

process occurred directly, in a matter of a few days, without the cells passing through an intermediate stem cell state—and it occurred while the cells remained in their normal residence within the pancreas of a live mouse. This feat was accomplished by injection into the animals of viruses that carried three genes known to be important in differentiation of beta cells in the embryo. In this case, the recipients of the injection were diabetic mice, and the transdifferentiation of a significant number of acinar cells into beta cells allowed the animals to regulate their blood sugar levels with much lower doses of insulin. It is also noteworthy that the adenoviruses used to deliver the genes in this experiment do not become a permanent part of the recipient cell, which removes some of the concerns about the use of viruses as gene carriers in humans. Since this initial report, a number of laboratories have developed in vitro techniques to directly convert one type of differentiated cell (typically a fibroblast) into another type of cell, such as a neuron, cardiomyocyte, or blood-cell precursor, in culture, without passing through a pluripotent intermediate. In all of these cases, transdifferentiation occurs when the original cells are forced to express certain genes that play a role in the normal embryonic differentiation of the other cell type. It is too early to know whether this type of direct reprogramming strategy has therapeutic potential, but it certainly raises the prospect that diseased cells that need to be replaced might be formed directly from other types of cells within the same organ.

1.4 | Viruses

By the end of the nineteenth century, the work of Louis Pasteur and others had convinced the scientific world that infectious diseases of plants and animals were due to bacteria. But studies of tobacco mosaic disease in tobacco plants and hoof-and-mouth disease in cattle pointed to the existence of another type of infectious agent. It was found, for example, that sap from a diseased tobacco plant could transmit mosaic disease to a healthy plant, even when the sap showed no evidence of bacteria in the light microscope. To gain further insight into the size and nature of the infectious agent, Dmitri Ivanovsky, a Russian biologist, forced the sap from a diseased plant through filters whose pores were so small that they retarded the passage of the smallest known bacterium. The filtrate was still infective, causing Ivanovsky to conclude in 1892

that certain diseases were caused by pathogens that were even smaller, and presumably simpler, than the smallest known bacteria. These pathogens became known as **viruses**.

In 1935, Wendell Stanley of the Rockefeller Institute reported that the virus responsible for tobacco mosaic disease could be crystallized and that the crystals were infective. Substances that form crystals have a highly ordered, well-defined structure and are vastly less complex than the simplest cells. Stanley mistakenly concluded that tobacco mosaic virus (TMV) was a protein. In fact, TMV is a rod-shaped particle consisting of a single molecule of RNA surrounded by a helical shell composed of protein subunits (Figure 1.21).

Figure 1.21 Tobacco mosaic virus (TMV). (a) Model of a portion of a TMV particle. The protein subunits, which are identical along the entire rod-shaped particle, enclose a single helical RNA molecule (red). (b) Electron micrograph of TMV particles after phenol has removed the

protein subunits from the middle part of the upper particle and the ends of the lower particle. Intact rods are approximately 300 nm long and 18 nm in diameter. (A&B: COURTESY OF GERALD STUBBS, KEUCHI NAMBA, AND DONALD CASPAR.)

Figure 1.22 Virus diversity. The structures of (a) an adenovirus, (b) a human immunodeficiency virus (HIV), and (c) a T-even bacteriophage. *Note:* These viruses are not drawn to the same scale.

Viruses are responsible for dozens of human diseases, including AIDS, polio, influenza, cold sores, measles, and a few types of cancer. Viruses occur in a wide variety of very different shapes, sizes, and constructions, but all of them share certain common properties. All viruses are obligatory intracellular parasites; that is, they cannot reproduce unless present within a host cell. Depending on the specific virus, the host may be a plant, animal, or bacterial cell. Outside of a living cell, the virus exists as a particle, or **virion**, which is little more than a macromolecular package. The virion contains a small amount of genetic material that, depending on the virus, can be single-stranded or double-stranded, RNA or DNA. Remarkably, some viruses have as few as three or four different genes, but others may have as many as several hundred. The genetic material of the virion is surrounded by a protein capsule, or *capsid*. Virions are macromolecular aggregates, inanimate particles that by themselves are unable to reproduce, metabolize, or carry on any of the other activities associated with life. For this reason, viruses are not considered to be organisms and are not described as being alive.

Viral capsids are generally made up of a specific number of subunits. There are numerous advantages to construction by subunit, one of the most apparent being an economy of genetic information. If a viral coat is made of many copies of a single protein, as is that of TMV, or a few proteins, as are the coats of many other viruses, the virus needs only one or a few genes to code for its protein container. Many viruses have a capsid whose subunits are organized into a polyhedron, that is, a structure having planar faces. A particularly common polyhedral shape of viruses is the 20-sided *icosahedron*. For example, adenovirus,

which causes respiratory infections in mammals, has an icosahedral capsid (Figure 1.22a). In many animal viruses, including the *human immunodeficiency virus (HIV)* responsible for AIDS, the protein capsid is surrounded by a lipid-containing outer envelope that is derived from the modified plasma membrane of the host cell as the virus buds from the host-cell surface (Figure 1.22b). Bacterial viruses, or *bacteriophages*, are among the most complex viruses (Figure 1.22c). They are also the most abundant biological entities on Earth. The T bacteriophages (which were used in key experiments that revealed the structure and properties of the genetic material) consist of a polyhedral head containing DNA, a cylindrical stalk through which the DNA is injected into the bacterial cell, and tail fibers, which together cause the particle to resemble a landing module for the moon.

Each virus has on its surface a protein that is able to bind to a particular surface component of its host cell. For example, the protein that projects from the surface of the HIV particle (labeled gp120 in Figure 1.22b, which stands for glycoprotein of molecular mass 120,000 daltons⁴) interacts with a specific protein (called CD4) on the surface of certain white blood cells, facilitating entry of the virus into its host cell. The interaction between viral and host proteins determines the specificity of the virus, that is, the types of host cells that the virus can enter and infect. Some viruses have a wide *host range*, being able to infect cells from a variety of different organs or host species. The virus that causes rabies, for example, is able

⁴One dalton is equivalent to one unit of atomic mass, the mass of a single hydrogen (¹H) atom.

to infect many different types of mammalian hosts, including dogs, bats, and humans. Most viruses, however, have a relatively narrow host range. This is true, for example, of human cold and influenza viruses, which are generally able to infect only the respiratory epithelial cells of human hosts.

A change in host-cell specificity can have striking consequences. This point is dramatically illustrated by the 1918 influenza pandemic, which killed more than 30 million people

(a) 0.2 μm

(b) 0.1 μm

Figure 1.23 A virus infection. (a) Micrograph showing a late stage in the infection of a bacterial cell by a bacteriophage. worldwide. The virus was especially lethal in young adults, who do not normally fall victim to influenza. In fact, the 675,000 deaths from this virus in the United States temporarily lowered average life expectancy by several years. In one of the most acclaimed—and controversial—feats of the past few years, researchers have been able to determine the genomic sequence of the virus responsible for this pandemic and to reconstitute the virus in its full virulent state. This was accomplished by isolating the viral genes (which are part of a genome consisting of 8 separate RNA molecules encoding 11 different proteins) from the preserved tissues of victims who had died from the infection 90 years earlier. The best preserved samples were obtained from a Native American woman who had been buried in the Alaskan permafrost. The sequence of the “1918 virus” suggested that the pathogen had jumped from birds to humans. Although the virus had accumulated a considerable number of mutations, which adapted it to a mammalian host, it had never exchanged genetic material with that of a human influenza virus as had been thought likely.

Analysis of the sequence of the 1918 virus has provided some clues to explain why it was so deadly and how it spread so efficiently from one human to another. Using the genomic sequence, researchers reconstituted the 1918 virus into infectious particles, which were found to be exceptionally virulent in laboratory tests. Whereas laboratory mice normally survive infection by modern human influenza viruses, the reconstituted 1918 strain killed 100 percent of infected mice and produced enormous numbers of viral particles in the animals’ lungs. Because of the potential risk to public health, publication of the full sequence of the 1918 virus and its reconstitution went forward only after approval by governmental safety panels and the demonstration that existing influenza vaccines and drugs protect mice from the reconstituted virus.

There are two basic types of viral infection. (1) In most cases, the virus arrests the normal synthetic activities of the host and redirects the cell to use its available materials to manufacture viral nucleic acids and proteins, which assemble into new virions. Viruses, in other words, do not grow like cells; they are assembled from components directly into the mature-sized virions. Ultimately, the infected cell ruptures (*lyses*) and releases a new generation of viral particles capable of infecting neighboring cells. An example of this type of *lytic* infection is shown in Figure 1.23a. (2) In other cases, the infecting virus does not lead to the death of the host cell, but instead inserts (*integrates*) its DNA into the DNA of the host cell’s chromosomes. The integrated viral DNA is called a **provirus**. An integrated provirus can have different effects depending on the type of virus and host cell. For example,

- Bacterial cells containing a provirus behave normally until exposed to a stimulus, such as ultraviolet radiation, that activates the dormant viral DNA, leading to the lysis of the cell and release of viral progeny.
- Some animal cells containing a provirus produce new viral progeny that bud at the cell surface without lysing the infected cell. Human immunodeficiency virus (HIV) acts in this way; an infected cell may remain alive for a period, acting as a factory for the production of new virions (Figure 1.23b).

- Some animal cells containing a provirus lose control over their own growth and division and become malignant. This phenomenon is readily studied in the laboratory by infecting cultured cells with the appropriate tumor virus.

Viruses are not without their virtues. Because the activities of viral genes mimic those of host genes, investigators have used viruses for decades as a research tool to study the mechanism of DNA replication and gene expression in their much more complex hosts. In addition, viruses are now being used as a means to introduce foreign genes into human cells, a technique that will likely serve as the basis for the treatment of human diseases by gene therapy. Lastly, insect- and bacteria-killing viruses may play an increasing role in the war against insect pests and bacterial pathogens. Bacteriophages have been used for decades to treat bacterial infections in eastern Europe and Russia, while physicians in the West have relied on antibiotics. Given the rise in antibiotic-resistant bacteria, bacteriophages may be making a comeback on the heels of promising studies on infected mice. Several biotechnology companies are now producing bacteriophages intended to combat bacterial infections and to protect certain foods from bacterial contamination.

Viroids

It came as a surprise in 1971 to discover that viruses are not the simplest types of infectious agents. In that year, T. O. Diener of the U.S. Department of Agriculture reported that potato spindle-tuber disease, which causes potatoes to become

gnarled and cracked, is caused by an infectious agent consisting of a small circular RNA molecule that totally lacks a protein coat. Diener named the pathogen a **viroid**. The RNAs of viroids range in size from about 240 to 600 nucleotides, one-tenth the size of the smaller viruses. No evidence has been found that the naked viroid RNA encodes any proteins. Rather, any biochemical activities in which viroids engage take place using host-cell proteins. For example, duplication of the viroid RNA within an infected cell utilizes the host's RNA polymerase II, an enzyme that normally transcribes the host's DNA into messenger RNAs. Viroids are thought to cause disease by interfering with the cell's normal path of gene expression. The effect on crops can be serious: a viroid disease called *cadang-cadang* has devastated the coconut palm groves of the Philippines, and another viroid has wreaked havoc on the chrysanthemum industry in the United States. The discovery of a different type of infectious agent even simpler than a viroid is described in the Human Perspective in Chapter 2.

REVIEW

1. What properties distinguish a virus from a bacterium?
2. What types of infections are viruses able to cause?
3. Compare and contrast: nucleoid and nucleus; the flagellum of a bacterium and a sperm; an archaebacterium and a cyanobacterium; nitrogen fixation and photosynthesis; bacteriophages and tobacco mosaic virus; a provirus and a virion.

EXPERIMENTAL PATHWAYS

The Origin of Eukaryotic Cells

We have seen in this chapter that cells can be divided into two groups: prokaryotic cells and eukaryotic cells. Almost from the time this division of cellular life was proposed, biologists have been fascinated by the question: What is the origin of the eukaryotic cell? It is generally (but not universally) agreed that prokaryotic cells (1) arose before eukaryotic cells and (2) gave rise to eukaryotic cells. The first point can be verified directly from the fossil record, which shows that prokaryotic cells were present in rocks approximately 2.7 billion years old (page 7), which is roughly one billion years before any evidence is seen of eukaryotes. The second point follows from the fact that the two types of cells have to be related to one another because they share many complex traits (e.g., very similar genetic codes, enzymes, metabolic pathways, and plasma membranes) that could not have evolved independently in different organisms.

Up until about 1970, it was generally believed that eukaryotic cells evolved from prokaryotic cells by a process of gradual evolution in which the organelles of the eukaryotic cell became progressively more complex. Acceptance of this concept changed dramatically about that time largely through the work of Lynn Margulis, then at Boston University. Margulis resurrected an idea that had been proposed earlier, and dismissed, that certain organelles of a eukaryotic cell—most notably the mitochondria and chloroplasts—had evolved from smaller prokaryotic cells that had taken up residence in the cytoplasm of a larger host cell.^{1,2} This hypothesis is referred to as the

endosymbiont theory because it describes how a single “composite” cell of greater complexity could evolve from two or more separate, simpler cells living in a symbiotic relationship with one another.

Our earliest prokaryotic ancestors were presumed to have been anaerobic heterotrophic cells: *anaerobic* meaning they derived their energy from food matter without employing molecular oxygen (O₂) and *heterotrophic* meaning they were unable to synthesize organic compounds from inorganic precursors (such as CO₂ and water), but instead had to obtain preformed organic compounds from their environment.

According to one version of the endosymbiont theory, a large, anaerobic, heterotrophic prokaryote ingested a small, aerobic prokaryote (step 1, Figure 1). Resisting digestion within the cytoplasm, the small aerobic prokaryote took up residence as a permanent endosymbiont. As the host cell reproduced, so did the endosymbiont, so that a colony of these composite cells was soon produced. Over many generations, endosymbionts lost many of the traits that were no longer required for survival, and the once-independent oxygen-respiring microbes evolved into precursors of modern-day mitochondria (step 2, Figure 1).

A cell whose ancestors had formed through the sequence of symbiotic events just described could have given rise to a line of cells that evolved other basic characteristics of eukaryotic cells, including a system of membranes (a nuclear membrane, endoplasmic reticulum,

Figure 1 A model depicting possible steps in the evolution of eukaryotic cells, including the origin of mitochondria and chloroplasts by endosymbiosis. In step 1, a large anaerobic, heterotrophic prokaryote takes in a small aerobic prokaryote. Evidence strongly indicates that the engulfed prokaryote was an ancestor of modern-day rickettsia, a group of bacteria that causes typhus and other diseases. In step 2, the aerobic endosymbiont has evolved into a mitochondrion. In step 3, a portion of the plasma membrane has invaginated and is seen in the process of evolving into a nuclear envelope and associated endoplasmic reticulum. The pre-eukaryote depicted in step 3 gives rise to two major groups of eukaryotes. In one path (step 4), a primitive eukaryote evolves into nonphotosynthetic protist, fungal, and animal cells. In the other path (step 5), a primitive eukaryote takes in a photosynthetic prokaryote, which will become an endosymbiont and evolve into a chloroplast. (Note: The engulfment of the symbiont shown in step 1 could have occurred after development of some of the internal membranes, but evidence suggests it was a relatively early step in the evolution of eukaryotes.)

Golgi complex, lysosomes), a complex cytoskeleton, and a mitotic type of cell division. These characteristics are proposed to have arisen by a gradual process of evolution, rather than in a single step as might occur through acquisition of an endosymbiont. The endoplasmic reticulum and nuclear membranes, for example, might have been derived from a portion of the cell's outer plasma membrane that became internalized and then modified into a different type of membrane (step 3, Figure 1). A cell that possessed internal membrane-bound compartments would have been an ancestor of a heterotrophic eukaryotic cell, such as a fungal cell or a protist (step 4, Figure 1). The oldest fossils thought to be the remains of eukaryotes date back about 1.8 billion years.

Margulis proposed that the acquisition of another endosymbiont, specifically a cyanobacterium, converted an early heterotrophic eukaryote into an ancestor of photosynthetic eukaryotes: the green algae and plants (step 5, Figure 1).³ The acquisition of chloroplasts (roughly one billion years ago) must have been one of the last steps in the sequence of endosymbioses because these organelles are only present in plants and algae. In contrast, all known groups of eukaryotes either (1) possess mitochondria or (2) show definitive evidence they have evolved from organisms that possessed these organelles.^a The concept that mitochondria and chloroplasts arose via evolution from symbiotic organisms is now supported by an overwhelming body of evidence, some of which will be described in numerous chapters of this text.

The division of all living organisms into two categories, prokaryotes and eukaryotes, reflects a basic dichotomy in the structures of cells, but it is not necessarily an accurate phylogenetic distinction, that is, one that reflects the evolutionary relationships among living organisms. How does one determine evolutionary relationships among organisms that have been separated in time for billions of years, such as prokaryotes and eukaryotes? Most taxonomic schemes that attempt to classify organisms are based heavily on anatomic or

^aThere are a number of anaerobic unicellular eukaryotes (e.g., the intestinal parasite *Giardia*) that lack mitochondria. For years, these organisms formed the basis for a proposal that mitochondrial endosymbiosis was a late event that took place after the evolution of these mitochondria-lacking groups. However, recent analysis of the nuclear DNA of these organisms indicates the presence of genes that were likely transferred to the nucleus from mitochondria, suggesting that the ancestors of these organisms lost their mitochondria during the course of evolution.

physiologic characteristics. In 1965, Emile Zuckerkandl and Linus Pauling suggested an alternate approach based on comparisons of the structure of informational molecules (proteins and nucleic acids) of living organisms.⁴ Differences between organisms in the sequence of amino acids that make up a protein or the sequence of nucleotides that make up a nucleic acid are the result of mutations in DNA that have been transmitted to offspring. Mutations can accumulate in a given gene at a relatively constant rate over long periods of time. Consequently, comparisons of amino acid or nucleotide sequences can be used to determine how closely organisms are related to one

another. For example, two organisms that are closely related, that is, have diverged only recently from a common ancestor, should have fewer sequence differences in a particular gene than two organisms that are distantly related, that is, do not have a recent common ancestor. Using this type of sequence information as an “evolutionary clock,” researchers can construct phylogenetic trees showing proposed pathways by which different groups of living organisms may have diverged from one another during the course of evolution.

Beginning in the mid-1970s, Carl Woese and his colleagues at the University of Illinois began a series of studies that compared the nucleotide sequence in different organisms of the RNA molecule that resides in the small subunit of the ribosome. This RNA—which is called the 16S rRNA in prokaryotes or the 18S rRNA in eukaryotes—was chosen because it is present in large quantities in all cells, it is easy to purify, and it tends to change only slowly over long periods of evolutionary time, which means that it could be used to study relationships of very distantly related organisms. There was one major disadvantage: nucleic acid sequencing at the time required laborious, time-consuming methods. In their approach, they purified the 16S rRNA from a particular source, then subjected the preparation to an enzyme, T1 ribonuclease, that digests the molecule into short fragments called oligonucleotides. The oligonucleotides in the mixture were then separated from one another by two-dimensional electrophoresis to produce a two-dimensional “fingerprint” as shown in Figure 2. Once they were separated, the nucleotide sequence of each of the oligonucleotides could be determined and the sequences from various organisms compared. In one of their first studies, Woese and his colleagues analyzed the 16S rRNA present in the ribosomes of chloroplasts from the photosynthetic protist *Euglena*.⁵ They found that the sequence of this chloroplast rRNA molecule was much more similar to that of the 16S rRNA found in ribosomes of cyanobacteria than it was to its counterpart in the ribosomes from eukaryotic cytoplasm. This finding provided strong evidence for the symbiotic origin of chloroplasts from cyanobacteria.

In 1977, Woese and George Fox published a landmark paper in the study of molecular evolution.⁶ They compared the nucleotide sequences of small-subunit rRNAs that had been purified from 13 different prokaryotic and eukaryotic species. The data from a comparison of all possible pairs of these organisms are shown in Table 1. The numbers along the top identify the organisms by the same

Figure 2 Two-dimensional electrophoretic fingerprint of a T1 digest of chloroplast 16S ribosomal RNA. The RNA fragments were electrophoresed in one direction at pH 3.5 and then in a second direction at pH 2.3. (FROM L. B. ZABLEN ET AL., PROC. NAT'L. ACAD. SCI. U.S.A. 72:2419, 1975. COURTESY CARL WOESE, UNIVERSITY OF ILLINOIS.)

numbers used along the left margin of the table. Each value in the table reflects the similarity in sequence between rRNAs from the two organisms being compared: the lower the number, the less similar the two sequences. They found that the sequences clustered into three distinct groups, as indicated in the table. It is evident that the rRNAs within each group (numbers 1–3, 4–9, and 10–13) are much more similar to one another than they are to rRNAs of the other two groups. The first of the groups shown in the table contains only eukaryotes; the second group contains the “typical” bacteria (gram-positive, gram-negative, and cyanobacteria); and the third group contains several species of methanogenic (methane-producing) “bacteria.” Woese and Fox concluded, to their surprise, that the methanogenic organisms “appear to be no more related to typical bacteria than they are to eukaryotic cytoplasm.” These results suggested that the members of these three groups represent three distinct evolutionary lines that branched apart from one another at a very early stage in the evolution of cellular organisms. Consequently, they assigned these organisms to three different kingdoms, which they named the Urkaryotes, Eubacteria, and Archaeobacteria, a terminology that divided the prokaryotes into two fundamentally distinct groups.

Figure 3 A phylogenetic tree based on rRNA sequence comparisons showing the three domains of life. The Archaea are divided into two subgroups as indicated. (FROM C. R. WOESE ET AL., PROC. NAT'L. ACAD. SCI. U.S.A. 87:4578, 1990.)

Subsequent research provided support for the concept that prokaryotes could be divided into two distantly related lineages, and it expanded the ranks of the archaeobacteria to include at least two other groups, the thermophiles, which live in hot springs and ocean vents, and the halophiles, which live in very salty lakes and seas. In 1989, two published reports rooted the tree of life and suggested that the archaeobacteria were actually more closely related to eukaryotes than they were to eubacteria.^{7,8} Both groups of researchers compared the amino acid sequences of several proteins that were present in a wide variety of different prokaryotes, eukaryotes, mitochondria, and chloroplasts. A phylogenetic tree constructed from sequences of ribosomal RNAs, which comes to the same conclusion, is shown in Figure 3.⁹ In this latter paper, Woese and colleagues proposed a revised taxonomic scheme, which has been widely accepted. In this scheme, the archaeobacteria, eubacteria, and eukaryotes are assigned to separate domains, which are named Archaea, Bacteria, and Eucarya, respectively.^b Each domain can then be divided into one or more kingdoms; the Eucarya, for example, can be divided into the traditional kingdoms containing fungi, protists, plants, and animals.

According to the model in Figure 3, the first major split in the tree of life produced two separate lineages, one leading to the Bacteria and the other leading to both the Archaea and the Eucarya. If this view is correct, it was an archaeobacterium, not a eubacterium, that took in a symbiont and gave rise to the lineage that led to the first eukaryotic cells. Although the host prokaryote was presumably an archaeobacterium, the symbionts that evolved into mitochondria and chloroplasts were almost certainly eubacteria, as indicated by their close relationship with modern members of this group.

Up until 1995, phylogenetic trees of the type shown in Figure 3 were based primarily on the analysis of the gene encoding the 16S–18S rRNA. By then, phylogenetic comparisons of a number of other genes were suggesting that the scheme depicted in Figure 3 might be oversimplified. Questions about the origin of prokaryotic and eukaryotic cells came into sharp focus between 1995 and 1997 with the publication of the entire sequences of a number of prokaryotic genomes, both archaeobacterial and eubacterial, and the genome of a eukaryote, the yeast *Saccharomyces cerevisiae*. Researchers could now compare the sequences of hundreds of genes simultaneously, and this analysis raised a number of puzzling questions and blurred

^bMany biologists dislike the terms *archaeobacteria* and *eubacteria*. Although these terms have gradually faded from the literature, being replaced simply by *archaea* and *bacteria*, many researchers in this field continue to use the former terms in published articles. Given that this is an introductory chapter in an introductory text, I have continued to refer to these organisms as archaeobacteria and eubacteria to avoid possible confusion over the meaning of the term *bacterial*.

the lines of distinction between the three domains.¹⁰ For example, the genomes of several archaeobacteria showed the presence of a significant number of eubacterial genes. For the most part, those genes in archaeobacteria whose products are involved with informational processes (chromosome structure, transcription, translation, and replication) were very different from their counterparts in eubacterial cells and, in fact, resembled the corresponding genes in eukaryotic cells. This observation fit nicely with the scheme in Figure 3. In contrast, many of the genes in archaeobacteria that encode the enzymes of metabolism exhibited an unmistakable eubacterial character.^{11,12} The genomes of eubacterial species also showed evidence of a mixed origin, often containing a significant number of genes that bore an archaeobacterial character.¹³

Most investigators who study the origin of ancient organisms have held on to the basic outline of the phylogenetic tree as demarcated in Figure 3 and argue that the presence of eubacteria-like genes in archaeobacteria, and vice versa, is the result of the transfer of genes from one species to another, a phenomenon referred to as *lateral gene transfer (LGT)*.¹⁴ According to the original premise that led to the phylogenetic tree of Figure 3, genes are inherited from one's parents, not from one's neighbors. This is the premise that allows an investigator to conclude that two species are closely related when they both possess a gene (e.g., the rRNA gene) of similar nucleotide sequence. If, however, cells can pick up genes from other species in their environment, then two species that are actually unrelated may possess genes of very similar sequence. An early measure of the importance of lateral gene transfer in the evolution of prokaryotes came from a study that compared the genomes of two related eubacteria, *Escherichia* and *Salmonella*. It was found that 755 genes or nearly 20 percent of the *E. coli* genome is derived from “foreign” genes transferred into the *E. coli* genome over the past 100 million years, which is the time when the two eubacteria diverged. These 755 genes were acquired as the result of at least 234 separate lateral transfers from many different sources.¹⁵ (The effect of lateral gene transfer on antibiotic resistance in pathogenic bacteria is discussed in the Human Perspective of Chapter 3.)

If genomes are a mosaic composed of genes from diverse sources, how does one choose which genes to use in determining phylogenetic relationships? According to one viewpoint, genes that are involved in informational activities (transcription, translation, replication) make the best subjects for determining phylogenetic relationships, because such genes are less likely to be transferred laterally than genes involved in metabolic reactions.¹⁶ These authors argue that the products of informational genes (e.g., rRNAs) are parts of large complexes whose components must interact with many other molecules. It is unlikely that a foreign gene product could

become integrated into the existing machinery. When “informational genes” are used as the subjects of comparison, archaeobacteria and eubacteria tend to separate into distinctly different groups, whereas archaeobacteria and eukaryotes tend to group together as evolutionary relatives, just as they do in Figure 3. ^{See reference 17 for further discussion.}

Analysis of eukaryotic genomes have produced similar evidence of a mixed heritage. Studies of the yeast genome show unmistakable presence of genes derived from both archaeobacteria and eubacteria. The “informational genes” tend to have an archaeal character and the “metabolic genes” a eubacterial character.¹⁸ There are several possible explanations for the mixed character of the eukaryotic genome. Eukaryotic cells may have evolved from archaeobacterial ancestors and then picked up genes from eubacteria with which they shared environments. In addition, some of the genes in the nucleus of a eukaryotic cell are clearly derived from eubacterial genes that have been transferred from the genome of the symbionts that evolved into mitochondria and chloroplasts.¹⁹ A number of researchers have taken a more radical position and proposed that the eukaryote genome was originally derived from the fusion of an archaeobacterial and a eubacterial cell followed by the integration of their two genomes.^{e.g., 20} Given these various routes of gene acquisition, it is evident that no simple phylogenetic tree, such as that depicted in Figure 3, can represent the evolutionary history of the entire genome of an organism.^{Reviewed in 21–23} Instead, each gene or group of genes of a particular genome may have its own unique evolutionary tree, which can be a disconcerting thought to scientists seeking to determine the origin of our earliest eukaryotic ancestors.

Synopsis

The cell theory has three tenets. (1) All organisms are composed of one or more cells; (2) the cell is the basic organizational unit of life; and (3) all cells arise from preexisting cells. (p. 2)

The properties of life, as exhibited by cells, can be described by a collection of properties. Cells are very complex and their substructure is highly organized and predictable. The information to build a cell is encoded in its genes. Cells reproduce by cell division; their activities are fueled by chemical energy; they carry out enzymatically controlled chemical reactions; they engage in numerous mechanical activities; they respond to stimuli; and they are capable of a remarkable level of self-regulation. (p. 3)

Cells are either prokaryotic or eukaryotic. Prokaryotic cells are found only among archaeobacteria and eubacteria, whereas all other types of organisms—protists, fungi, plants, and animals—are composed of eukaryotic cells. Prokaryotic and eukaryotic cells share many common features, including a similar cellular membrane, a common system for storing and using genetic information, and similar metabolic pathways. Prokaryotic cells are the simpler type,

lacking the complex membranous organelles (e.g., endoplasmic reticulum, Golgi complex, mitochondria, and chloroplasts), chromosomes, and cytoskeleton characteristic of the cells of eukaryotes. The two cell types can also be distinguished by their mechanism of cell division, their locomotor structures, and the type of cell wall they produce (if a cell wall is present). Complex plants and animals contain many different types of cells, each specialized for particular activities. (p.7)

Cells are almost always microscopic in size. Bacterial cells are typically 1 to 5 μm in length, whereas eukaryotic cells are typically 10 to 30 μm . Cells are microscopic in size for a number of reasons: their nuclei possess a limited number of copies of each gene; the surface area (which serves as the cell's exchange surface) becomes limiting as a cell increases in size; and the distance between the cell surface and interior becomes too great for the cell's needs to be met by simple diffusion. (p. 17)

Viruses are noncellular pathogens that can only reproduce when present within a living cell. Outside of the cell, the virus exists as a

macromolecular package, or virion. Virions occur in a variety of shapes and sizes, but all of them consist of viral nucleic acid enclosed in a wrapper containing viral proteins. Viral infections may lead to either (1) the destruction of the host cell with accompanying pro-

duction of viral progeny, or (2) the integration of viral nucleic acid into the DNA of the host cell, which often alters the activities of that cell. Viruses are not considered to be living organisms. (p. 23)

Analytic Questions

1. Consider some question about cell structure or function that you would be interested in answering. Would the data required to answer the question be easier to collect by working on an entire plant or animal or on a population of cultured cells? What might be the advantages and disadvantages of working on a whole organism versus a cell culture?
2. Figure 1.3 shows an intestinal epithelial cell with large numbers of microvilli. What is the advantage to the organism of having these microvilli? What do you expect would happen to an individual that lacked such microvilli as the result of an inherited mutation?
3. The first human cells to be successfully cultured were derived from a malignant tumor. Do you think this simply reflects the availability of cancer cells, or might such cells be better subjects for cell culture? Why?
4. The drawings of plant and animal cells in Figure 1.8*b,c* include certain structures that are present in plant cells but absent in animal cells. How do you think each of these structures affects the life of the plant?
5. It was noted that cells possess receptors on their surface that allow them to respond to specific stimuli. Many cells in the human body possess receptors that allow them to bind specific hormones that circulate in the blood. Why do you think these hormone receptors are important? What would be the effect on the physiological activities of the body if cells lacked these receptors, or if all cells had the same receptors?
6. If you were to argue that viruses are living organisms, what features of viral structure and function might you use in your argument?
7. If we presume that activities within cells do occur in a manner analogous to that shown in the Rube Goldberg cartoon of Figure 1.7, how would this differ from a human activity, such as building a car on an assembly line or shooting a free throw in a basketball game?
8. Unlike bacterial cells, the nucleus of a eukaryotic cell is bounded by a double-layered membrane studded by complex pores. How do you think this might affect traffic between the DNA and cytoplasm of a eukaryotic cell compared to that of a prokaryotic cell?
9. Examine the photograph of the ciliated protist in Figure 1.16 and consider some of the activities in which this cell engages that a muscle or nerve cell in your body does not.
10. Which type of cell would you expect to achieve the largest volume: a highly flattened cell or a spherical cell? Why?
11. Suppose you were a scientist living in the 1890s and were studying a disease of tobacco crops that stunted the growth of the plants and mottled their leaves. You find that the sap from a diseased plant, when added to a healthy plant, is capable of transmitting the disease to that plant. You examine the sap in the best light microscopes of the period and see no evidence of bacteria. You force the sap through filters whose pores are so small that they retard the passage of the smallest known bacteria, yet the fluid that passes through the filters is still able to transmit the disease. Like Dimitri Ivanovsky, who conducted these experiments more than a hundred years ago, you would probably conclude that the infectious agent was an unknown type of unusually small bacterium. What kinds of experiments might you perform today to test this hypothesis?
12. Most evolutionary biologists believe that all mitochondria have evolved from a single ancestral mitochondrion and all chloroplasts have evolved from a single ancestral chloroplast. In other words, the symbiotic event that gave rise to each of these organelles occurred only once. If this is the case, where on the phylogenetic tree of Figure 3, page 29, would you place the acquisition of each of these organelles?
13. Publication of the complete sequence of the 1918 flu virus and reconstitution of active viral particles was met with great controversy. Those who favored publication of the work argued that this type of information can help to better understand the virulence of influenza viruses and help develop better therapeutics against them. Those opposed to its publication argued that the virus could be reconstituted by bioterrorists or that another pandemic could be created by the accidental release of the virus by a careless investigator. What is your opinion on the merits of conducting this type of work?

Protein Misfolding Can Have Deadly Consequences

EXPERIMENTAL PATHWAYS: Chaperones: Helping
Proteins Reach Their Proper Folded State

We will begin this chapter with a brief examination of the atomic basis of matter, a subject that may seem out of place in a biology textbook. Yet life is based on the properties of atoms and is governed by the same principles of chemistry and physics as all other types of matter. The cellular level of organization is only a small step from the atomic level, as will become evident when we examine the importance of the movement of a few atoms of a molecule during such activities as muscle contraction or the transport of substances across cell membranes. The properties of cells and their organelles derive directly from the activities of the molecules of which they are composed. Consider a process such as cell division, which can be followed in considerable detail under a simple light microscope. To understand the activities that occur when a cell divides, one needs to know, for example, about the interactions between DNA and protein molecules that cause the chromosomes to condense into rod-shaped packages that can be separated into different cells; the molecular construction of protein-containing microtubules that allows them to disassemble at one moment in the cell and reassemble the next moment in an entirely different cellular location; and the properties of lipid molecules that make the outer cell membrane deformable so that it can be pulled into the middle of a cell, thereby pinching the cell in two. It is impossible even to begin to understand

A complex between two different macromolecules. A portion of a DNA molecule (shown in blue) is complexed to a protein that consists of two polypeptide subunits, one red and the other yellow. Those parts of the protein that are seen to be inserted into the grooves of the DNA have recognized and bound to a specific sequence of nucleotides in the nucleic acid molecule. (COURTESY OF A. R. FERRÉ-D'AMARÉ AND STEPHEN K. BURLEY.)

cellular function without a reasonable knowledge of the structure and properties of the major types of biological molecules. This is the goal of the present chapter: to provide the necessary

information about the chemistry of life to allow the reader to understand the basis of life. We will begin by considering the types of bonds that atoms can form with one another.

2.1 | Covalent Bonds

The atoms that make up a molecule are joined together by **covalent bonds** in which pairs of electrons are shared between pairs of atoms. The formation of a covalent bond between two atoms is governed by the fundamental principle that an atom is most stable when its outermost electron shell is filled. Consequently, the number of bonds an atom can form depends on the number of electrons needed to fill its outer shell.

The electronic structure of a number of atoms is shown in Figure 2.1. The outer (and only) shell of a hydrogen or helium

atom is filled when it contains two electrons; the outer shells of the other atoms in Figure 2.1 are filled when they contain eight electrons. Thus, an oxygen atom, with six outer-shell electrons, can fill its outer shell by combining with two hydrogen atoms, forming a molecule of water. The oxygen atom is linked to each hydrogen atom by a *single* covalent bond (denoted as H:O or H—O). The formation of a covalent bond is accompanied by the release of energy, which must be reabsorbed at some later time if the bond is to be broken. The energy required to cleave C—H, C—C, or C—O covalent bonds is quite large—typically between 80 and 100 kilocalories per mole (kcal/mol)¹ of molecules—making these bonds stable under most conditions.

¹One calorie is the amount of thermal energy required to raise the temperature of one gram of water one degree centigrade. One kilocalorie (kcal) equals 1000 calories (or one large Calorie). In addition to calories, energy can also be expressed in Joules, which is a term that was used historically to measure energy in the form of work. One kilocalorie is equivalent to 4186 Joules. Conversely, 1 Joule = 0.239 calories. A mole is equal to Avogadro's number (6×10^{23}) of molecules. A mole of a substance is its molecular weight expressed in grams.

Figure 2.1 A representation of the arrangement of electrons in a number of common atoms. Electrons are present around an atom's nucleus in "clouds" or *orbitals* that are roughly defined by their boundaries, which may have a spherical or dumbbell shape. Each orbital contains a maximum of two electrons, which is why the electrons (dark dots in the drawing) are grouped in pairs. The innermost shell contains a single orbital (thus two electrons), the second shell contains four orbitals (thus eight electrons), the third shell also contains four orbitals, and so forth. The number of outer-shell electrons is a primary

determinant of the chemical properties of an element. Atoms with a similar number of outer-shell electrons have similar properties. Lithium (Li) and sodium (Na), for example, have one outer-shell electron, and both are highly reactive metals. Carbon (C) and silicon (Si) atoms can each bond with four different atoms. Because of its size, however, a carbon atom can bond to other carbon atoms, forming long-chained organic molecules, whereas silicon is unable to form comparable molecules. Neon (Ne) and argon (Ar) have filled outer shells, making these atoms highly nonreactive; they are referred to as inert gases.

In many cases, two atoms can become joined by bonds in which more than one pair of electrons are shared. If two electron pairs are shared, as occurs in molecular oxygen (O₂), the covalent bond is a *double bond*, and if three pairs of electrons are shared (as in molecular nitrogen, N₂), it is a *triple bond*. Quadruple bonds are not known to occur. The type of bond between atoms has important consequences in determining the shapes of molecules. For example, atoms joined by a single bond are able to rotate relative to one another, whereas the atoms of double (and triple) bonds lack this ability. As illustrated in Figure 6.6, double bonds can function as energy-capturing centers, driving such vital processes as respiration and photosynthesis.

When atoms of the same element bond to one another, as in H₂, the electron pairs of the outer shell are equally shared between the two bonded atoms. When two unlike atoms are covalently bonded, however, the positively charged nucleus of one atom exerts a greater attractive force on the outer electrons than the other. Consequently, the shared electrons tend to be located more closely to the atom with the greater attractive force, that is, the more **electronegative atom**. Among the atoms most commonly present in biological molecules, nitrogen and oxygen are strongly electronegative.

Polar and Nonpolar Molecules

Let's examine a molecule of water. Water's single oxygen atom attracts electrons much more forcefully than do either of its hydrogen atoms. As a result, the O—H bonds of a water molecule are said to be *polarized*, such that one of the atoms has a partial negative charge and the other a partial positive charge. This is generally denoted in the following manner:

Molecules, such as water, that have an asymmetric distribution of charge (or *dipole*) are referred to as **polar** molecules. Polar molecules of biological importance contain one or more electronegative atoms, usually O, N, and/or S. Molecules that lack electronegative atoms and strongly polarized bonds, such as molecules that consist entirely of carbon and hydrogen atoms, are said to be **nonpolar**. The presence of strongly polarized bonds is of utmost importance in determining the reactivity of molecules. Large nonpolar molecules, such as waxes and fats, are relatively inert. Some of the more interesting biological molecules, including proteins and phospholipids, contain both polar and nonpolar regions, which behave very differently.

Ionization

Some atoms are so strongly electronegative that they can capture electrons from other atoms during a chemical reaction. For example, when the elements sodium (a silver-colored metal) and chlorine (a toxic gas) are mixed, the single electron in the outer shell of each sodium atom migrates to the electron-deficient chlorine atom. As a result, these two atoms are transformed into charged **ions**.

Because the chloride ion has an extra electron (relative to the number of protons in its nucleus), it has a negative charge (Cl⁻) and is termed an **anion**. The sodium atom, which has lost an electron, has an extra positive charge (Na⁺) and is termed a **cation**. When present in crystals, these two ions form sodium chloride, or table salt.

The Na⁺ and Cl⁻ ions depicted above are relatively stable because they possess filled outer shells. A different arrangement of electrons within an atom can produce a highly reactive species, called a *free radical*. The structure of free radicals and their importance in biology are considered in the accompanying Human Perspective.

REVIEW

1. Oxygen atoms have eight protons in their nucleus. How many electrons do they have? How many orbitals are in the inner electron shell? How many electrons are in the outer shell? How many more electrons can the outer shell hold before it is filled?
2. Compare and contrast: a sodium atom and a sodium ion; a double bond and a triple bond; an atom of weak and strong electronegativity; the electron distribution around an oxygen atom bound to another oxygen atom and an oxygen atom bound to two hydrogen atoms.

2.2 | Noncovalent Bonds

Covalent bonds are strong bonds between the atoms that make up a molecule. Interactions between molecules (or between different parts of a large biological molecule) are governed by a variety of weaker linkages called noncovalent bonds. **Noncovalent bonds** do not depend on shared electrons but rather on attractive forces between atoms having an opposite charge. Individual noncovalent bonds are weak (about 1 to 5 kcal/mol) and are thus readily broken and reformed. As will be evident throughout this book, this feature allows noncovalent bonds to mediate the dynamic interactions among molecules in the cell.

Even though individual noncovalent bonds are weak, when large numbers of them act in concert, as between the two strands of a DNA molecule or between different parts of a large protein, their attractive forces are additive. Taken as a whole, they provide the structure with considerable stability.

THE HUMAN PERSPECTIVE

Free Radicals as a Cause of Aging

During the course of this textbook, we will discuss several different biological factors that are thought to contribute to the process of aging. Here we will consider one of these factors: the gradual accumulation of damage to our body's tissues. The most destructive damage probably occurs to DNA. Alterations in DNA lead to the production of faulty genetic messages that promote gradual cellular deterioration. How does cellular damage occur, and why should it occur more rapidly in a shorter lived animal, such as a chimpanzee, than a human? The answer may reside at the atomic level.

Atoms are stabilized when their shells are filled with electrons. Electron shells consist of orbitals, each of which can hold a maximum of two electrons. Atoms or molecules that have orbitals containing a single unpaired electron tend to be highly unstable—they are called **free radicals**. Free radicals may be formed when a covalent bond is broken such that each portion keeps one-half of the shared electrons, or they may be formed when an atom or molecule accepts a single electron transferred during an oxidation–reduction reaction. For example, water can be converted into free radicals when exposed to radiation from the sun:

Free radicals are extremely reactive and capable of chemically altering many types of molecules, including proteins, nucleic acids, and lipids. This is illustrated by the fact that certain cells of the immune system generate free radicals within their cytoplasm as a means to kill bacteria that these immune cells have ingested. The formation of hydroxyl radicals is probably a major reason that sunlight is so damaging to skin.

In 1956, Denham Harman of the University of Nebraska proposed that aging results from tissue damage caused by free radicals. Because the subject of free radicals was not one with which biologists and physicians were familiar, the proposal failed to generate significant interest. Then, in 1969, Joe McCord and Irwin Fridovich of Duke University discovered an enzyme, superoxide dismutase (SOD), whose sole function was the destruction of the superoxide radical ($\text{O}_2^{\cdot-}$), a type of free radical formed when molecular oxygen picks up an extra electron. SOD catalyzes the following reaction:

Hydrogen peroxide is also a potentially reactive oxidizing agent, which is why it is often used as a disinfectant and bleaching agent. If it is not rapidly destroyed, H_2O_2 can break down to form hydroxyl radicals that attack the cell's macromolecules. Hydrogen peroxide is normally destroyed in the cell by the enzymes catalase or glutathione peroxidase.

Subsequent research has revealed that superoxide radicals are formed within cells during normal oxidative metabolism and that a superoxide dismutase is present in the cells of diverse organisms, from bacteria to humans. In fact, animals possess three different versions (isoforms) of SOD: a cytosolic, mitochondrial, and extracellular isoform. It is estimated that as much as 1–2 percent of the oxygen taken into human mitochondria can be converted to hydrogen peroxide rather than to water, the normal end product of respiration. The importance of SOD is most clearly revealed in studies of mutant bacteria and yeast that lack the enzyme; these cells are unable to grow in the presence of oxygen. Similarly, mice that are lacking the mitochondrial version of the enzyme (SOD2) are not able to survive more than a week or so after birth. Conversely, mice that have been genetically engineered so that their mitochondria contain elevated levels of the H_2O_2 -destroying enzyme catalase live 20 percent longer, on average, than untreated controls. This finding, reported in 2005, marked the first demonstration that enhanced antioxidant defenses can increase the life span of a mammal. Although the destructive potential of free radicals, such as superoxide and hydroxyl radicals, is unquestioned, the importance of these agents as a factor in aging remains controversial.

A related area of research concerns the study of substances called antioxidants that are able to destroy free radicals in the test tube. The sale of these substances provides a major source of revenue for the vitamin/supplements industry. Common antioxidants found in the body include glutathione, vitamins E and C, and beta-carotene (the orange pigment in carrots and other vegetables). Although these substances may prove beneficial in the diet because of their ability to destroy free radicals, studies with rats and mice have failed to provide convincing evidence that they retard the aging process or increase maximum life span.

We will examine several types of noncovalent bonds that are important in cells.

Ionic Bonds: Attractions between Charged Atoms

A crystal of table salt is held together by an electrostatic attraction between positively charged Na^+ and negatively charged Cl^- ions. This type of attraction between fully charged components is called an **ionic bond** (or a *salt bridge*). Ionic bonds within a salt crystal may be quite strong. How-

ever, if a crystal of salt is dissolved in water, each of the individual ions becomes surrounded by water molecules, which inhibit oppositely charged ions from approaching one another closely enough to form ionic bonds (Figure 2.2). Because cells are composed primarily of water, bonds between *free* ions are of little importance. In contrast, weak ionic bonds between oppositely charged groups of large biological molecules are of considerable importance. For example, when negatively charged phosphate atoms in a DNA molecule are closely associated with positively charged groups on the surface of a

Figure 2.2 The dissolution of a salt crystal. When placed in water, the Na^+ and Cl^- ions of a salt crystal become surrounded by water molecules, breaking the ionic bonds between the two ions. As the salt dissolves, the negatively charged oxygen atoms of the water molecules associate with the positively charged sodium ions, and the positively charged hydrogen atoms of the water molecules associate with the negatively charged chloride ions.

protein (Figure 2.3), ionic bonds between them help hold the complex together. The strength of ionic bonds in a cell is generally weak (about 3 kcal/mol) due to the presence of water, but deep within the core of a protein, where water is often excluded, such bonds can be much stronger.

Hydrogen Bonds

When a hydrogen atom is covalently bonded to an electronegative atom, particularly an oxygen or a nitrogen atom, the single pair of shared electrons is greatly displaced toward the nucleus of the electronegative atom, leaving the hydrogen atom with a partial positive charge. As a result, the bare, positively charged nucleus of the hydrogen atom can approach near enough to an unshared pair of outer electrons of a second electronegative atom to form an attractive interaction (Figure 2.4). This weak attractive interaction is called a **hydrogen bond**.

Hydrogen bonds occur between most polar molecules and are particularly important in determining the structure and properties of water (discussed later). Hydrogen bonds also form between polar groups present in large biological molecules, as occurs between the two strands of a DNA molecule (see Figure 2.3). Because their strength is additive, the large number of hydrogen bonds between the strands makes the DNA duplex a stable structure. However, because individual hydrogen bonds are weak (2–5 kcal/mol), the two strands can be partially separated to allow enzymes access to individual strands of the DNA molecule.

Hydrophobic Interactions and van der Waals Forces

Because of their ability to interact with water, polar molecules, such as sugars and amino acids (described shortly), are said to

Figure 2.3 Noncovalent ionic bonds play an important role in holding the protein molecule on the right (yellow atoms) to the DNA molecule on the left. Ionic bonds form between positively charged nitrogen atoms in the protein and negatively charged oxygen atoms in the DNA. The DNA molecule itself consists of two separate strands held together by noncovalent hydrogen bonds. Although a single noncovalent bond is relatively weak and easily broken, large numbers of these bonds between two molecules, as between two strands of DNA, make the overall complex quite stable. (TOP IMAGE COURTESY OF STEPHEN HARRISON.)

be **hydrophilic**, or “water loving.” Nonpolar molecules, such as steroid or fat molecules, are essentially insoluble in water because they lack the charged regions that would attract them to the poles of water molecules. When nonpolar compounds are mixed with water, the nonpolar, **hydrophobic** (“water fearing”) molecules are forced into aggregates, which minimizes their exposure to the polar surroundings (Figure 2.5).

Figure 2.4 Hydrogen bonds form between a bonded electronegative atom, such as nitrogen or oxygen, which bears a partial negative charge, and a bonded hydrogen atom, which bears a partial positive charge. Hydrogen bonds (about 0.18 nm) are typically about twice as long as the much stronger covalent bonds.

This association of nonpolar molecules is called a **hydrophobic interaction**. This is why droplets of fat molecules rapidly reappear on the surface of beef or chicken soup even after the liquid is stirred with a spoon. This is also the reason that nonpolar groups tend to localize within the interior of most soluble proteins away from the surrounding water molecules.

Figure 2.5 In a hydrophobic interaction, the nonpolar (hydrophobic) molecules are forced into aggregates, which minimizes their exposure to the surrounding water molecules.

Hydrophobic interactions of the type just described are not classified as true bonds because they do not result from an attraction between hydrophobic molecules.² In addition to this type of interaction, hydrophobic groups can form weak bonds with one another based on electrostatic attractions. Polar molecules associate because they contain permanent asymmetric charge distributions within their structure. Closer examination of the covalent bonds that make up a nonpolar molecule (such as H_2 or CH_4) reveals that electron distributions are not always symmetric. The distribution of electrons around an atom at any given instant is a statistical matter and, therefore, varies from one instant to the next. Consequently, at any given time, the electron density may happen to be greater on one side of an atom, even though the atom shares the electrons equally with some other atom. These transient asymmetries in electron distribution result in momentary separations of charge (*dipoles*) within the molecule. If two molecules with transitory dipoles are very close to one another and oriented in the appropriate manner, they experience a weak attractive force, called a **van der Waals force**, that bonds them together. Moreover, the formation of a temporary separation of charge in one molecule can *induce* a similar separation in an adjacent molecule. In this way, additional attractive forces can be generated between nonpolar molecules. A single van der Waals force is very weak (0.1 to 0.3 kcal/mol) and very sensitive to the distance that separates the two atoms (Figure 2.6a). As we will see in later chapters, however, biological molecules that interact with one another, for example, an antibody and a protein on the surface of a virus, often possess complementary shapes. As a result, many atoms of both interactants may have the opportunity to approach each other very closely (Figure 2.6b), making van der Waals forces important in biological interactions.

The Life-Supporting Properties of Water

Life on Earth is totally dependent on water, and water may be essential to the existence of life anywhere in the universe. Even though it contains only three atoms, a molecule of water has a unique structure that gives the molecule extraordinary properties.³ Most importantly,

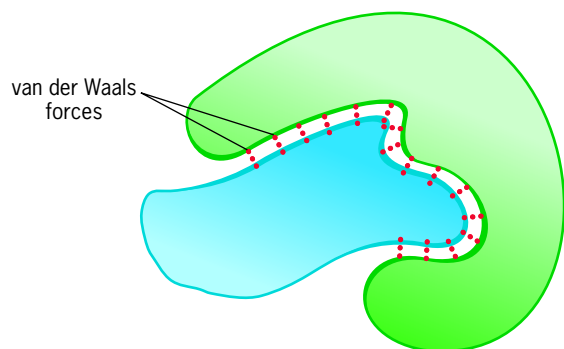

1. Water is a highly asymmetric molecule with the O atom at one end and the two H atoms at the opposite end.
2. Each of the two covalent bonds in the molecule is highly polarized.

²This statement reflects an accepted hypothesis that hydrophobic interactions are driven by increased entropy (disorder). When a hydrophobic group projects into an aqueous solvent, the water molecules become ordered in a cage around the hydrophobic group. These solvent molecules become disordered when the hydrophobic group withdraws from the surrounding solvent. A discussion of this and other views can be found in *Nature* 437:640, 2005 and *Curr. Opin. Struct. Biol.* 16:152, 2006.

³One way to appreciate the structure of water is by comparing it to H_2S . Like oxygen, sulfur has six outer-shell electrons and forms single bonds with two hydrogen atoms. But because sulfur is a larger atom, it is less electronegative than oxygen, and its ability to form hydrogen bonds is greatly reduced. At room temperature, H_2S is a gas, not a liquid. In fact, the temperature has to drop to -86°C before H_2S freezes into a solid.

(a)

(b)

Figure 2.6 Van der Waals forces. (a) As two atoms approach each other, they experience a weak attractive force that increases up to a specific distance, typically about 4 Å. If the atoms approach more closely, their electron clouds repel one another, causing the atoms to be forced apart. (b) Although individual van der Waals forces are very weak and transient, large numbers of such attractive forces can be formed if two macromolecules have a complementary surface, as is indicated schematically in this figure (see Figure 2.40 for an example).

- All three atoms in a water molecule are adept at forming hydrogen bonds.

The life-supporting attributes of water stem from these properties.

Each molecule of water can form hydrogen bonds with as many as four other water molecules, producing a highly interconnected network of molecules (Figure 2.7). Each hydrogen bond is formed when the partially positive-charged hydrogen of one water molecule becomes aligned next to a partially negative-charged oxygen atom of another water molecule. Because of their extensive hydrogen bonding, water molecules have an unusually strong tendency to adhere to one another. This feature is most evident in the thermal properties of water. For example, when water is heated, most of the thermal energy is consumed in disrupting hydrogen bonds rather than contributing to molecular motion (which is measured as an increased temperature). Similarly, evaporation from the liquid to the gaseous state requires that water molecules break the hydrogen bonds holding them to their neighbors, which is why it takes so much energy to convert water to steam. Mam-

Figure 2.7 Hydrogen bond formation between neighboring water molecules. Each H atom of the molecule has about four-tenths of a full positive charge, and the single O atom has about eight-tenths of a full negative charge.

mals take advantage of this property when they sweat because the heat required to evaporate the water is absorbed from the body, which thus becomes cooler.

The small volume of aqueous fluid present within a cell contains a remarkably complex mixture of dissolved substances, or *solutes*. In fact, water is able to dissolve more types of substances than any other solvent. But water is more than just a solvent; it determines the structure of biological molecules and the types of interactions in which they can engage. Water is the fluid matrix around which the insoluble fabric of the cell is constructed. It is also the medium through which materials move from one compartment of the cell to another; it is a reactant or product in many cellular reactions; and it protects the cell in many ways—from excessive heat, cold, or damaging radiation.

Water is such an important factor in a cell because it is able to form weak interactions with so many different types of chemical groups. Recall from page 35 how water molecules, with their strongly polarized O—H bonds, form a shell around ions, separating the ions from one another. Similarly, water molecules form hydrogen bonds with organic molecules that contain polar groups, such as amino acids and sugars, which ensures their solubility within the cell. Water also plays a key role in maintaining the structure and function of macromolecules and the complexes that they form (such as membranes). Figure 2.8 shows the ordered arrangement of water molecules between two subunits of a protein molecule. The water molecules are hydrogen bonded to each other and to specific amino acids of the protein.

REVIEW

- Describe some of the properties that distinguish covalent and noncovalent bonds.
- Why do polar molecules, such as table sugar, dissolve so readily in water? Why do fat droplets form on the surface of an aqueous solution? Why does sweating help cool the body?

Figure 2.8 The importance of water in protein structure. The water molecules (each with a single red oxygen atom and two smaller gray hydrogen atoms) are shown in their ordered locations between the two subunits of a clam hemoglobin molecule. 2.3 | Acids, Bases, and Buffers

Protons are not only found within atomic nuclei, they are also released into the medium whenever a hydrogen atom loses a shared electron. Consider acetic acid—the distinctive ingredient of vinegar—which can undergo the following reaction, described as a *dissociation*.

A molecule that is capable of releasing (donating) a hydrogen ion is termed an **acid**. The proton released by the acetic acid molecule in the previous reaction does not remain in the free state; instead, it combines with another molecule. Possible reactions involving a proton include

- Combination with a water molecule to form a hydronium ion (H_3O^+).

- Combination with a hydroxyl ion (OH^-) to form a molecule of water.

- Combination with an amino group ($-\text{NH}_2$) in a protein to form a charged amine.

Table 2.1 Strengths of Acids and Bases

	Acids		Bases
Very weak	H_2O	OH^-	Strong
Weak	NH_4^+	NH_3	Weak
	H_2S	S^{2-}	
	CH_3COOH	CH_3COO^-	
	H_2CO_3	HCO_3^-	
Strong	H_3O^+	H_2O	Very weak
	HCl	Cl^-	
	H_2SO_4	SO_4^{2-}	

Any molecule that is capable of accepting a proton is defined as a **base**. Acids and bases exist in pairs, or *couples*. When the acid loses a proton (as when acetic acid gives up a hydrogen ion), it becomes a base (in this case, acetate ion), which is termed the *conjugate base* of the acid. Similarly, when a base (such as an $-\text{NH}_2$ group) accepts a proton, it forms an acid (in this case $-\text{NH}_3^+$), which is termed the *conjugate acid* of that base. Thus, the acid always contains one more positive charge than its conjugate base. Water is an example of an *amphoteric* molecule, that is, one that can serve both as an acid and a base:

We will discuss another important group of amphoteric molecules, the amino acids, on page 50.

Acids vary markedly with respect to the ease with which the molecule gives up a proton. The more readily the proton is lost, that is, the less strong the attraction of a conjugate base for its proton, the stronger the acid. Hydrogen chloride is a very strong acid, one that will readily transfer its proton to water molecules. The conjugate base of a strong acid, such as HCl , is a weak base (Table 2.1). Acetic acid, in contrast, is a relatively weak acid because for the most part it remains undissociated when dissolved in water. In a sense, one can consider the degree of dissociation of an acid in terms of the competition for protons among the components of a solution. Water is a better competitor, that is, a stronger base, than chloride ion, so HCl completely dissociates. In contrast, acetate ion is a stronger base than water, so it remains largely as undissociated acetic acid.

The acidity of a solution is measured by the concentration of hydrogen ions⁴ and is expressed in terms of **pH**.

$$\text{pH} = -\log [\text{H}^+]$$

where $[\text{H}^+]$ is the molar concentration of protons. For example, a solution having a pH of 5 contains a hydrogen ion concentration of 10^{-5} M. Because the pH scale is logarithmic, an increase of one pH unit corresponds to a tenfold decrease in H^+ concentration (or a tenfold increase in OH^- concentration). Stomach juice (pH 1.8), for example, has nearly one million times the H^+ concentration of blood (pH 7.4).

⁴In aqueous solutions, protons do not exist in the free state, but rather as H_3O^+ or H_5O_2^+ . For the sake of simplicity, we will refer to them simply as protons or hydrogen ions.

When a water molecule dissociates into a hydroxyl ion and a proton, $\text{H}_2\text{O} \rightarrow \text{H}^+ + \text{OH}^-$, the equilibrium constant for the reaction can be expressed as:

$$K_{\text{eq}} = \frac{[\text{H}^+][\text{OH}^-]}{\text{H}_2\text{O}}$$

Because the concentration of pure water is always 55.51 M, we can generate a new constant, K_{w} , the *ion-product constant* for water,

$$K_{\text{w}} = [\text{H}^+][\text{OH}^-]$$

which is equal to 10^{-14} at 25°C . In pure water, the concentration of both H^+ and OH^- is approximately 10^{-7} M. The extremely low level of dissociation of water indicates that it is a very weak acid. In the presence of an acid, the concentration of hydrogen ions rises and the concentration of hydroxyl ions drops (as a result of combination with protons to form water), so that the ion product remains at 10^{-14} .

Most biological processes are acutely sensitive to pH because changes in hydrogen ion concentration affect the ionic state of biological molecules. For example, as the hydrogen ion concentration increases, the $-\text{NH}_2$ group of the amino acid arginine becomes protonated to form $-\text{NH}_3^+$, which can disrupt the activity of the entire protein. Even slight changes in pH can impede biological reactions. Organisms, and the cells they comprise, are protected from pH fluctuations by **buffers**—compounds that react with free hydrogen or hydroxyl ions, thereby resisting changes in pH. Buffer solutions usually contain a weak acid together with its conjugate base. Blood, for example, is buffered by carbonic acid and bicarbonate ions, which normally hold blood pH at about 7.4.

If the hydrogen ion concentration rises (as occurs during exercise), the bicarbonate ions combine with the excess protons, removing them from solution. Conversely, excess OH^- ions (which are generated during hyperventilation) are neutralized by protons derived from carbonic acid. The pH of the fluid within the cell is regulated in a similar manner by a phosphate buffer system consisting of H_2PO_4^- and HPO_4^{2-} .

REVIEW

1. If you were to add hydrochloric acid to water, what effect would this have on the hydrogen ion concentration? on the pH? on the ionic charge of any proteins in solution?
2. What is the relationship between a base and its conjugate acid?

2.4 | The Nature of Biological Molecules

The bulk of an organism is water. If the water is evaporated away, most of the remaining dry weight consists of molecules containing atoms of carbon. When first discovered, it was

thought that carbon-containing molecules were present only in living organisms and thus were referred to as *organic molecules* to distinguish them from *inorganic molecules* found in the inanimate world. As chemists learned to synthesize more and more of these carbon-containing molecules in the lab, the mystique associated with organic compounds disappeared. The compounds produced by living organisms are called **biochemicals**.

The chemistry of life centers around the chemistry of the carbon atom. The essential quality of carbon that has allowed it to play this role is the incredible number of molecules it can form. Having four outer-shell electrons, a carbon atom can bond with up to four other atoms. Most importantly, each carbon atom is able to bond with other carbon atoms so as to construct molecules with backbones containing long chains of carbon atoms. Carbon-containing backbones may be linear, branched, or cyclic.

Cholesterol, whose structure is depicted in Figure 2.9, illustrates various arrangements of carbon atoms.

Both the size and electronic structure of carbon make it uniquely suited for generating large numbers of molecules, several hundred thousand of which are known. In contrast, silicon, which is just below carbon in the periodic table and also has four outer-shell electrons (see Figure 2.1), is too large for its positively charged nucleus to attract the outer-shell electrons of neighboring atoms with sufficient force to hold such large molecules together. We can best understand

Figure 2.9 Cholesterol, whose structure illustrates how carbon atoms (represented by the black balls) are able to form covalent bonds with as many as four other carbon atoms. As a result, carbon atoms can be linked together to form the backbones of a virtually unlimited variety of organic molecules. The carbon backbone of a cholesterol molecule includes four rings, which is characteristic of steroids (e.g., estrogen, testosterone, cortisol). The cholesterol molecule shown here is drawn as a ball-and-stick model, which is another way that molecular structure is depicted.

the nature of biological molecules by starting with the simplest group of organic molecules, the *hydrocarbons*, which contain only carbon and hydrogen atoms. The molecule ethane (C_2H_6) is a simple hydrocarbon

consisting of two atoms of carbon in which each carbon is bonded to the other carbon as well as to three atoms of hydrogen. As more carbons are added, the skeletons of organic molecules increase in length and their structure becomes more complex.

Functional Groups

Hydrocarbons do not occur in significant amounts within most living cells (though they constitute the bulk of the fossil fuels formed from the remains of ancient plants and animals). Many of the organic molecules that are important in biology contain chains of carbon atoms, like hydrocarbons, but certain hydrogen atoms are replaced by various **functional groups**. Functional groups are particular groupings of atoms that often behave as a unit and give organic molecules their physical properties, chemical reactivity, and solubility in aqueous solution. Some of the more common functional groups are listed in Table 2.2. Two of the most common linkages between functional groups are **ester bonds**, which form between carboxylic acids and alcohols, and **amide bonds**, which form between carboxylic acids and amines.

Most of the groups in Table 2.2 contain one or more electronegative atoms (N, P, O, and/or S) and make organic molecules more polar, more water soluble, and more reactive. Several of these functional groups can ionize and become positively or negatively charged. The effect on molecules by the

substitution of various functional groups is readily demonstrated. The hydrocarbon ethane (CH_3CH_3) depicted above is a toxic, flammable gas. Replace one of the hydrogens with a hydroxyl group ($-OH$) and the molecule (CH_3CH_2OH) becomes palatable—it is ethyl alcohol. Substitute a carboxyl group ($-COOH$) and the molecule becomes acetic acid (CH_3COOH), the strong-tasting ingredient in vinegar. Substitute a sulfhydryl group ($-SH$), and you have formed CH_3CH_2SH , a strong, foul-smelling agent, ethyl mercaptan, used by biochemists in studying enzyme reactions.

A Classification of Biological Molecules by Function

The organic molecules commonly found within living cells can be divided into several categories based on their role in metabolism.

1. **Macromolecules.** The molecules that form the structure and carry out the activities of cells are huge, highly organized molecules called **macromolecules**, which contain anywhere from dozens to millions of carbon atoms. Because of their size and the intricate shapes that macromolecules can assume, some of these molecular giants can perform complex tasks with great precision and efficiency. The presence of macromolecules, more than any other characteristic, endows organisms with the properties of life and sets them apart chemically from the inanimate world.

Macromolecules can be divided into four major categories: proteins, nucleic acids, polysaccharides, and certain lipids. The first three types are *polymers* composed of a large number of low-molecular-weight building blocks, or *monomers*. These macromolecules are constructed from monomers by a process of *polymerization* that resembles coupling railroad cars onto a train (Figure 2.10). The basic structure and function of each type of macromolecule are similar in all organisms. It is not until you look at the specific sequences of monomers that make up individual macromolecules that the diversity among organisms becomes apparent.

2. **The building blocks of macromolecules.** Most of the macromolecules within a cell have a short lifetime compared with the cell itself; with the exception of the cell's DNA, they are continually broken down and replaced by new macromolecules. Consequently, most cells contain a supply (or *pool*) of low-molecular-weight precursors that are ready to be incorporated into macromolecules. These

Table 2.2 Functional Groups

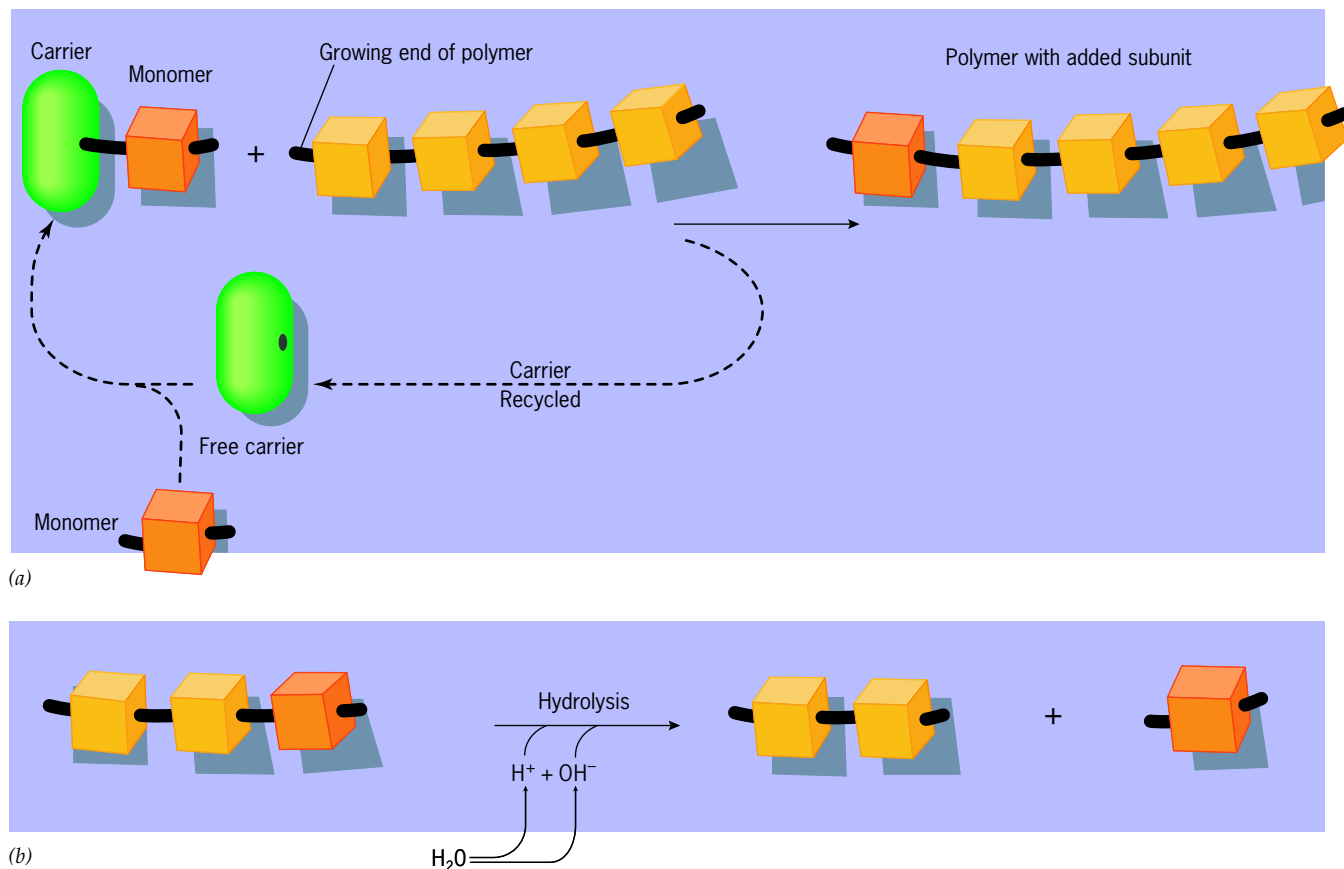

Figure 2.10 Monomers and polymers; polymerization and hydrolysis. (a) Polysaccharides, proteins, and nucleic acids consist of monomers (subunits) linked together by covalent bonds. Free monomers do not simply react with each other to become macromolecules. Rather, each monomer is first activated by attachment

to a carrier molecule that subsequently transfers the monomer to the end of the growing macromolecule. (b) A macromolecule is disassembled by hydrolysis of the bonds that join the monomers together. Hydrolysis is the splitting of a bond by water. All of these reactions are catalyzed by specific enzymes.

include sugars, which are the precursors of polysaccharides; amino acids, which are the precursors of proteins; nucleotides, which are the precursors of nucleic acids; and fatty acids, which are incorporated into lipids.

3. **Metabolic intermediates (metabolites).** The molecules in a cell have complex chemical structures and must be synthesized in a step-by-step sequence beginning with specific starting materials. In the cell, each series of chemical reactions is termed a **metabolic pathway**. The cell starts with compound A and converts it to compound B, then to compound C, and so on, until some functional end product (such as an amino acid building block of a protein) is produced. The compounds formed along the pathways leading to the end products might have no function per se and are called **metabolic intermediates**.
4. **Molecules of miscellaneous function.** This is obviously a broad category of molecules but not as large as you might expect; the vast bulk of the dry weight of a cell is made up of macromolecules and their direct precursors. The molecules of miscellaneous function include such substances as vitamins, which function primarily as adjuncts to proteins; certain steroid or amino acid hormones; molecules

involved in energy storage, such as ATP; regulatory molecules such as cyclic AMP; and metabolic waste products such as urea.

REVIEW

1. What properties of a carbon atom are critical to life?
2. Draw the structures of four different functional groups. How would each of these groups alter the solubility of a molecule in water?

2.5 | Four Types of Biological Molecules

The macromolecules just described can be divided into four types of organic molecules: carbohydrates, lipids, proteins, and nucleic acids. The localization of these molecules in a number of cellular structures is shown in an overview in Figure 2.11.

Figure 2.11 An overview of the types of biological molecules that make up various cellular structures.

Carbohydrates

Carbohydrates (or **glycans** as they are often called) include simple sugars (or *monosaccharides*) and all larger molecules constructed of sugar building blocks. Carbohydrates function primarily as stores of chemical energy and as durable building materials for biological construction. Most sugars have the general formula $(\text{CH}_2\text{O})_n$. The sugars of importance in cellular metabolism have values of n that range from 3 to 7. Sugars containing three carbons are known as *trioses*, those with four carbons as *tetroses*, those with five carbons as *pentoses*, those with six carbons as *hexoses*, and those with seven carbons as *heptoses*.

The Structure of Simple Sugars Each sugar molecule consists of a backbone of carbon atoms linked together in a linear array by single bonds. Each of the carbon atoms of the backbone is linked to a single hydroxyl group, except for one that bears a *carbonyl* ($\text{C}=\text{O}$) group. If the carbonyl group is located at an internal position (to form a ketone group), the sugar is a *ketose*, such as fructose, which is shown in Figure 2.12*a*. If the carbonyl is located at one end of the sugar, it forms an aldehyde group and the molecule is known as an *aldose*, as exemplified by glucose, which is shown in Figure 2.12*b–f*. Because of their large numbers of hydroxyl groups, sugars tend to be highly water soluble.

Although the straight-chained formulas shown in Figure 2.12*a,b* are useful for comparing the structures of various sugars, they do not reflect the fact that sugars with five or more carbon atoms undergo a self-reaction (Figure 2.12*c*) that converts them into a closed, or ring-containing, molecule. The ring forms of sugars are usually depicted as flat (*planar*) structures (Figure 2.12*d*) lying perpendicular to the plane of the paper with the thickened line situated closest to the reader. The H and OH groups lie parallel to the plane of the paper,

Figure 2.12 The structures of sugars. (a) Straight-chain formula of fructose, a ketohexose [keto, indicating the carbonyl (yellow), is located internally, and hexose because it consists of six carbons]. (b) Straight-chain formula of glucose, an aldohexose (aldo because the carbonyl is located at the end of the molecule). (c) Self-reaction in which glucose is converted from an open chain to a closed ring (a pyranose ring). (d) Glucose is commonly depicted in the form of a flat (planar) ring

lying perpendicular to the page with the thickened line situated closest to the reader and the H and OH groups projecting either above or below the ring. The basis for the designation α -D-glucose is discussed in the following section. (e) The chair conformation of glucose, which depicts its three-dimensional structure more accurately than the flattened ring of part *d*. (f) A ball-and-stick model of the chair conformation of glucose.

projecting either above or below the ring of the sugar. In actual fact, the sugar ring is not a planar structure, but usually exists in a three-dimensional conformation resembling a chair (Figure 2.12e,f).

Stereoisomerism As noted earlier, a carbon atom can bond with four other atoms. The arrangement of the groups around a carbon atom can be depicted as in Figure 2.13a with the carbon placed in the center of a tetrahedron and the bonded groups projecting into its four corners. Figure 2.13b depicts a molecule of glyceraldehyde, which is the only aldotriose. The second carbon atom of glyceraldehyde is linked to four different groups ($-\text{H}$, $-\text{OH}$, $-\text{CHO}$, and $-\text{CH}_2\text{OH}$). If the four groups bonded to a carbon atom are all different, as in glyceraldehyde, then two possible configura-

Figure 2.13 Stereoisomerism of glyceraldehyde. (a) The four groups bonded to a carbon atom (labeled a, b, c, and d) occupy the four corners of a tetrahedron with the carbon atom at its center. (b) Glyceraldehyde is the only three-carbon aldose; its second carbon atom is bonded to four different groups ($-\text{H}$, $-\text{OH}$, $-\text{CHO}$, and $-\text{CH}_2\text{OH}$). As a result, glyceraldehyde can exist in two possible configurations that are not superimposable, but instead are mirror images of each other as indicated. These two stereoisomers (or enantiomers) can be distinguished by the configuration of the four groups around the asymmetric (or *chiral*) carbon atom. Solutions of these two isomers rotate plane-polarized light in opposite directions and, thus, are said to be optically active. (c) Straight-chain formulas of glyceraldehyde. By convention, the D-isomer is shown with the OH group on the right.

rations exist that cannot be superimposed on one another. These two molecules (termed *stereoisomers* or *enantiomers*) have essentially the same chemical reactivities, but their structures are mirror images (not unlike a pair of right and left human hands). By convention, the molecule is called D-glyceraldehyde if the hydroxyl group of carbon 2 projects to the right, and L-glyceraldehyde if it projects to the left (Figure 2.13c). Because it acts as a site of stereoisomerism, carbon 2 is referred to as an *asymmetric* carbon atom.

As the backbone of sugar molecules increases in length, so too does the number of asymmetric carbon atoms and, consequently, the number of stereoisomers. Aldotetroses have two asymmetric carbons and thus can exist in four different configurations (Figure 2.14). Similarly, there are 8 different aldopentoses and 16 different aldohexoses. The designation of each of these sugars as D or L is based by convention on the arrangement of groups attached to the asymmetric carbon atom farthest from the aldehyde (the carbon associated with the aldehyde is designated C1). If the hydroxyl group of this carbon projects to the right, the aldose is a D-sugar; if it projects to the left, it is an L-sugar. The enzymes present in living cells can distinguish between the D and L forms of a sugar. Typically, only one of the stereoisomers (such as D-glucose and L-fucose) is used by cells.

The self-reaction in which a straight-chain glucose molecule is converted into a six-membered (*pyranose*) ring was shown in Figure 2.12c. Unlike its precursor in the open chain, the C1 of the ring bears four different groups and thus becomes a new center of asymmetry within the sugar molecule. Because of this extra asymmetric carbon atom, each type of pyranose exists as α and β stereoisomers (Figure 2.15). By convention, the molecule is an α -pyranose when the OH group of the first carbon projects below the plane of the ring, and a β -pyranose when the hydroxyl projects upward. The difference between the two forms has important biological consequences, resulting, for example, in the compact shape of glycogen and starch molecules and the extended conformation of cellulose (discussed later).

Linking Sugars Together Sugars can be joined to one another by covalent **glycosidic bonds** to form larger molecules. Glycosidic bonds form by reaction between carbon atom C1 of one sugar and the hydroxyl group of another sugar, generating a $-\text{C}-\text{O}-\text{C}-$ linkage between the two sugars. As discussed below (and indicated in Figures 2.16 and 2.17), sugars can be joined by quite a variety of different glycosidic

Figure 2.14 Aldotetroses. Because they have two asymmetric carbon atoms, aldotetroses can exist in four configurations.

Figure 2.15 Formation of an α - and β -pyranose. When a molecule of glucose undergoes self-reaction to form a pyranose ring (i.e., a six-membered ring), two stereoisomers are generated. The two isomers are in equilibrium with each other through the open-chain form of the

molecule. By convention, the molecule is an α -pyranose when the OH group of the first carbon projects below the plane of the ring, and a β -pyranose when the hydroxyl group projects upward.

bonds. Molecules composed of only two sugar units are *disaccharides* (Figure 2.16). Disaccharides serve primarily as readily available energy stores. Sucrose, or table sugar, is a major component of plant sap, which carries chemical energy from one part of the plant to another. Lactose, present in the milk of most mammals, supplies newborn mammals with fuel for early growth and development. Lactose in the diet is hydrolyzed by the enzyme lactase, which is present in the plasma membranes of the cells that line the intestine. Many people lose this enzyme after childhood and find that eating dairy products causes digestive discomfort.

Sugars may also be linked together to form small chains called **oligosaccharides** (*oligo* = few). Most often such chains are found covalently attached to lipids and proteins, converting them into glycolipids and glycoproteins, respectively. Oligosaccharides are particularly important on the glycolipids and glycoproteins of the plasma membrane, where they project from the cell surface (see Figure 4.4c). Because oligosaccharides may

be composed of many different combinations of sugar units, these carbohydrates can play an informational role; that is, they can serve to distinguish one type of cell from another and help mediate specific interactions of a cell with its surroundings.

Polysaccharides By the middle of the nineteenth century, it was known that the blood of people suffering from diabetes had a sweet taste due to an elevated level of glucose, the key sugar in energy metabolism. Claude Bernard, a prominent French physiologist of the period, was looking for the cause of diabetes by investigating the source of blood sugar. It was assumed at the time that any sugar present in a human or an animal had to have been previously consumed in the diet. Working with dogs, Bernard found that, even if the animals were placed on a diet totally lacking carbohydrates, their blood still contained a normal amount of glucose. Clearly, glucose could be formed in the body from other types of compounds.

After further investigation, Bernard found that glucose enters the blood from the liver. Liver tissue, he found, contains an insoluble polymer of glucose he named **glycogen**. Bernard concluded that various food materials (such as proteins) were carried to the liver where they were chemically converted to glucose and stored as glycogen. Then, as the body needed sugar for fuel, the glycogen in the liver was transformed to glucose, which was released into the bloodstream to satisfy glucose-depleted tissues. In Bernard's hypothesis, the balance between glycogen formation and glycogen breakdown in the liver was the prime determinant in maintaining the relatively constant (*homeostatic*) level of glucose in the blood.

Bernard's hypothesis proved to be correct. The molecule he named glycogen is a type of **polysaccharide**—a polymer of sugar units joined by glycosidic bonds.

Glycogen and Starch: Nutritional Polysaccharides Glycogen is a branched polymer containing only one type of monomer: glucose (Figure 2.17a). Most of the sugar units of a glycogen molecule are joined to one another by $\alpha(1 \rightarrow 4)$ glycosidic bonds (type 2 bond in Figure 2.17a). Branch points contain a sugar joined to three neighboring units rather than to two, as in the unbranched segments of the polymer. The extra neighbor, which forms the branch, is linked by an $\alpha(1 \rightarrow 6)$ glycosidic bond (type 1 bond in Figure 2.17a).

Figure 2.16 Disaccharides. Sucrose and lactose are two of the most common disaccharides. Sucrose is composed of glucose and fructose joined by an $\alpha(1 \rightarrow 2)$ linkage, whereas lactose is composed of glucose and galactose joined by a $\beta(1 \rightarrow 4)$ linkage.

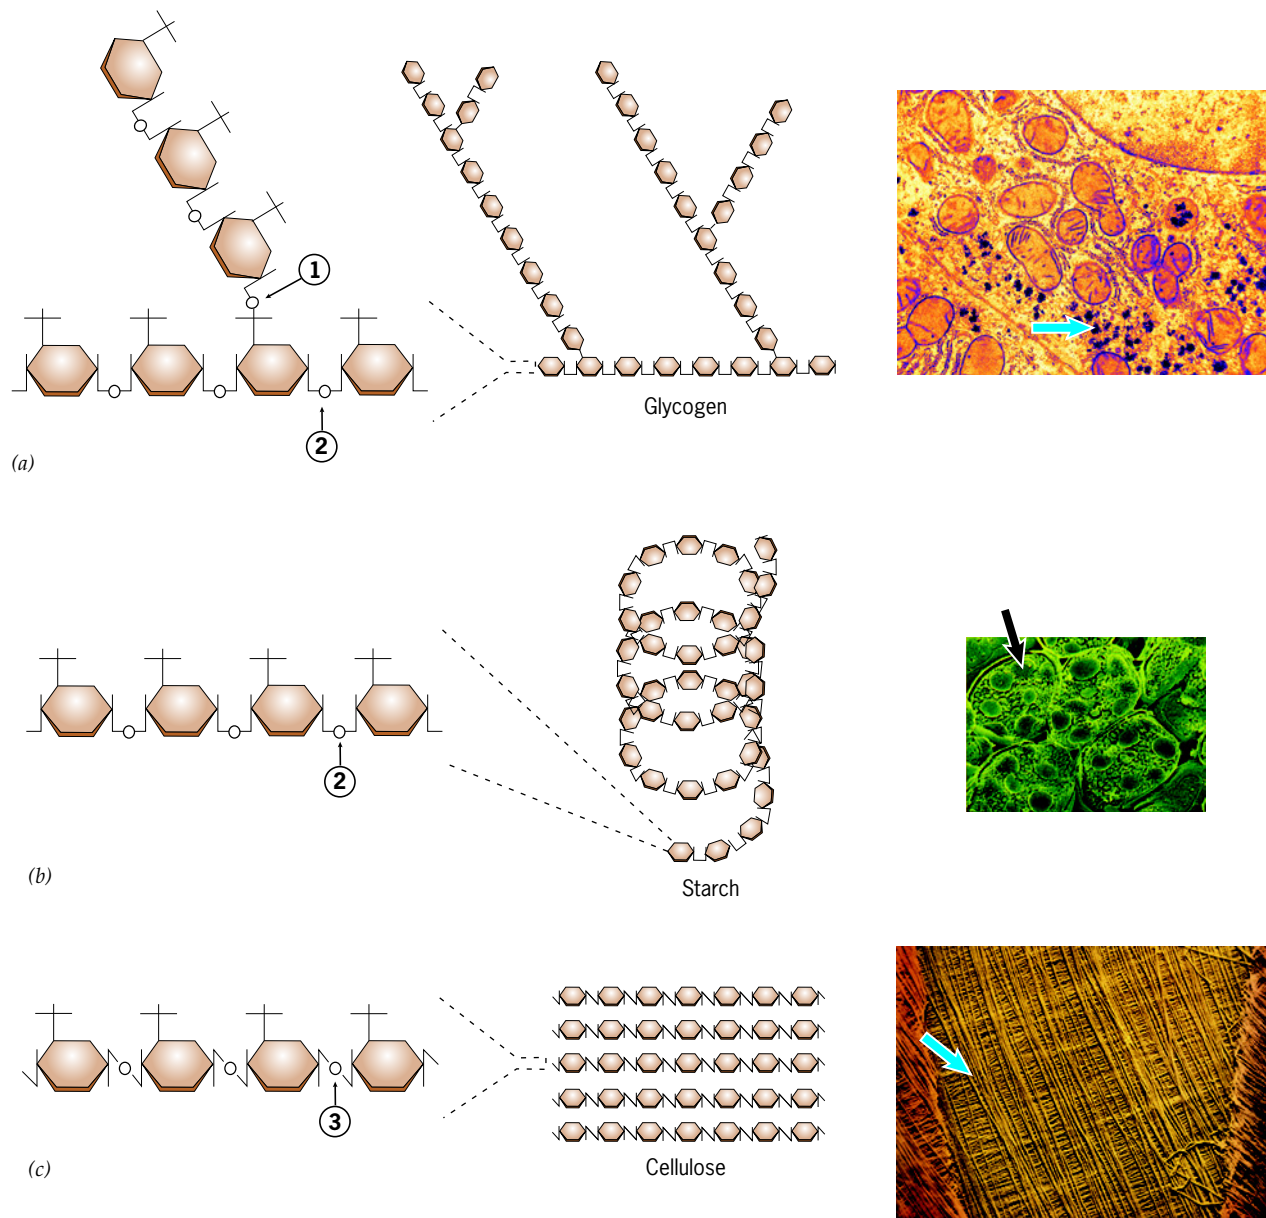

Figure 2.17 Three polysaccharides with identical sugar monomers but dramatically different properties. Glycogen (a), starch (b), and cellulose (c) are each composed entirely of glucose subunits, yet their chemical and physical properties are very different due to the distinct ways that the monomers are linked together (three different types of linkages are indicated by the circled numbers). Glycogen molecules are the most highly branched, starch molecules assume a helical arrangement, and cellulose molecules are unbranched and highly

extended. Whereas glycogen and starch are energy stores, cellulose molecules are bundled together into tough fibers that are suited for their structural role. Colorized electron micrographs show glycogen granules in a liver cell, starch grains (amyloplasts) in a plant seed, and cellulose fibers in a plant cell wall; each is indicated by an arrow. [PHOTO INSERTS: (TOP) DON FAWCETT/PHOTO RESEARCHERS, INC.; (CENTER) JEREMY BURGESS/PHOTO RESEARCHERS, INC.; (BOTTOM) BIOPHOTO ASSOCIATES/PHOTO RESEARCHERS, INC.]

Glycogen serves as a storehouse of surplus chemical energy in most animals. Human skeletal muscles, for example, typically contain enough glycogen to fuel about 30 minutes of moderate activity. Depending on various factors, glycogen typically ranges in molecular weight from about one to four million daltons. When stored in cells, glycogen is highly concentrated in what appears as dark-staining, irregular granules in electron micrographs (Figure 2.17a, right).

Most plants bank their surplus chemical energy in the form of **starch**, which like glycogen is also a polymer of glucose. Potatoes and cereals, for example, consist primarily of starch. Starch is actually a mixture of two different polymers, amylose and amylopectin. Amylose is an unbranched, helical molecule whose sugars are joined by $\alpha(1 \rightarrow 4)$ linkages (Figure 2.17b), whereas amylopectin is branched. Amylopectin differs from glycogen in being much less branched and having

an irregular branching pattern. Starch is stored as densely packed granules, or *starch grains*, which are enclosed in membrane-bound organelles (*plastids*) within the plant cell (Figure 2.17*b*, right). Although animals don't synthesize starch, they possess an enzyme (*amylase*) that readily hydrolyzes it.

Cellulose, Chitin, and Glycosaminoglycans: Structural Polysaccharides Whereas some polysaccharides constitute easily digested energy stores, others form tough, durable structural materials. Cotton and linen, for example, consist largely of **cellulose**, which is the major component of plant cell walls. Cotton textiles owe their durability to the long, unbranched cellulose molecules, which are ordered into side-by-side aggregates to form molecular cables (Figure 2.17*c*, right panel) that are ideally constructed to resist pulling (tensile) forces. Like glycogen and starch, cellulose consists solely of glucose monomers; its properties differ dramatically from these other polysaccharides because the glucose units are joined by $\beta(1 \rightarrow 4)$ linkages (bond 3 in Figure 2.17*c*) rather than $\alpha(1 \rightarrow 4)$ linkages. Ironically, multicellular animals (with rare exception) lack the enzyme needed to degrade cellulose, which happens to be the most abundant organic material on Earth and rich in chemical energy. Animals that “make a living” by digesting cellulose, such as termites and sheep, do so by harboring bacteria and protozoa that synthesize the necessary enzyme, cellulase.

Not all biological polysaccharides consist of glucose monomers. *Chitin* is an unbranched polymer of the sugar *N*-acetylglucosamine, which is similar in structure to glucose but has an acetyl amino group instead of a hydroxyl group bonded to the second carbon atom of the ring.

Chitin occurs widely as a structural material among invertebrates, particularly in the outer covering of insects, spiders, and crustaceans. Chitin is a tough, resilient, yet flexible material not unlike certain plastics. Insects owe much of their success to this highly adaptive polysaccharide (Figure 2.18).

Another group of polysaccharides that has a more complex structure is the **glycosaminoglycans** (or **GAGs**). Unlike other polysaccharides, they have the structure —A—B—A—B—, where A and B represent two different sugars. The best-studied GAG is heparin, which is secreted by cells in the lungs and other tissues in response to tissue injury. Heparin inhibits blood coagulation, thereby preventing the formation of clots that can block the flow of blood to the heart or lungs. Heparin accomplishes this feat by activating an inhibitor (antithrombin) of a key enzyme (thrombin) that is required for blood coagulation. Heparin, which is normally extracted from pig tissue, has been used for decades to prevent blood clots in patients following major surgery. Unlike heparin, most GAGs

Figure 2.18 Chitin is the primary component of the outer skeleton of this grasshopper. (ANTHONY BANNISTER/GALLO IMAGES/© CORBIS)

are found in the spaces that surround cells, and their structure and function are discussed in Section 7.1. The most complex polysaccharides are found in plant cell walls (Section 7.6).

Lipids

Lipids are a diverse group of nonpolar biological molecules whose common properties are their ability to dissolve in organic solvents, such as chloroform or benzene, and their inability to dissolve in water—a property that explains many of their varied biological functions. Lipids of importance in cellular function include fats, steroids, and phospholipids.

Fats Fats consist of a glycerol molecule linked by ester bonds to three fatty acids; the composite molecule is termed a **triacylglycerol** (Figure 2.19*a*). We will begin by considering the structure of **fatty acids**. Fatty acids are long, unbranched hydrocarbon chains with a single carboxyl group at one end (Figure 2.19*b*). Because the two ends of a fatty acid molecule have a very different structure, they also have different properties. The hydrocarbon chain is hydrophobic, whereas the carboxyl group (—COOH), which bears a negative charge at physiological pH, is hydrophilic. Molecules having both hydrophobic and hydrophilic regions are said to be **amphipathic**; such molecules have unusual and biologically important properties. The properties of fatty acids can be appreciated by considering the use of a familiar product: soap, which consists of fatty acids. In past centuries, soaps were made by heating animal fat in strong alkali (NaOH or KOH) to break the bonds between the fatty acids and the glycerol.

Tristearate
(c)

Linseed oil
(d)

Figure 2.19 Fats and fatty acids. (a) The basic structure of a triacylglycerol (also called a triglyceride or a neutral fat). The glycerol moiety, indicated in orange, is linked by three ester bonds to the carboxyl groups of three fatty acids whose tails are indicated in green. (b) Stearic acid, an 18-carbon saturated fatty acid that is common in animal fats. (c) Space-filling model of tristearate, a triacylglycerol containing three identical stearic acid chains. (d) Space-filling model of linseed oil, a triacylglycerol derived from flax seeds that contains three unsaturated fatty acids (linoleic, oleic, and linolenic acids). The sites of unsaturation, which produce kinks in the molecule, are indicated by the yellow-orange bars.

Today, most soaps are made synthetically. Soaps owe their grease-dissolving capability to the fact that the hydrophobic end of each fatty acid can embed itself in the grease, whereas the hydrophilic end can interact with the surrounding water.

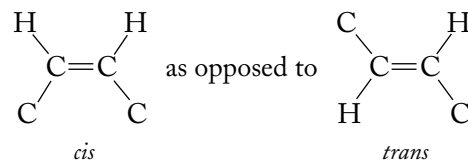

Figure 2.20 Soaps consist of fatty acids. In this schematic drawing of a soap micelle, the nonpolar tails of the fatty acids are directed inward, where they interact with the greasy matter to be dissolved. The negatively charged heads are located at the surface of the micelle, where they interact with the surrounding water. Membrane proteins, which also tend to be insoluble in water, can also be solubilized in this way by extraction of membranes with detergents.

As a result, greasy materials are converted into complexes (*micelles*) that can be dispersed by water (Figure 2.20).

Fatty acids differ from one another in the length of their hydrocarbon chain and the presence or absence of double bonds. Fatty acids present in cells typically vary in length from 14 to 20 carbons. Fatty acids that lack double bonds, such as stearic acid (Figure 2.19b), are described as **saturated**; those possessing double bonds are **unsaturated**. Naturally occurring fatty acids have double bonds in the *cis* configuration. Double bonds (of the *cis* configuration)

produce kinks in a fatty acid chain. Consequently, the more double bonds that fatty acid chains possess, the less effectively these long chains can be packed together. This lowers the temperature at which a fatty acid-containing lipid melts. Tristearate, whose fatty acids lack double bonds (Figure 2.19c), is a common component of animal fats and remains in a solid state well above room temperature. In contrast, the profusion of double bonds in vegetable fats accounts for their liquid state—both in the plant cell and on the grocery shelf—and for their being labeled as “polyunsaturated.” Fats that are liquid at room temperature are described as **oils**. Figure 2.19d shows

the structure of linseed oil, a highly volatile lipid extracted from flax seeds, that remains a liquid at a much lower temperature than does tristearate. Solid shortenings, such as margarine, are formed from unsaturated vegetable oils by chemically reducing the double bonds with hydrogen atoms (a process termed *hydrogenation*). The hydrogenation process also converts some of the *cis* double bonds into *trans* double bonds, which are straight rather than kinked. This process generates partially hydrogenated or *trans*-fats.

A molecule of fat can contain three identical fatty acids (as in Figure 2.19c), or it can be a *mixed fat*, containing more than one fatty acid species (as in Figure 2.19d). Most natural fats, such as olive oil or butterfat, are mixtures of molecules having different fatty acid species.

Fats are very rich in chemical energy; a gram of fat contains over twice the energy content of a gram of carbohydrate (for reasons discussed in Section 3.1). Carbohydrates function primarily as a short-term, rapidly available energy source, whereas fat reserves store energy on a long-term basis. It is estimated that a person of average size contains about 0.5 kilograms (kg) of carbohydrate, primarily in the form of glycogen. This amount of carbohydrate provides approximately 2000 kcal of total energy. During the course of a strenuous day's exercise, a person can virtually deplete his or her body's entire store of carbohydrate. In contrast, the average person contains approximately 16 kg of fat (equivalent to 144,000 kcal of energy), and as we all know, it can take a very long time to deplete our store of this material.

Figure 2.21 The structure of steroids. All steroids share the basic four-ring skeleton. The seemingly minor differences in chemical structure between cholesterol, testosterone, and estrogen generate profound biological differences.

Because they lack polar groups, fats are extremely insoluble in water and are stored in cells in the form of dry lipid droplets. Since lipid droplets do not contain water as do glycogen granules, they represent an extremely concentrated storage fuel. In many animals, fats are stored in special cells (*adipocytes*) whose cytoplasm is filled with one or a few large lipid droplets. Adipocytes exhibit a remarkable ability to change their volume to accommodate varying quantities of fat.

Steroids Steroids are built around a characteristic four-ringed hydrocarbon skeleton. One of the most important steroids is *cholesterol*, a component of animal cell membranes and a precursor for the synthesis of a number of steroid hormones, such as testosterone, progesterone, and estrogen (Figure 2.21). Cholesterol is largely absent from plant cells, which is why vegetable oils are considered “cholesterol-free,” but plant cells may contain large quantities of related compounds.

Phospholipids The chemical structure of a common phospholipid is shown in Figure 2.22. The molecule resembles a fat (triacylglycerol), but has only two fatty acid chains rather than three; it is a *diacylglycerol*. The third hydroxyl of the glycerol backbone is covalently bonded to a phosphate group, which in turn is covalently bonded to a small polar group, such as choline, as shown in Figure 2.22. Thus, unlike fat molecules, phospholipids contain two ends that have very different properties: the end containing the phosphate group has a distinctly hydrophilic character; the other end composed of the two fatty acid tails has a distinctly hydrophobic character. Because phospholipids function primarily in cell membranes, and because the properties of cell membranes depend on their phospholipid components, they will be discussed further in Sections 4.3 and 15.2 in connection with cell membranes.

Figure 2.22 The phospholipid phosphatidylcholine. The molecule consists of a glycerol backbone whose hydroxyl groups are covalently bonded to two fatty acids and a phosphate group. The negatively charged phosphate is also bonded to a small, positively charged choline group. The end of the molecule that contains the phosphorylcholine is hydrophilic, whereas the opposite end, consisting of the fatty acid tail, is hydrophobic. The structure and function of phosphatidylcholine and other phospholipids are discussed at length in Section 4.3.

Proteins

Proteins are the macromolecules that carry out virtually all of a cell's activities; they are the molecular tools and machines that make things happen. As enzymes, proteins vastly accelerate the rate of metabolic reactions; as structural cables, proteins provide mechanical support both within cells and outside their perimeters (Figure 2.23a); as hormones, growth factors, and gene activators, proteins perform a wide variety of regulatory functions; as membrane receptors and transporters, proteins determine what a cell reacts to and what types of substances enter or leave the cell; as contractile filaments and molecular motors, proteins constitute the machinery for biological movements. Among their many other functions, proteins act as antibodies, serve as toxins, form blood clots, absorb or refract light (Figure 2.23b), and transport substances from one part of the body to another.

How can one type of molecule have so many varied functions? The explanation resides in the virtually unlimited molecular structures that proteins, *as a group*, can assume. Each protein, however, has a unique and defined structure that enables it to carry out a particular function. Most importantly, proteins have shapes and surfaces that allow them to interact *selectively* with other molecules. Proteins, in other words, exhibit a high degree of **specificity**. It is possible, for example, for a particular DNA-cutting enzyme to recognize a segment of DNA containing one specific sequence of eight nucleotides, while ignoring all the other 65,535 possible sequences composed of this number of nucleotides.

The Building Blocks of Proteins Proteins are polymers made of amino acid monomers. Each protein has a unique se-

quence of amino acids that gives the molecule its unique properties. Many of the capabilities of a protein can be understood by examining the chemical properties of its constituent amino acids. Twenty different amino acids are commonly used in the construction of proteins, whether from a virus or a human. There are two aspects of amino acid structure to consider: that which is common to all of them and that which is unique to each. We will begin with the shared properties.

The Structures of Amino Acids All amino acids have a carboxyl group and an amino group, which are separated from each other by a single carbon atom, the α -carbon (Figure 2.24a,b). In a neutral aqueous solution, the α -carboxyl group loses its proton and exists in a negatively charged state ($-\text{COO}^-$), and the α -amino group accepts a proton and exists in a positively charged state (NH_3^+) (Figure 2.24b). We saw on page 44 that carbon atoms bonded to four different groups can exist in two configurations (*stereoisomers*) that cannot be superimposed on one another. Amino acids also have asymmetric carbon atoms. With the exception of glycine, the α -carbon of amino acids bonds to four different groups so that each amino acid can exist in either a D or an L form (Figure 2.25). Amino acids used in the synthesis of a protein on a ribosome are always L-amino acids. The “selection” of L-amino acids must have occurred very early in cellular evolution and has been conserved for billions of years. Microorganisms, however, use D-amino acids in the synthesis of certain small peptides, including those of the cell wall and several antibiotics (e.g., gramicidin A).

During the process of protein synthesis, each amino acid becomes joined to two other amino acids, forming a long, continuous, unbranched polymer called a **polypeptide chain**.

(a)

Figure 2.23 Two examples of the thousands of biological structures composed predominantly of protein. These include (a) feathers, which are adaptations in birds for thermal insulation, flight, and sex

(b)

recognition; and (b) the lenses of eyes, as in this spider, which focus light rays. (A: DARRELL GULIN/GETTY IMAGES; B: THOMAS SHAHAN/PHOTO RESEARCHERS, INC.)

Figure 2.24 Amino acid structure. Ball-and-stick model (a) and chemical formula (b) of a generalized amino acid in which R can be any of a number of chemical groups (see Figure 2.26). (c) The formation of a peptide bond occurs by the condensation of two amino acids, drawn here in the uncharged state. In the cell, this reaction occurs on a ribosome as an amino acid is transferred from a carrier (a tRNA molecule) onto the end of the growing polypeptide chain (see Figure 11.49).

Figure 2.25 Amino acid stereoisomerism. Because the α -carbon of all amino acids except glycine is bonded to four different groups, two stereoisomers can exist. The D and L forms of alanine are shown.

The amino acids that make up a polypeptide chain are joined by **peptide bonds** that result from the linkage of the carboxyl group of one amino acid to the amino group of its neighbor, with the elimination of a molecule of water (Figure 2.24c). A polypeptide chain composed of a string of amino acids joined by peptide bonds has the following backbone:

The “average” polypeptide chain contains about 450 amino acids. The longest known polypeptide, found in the muscle protein titin, contains more than 30,000 amino acids. Once incorporated into a polypeptide chain, amino acids are termed *residues*. The residue on one end of the chain, the *N-terminus*, contains an amino acid with a free (unbonded) α -amino group, whereas the residue at the opposite end, the *C-terminus*, has a free α -carboxyl group. In addition to amino acids, many proteins contain other types of components that are added after the polypeptide is synthesized. These include carbohydrates (to form glycoproteins), metal-containing groups (to form metalloproteins) and organic groups (e.g., flavoproteins).

The Properties of the Side Chains The backbone, or main chain, of the polypeptide is composed of that part of each amino acid that is common to all of them. The **side chain** or **R group** (Figure 2.24), bonded to the α -carbon, is highly variable among the 20 building blocks, and it is this variability that ultimately gives proteins their diverse structures and activities. If the various amino acid side chains are considered together, they exhibit a large variety of structural features, ranging from fully charged to hydrophobic, and they can participate in a wide variety of covalent and noncovalent bonds. As discussed in the following chapter, the side chains of the amino acids are important in both *intramolecular* interactions, which determine the structure and activity of the molecule, and *intermolecular* interactions, which determine the relationship of a polypeptide with other molecules, including other polypeptides (page 61).

Amino acids are classified on the character of their side chains. They fall roughly into four categories: polar and charged, polar and uncharged, nonpolar, and those with unique properties (Figure 2.26).

1. **Polar, charged.** Amino acids of this group include aspartic acid, glutamic acid, lysine, and arginine. These four amino acids contain side chains that become fully charged; that is, the side chains contain relatively strong organic acids and bases. The ionization reactions of glutamic acid and

Polar charged

Properties of side chains (R groups):

Hydrophilic side chains act as acids or bases which tend to be fully charged (+ or -) under physiologic conditions. Side chains form ionic bonds and are often involved in chemical reactions.

Polar uncharged

Properties of side chains:

Hydrophilic side chains tend to have partial + or - charge allowing them to participate in chemical reactions, form H-bonds, and associate with water.

Nonpolar

Properties of side chains:

Hydrophobic side chain consists almost entirely of C and H atoms. These amino acids tend to form the inner core of soluble proteins, buried away from the aqueous medium. They play an important role in membranes by associating with the lipid bilayer.

Side chains with unique properties

Side chain consists only of hydrogen atom and can fit into either a hydrophilic or hydrophobic environment. Glycine often resides at sites where two polypeptides come into close contact.

Though side chain has polar, uncharged character, it has the unique property of forming a covalent bond with another cysteine to form a disulfide link.

Though side chain has hydrophobic character, it has the unique property of creating kinks in polypeptide chains and disrupting ordered secondary structure.

Figure 2.26 The chemical structure of amino acids. These 20 amino acids represent those most commonly found in proteins and, more specifically, those encoded by DNA. Other amino acids occur as the result of a modification to one of those shown here. The amino acids

are arranged into four groups based on the character of their side chains, as described in the text. All molecules are depicted as free amino acids in their ionized state as they would exist in solution at neutral pH.

Figure 2.27 The ionization of charged, polar amino acids. (a) The side chain of glutamic acid loses a proton when its carboxylic acid group ionizes. The degree of ionization of the carboxyl group depends on the pH of the medium: the greater the hydrogen ion concentration (the lower the pH), the smaller the percentage of carboxyl groups that are present in the ionized state. Conversely, a rise in pH leads to an increased ionization of the proton from the carboxyl group, increasing the percentage of negatively charged glutamic acid side chains. The pH at which 50 percent of the side chains are ionized and 50 percent are unionized is called the pK, which is 4.4 for the side chain of free glutamic acid. At physiologic pH, virtually all of the glutamic acid residues of a polypeptide are negatively charged. (b) The side chain of lysine becomes ionized when its amino group gains a proton. The greater the hydroxyl ion concentration (the higher the pH), the smaller the percentage of amino groups that are positively charged. The pH at which 50 percent of the side chains of lysine are charged and 50 percent are uncharged is 10.0, which is the pK for the side chain of free lysine. At physiologic pH, virtually all of the lysine residues of a polypeptide are positively charged. Once incorporated into a polypeptide, the pK of a charged group can be greatly influenced by the surrounding environment.

lysine are shown in Figure 2.27. At physiologic pH, the side chains of these amino acids are almost always present in the fully charged state. Consequently, they are able to form ionic bonds with other charged species in the cell. For example, the positively charged arginine residues of histone proteins are linked by ionic bonds to the negatively charged phosphate groups of DNA (see Figure 2.3). Histidine is also considered a polar, charged amino acid, though in most cases it is only partially charged at physiologic pH. In fact, because of its ability to gain or lose a proton in physiologic pH ranges, histidine is a particularly important residue in the active site of many proteins (as in Figure 3.13).

- Polar, uncharged.** The side chains of these amino acids have a partial negative or positive charge and thus can

form hydrogen bonds with other molecules including water. These amino acids are often quite reactive. Included in this category are asparagine and glutamine (the amides of aspartic acid and glutamic acid), threonine, serine, and tyrosine.

- Nonpolar.** The side chains of these amino acids are hydrophobic and are unable to form electrostatic bonds or interact with water. The amino acids of this category are alanine, valine, leucine, isoleucine, tryptophan, phenylalanine, and methionine. The side chains of the nonpolar amino acids generally lack oxygen and nitrogen. They vary primarily in size and shape, which allows one or another of them to pack tightly into a particular space within the core of a protein, associating with one another as the result of van der Waals forces and hydrophobic interactions.
- The other three amino acids**—glycine, proline, and cysteine—have unique properties that separate them from the others. The side chain of glycine consists of only a hydrogen atom, and glycine is a very important amino acid for just this reason. Owing to its lack of a side chain, glycine residues provide a site where the backbones of two polypeptides (or two segments of the same polypeptide) can approach one another very closely. In addition, glycine is more flexible than other amino acids and allows parts of the backbone to move or form a hinge. Proline is unique in having its α -amino group as part of a ring (making it an imino acid). Proline is a hydrophobic amino acid that does not readily fit into an ordered secondary structure, such as an α helix (page 55), often producing kinks or hinges. Cysteine contains a reactive sulfhydryl ($-\text{SH}$) group and is often covalently linked to another cysteine residue, as a **disulfide ($-\text{SS}-$) bridge**.

Disulfide bridges often form between two cysteines that are distant from one another in the polypeptide backbone or even in two separate polypeptides. Disulfide bridges help stabilize the intricate shapes of proteins, particularly those present outside of cells where they are subjected to added physical and chemical stress.

Not all of the amino acids described in this section are found in all proteins, nor are the various amino acids distributed in an equivalent manner. A number of other amino acids

are also found in proteins, but they arise by alterations to the side chains of the 20 basic amino acids *after* their incorporation into a polypeptide chain. For this reason they are called **posttranslational modifications (PTMs)**. Dozens of different types of PTMs have been documented. The most widespread and important PTM is the reversible addition of a phosphate group to a serine, threonine, or tyrosine residue. Lysine acetylation is another widespread and important PTM affecting thousands of proteins in a mammalian cell. PTMs can generate dramatic changes in the properties and function of a protein, most notably by modifying its three-dimensional structure, level of activity, localization within the cell, life span, and/or its interactions with other molecules. The presence or absence of a single phosphate group on a key regulatory protein has the potential to determine whether or not a cell will behave as a cancer cell or a normal cell. Because of PTMs, a single polypeptide can exist as a number of distinct biological molecules.

The ionic, polar, or nonpolar character of amino acid side chains is very important in protein structure and function. Most soluble (i.e., nonmembrane) proteins are constructed so that the polar residues are situated at the surface of the molecule where they can associate with the surrounding water and contribute to the protein's solubility in aqueous solution

(Figure 2.28*a*). In contrast, the nonpolar residues are situated predominantly in the core of the molecule (Figure 2.28*b*). The hydrophobic residues of the protein interior are often tightly packed together, creating a type of three-dimensional jigsaw puzzle in which water molecules are generally excluded. Hydrophobic interactions among the nonpolar side chains of these residues are a driving force during protein folding (page 64) and contribute substantially to the overall stability of the protein. In many enzymes, reactive polar groups project into the nonpolar interior, giving the protein its catalytic activity. For example, a nonpolar environment can enhance ionic interactions between charged groups that would be lessened by competition with water in an aqueous environment. Some reactions that might proceed at an imperceptibly slow rate in water can occur in millionths of a second within the protein.

The Structure of Proteins Nowhere in biology is the intimate relationship between form and function better illustrated than with proteins. The structure of most proteins is completely defined and predictable. Each amino acid in one of these giant macromolecules is located at a specific site within the structure, giving the protein the precise shape and reactivity required for the job at hand. Protein structure can be described at several levels of organization, each emphasizing a

(a)

Figure 2.28 Disposition of hydrophilic and hydrophobic amino acid residues in the soluble protein cytochrome c. (a) The hydrophilic side chains, which are shown in green, are located primarily at the surface of the protein where they contact the surrounding aqueous medium. (b) The hydrophobic residues, which are shown in red, are located

primarily within the center of the protein, particularly in the vicinity of the central heme group. (ILLUSTRATION, IRVING GEIS. IMAGE FROM IRVING GEIS COLLECTION/HOWARD HUGHES MEDICAL INSTITUTE. RIGHTS OWNED BY HHMI. REPRODUCED BY PERMISSION ONLY.)

Figure 2.29 Scanning electron micrograph of a red blood cell from a person with sickle cell anemia. Compare with the micrograph of a normal red blood cell of Figure 4.32a. (COURTESY OF J. T. THORNWAITE, B. F. CAMERON, AND R. C. LEIF.)

different aspect and each dependent on different types of interactions. Customarily, four such levels are described: *primary*, *secondary*, *tertiary*, and *quaternary*. The first, primary structure, concerns the amino acid sequence of a protein, whereas the latter three levels concern the organization of the molecule in space. To understand the mechanism of action and biological function of a protein it is essential to know how that protein is constructed.

Primary Structure The primary structure of a polypeptide is the specific linear sequence of amino acids that constitute the chain. With 20 different building blocks, the number of different polypeptides that can be formed is 20^n , where n is the number of amino acids in the chain. Because most polypeptides contain well over 100 amino acids, the variety of possible sequences is essentially unlimited. The information for the precise order of amino acids in every protein that an organism can produce is encoded within the genome of that organism.

As we will see later, the amino acid sequence provides the information required to determine a protein's three-dimensional shape and thus its function. The sequence of amino acids, therefore, is all-important, and changes that arise in the sequence as a result of genetic mutations in the DNA may not be readily tolerated. The earliest and best-studied example of this relationship is the change in the amino acid sequence of hemoglobin that causes the disease *sickle cell anemia*. This severe, inherited anemia results solely from a single change in amino acid sequence within the hemoglobin molecule: a nonpolar valine residue is present where a charged glutamic acid is normally located. This change in hemoglobin structure can have a dramatic effect on the shape of red blood cells, converting them from disk-shaped cells to sickle-shaped cells (Figure 2.29), which tend to clog small blood vessels, causing pain and life-threatening crises. Not all amino acid changes have such a dramatic effect, as evidenced by the

differences in amino acid sequence in the same protein among related organisms. The degree to which changes in the primary sequence are tolerated depends on the degree to which the shape of the protein or the critical functional residues are disturbed.

The first amino acid sequence of a protein was determined by Frederick Sanger and co-workers at Cambridge University in the early 1950s. Beef insulin was chosen for the study because of its availability and its small size—two polypeptide chains of 21 and 30 amino acids each. The *sequencing* of insulin was a momentous feat in the newly emerging field of molecular biology. It revealed that proteins, the most complex molecules in cells, have a definable substructure that is neither regular nor repeating, unlike those of polysaccharides. Each particular polypeptide, whether insulin or some other species, has a precise sequence of amino acids that does not vary from one molecule to another. With the advent of techniques for rapid DNA sequencing (see Section 18.14), the primary structure of a polypeptide can be deduced from the nucleotide sequence of the encoding gene. In the past few years, the complete sequences of the genomes of hundreds of organisms, including humans, have been determined. This information will eventually allow researchers to learn about every protein that an organism can manufacture. However, translating information about primary sequence into knowledge of higher levels of protein structure remains a formidable challenge.

Secondary Structure All matter exists in space and therefore has a three-dimensional expression. Proteins are formed by linkages among vast numbers of atoms; consequently their shape is complex. The term **conformation** refers to the three-dimensional arrangement of the atoms of a molecule, that is, to their spatial organization. Secondary structure describes the conformation of portions of the polypeptide chain. Early studies on secondary structure were carried out by Linus Pauling and Robert Corey of the California Institute of Technology. By studying the structure of simple peptides consisting of a few amino acids linked together, Pauling and Corey concluded that polypeptide chains exist in preferred conformations that provide the maximum possible number of hydrogen bonds between neighboring amino acids.

Two conformations were proposed. In one conformation, the backbone of the polypeptide assumed the form of a cylindrical, twisting spiral called the **alpha (α) helix** (Figure 2.30a,b). The backbone lies on the inside of the helix, and the side chains project outward. The helical structure is stabilized by hydrogen bonds between the atoms of one peptide bond and those situated just above and below it along the spiral (Figure 2.30c). The X-ray diffraction patterns of actual proteins produced during the 1950s bore out the existence of the α helix, first in the protein keratin found in hair and later in various oxygen-binding proteins, such as myoglobin and hemoglobin (see Figure 2.34). Surfaces on opposite sides of an α helix may have contrasting properties. In water-soluble proteins, the outer surface of an α helix often contains polar residues in contact with the solvent, whereas the surface facing inward typically contains nonpolar side chains.

Figure 2.30 The alpha helix. (a) Tubular representation of an α helix. The atoms of the main chain would just fit within a tube of this radius. (b) The helical path around a central axis taken by the polypeptide backbone in a region of α helix. Each complete (360°) turn of the helix corresponds to 3.6 amino acid residues. The distance along the axis between adjacent residues is 1.5 \AA . (c) The arrangement of the atoms of the backbone of the α helix and the hydrogen bonds that form between amino acids. Because of the helical rotation, the peptide bonds of every fourth amino acid come into close proximity. The approach of the carbonyl group ($\text{C}=\text{O}$) of one peptide bond to the imine group ($\text{H}-\text{N}$) of another peptide bond results in the formation of hydrogen bonds between them. The hydrogen bonds (orange bars) are essentially parallel to the axis of the cylinder and thus hold the turns of the chain together. (A: FROM JAYNATH R. BANAVAR AND AMOS MARITAN. FIGURE CREATED BY TIMOTHY LEZON. REPRINTED WITH PERMISSION FROM THE ANNUAL REVIEW OF BIOPHYSICS, VOLUME 36; ©2007, BY ANNUAL REVIEWS, INC.)

The second conformation proposed by Pauling and Corey was the **beta (β)-pleated sheet**, which consists of several segments of a polypeptide lying side by side (Figure 2.31a). Unlike the coiled, cylindrical form of the α helix, the backbone of each segment of polypeptide (or **β strand**) in a β sheet assumes a folded or pleated conformation (Figure 2.31b). Like the α helix, the β sheet is also characterized by a large number

of hydrogen bonds, but these are oriented perpendicular to the long axis of the polypeptide chain and project across from one part of the chain to another (Figure 2.31c). The strands of a β sheet can be arranged either parallel or antiparallel (as in Figure 2.31a) to one another. Like the α helix, the β sheet has also been found in many different proteins. Because β strands are highly extended, the β sheet resists pulling (tensile) forces.

Figure 2.31 The β -pleated sheet. (a) Tubular representation of an antiparallel β sheet. (b) Each polypeptide of a β sheet assumes an extended but pleated conformation referred to as a β strand. The pleats result from the location of the α -carbons above and below the plane of the sheet. Successive side chains (R groups in the figure) project upward and downward from the backbone. The distance along the axis between adjacent residues is 3.5 \AA . (c) A β -pleated sheet consists of a number of β strands that lie parallel to one another and are joined together by a regular array of hydrogen bonds between the carbonyl and imine groups of the neighboring backbones. Neighboring segments of the polypeptide backbone may lie either parallel (in the same N-terminal \rightarrow C-terminal direction) or antiparallel (in the opposite N-terminal \rightarrow C-terminal direction). (A: FROM JAYNATH R. BANAVAR AND AMOS MARITAN. FIGURE CREATED BY TIMOTHY LEZON. Figure 2.32 A ribbon model of ribonuclease. The regions of α helix are depicted as spirals and β strands as flattened ribbons with the arrows indicating the N-terminal \rightarrow C-terminal direction of the polypeptide. Those segments of the chain that do not adopt a regular secondary structure (i.e., an α helix or β strand) consist largely of loops and turns. Disulfide bonds are shown in yellow. (HAND DRAWN BY JANE S. RICHARDSON.)

Figure 2.33 An X-ray diffraction pattern of myoglobin. The pattern of spots is produced as a beam of X-rays is diffracted by the atoms in the protein crystal, causing the X-rays to strike the film at specific sites. Information derived from the position and intensity (darkness) of the spots can be used to calculate the positions of the atoms in the protein that diffracted the beam, leading to complex structures such as that shown in Figure 2.34. (COURTESY OF JOHN C. KENDREW.)

Silk is composed of a protein containing an extensive amount of β sheet; silk fibers are thought to owe their strength to this architectural feature. Remarkably, a single fiber of spider silk, which may be a tenth the thickness of a human hair, is roughly five times stronger than a steel fiber of comparable weight.

Those portions of a polypeptide chain not organized into an α helix or a β sheet may consist of hinges, turns, loops, or finger-like extensions. Often, these are the most flexible portions of a polypeptide chain and the sites of greatest biological activity. For example, antibody molecules are known for their specific interactions with other molecules (antigens); these interactions are mediated by a series of loops at one end of the antibody molecule (see Figures 17.15 and 17.16). The various types of secondary structures are most simply depicted as shown in Figure 2.32: α helices are represented by helical ribbons, β strands as flattened arrows, and connecting segments as thinner strands.

Tertiary Structure The next level above secondary structure is tertiary structure, which describes the conformation of the entire polypeptide. Whereas secondary structure is stabilized primarily by hydrogen bonds between atoms that form the peptide bonds of the backbone, tertiary structure is stabilized by an array of noncovalent bonds between the diverse side chains of the protein. Secondary structure is largely limited to a small number of conformations, but tertiary structure is virtually unlimited.

The detailed tertiary structure of a protein is usually determined using the technique of **X-ray crystallography**.⁵ In this technique (which is described in more detail in Sections 3.2 and 18.8), a crystal of the protein is bombarded by a thin beam of X-rays, and the radiation that is scattered (diffracted) by the electrons of the protein's atoms is allowed to strike a radiation-sensitive plate or detector, forming an image of spots, such as those of Figure 2.33. When these diffraction patterns are subjected to complex mathematical analysis, an investigator can work backward to derive the structure responsible for producing the pattern.

For many years it was presumed that all proteins had a fixed three-dimensional structure, which gave each protein its unique properties and specific functions. It came as a surprise to discover over the past decade or so that many proteins of higher organisms contain sizable segments that lack a defined conformation. Examples of proteins containing these types of unstructured (or *disordered*) segments can be seen in the models of the PrP protein in Figure 1 on page 67 and the histone tails in Figure 12.13c. The disordered regions in these proteins are depicted as dashed lines in the images, conveying the

⁵The three-dimensional structure of small proteins can also be determined by nuclear magnetic resonance (NMR) spectroscopy, which is not discussed in this text (see the supplement to the July issue of *Nature Struct. Biol.*, 1998, *Nature Struct. Biol.* 7:982, 2000, and *Trends Biochem. Sci.* 34: 601, 2009 for reviews of this technology). Figure 1a, page 67, shows an NMR-derived structure.

fact that these segments of the polypeptide (like pieces of spaghetti) can occupy many different positions and, thus, cannot be studied by X-ray crystallography. Disordered segments tend to have a predictable amino acid composition, being enriched in charged and polar residues and deficient in hydrophobic residues. You might be wondering whether proteins lacking a fully defined structure could be engaged in a useful function. In fact, the disordered regions of such proteins play key roles in vital cellular processes, often binding to DNA or to other proteins. Remarkably, these segments often undergo a physical transformation once they bind to an appropriate partner and are then seen to possess a defined, folded structure.

Most proteins can be categorized on the basis of their overall conformation as being either **fibrous proteins**, which have an elongated shape, or **globular proteins**, which have a compact shape. Most proteins that act as structural materials outside living cells are fibrous proteins, such as collagens and elastins of connective tissues, keratins of hair and skin, and silk. These proteins resist pulling or shearing forces to which they are exposed. In contrast, most proteins within the cell are globular proteins.

Myoglobin: The First Globular Protein Whose Tertiary Structure Was Determined The polypeptide chains of globular proteins are folded and twisted into complex shapes. Distant points on the linear sequence of amino acids are brought next to each other and linked by various types of bonds. The first glimpse at the tertiary structure of a globular protein came in 1957 through the X-ray crystallographic studies of John Kendrew and his colleagues at Cambridge University using X-ray dif-

fraction patterns such as that shown in Figure 2.33. The protein they reported on was myoglobin.

Myoglobin functions in muscle tissue as a storage site for oxygen; the oxygen molecule is bound to an iron atom in the center of a heme group. (The heme is an example of a *prosthetic group*, i.e., a portion of the protein that is not composed of amino acids, which is joined to the polypeptide chain after its assembly on the ribosome.) It is the heme group of myoglobin that gives most muscle tissue its reddish color. The first report on the structure of myoglobin provided a low-resolution profile sufficient to reveal that the molecule was compact (globular) and that the polypeptide chain was folded back on itself in a complex arrangement. There was no evidence of regularity or symmetry within the molecule, such as that revealed in the earlier description of the DNA double helix. This was not surprising considering the singular function of DNA and the diverse functions of protein molecules.

The earliest crude profile of myoglobin revealed eight rod-like stretches of α helix ranging from 7 to 24 amino acids in length. Altogether, approximately 75 percent of the 153 amino acids in the polypeptide chain is in the α -helical conformation. This is an unusually high percentage compared with that for other proteins that have since been examined. No β -pleated sheet was found. Subsequent analyses of myoglobin using additional X-ray diffraction data provided a much more detailed picture of the molecule (Figures 2.34a and 3.16). For example, it was shown that the heme group is situated within a pocket of hydrophobic side chains that promotes the binding of oxygen without the oxidation (loss of electrons) of the iron atom. Myoglobin contains no disulfide bonds; the tertiary structure of the protein is held together

(a)

Figure 2.34 The three-dimensional structure of myoglobin. (a) The tertiary structure of whale myoglobin. Most of the amino acids are part of α helices. The nonhelical regions occur primarily as turns, where the polypeptide chain changes direction. The position of the heme is indicated in red. (b) The three-dimensional structure of myoglobin (heme

indicated in red). The positions of all of the molecule's atoms, other than hydrogen, are shown. (A: ILLUSTRATION, IRVING GEIS. IMAGE FROM IRVING GEIS COLLECTION/HOWARD HUGHES MEDICAL INSTITUTE. RIGHTS OWNED BY HHMI. REPRODUCED BY PERMISSION ONLY; B: KEN EDWARD/PHOTO RESEARCHERS.)

exclusively by noncovalent interactions. All of the noncovalent bonds thought to occur between side chains within proteins—hydrogen bonds, ionic bonds, and van der Waals forces—have been found (Figure 2.35). Unlike myoglobin, most globular proteins contain both α helices and β sheets. Most importantly, these early landmark studies revealed that each protein has a unique tertiary structure that can be correlated with its amino acid sequence and its biological function.

Protein Domains Unlike myoglobin, most eukaryotic proteins are composed of two or more spatially distinct modules, or **domains**, that fold independent of one another. For example, the mammalian enzyme phospholipase C, shown in the central part of Figure 2.36, consists of four distinct domains, colored differently in the drawing. The different domains of a polypeptide often represent parts that function in a semi-independent manner. For example, they might bind different factors, such as a coenzyme and a substrate or a DNA strand and another protein, or they might move relatively independent of one another. Protein domains are often identified with a specific function. For example, proteins containing a PH domain bind to membranes containing a specific phospholipid, whereas proteins containing a chromodomain bind to a methylated lysine residue in another protein. The functions of a newly identified protein can usually be predicted by the domains of which it is made.

Many polypeptides containing more than one domain are thought to have arisen during evolution by the fusion of genes that encoded different ancestral proteins, with each domain representing a part that was once a separate molecule. Each domain of the mammalian phospholipase C molecule, for example, has been identified as a homologous unit in another

protein (Figure 2.36). Some domains have been found only in one or a few proteins. Other domains have been shuffled widely about during evolution, appearing in a variety of proteins whose other regions show little or no evidence of an evolutionary relationship. Shuffling of domains creates proteins with unique combinations of activities. On average, mammalian proteins tend to be larger and contain more domains than proteins of less complex organisms, such as fruit flies and yeast.

Dynamic Changes within Proteins Although X-ray crystallographic structures possess exquisite detail, they are static images frozen in time. Proteins, in contrast, are not static and inflexible, but capable of considerable internal movements. Proteins are, in other words, molecules with “moving parts.” Because they are tiny, nanometer-sized objects, proteins can be greatly influenced by the energy of their environment. Random, small-scale fluctuations in the arrangement of the bonds within a protein create an incessant thermal motion within the molecule. Spectroscopic techniques, such as nuclear magnetic resonance (NMR), can monitor dynamic

Figure 2.35 Types of noncovalent bonds maintaining the conformation of proteins.

Figure 2.36 Proteins are built of structural units, or domains. The mammalian enzyme phospholipase C is constructed of four domains, indicated in different colors. The catalytic domain of the enzyme is shown in blue. Each of the domains of this enzyme can be found independently in other proteins as indicated by the matching color. (FROM LIISA HOLM AND CHRIS SANDER, STRUCTURE 5:167, © 2007, WITH PERMISSION FROM ELSEVIER.)

movements within proteins, and they reveal shifts in hydrogen bonds, waving movements of external side chains, and the full rotation of the aromatic rings of tyrosine and phenylalanine residues about one of the single bonds. The important role that such movements can play in a protein's function is illustrated in studies of acetylcholinesterase, the enzyme responsible for degrading acetylcholine molecules that are left behind following the transmission of an impulse from one nerve cell to another (Section 4.8). When the tertiary structure of acetylcholinesterase was first revealed by X-ray crystallography, there was no obvious pathway for acetylcholine molecules to enter the enzyme's catalytic site, which was situated at the bottom of a deep gorge in the molecule. In fact, the narrow entrance to the site was completely blocked by the presence of a number of bulky amino acid side chains. Using high-speed computers, researchers have been able to simulate the random movements of thousands of atoms within the enzyme, a feat that cannot be accomplished using experimental techniques. These molecular dynamic (MD) simulations indicated that movements of side chains within the protein would lead to the rapid opening and closing of a "gate" that would allow acetylcholine molecules to diffuse into the enzyme's catalytic site (Figure 2.37). The X-ray crystallographic structure of a protein (i.e., its *crystal structure*) can be considered an average structure, or "ground state." A protein can undergo dynamic excursions from the ground state and assume alternate conformations that are accessible based on the amount of energy that the protein contains.

Predictable (nonrandom) movements within a protein that are triggered by the binding of a specific molecule are described as **conformational changes**. Conformational changes typically involve the coordinated movements of various parts of the molecule. A comparison of the polypeptides depicted in Figures 3a and 3b on page 82 shows the dramatic conformational change that occurs in a bacterial protein (GroEL) when it interacts with another protein (GroES). Virtually every activity in which a protein takes part is accompanied by conformational changes within the molecule (see <http://molmovdb.org> to watch examples). The conformational change in the protein myosin that occurs during muscle contraction is shown in Figures 9.60 and 9.61. In this case, binding of myosin to an actin molecule leads to a small (20°) rotation of the head of the myosin, which results in a 50 to 100 Å movement of the adjacent actin filament. The importance of this dynamic event can be appreciated if you consider that the movements of your body result from the additive effect of millions of conformational changes taking place within the contractile proteins of your muscles.

Quaternary Structure Whereas many proteins such as myoglobin are composed of only one polypeptide chain, most are made up of more than one chain, or **subunit**. The subunits may be linked by covalent disulfide bonds, but most often they are held together by noncovalent bonds as occur typically between hydrophobic "patches" on the complementary surfaces of neighboring polypeptides. Proteins composed of subunits are said to have **quaternary structure**. Depending on the protein, the polypeptide chains may be identical or nonidentical. A protein composed of two identical subunits is described as a

Figure 2.37 Dynamic movements within the enzyme **acetylcholinesterase**. A portion of the enzyme is depicted here in two different conformations: (1) a closed conformation (left) in which the entrance to the catalytic site is blocked by the presence of aromatic rings that are part of the side chains of tyrosine and phenylalanine residues (shown in purple) and (2) an open conformation (right) in which the aromatic rings of these side chains have swung out of the way, opening the "gate" to allow acetylcholine molecules to enter the catalytic site. These images are constructed using computer programs that take into account a host of information about the atoms that make up the molecule, including bond lengths, bond angles, electrostatic attraction and repulsion, van der Waals forces, etc. Using this information, researchers are able to simulate the movements of the various atoms over a very short time period, which provides images of the conformations that the protein can assume. An animation of this image can be found on the Web at <http://mccammon.ucsd.edu> (COURTESY OF J. ANDREW MCCAMMON.)

homodimer, whereas a protein composed of two nonidentical subunits is a *heterodimer*. A ribbon drawing of a homodimeric protein is depicted in Figure 2.38a. The two subunits of the protein are drawn in different colors, and the hydrophobic residues that form the complementary sites of contact are indicated. The best-studied multisubunit protein is hemoglobin, the O_2 -carrying protein of red blood cells. A molecule of human hemoglobin consists of two α -globin and two β -globin polypeptides (Figure 2.38b), each of which binds a single molecule of oxygen. Elucidation of the three-dimensional structure of hemoglobin by Max Perutz of Cambridge University in 1959 was one of the early landmarks in the study of molecular biology. Perutz demonstrated that each of the four globin polypeptides of a hemoglobin molecule has a tertiary structure similar to that of myoglobin, a fact that strongly suggested the two proteins had evolved from a common ancestral polypeptide with a common O_2 -binding mechanism. Perutz also compared the structure of the oxygenated and deoxygenated versions of hemoglobin. In doing so, he discovered that the binding of oxygen was accompanied by the movement of the bound iron atom closer to the plane of the heme group. This seemingly inconsequential shift in position of a single atom pulled on an α helix to which the iron is connected, which in turn led to a series of increasingly larger movements within and between the subunits. This finding revealed for the

first time that the complex functions of proteins may be carried out by means of small changes in their conformation.

Protein–Protein Interactions Even though hemoglobin consists of four subunits, it is still considered a single protein with a single function. Many examples are known in which

(a)

(b)

Figure 2.38 Proteins with quaternary structure. (a) Drawing of transforming growth factor- $\beta 2$ (TGF- $\beta 2$), a protein that is a dimer composed of two identical subunits. The two subunits are colored yellow and blue. Shown in white are the cysteine side chains and disulfide bonds. The spheres shown in yellow and blue are the hydrophobic residues that form the interface between the two subunits. (b) Drawing of a hemoglobin molecule, which consists of two α -globin chains and two β -globin chains (a heterotetramer) joined by noncovalent bonds. When the four globin polypeptides are assembled into a complete hemoglobin molecule, the kinetics of O_2 binding and release are quite different from those exhibited by isolated polypeptides. This is because the binding of O_2 to one polypeptide causes a conformational change in the other polypeptides that alters their affinity for O_2 molecules. (A: FROM S. DAOPIN ET AL., SCIENCE 257:372, COURTESY OF DAVID R. DAVIES, © 1992, REPRODUCED WITH PERMISSION FROM AAAS; B: ILLUSTRATION, IRVING GEIS. IMAGE FROM IRVING GEIS REPRODUCED WITH PERMISSION FROM AAAS. COLLECTION/HOWARD HUGHES MEDICAL INSTITUTE. RIGHTS OWNED BY HHMI. REPRODUCED BY PERMISSION ONLY.)

different proteins, each with a specific function, become physically associated to form a much larger **multiprotein complex**. One of the first multiprotein complexes to be discovered and studied was the pyruvate dehydrogenase complex of the bacterium *Escherichia coli*, which consists of 60 polypeptide chains constituting three different enzymes (Figure 2.39). The enzymes that make up this complex catalyze a series of reactions connecting two metabolic pathways, glycolysis and the TCA cycle (see Figure 5.7). Because the enzymes are so closely associated, the product of one enzyme can be channeled directly to the next enzyme in the sequence without becoming diluted in the aqueous medium of the cell.

Multiprotein complexes that form within the cell are not necessarily stable assemblies, such as the pyruvate dehydrogenase complex. In fact, most proteins interact with other proteins in highly dynamic patterns, associating and dissociating depending on conditions within the cell at any given time. Interacting proteins tend to have complementary surfaces. Often a projecting portion of one molecule fits into a pocket within its partner. Once the two molecules have come into close contact, their interaction is stabilized by noncovalent bonds.

The reddish-colored object in Figure 2.40a is called an SH3 domain, and it is found as part of more than 200 different proteins involved in molecular signaling. The surface of an SH3 domain contains shallow hydrophobic “pockets” that become filled by complementary “knobs” projecting from another protein (Figure 2.40b). A large number of different structural domains have been identified that, like SH3, act as adaptors to mediate interactions between proteins. In many cases, protein–protein interactions are regulated by modifications, such as the addition of a phosphate group to a key amino acid, which act as a switch to turn on or off the protein’s ability to bind a protein partner. As more and more complex molecular activities have been discovered, the importance of

Figure 2.39 Pyruvate dehydrogenase: a multiprotein complex. (a) Electron micrograph of a negatively stained pyruvate dehydrogenase complex isolated from *E. coli*. Each complex contains 60 polypeptide chains constituting three different enzymes. Its molecular mass approaches 5 million daltons. (b) A model of the pyruvate dehydrogenase complex. The core of the complex consists of a cube-like cluster of dihydrolipoyl transacetylase molecules. Pyruvate dehydrogenase dimers (black spheres) are distributed symmetrically along the edges of the cube, and dihydrolipoyl dehydrogenase dimers (small gray spheres) are positioned in the faces of the cube. interactions among proteins has become increasingly apparent. For example, such diverse processes as DNA synthesis, ATP formation, and RNA processing are all accomplished by “molecular machines” that consist of a large number of interacting proteins, some of which form stable relationships and others transient liaisons. Several hundred different protein complexes have been purified in large-scale studies on yeast.

Most investigators who study protein–protein interactions want to know whether one protein they are working with, call it protein X, interacts physically with another protein, call it protein Y. This type of question can be answered using a genetic technique called the yeast two-hybrid (Y2H) assay, which is discussed in Section 18.7 and illustrated in Figure 18.27. In this technique, *genes* encoding the two proteins

being studied are introduced into the same yeast cell. If the yeast cell tests positive for a particular reporter protein, which is indicated by an obvious color change in the yeast cell, then the two proteins in question had to have interacted within the yeast cell nucleus.

Interactions between proteins are generally studied one at a time, producing the type of data seen in Figure 2.40. In recent years, a number of research teams have set out to study protein–protein interactions on a global scale. For example, one might want to know all of the interactions that occur among the 14,000 or so proteins encoded by the genome of the fruit fly *Drosophila melanogaster*. Now that the entire genome of this insect has been sequenced, virtually every gene within the genome is available as an individual DNA segment that can be cloned and used as desired. Consequently, it should be possible to test the proteins encoded by the fly genome, two at a time, for possible interactions in a Y2H assay. One study of this type reported that, of the millions of possible combinations, more than 20,000 interactions were detected among 7048 fruit-fly proteins tested.

Although the Y2H assay has been the mainstay in the study of protein–protein interactions for more than 15 years, it is an indirect assay (see Figure 18.27) and is fraught with uncertainties. On one hand, a large percentage of interactions known to occur between specific proteins fail to be detected in these types of experiments. The Y2H assay, in other words, gives a significant number of false negatives. The Y2H assay is also known to generate a large number of false positives; that is, it indicates that two proteins are capable of interacting when it is known from other studies that they do not do so under normal conditions within cells. In the study of fruit-fly proteins described above, the authors used computer analyses to narrow the findings from the original 20,000 interactions to approximately 5000 interactions in which they had high confidence. Overall, it is estimated that, on average, each protein encoded in the genome of a eukaryotic organism interacts with about five different protein partners. According to this estimate, human proteins would engage in roughly 100,000 different interactions.

The results from large-scale protein–protein interaction studies can be presented in the form of a network, such as that shown in Figure 2.41. This figure displays the potential binding partners of the various yeast proteins that contain an SH3 domain (see Figure 2.40a) and illustrates the complexities of such interactions at the level of an entire organism. In this particular figure, only those interactions detected by two entirely different assays (Y2H and a biochemical technique that involves purification and analysis of protein complexes) are displayed, which makes the conclusions much more reliable than those based on a single technology. Those proteins that have multiple binding partners, such as Las17 situated near the center of Figure 2.41, are referred to as *hubs*. Hub proteins are more likely than non-hub proteins to be essential proteins, that is, proteins that the organism cannot survive without. Some hub proteins have several different binding interfaces and are capable of binding a number of different binding partners at the same time. In contrast, other hubs have a single binding interface, which is capable of binding several different partners, but only one at a time. Examples of each of these

Figure 2.41 A network of protein–protein interactions. Each red line represents an interaction between two yeast proteins, which are indicated by the named black dots. In each case, the arrow points from an SH3 domain protein to a target protein with which it can bind. The 59 interactions depicted here were detected using two different types of techniques that measure protein–protein interactions. (See *Trends Biochem. Sci.* 34:1, and 579, 2009, for discussion of the validity of protein–protein interaction studies.) (FROM A.H.Y. TONG, ET AL., *SCIENCE* 295:323, 2002, COPYRIGHT © 2002. REPRINTED WITH PERMISSION FROM AAAS.)

types of hub proteins are illustrated in Figure 2.42. The hub protein depicted in Figure 2.42a plays a central role in the process of gene expression, while that shown in Figure 2.42b plays an equally important role in the process of cell division.

Aside from obtaining a lengthy list of *potential* interactions, what do we learn about cellular activities from these types of large-scale studies? Most importantly, they provide a guideline for further investigation. Genome-sequencing projects have provided scientists with the amino acid sequences of a huge number of proteins whose very existence was previ-

ously unknown. What do these proteins do? One approach to determining a protein's function is to identify the proteins with which it associates. If, for example, a known protein has been shown to be involved in DNA replication, and an unknown protein is found to interact with the known protein, then it is likely that the unknown protein is also part of the cell's DNA-replication machinery. Thus, regardless of their limitations, these large-scale Y2H studies (and others using different assays not discussed) provide the starting point to explore a myriad of previously unknown protein–protein interactions, each of which has the potential to lead investigators to a previously unknown biological process.

Protein Folding The elucidation of the tertiary structure of myoglobin in the late 1950s led to an appreciation for the complexity of protein architecture. An important question immediately arose: How does such a complex, folded, asymmetric organization arise in the cell? The first insight into this problem began with a serendipitous observation in 1956 by Christian Anfinsen at the National Institutes of Health. Anfinsen was studying the properties of ribonuclease A, a small enzyme that consists of a single polypeptide chain of 124 amino acids with 4 disulfide bonds linking various parts of the chain. The disulfide bonds of a protein are typically broken (reduced) by adding a reducing agent, such as mercaptoethanol, which converts each disulfide bridge to a pair of sulfhydryl (—SH) groups (see drawing, page 53). To make all of the disulfide bonds accessible to the reducing agent, Anfinsen found that the molecule had to first be partially unfolded. The unfolding or disorganization of a protein is termed **denaturation**, and it can be brought about by a variety of agents, including detergents, organic solvents, radiation, heat, and compounds such as urea and guanidine chloride, all of which interfere with the various interactions that stabilize a protein's tertiary structure.

Figure 2.42 Protein–protein interactions of hub proteins. (a) The enzyme RNA polymerase II, which synthesizes messenger RNAs in the cell, binds a multitude of other proteins simultaneously using multiple interfaces. (b) The enzyme Cdc28, which phosphorylates other proteins as it regulates the cell division cycle of budding yeast.

Cdc28 binds a number of different proteins (Cln1–Cln3) at the same interface, which allows only one of these partners to bind at a time. (FROM DAMIEN DEVOS AND ROBERT B. RUSSELL, *CURR. OPIN. STRUCT. BIOL.* 17:373, © 2007, WITH PERMISSION OF ELSEVIER.)

When Anfinsen treated ribonuclease molecules with mercaptoethanol and concentrated urea, he found that the preparation lost all of its enzymatic activity, which would be expected if the protein molecules had become totally unfolded. When he removed the urea and mercaptoethanol from the preparation, he found, to his surprise, that the molecules regained their normal enzymatic activity. The active ribonuclease molecules that had re-formed from the unfolded protein were indistinguishable both structurally and functionally from the correctly folded (i.e., **native**) molecules present at the beginning of the experiment (Figure 2.43). After extensive study, Anfinsen concluded that the linear sequence of amino acids contained all of the information required for the formation of the polypeptide's three-dimensional conformation. Ribonuclease, in other words, is capable of **self-assembly**. As discussed in Chapter 3, events tend to progress toward states of lower energy. According to this concept, the tertiary structure that a polypeptide chain assumes after folding is the accessible structure with the lowest energy, which makes it the most thermodynamically stable structure that can be formed by that chain. It would appear that evolution selects for those amino acid sequences that generate a polypeptide chain capable of spontaneously arriving at a meaningful native state in a biologically reasonable time period.

There have been numerous controversies in the study of protein folding. Many of these controversies stem from the fact that the field is characterized by highly sophisticated experimental, spectroscopic, and computational procedures that are required to study complex molecular events that typically occur on a microsecond timescale. These efforts have often yielded conflicting results and have generated data that are

Figure 2.43 Denaturation and refolding of ribonuclease. A native ribonuclease molecule (with intramolecular disulfide bonds indicated) is reduced and unfolded with β -mercaptoethanol and 8 M urea. After removal of these reagents, the protein undergoes spontaneous refolding. (FROM C. J. EPSTEIN, R. F. GOLDBERGER, AND C. B. ANFINSEN, COLD SPRING HARBOR SYMP. QUANT. BIOL. 28:439, 1963. REPRINTED WITH PERMISSION FROM COLD SPRING HARBOR LABORATORY PRESS.)

open to more than one interpretation. For the sake of simplicity, we will restrict the discussion to “simple” proteins, such as ribonuclease, that consist of a single domain. One fundamental issue that has been extensively debated is whether all of the members of a population of unfolded proteins of a single species fold along a similar pathway or fold by means of a diverse set of routes that somehow converge upon the same native state. Recent studies that have simulated folding with the aid of specialized supercomputers appear to have swung the consensus toward the idea that single-domain proteins fold along a single dominant pathway characterized by a unique, relatively well-defined transition state (see Figure 2.45).

Another issue that has been roundly debated concerns the types of events that occur at various stages during the folding process. In the course depicted in Figure 2.44a, protein folding is initiated by interactions among neighboring residues that lead to the formation of much of the secondary structure of the molecule. Once the α helices and β sheets are formed, subsequent folding is driven by hydrophobic interactions that bury nonpolar residues together in the central core of the protein. According to an alternate scheme shown in Figure 2.44b, the first major event in protein folding is the hydrophobic collapse of the polypeptide to form a compact structure in which the backbone adopts a native-like topology. Only after this collapse does significant secondary structure develop. Recent studies indicate that the two pathways depicted in Figure 2.44 lie at opposite extremes, and that most proteins probably fold by a middle-of-the-road scheme in which secondary structure formation and compaction occur simultaneously. These early

Figure 2.45 Along the folding pathway. The image on the left shows the native tertiary structure of the enzyme acyl-phosphatase. The image on the right is the transition structure, which represents the state of the molecule at the top of an energy barrier that must be crossed if the protein is going to reach the native state. The transition structure consists of numerous individual lines because it is a set (ensemble) of closely related structures. The overall architecture of the transition structure is similar to that of the native protein, but many of the finer structural features of the fully folded protein have yet to emerge. Conversion of the transition state to the native protein involves completing secondary structure formation, tighter packing of the side chains, and finalizing the burial of hydrophobic side chains from the aqueous solvent. (FROM K. LINDORFF-LARSEN, ET AL, *TRENDS BIOCHEM. SCI.* 30:14, 2005, FIG. 1B. © 2005, WITH PERMISSION FROM ELSEVIER. IMAGE FROM CHRISTOPHER DOBSON.)

folding events lead to the formation of a partially folded, transient structure that resembles the native protein but lacks many of the specific interactions between amino acid side chains that are present in the fully folded molecule (Figure 2.45).

If the information that governs folding is embedded in a protein's amino acid sequence, then alterations in this sequence have the potential to change the way a protein folds, leading to an abnormal tertiary structure. In fact, many mutations responsible for inherited disorders have been found to alter a protein's three-dimensional structure. In some cases, the consequences of protein misfolding can be fatal. Two examples of fatal neurodegenerative diseases that result from abnormal protein folding are discussed in the accompanying Human Perspective.

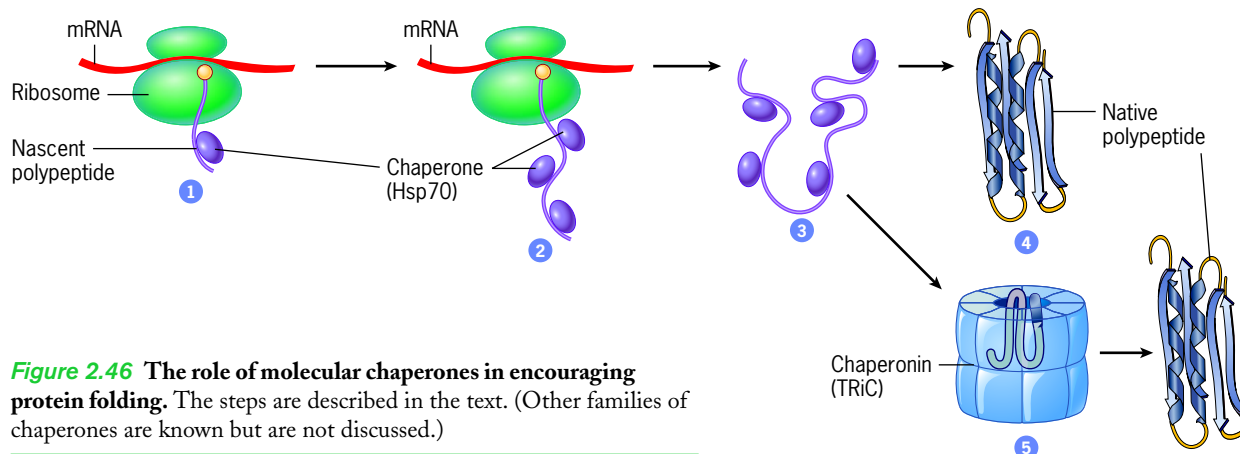

Figure 2.46 The role of molecular chaperones in encouraging protein folding. The steps are described in the text. (Other families of chaperones are known but are not discussed.)

The Role of Molecular Chaperones Not all proteins are able to assume their final tertiary structure by a simple process of self-assembly. This is not because the primary structure of these proteins lacks the required information for proper folding, but rather because proteins undergoing folding have to be prevented from interacting nonselectively with other molecules in the crowded compartments of the cell. Several families of proteins have evolved whose function is to help unfolded or misfolded proteins achieve their proper three-dimensional conformation. These “helper proteins” are called **molecular chaperones**, and they selectively bind to short stretches of hydrophobic amino acids that tend to be exposed in nonnative proteins but buried in proteins having a native conformation.

Figure 2.46 depicts the activities of two families of molecular chaperones that operate in the cytosol of eukaryotic cells. Molecular chaperones are involved in a multitude of activities within cells, ranging from the import of proteins into organelles (see Figure 8.47a) to the prevention and reversal of protein aggregation. We will restrict the discussion to their actions on newly synthesized proteins. Polypeptide chains are synthesized on ribosomes by the addition of amino acids, one at a time, beginning at the chain's N-terminus (step 1, Figure 2.46). Chaperones of the Hsp70 family bind to elongating polypeptide chains as they emerge from an exit channel within the large subunit of the ribosome (step 2). Hsp70 chaperones are thought to prevent these partially formed polypeptides (i.e., *nascent* polypeptides) from binding to other proteins in the cytosol, which would cause them either to aggregate or misfold. Once their synthesis has been completed (step 3), many of these proteins are simply released by the chaperones into the cytosol where they spontaneously fold into their native state (step 4). Other proteins are repeatedly bound and released by chaperones until they finally reach their fully folded state. Many of the larger polypeptides are transferred from Hsp70 proteins to a different type of chaperone called a *chaperonin* (step 5). Chaperonins are cylindrical protein complexes that contain chambers in which newly synthesized polypeptides can fold without interference from other macromolecules in the cell. TRiC is a chaperonin thought to assist in the folding of up to 15 percent of the polypeptides synthesized in mammalian cells. The discovery and mechanism of action of Hsp70 and chaperonins are discussed in depth in the Experimental Pathways on page 80.

Protein Misfolding Can Have Deadly Consequences

In April 1996 a paper was published in the medical journal *Lancet* that generated widespread alarm in the populations of Europe. The paper described a study of 10 persons afflicted with Creutzfeldt-Jakob disease (CJD), a rare, fatal disorder that attacks the brain, causing a loss of motor coordination and dementia. Like numerous other diseases, CJD can occur as an inherited disease that runs in certain families or as a sporadic form that appears in individuals who have no family history of the disease. Unlike virtually every other inheritable disease, however, CJD can also be *acquired*. Until recently, persons who had acquired CJD had been recipients of organs or organ products that were donated by a person with undiagnosed CJD. The cases described in the 1996 *Lancet* paper had also been acquired, but the apparent source of the disease was contaminated beef that the infected individuals had eaten years earlier. The contaminated beef was derived from cattle raised in England that had contracted a neurodegenerative disease that caused the animals to lose motor coordination and develop demented behavior. The disease became commonly known as “mad cow disease.” Patients who have acquired CJD from eating contaminated beef can be distinguished by several criteria from those who suffer from the classical forms of the disease. To date, roughly 200 people have died of CJD acquired from contaminated beef, and the numbers of such deaths have been declining.¹

A disease that runs in families can invariably be traced to a faulty gene, whereas diseases that are acquired from a contaminated source can invariably be traced to an infectious agent. How can the same disease be both inherited and infectious? The answer to this question has emerged gradually over the past several decades, beginning with observations by D. Carleton Gajdusek in the 1960s on a strange malady that once afflicted the native population of Papua, New Guinea. Gajdusek showed that these islanders were contracting a fatal neurodegenerative disease—which they called “kuru”—during a funeral ritual in which they ate the brain tissue of a recently deceased relative. Autopsies of the brains of patients who had died of kuru showed a distinct pathology, referred to as *spongiform encephalopathy*, in which certain brain regions were riddled with microscopic holes (vacuolations), causing the tissue to resemble a sponge.

It was soon shown that the brains of islanders suffering from kuru were strikingly similar in microscopic appearance to the brains of persons afflicted with CJD. This observation raised an important question: Did the brain of a person suffering from CJD, which was known to be an inherited disease, contain an infectious agent? In 1968, Gajdusek showed that when extracts prepared from a biopsy of the brain of a person who had died from CJD were injected into a suitable laboratory animal, that animal did indeed develop a spongiform encephalopathy similar to that of kuru or CJD. Clearly, the extracts contained an infectious agent, which at the time was presumed to be a virus.

In 1982, Stanley Prusiner of the University of California, San Francisco, published a paper suggesting that, unlike viruses, the infectious agent responsible for CJD lacked nucleic acid and instead was

composed solely of protein. He called the protein a *prion*. This “protein only” hypothesis, as it is called, was originally met with considerable skepticism, but subsequent studies by Prusiner and others have provided overwhelming support for the proposal. It was presumed initially that the prion protein was an external agent—some type of virus-like particle lacking nucleic acid. Contrary to this expectation, the prion protein was soon shown to be encoded by a gene (called *PRNP*) within the cell’s own chromosomes. The gene is expressed within *normal*/brain tissue and encodes a protein designated PrP^C (standing for prion protein cellular) that resides at the surface of nerve cells. The precise function of PrP^C remains a mystery. A modified version of the protein (designated PrP^{Sc}, standing for prion protein scrapie) is present in the brains of humans with CJD. Unlike the normal PrP^C, the modified version of the protein accumulates within nerve cells, forming aggregates that kill the cells.

In their purified states, PrP^C and PrP^{Sc} have very different physical properties. PrP^C remains as a monomeric molecule that is soluble in salt solutions and is readily destroyed by protein-digesting enzymes. In contrast, PrP^{Sc} molecules interact with one another to form insoluble fibrils that are resistant to enzymatic digestion. Based on these differences, one might expect these two forms of the PrP protein to be composed of distinctly different sequences of amino acids, but this is not the case. The two forms can have identical amino acid sequences, but they differ in the way the polypeptide chain folds to form the three-dimensional protein molecule (Figure 1). Whereas a PrP^C molecule consists largely of α -helical segments and interconnecting coils, the core of a PrP^{Sc} molecule consists largely of β sheet.

It is not hard to understand how a mutant polypeptide might be less stable and more likely to fold into the abnormal PrP^{Sc} conformation, but how is such a protein able to act as an infectious agent? According to the prevailing hypothesis, an abnormal prion molecule (PrP^{Sc}) can bind to a normal protein molecule (PrP^C) and cause the normal protein to fold into the abnormal form. This conversion can be shown to occur in the test tube: addition of PrP^{Sc} to a preparation of PrP^C can convert the PrP^C molecules into the PrP^{Sc} conformation. According to this hypothesis, the appearance of the abnormal protein in the body—whether as a result of a rare misfolding event in the case of sporadic disease or by exposure to contaminated beef—starts a chain reaction in which normal protein molecules in the cells are gradually converted to the misshapen prion form as they are recruited into growing insoluble fibrils. The precise mechanism by which prions lead to neurodegeneration remains unclear.

CJD is a rare disease caused by a protein with unique infective properties. Alzheimer’s disease (AD), on the other hand, is a common disorder that strikes as many as 10 percent of individuals who are at least 65 years of age and perhaps 40 percent of individuals who are 80 years or older. Persons with AD exhibit memory loss, confusion, and a loss of reasoning ability. CJD and AD share a number of important features. Both are fatal neurodegenerative diseases that can occur in either an inherited or sporadic form. Like CJD, the brain of a person with Alzheimer’s disease contains fibrillar deposits of an insoluble material referred to as *amyloid* (Figure 2).² In both

¹On the surface, this would suggest that the epidemic has run its course, but there are several reasons for public health officials to remain concerned. For one, studies of tissues that had been removed during surgeries in England indicate that thousands of people are likely to be infected with the disease without exhibiting symptoms (discussed in *Science* 335:411, 2012). Even if these individuals never develop clinical disease, they remain potential carriers who could pass CJD on to others through blood transfusions. In fact, at least two individuals are believed to have contracted CJD after receiving blood from a donor harboring the disease. These findings underscore the need to test blood for the presence of the responsible agent (whose nature is discussed below).

²It should be noted that the term amyloid is not restricted to the abnormal protein found in AD. Many different proteins are capable of assuming an abnormal conformation that is rich in β -sheet, which causes the protein monomers to aggregate into characteristic amyloid fibrils that bind certain dyes. Amyloid fibrils are defined by their molecular structure in which the β -strands are oriented perpendicular to the long axis of the fibrils. The PrP^{Sc}-forming fibrils of prion diseases are also described as amyloid.

Figure 1 A contrast in structure. (a) Tertiary structure of the normal (PrP^{C}) protein as determined by NMR spectroscopy. The orange portions represent α -helical segments, and the blue portions are short β strands. The yellow dotted line represents the N-terminal portion of the polypeptide, which lacks defined structure. (b) A proposed model of the abnormal, infectious (PrP^{Sc}) prion protein, which consists largely of β -sheet. The actual tertiary structure of the prion protein has not been determined. The two molecules shown in this figure are formed by polypeptide chains that can be identical in amino acid sequence but

fold very differently. As a result of the differences in folding, PrP^{C} remains soluble, whereas PrP^{Sc} produces aggregates that kill the cell. (The two molecules shown in this figure are called *conformers* because they differ only in conformation.) (A: FROM R. RIEK, ET AL., FEBS 413, 287, FIG. 1. © 1997, WITH PERMISSION FROM ELSEVIER. IMAGE FROM KURT WÜTHRICH. B: REPRINTED FROM S. B. PRUSINER, TRENDS BIOCHEM. SCI. 21:483, 1996 COPYRIGHT 1996, WITH PERMISSION FROM ELSEVIER.)

diseases, the fibrillar deposits result from the self-association of a polypeptide composed predominantly of β sheet. There are also many basic differences between the two diseases: the proteins that form the disease-causing aggregates are unrelated, the parts of the brain that are affected are distinct, and the protein responsible for AD is not considered to be an infectious agent (i.e., it does not spread in a contagious pattern from one person to another, although it may spread from cell to cell within the brain).

Over the past two decades, research on AD has been dominated by the *amyloid hypothesis*, which contends that the disease is caused by the production of a molecule, called the *amyloid β -peptide* ($\text{A}\beta$). $\text{A}\beta$ is originally part of a larger protein called the *amyloid precursor protein* (APP), which spans the nerve cell membrane. The $\text{A}\beta$ peptide is released from the APP molecule following cleavage by two specific enzymes, β -secretase and γ -secretase (Figure 3). The length of the $\text{A}\beta$ peptide is somewhat variable. The predominant species

(a)

Figure 2 Alzheimer's disease. (a) The defining characteristics of brain tissue from a person who died of Alzheimer's disease. (b) Amyloid plaques containing aggregates of the $\text{A}\beta$ peptide appear extracellularly (between nerve cells), whereas neurofibrillary tangles (NFTs) appear within the cells themselves. NFTs, which are discussed at the end of the Human

Perspective, are composed of misfolded tangles of a protein called tau that is involved in maintaining the microtubule organization of the nerve cell. Both the plaques and tangles have been implicated as a cause of the disease. (A: © THOMAS DEERINCK, NCMIR/PHOTO RESEARCHERS, INC. B: © AMERICAN HEALTH ASSISTANCE FOUNDATION.)

Figure 3 Formation of the A β peptide. The A β peptide is carved from the amyloid precursor protein (APP) as the result of cleavage by two enzymes, β -secretase and γ -secretase. It is interesting that APP and the two secretases are all proteins that span the membrane. Cleavage of APP occurs inside the cell (probably in the endoplasmic reticulum), and the A β product is ultimately secreted into the space outside of the cell. The γ -secretase can cut at either of two sites in the APP molecule, producing either A β 40 or A β 42 peptides, the latter of which is primarily responsible for production of the amyloid plaques seen in Figure 2. γ -Secretase is a multisubunit enzyme that cleaves its substrate at a site within the membrane.

has a length of 40 amino acids (designated as A β 40), but a minor species with two additional hydrophobic residues (designated as A β 42) is also produced. Both of these peptides can exist in a soluble form that consists predominantly of α helices, but A β 42 has a tendency to spontaneously refold into a very different conformation that contains considerable β -pleated sheet. It is the misfolded A β 42 version of the molecule that has the greatest potential to cause damage to the brain. A β 42 tends to self-associate to form small complexes (oligomers) as well as large aggregates that are visible as fibrils in the electron microscope. These amyloid fibrils are deposited outside of the nerve cells in the form of extracellular *amyloid plaques* (Figure 2). Although the issue is far from settled, a body of evidence suggests that it is the soluble oligomers that are most toxic to nerve cells, rather than the insoluble aggregates. Cultured nerve cells, for example, are much more likely to be damaged by the presence of soluble intracellular A β oligomers than by either A β monomers or extracellular fibrillar aggregates. In the brain, the A β oligomers appear to attack the synapses that connect one nerve cell to another and eventually lead to the death of the nerve cells. Persons who suffer from an inherited form of AD carry a mutation that leads to an increased production of the A β 42 peptide. Overproduction of A β 42 can be caused by possession of extra copies (duplications) of the *APP* gene, by mutations in the *APP* gene, or by mutations in genes (*PSEN1*, *PSEN2*) that encode subunits of γ -secretase. Individuals with such mutations exhibit symptoms of the disease at an early age, typically in their 50s. The fact that all mutations associated with these inherited, early-onset forms of AD lead to increased production of A β 42 is the strongest argument favoring amyloid formation

as the underlying basis of the disease. The strongest argument against the amyloid hypothesis is the weak correlation that can exist between the number and size of amyloid plaques in the brain and the severity of the disease. Elderly persons who show little or no sign of memory loss or dementia can have relatively high levels of amyloid deposits in their brain and those with severe disease can have little or no amyloid deposition.

All of the drugs currently on the market for the treatment of AD are aimed only at management of symptoms; none has any effect on stopping disease progression. With the amyloid hypothesis as the guiding influence, researchers have followed three basic strategies in the pursuit of new drugs for the prevention and/or reversal of mental decline associated with AD. These strategies are (1) to prevent the formation of the A β 42 peptide in the first place; (2) to remove the A β 42 peptide (or the amyloid deposits it produces) once it has been formed; and (3) to prevent the interaction between A β molecules, thereby preventing the formation of both oligomers and fibrillar aggregates. Before examining each of these strategies, we can consider how investigators can determine what type of drugs might be successful in the prevention or treatment of AD.

One of the best approaches to the development of treatments for human diseases is to find laboratory animals, particularly mice, that develop similar diseases, and use these animals to test the effectiveness of potential therapies. Animals that exhibit a disease that mimics a human disease are termed *animal models*. For whatever reason, the brains of aging mice show no evidence of the amyloid deposits found in humans, and, up until 1995, there was no animal model for AD. Then, in that year, researchers found that they could create a strain of mice that developed amyloid plaques in their brain and performed poorly at tasks that required memory. They created this strain by genetically engineering the mice to carry a mutant human *APP* gene, one responsible for causing AD in families. These genetically engineered (*transgenic*) mice have proven invaluable for testing potential therapies for AD. The greatest excitement in the field of AD therapeutics has centered on the second strategy mentioned above, and we can use these investigations to illustrate some of the steps required in the development of a new drug.

In 1999, Dale Schenk and his colleagues at Elan Pharmaceuticals published an extraordinary finding. They had discovered that the formation of amyloid plaques in mice carrying the mutant human *APP* gene could be blocked by repeatedly injecting the animals with the very same substance that causes the problem, the aggregated A β 42 peptide. In effect, the researchers had immunized (i.e., vaccinated) the mice against the disease. When young (6-week-old) mice were immunized with A β 42, they failed to develop the amyloid brain deposits as they grew older. When older (13-month-old) mice whose brains already contained extensive amyloid deposits were immunized with the A β 42, a significant fraction of the fibrillar deposits was cleared out of the nervous system. Even more importantly, the immunized mice performed better than their nonimmunized littermates on memory-based tests.

The dramatic success of these experiments on mice, combined with the fact that the animals showed no ill effects from the immunization procedure, led government regulators to quickly approve a Phase I clinical trial of the A β 42 vaccine. A Phase I clinical trial is the first step in testing a new drug or procedure in humans and usually comes after years of preclinical testing on cultured cells and animal models. Phase I tests are carried out on a small number of subjects and are designed to monitor the safety of the therapy and the optimal dose of the drug rather than its effectiveness against the disease.

None of the subjects in two separate Phase I trials of the A β vaccine showed any ill-effects from the injection of the amyloid peptide. As a result, the investigators were allowed to proceed to a Phase II clinical trial, which involves a larger group of subjects and is

designed to obtain a measure of the effectiveness of the procedure (or drug). This particular Phase II trial was carried out as a randomized, double-blind, placebo-controlled study. In this type of study:

1. the patients are *randomly* divided into two groups that are treated similarly except that one group is given the curative factor (protein, antibodies, drugs, etc.) being investigated and the other group is given a *placebo* (an inactive substance that has no therapeutic value), and
2. the study is *double-blinded*, which means that neither the researchers nor patients know who is receiving treatment and who is receiving the placebo.

The Phase II trial for the A β vaccine began in 2001 and enrolled more than 350 individuals in the United States and Europe who had been diagnosed with mild to moderate AD. After receiving two injections of synthetic β -amyloid (or a placebo), 6 percent of the subjects experienced a potentially life-threatening inflammation of the brain. Most of these patients were successfully treated with steroids, but the trial was discontinued.

Once it had become apparent that vaccination of patients with A β 42 had inherent risks, it was decided to pursue a safer form of immunization therapy, which is to administer antibodies directed against A β that have been produced outside the body. This type of approach is known as *passive immunization* because the person does not produce the therapeutic antibodies themselves. Passive immunization with an anti-A β 42 antibody (called bapineuzumab) had already proven capable of restoring memory function in transgenic mice and was quickly shown to be safe, and apparently effective, in Phase I and II clinical trials. The last step before government approval is a Phase III trial, which typically employs large numbers of subjects (a thousand or more at several research centers) and compares the effectiveness of the new treatment against standard approaches. The first results of the Phase III trials on bapineuzumab were reported in 2008 and were disappointing; there was little or no evidence that the antibody provided benefits in preventing the progression of the disease. Despite these findings, a large number of different antibodies targeting amyloid peptides are currently in clinical trials. Given the impact of AD on human health and the large amount of money that could be earned from this type of drug, pharmaceutical companies are willing to take the risk that one of these immunologic strategies will exhibit some therapeutic value.

Meanwhile, a comprehensive analysis of some of the patients who had been vaccinated with A β 42 in the original immunization trial from 2001 was also reported in 2008. Analysis of this patient group indicated that the A β 42 vaccination had had no effect on preventing disease progression. It was particularly striking that in several of these patients who had died of severe dementia, there were virtually no amyloid plaques left in their brains. This finding strongly suggests that removal of amyloid deposits in a patient already suffering the symptoms of mild-to-moderate dementia does not stop disease progression. These results can be interpreted in more than one way. One interpretation is that the amyloid deposits are not the cause of the symptoms of dementia. An alternate interpretation is that irreversible toxic effects of the deposits had already occurred by the time immunization had begun and it was too late to reverse the disease course using treatments that remove existing amyloid deposits. It is important to note, in this regard, that the formation of amyloid deposits in the brain begins 10 or more years before any clinical symptoms of AD are reported. It is possible that, if these treatments had started earlier, the symptoms of the disease might never have appeared. Recent advances in brain-imaging procedures now allow clinicians to observe amyloid deposits in the brains of individuals long before any symptoms of AD have developed (Figure 4). Based on these studies, it may be possible to begin preventive treatments in

persons who are at very high risk of developing AD before they develop symptoms. The first clinical trial of this type was begun in 2012 as several hundred individuals who would normally be destined to develop early-onset AD (due to mutations in the *PSEN1* gene) were treated with an anti-A β antibody in the hopes of blocking the future buildup of amyloid and preventing the disease.

Drugs have also been developed that follow the other two strategies outlined above. Alzhemed and scyllo-inositol are two small molecules that bind to A β peptides and block molecular aggregation and fibril formation. Clinical trials have failed to demonstrate that either drug is effective in stopping disease progression in patients with mild to moderate AD. The third strategy outlined above is to stop production of A β peptides. This can be accomplished by inhibiting either β - or γ -secretase, because both enzymes are required in the pathway that cleaves the APP precursor to release the internal peptide (Figure 3). Pharmaceutical companies have had great difficulty developing a β -secretase inhibitor that is both potent and small enough to enter the brain from the bloodstream. A number of potent γ -secretase inhibitors have been developed that block the production of all A β peptides, both in cultured nerve cells and in transgenic AD mice. But there is a biological problem that has to be overcome with this class of inhibitors. In addition to cleaving APP, γ -secretase activity is also required in a key signaling pathway involving a protein called Notch. Two of the most promising γ -secretase inhibitors, flurizan and semagacestat, have both failed to show

Figure 4 A neuroimaging technique that reveals the presence of amyloid in the brain. These PET (positron emission tomography) scans show the brains of two individuals that have ingested a radioactive compound, called Amyvid, that binds to amyloid deposits and appears red in the image. The top shows a healthy brain and the bottom a brain from a patient with AD, revealing extensive amyloid build-up. Amyloid deposits in the brain can be detected with this technique in persons who show no evidence of cognitive dysfunction. Such symptom-free individuals are presumed to be at high risk of going on to develop AD. Those who lack such deposits can be considered at very low risk of the disease in the near future. (COURTESY OF ELI LILLY/AVID PHARMACEUTICALS.)

any benefit in stopping AD progression. In addition to its lack of efficacy, semagacestat caused adverse side effects that were probably a result of blockade of the Notch pathway. The goal of drug designers is to develop a compound (e.g., begacestat) that blocks APP cleavage but does not interfere with cleavage of Notch.

Taken collectively, the apparent failure of all of these drugs, aimed at various steps in the formation of A β -containing aggregates and amyloid deposition, has left the field of AD therapeutics without a clear plan for the future. Some pharmaceutical companies are continuing to develop new drugs aimed at blocking the formation of amyloid aggregates, whereas others are moving in different directions. These findings also raise a more basic question: Is the A β peptide even part of the underlying mechanism that leads to AD? It hasn't been mentioned, but A β is not the only misfolded protein found in the brains of persons with AD. Another protein called tau, which functions as part of a nerve cell's cytoskeleton (Section 9.3), can develop into bundles of tangled cellular filaments called neurofibrillary tangles (or NFTs) (Figure 2) that interfere with the movement of substances down the length of the nerve cell. NFTs form when the tau molecules in nerve cells become excessively phosphorylated. Mutations in the gene that encodes tau have been found to cause a rare form of dementia (called FTD), which is characterized by the formation of NFTs. Thus, NFTs have been linked to dementia, but they have been largely ignored as a causative factor in AD pathogenesis, due primarily to the fact that the transgenic AD mouse models discussed above do not develop NFTs. If one extrapolates the results of these mouse studies to humans, they suggest that NFTs are not required for the cognitive decline that occurs in patients with AD. At the same time, however, autopsies of the brains of humans who died of AD suggest that NFT burden correlates

much better with cognitive dysfunction and neuronal loss than does the concentration of amyloid plaques. Given that mutations in genes in the A β pathway are clearly a cause of AD, and yet it is the NFT burden that correlates with cognitive decline, it would appear that *both* A β and NFTs must be involved in AD etiology. Many researchers believe that A β deposition somehow leads to NFT formation, but the mechanism by which this might occur remains unknown.

It is evident from this discussion that a great deal of work on AD has been based on transgenic mice carrying human AD genes. These animals have served as the primary preclinical subjects for testing AD drugs, and they have been used extensively in basic research that aims to understand the disease mechanisms responsible for the development of AD. But many questions have been raised as to how accurately these animal models mimic the disease in humans, particularly the sporadic human cases in which affected individuals lack the mutant genes that cause the animals to develop the corresponding disorder. In fact, one of the most promising new drugs at the time of this writing is one that acts on NFTs rather than β -amyloid. In this case, the drug methylthionium chloride (brand name Rember), which dissolves NFTs, was tested on a group of more than 300 patients with mild to moderate AD in a Phase II trial. The drug was found to reduce mental decline over a period of one year by an average of 81 percent compared to patients receiving a placebo. The drug is now being tested in a larger Phase III study, but no preliminary results have yet been reported. Other compounds that inhibit one of the enzymes (GSK-3) that adds phosphate groups to the tau protein are also being investigated as AD therapeutics. Clinical trials of one GSK-3 inhibitor, valproate, have been stopped due to adverse effects. (The results of studies on these and other treatments can be examined at www.alzforum.org/dis/tre/drc)

The Emerging Field of Proteomics With all of the attention on genome sequencing in recent years, it is easy to lose sight of the fact that genes are primarily information storage units, whereas proteins orchestrate cellular activities. Genome sequencing provides a kind of “parts list.” The human genome probably contains between 20,000 and 22,000 genes, each of which can potentially give rise to a variety of different proteins.⁶ To date, only a fraction of these molecules have been characterized.

The entire inventory of proteins that is produced by an organism, whether human or otherwise, is known as that organism's **proteome**. The term *proteome* is also applied to the inventory of all proteins that are present in a particular tissue, cell, or cellular organelle. Because of the sheer numbers of proteins that are currently being studied, investigators have sought to develop techniques that allow them to determine the properties or activities of a large number of proteins in a single experiment. A new term—**proteomics**—was coined to describe the expanding field of protein biochemistry. This term carries with it the concept that advanced technologies

and high-speed computers are used to perform large-scale studies on diverse arrays of proteins. This is the same basic approach that has proven so successful over the past decade in the study of genomes. But the study of proteomics is inherently more difficult than the study of genomics because proteins are more difficult to work with than DNA. In physical terms, one gene is pretty much the same as all other genes, whereas each protein has unique chemical properties and handling requirements. In addition, small quantities of a particular DNA segment can be expanded greatly using readily available enzymes, whereas protein quantities cannot be increased. This is particularly troublesome when one considers that many of the proteins regulating important cellular processes are present in only a handful of copies per cell.

Traditionally, protein biochemists have sought to answer a number of questions about particular proteins. These include: What specific activity does the protein demonstrate *in vitro*, and how does this activity help a cell carry out a particular function such as cell locomotion or DNA replication? What is the protein's three-dimensional structure? When does the protein appear in the development of the organism and in which types of cells? Where in the cell is it localized? Is the protein modified after synthesis by the addition of chemical groups (e.g., phosphates or sugars) and, if so, how does this modify its activity? How much of the protein is present, and how long does it survive before being degraded? Does the level of the protein change during physiologic activities or as

⁶There are a number of ways that a single gene can give rise to more than one polypeptide. Two of the most prominent mechanisms, alternative splicing and posttranslational modification, are discussed in other sections of the text. It can also be noted that many proteins have more than one distinct function. Even myoglobin, which has long been studied as an oxygen-storage protein, has recently been shown to be involved in the conversion of nitric oxide (NO) to nitrate (NO₃⁻).

Figure 2.47 © JOSEPH G. SUTLIFF.

the result of disease? Which other proteins in the cell does it interact with? Biologists have been attempting to answer these questions for decades but, for the most part, they've been doing it one protein at a time. Proteomics researchers attempt to answer similar questions on a more comprehensive scale using large-scale (or *high-throughput*) techniques (Figure 2.47). We have already seen how a systematic approach can be used to investigate protein–protein interactions (page 62). Let us turn our attention to the seemingly daunting task of identifying the vast array of proteins produced by a particular cell.

Figure 2.48 shows portions of two gels that were used to fractionate (separate) a mixture of proteins extracted from the same part of the brain of a human (Figure 2.48a) or a chimpanzee (Figure 2.48b). The proteins have been fractionated by a procedure called two-dimensional polyacrylamide gel elec-

trophoresis (described in detail in Section 18.7). The gels contain hundreds of different stained spots, each of which comprises a single protein, or at most a few proteins that have very similar physical properties and are therefore difficult to separate from one another. This technique, which was invented in the mid-1970s, was the first and is still one of the best ways to separate large numbers of proteins in a mixture. It is evident that virtually all of the spots on one gel have a counterpart in the other gel; those spots that are present in both gels correspond to homologous proteins shared by the two species. Certain spots are labeled by red numbers. Numbered spots correspond to proteins that exhibit differences in the two gels, either because (1) the proteins have migrated to a slightly different position (as the result of a difference in modification or amino acid sequence in the protein between the two organisms) (indicated by the double-headed arrows) or (2) the proteins are present in noticeably different amounts in the brains of the two organisms (indicated by the green arrows). In either case, this type of proteomic experiment provides an overview of the differences in protein expression in our brain compared to that of our closest living relative.

It is one thing to separate proteins from one another, but quite another to identify each of the separated molecules. In the past few years, two technologies—mass spectrometry and high-speed computation—have come together to make it possible to identify any or all of the proteins present in a gel such as those shown in Figure 2.48. As discussed in further detail in Section 18.7, mass spectrometry is a technique to determine the precise mass of a molecule or fragment of a molecule, which can then be used to identify that molecule. Suppose that we wanted to identify the protein present in the spot that is indicated by the red number 1. The protein that makes up the spot in question can be removed from the gel and digested into peptides with the enzyme trypsin. When

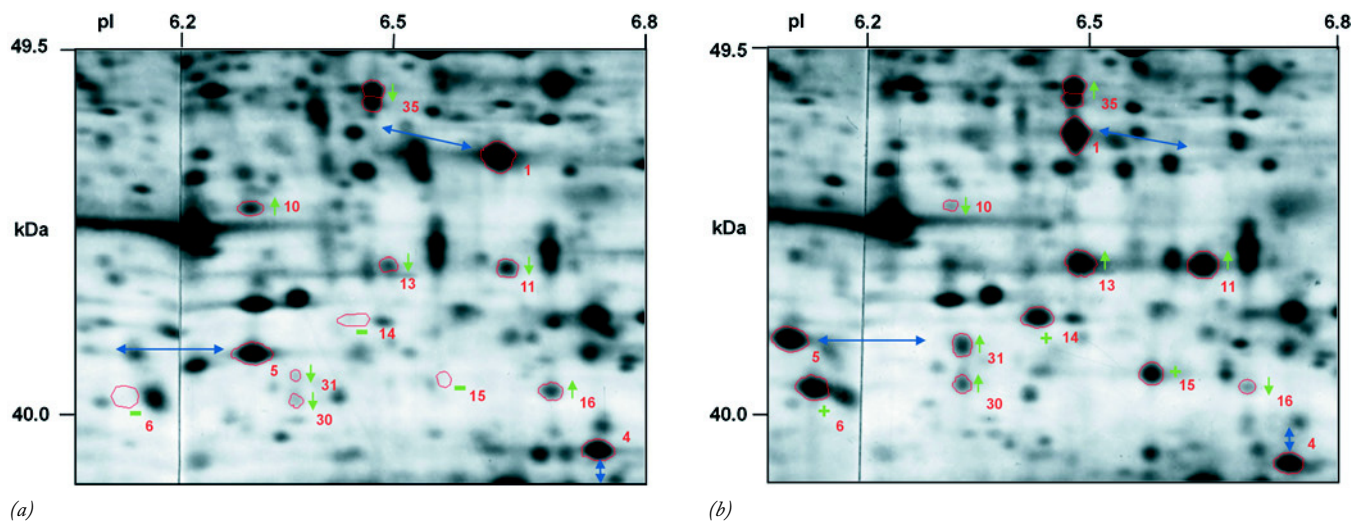

Figure 2.48 The study of proteomics often requires the separation of complex mixtures of proteins. The two electrophoretic gels shown here contain proteins extracted from the frontal cortex of humans (a) or chimpanzees (b). The numbered spots represent homologous proteins that show distinct differences in the two gels as discussed in the text.

(Note: This is only a small portion of a much larger gel that contains approximately 8500 spots that represent proteins synthesized by a primate brain.) (Note: The animals in this study had died of natural causes.) (FROM W. ENARD ET AL., SCIENCE 296:342, FIGURES 3A, B. © 2002, REPRINTED WITH PERMISSION FROM AAAS.)

Figure 2.49 Identifying proteins by mass spectrometry. A protein is isolated from a source (such as one of the spots on one of the gels of Figure 2.48) and subjected to digestion by the enzyme trypsin. The peptide fragments are then introduced into a mass spectrometer where they are ionized and separated according to their mass/charge (m/z) ratio. The separated peptides appear as a pattern of peaks whose precise m/z ratio is indicated. A comparison of these ratios to those obtained by a theoretical digest of virtual proteins encoded by the genome allows researchers to identify the protein being studied. In this case, the MS spectrum is that of horse myoglobin lacking its heme group. (DATA REPRINTED FROM J. R. YATES, *METHODS ENZYMOL.* 271:353, 1996. COPYRIGHT 1996, WITH PERMISSION FROM ELSEVIER.)

these peptides are introduced into a mass spectrometer, they are converted into gaseous ions and separated according to their mass/charge (m/z) ratio. The results are displayed as a series of peaks of known m/z ratio, such as that shown in Figure 2.49. The pattern of peaks constitutes a highly characteristic *peptide mass fingerprint* of that protein. But how can a protein be identified based on its peptide mass fingerprint?

The generation of peptide mass fingerprints is one element of the new proteomic technology. Another is based on advances in computer technology. Once a genome has been sequenced, the amino acid sequences of encoded proteins can be predicted. This list of “virtual proteins” can then be subjected to a theoretical trypsin digestion and the masses of the resulting virtual peptides calculated and entered into a database. Once this has been done, the actual peptide masses of a purified protein obtained by the mass spectrometer can be compared using high-speed supercomputers to the masses predicted by theoretical digests of all polypeptides encoded

by the genome. In most cases, the protein that has been isolated and subjected to mass spectrometry can be directly identified based on this type of database search. The protein labeled number 1 in the gels of Figure 2.48, for example, happens to be the enzyme aldose reductase. Mass spectrometers are not restricted to handling one purified protein at a time, but are also capable of analyzing proteins present in complex mixtures (Section 18.7). Mass spectrometry is particularly useful in revealing how the protein complement of a cell or tissue changes over time, as might occur, for example, after the secretion of a hormone within the body, or after taking a drug, or during a particular disease.

Many clinical researchers believe that proteomics will play an important role in advancing the practice of medicine. It is thought that most human diseases leave telltale patterns (or *biomarkers*) among the thousands of proteins present in the blood or other bodily fluids. Many efforts have been made to compare the proteins present in the blood of healthy individuals with those present in the blood of persons suffering from various diseases, especially cancer. For the most part, the results of these biomarker searches have proven generally unreliable in that the findings of one research group cannot be duplicated by the efforts of other groups. The primary difficulty stems from the fact that human blood serum is such a complex solution containing thousands of proteins that range in abundance over 9 or 10 orders of magnitude. To date, the level of technical and computational sophistication has not been up to the daunting task at hand, but that may be changing. It is hoped that, one day, it will be possible to use a single blood test to reveal the existence of early-stage heart, liver, or kidney disease that can be treated before it becomes a life-threatening condition.

Protein separation and mass spectrometric techniques don't tell us anything about a protein's function. Researchers have been working to devise techniques that allow protein function to be determined on a large scale, rather than one protein at a time. Several new technologies have been developed to accomplish this mission; we will consider only one—the use of *protein microarrays* (or *protein chips*). A protein microarray uses a solid surface, typically a glass microscope slide, which is covered by microscopic-sized spots, each containing an individual protein sample. Protein microarrays are constructed by the application of tiny volumes of individual proteins to specific sites on the slide, generating an array of proteins such as that shown in Figure 2.50a. The 6000 or so yeast proteins encoded by the yeast genome can fit comfortably as individual spots on a single glass slide.

Once a protein microarray has been created, the proteins that it contains can be screened for various types of activities. Let's consider the role of Ca^{2+} ions for a moment. Ca^{2+} ions play a key role in many activities, such as the formation of nerve impulses, the release of hormones into the blood, and muscle contraction. In each of these cases, Ca^{2+} ions act by attaching to a calcium-binding protein. As discussed in Chapter 15, calmodulin is an important calcium-binding protein, even in single-celled yeast. Figure 2.50b shows a small portion of a yeast-protein microarray that had been incubated with the protein calmodulin in the presence of Ca^{2+} ions. Those proteins in the array that display green fluorescence are ones that had bound calmodulin during the incubation and thus are

FIGURE IN FOCUS

The proteins spotted on the slide were synthesized in genetically engineered cells. The spots display red fluorescence because they have been incubated with a fluorescent antibody that can bind to all of the proteins in the array. (b) The left image shows a small portion of the protein array depicted in part a.

(b)

The right image shows the same portion of the array following incubation with calmodulin in the presence of calcium ions. The two proteins exhibiting green fluorescence are calmodulin-binding proteins. (c) Schematic illustration of the events occurring in part b where calmodulin has bound to two proteins of the microarray that have complementary binding sites. (A,B: FROM H. ZHU, ET AL., SCIENCE 293:2101, 2001, COURTESY OF MICHAEL SNYDER. © 2001, REPRINTED WITH PERMISSION FROM AAAS.)

(c)

likely to be involved in calcium signaling activity. Thirty-three new calmodulin-binding proteins were discovered in this particular protein screening experiment. These types of studies open the door to the analysis of the properties of large numbers of proteins of unknown function.

Protein chips are also expected to be used one day by clinical laboratories to screen for proteins that are characteristic of particular disorders. The simplest way to determine whether a particular protein characteristic of a disease is present in a blood or urine sample, and how much of that protein is present, is to measure the protein's interaction with a specific antibody. This is the basis, for example, of the PSA test used in routine screening of men for prostate cancer. PSA is a protein that is found in the blood of normal men, but is present at elevated levels in individuals with prostate cancer. PSA levels are determined by measuring the amount of protein in the blood that binds to anti-PSA antibodies. It is expected in the near future that biotechnology companies will be manufactur-

ing microarrays that contain antibodies capable of binding a number of different blood proteins. The presence and/or amount of these proteins would indicate that a person may be suffering from one or another of a wide variety of diseases.

Protein Engineering Advances in molecular biology have created the opportunity to design and mass-produce novel proteins that are different from those made by living organisms. It is possible with current DNA-synthesizing techniques to create an artificial gene that can be used in the production of a protein having any desired sequence of amino acids. Polypeptides can also be synthesized from "scratch" using chemical techniques. This latter strategy allows researchers to incorporate building blocks other than the 20 amino acids that normally occur in nature.

The problem with these types of engineering efforts is in knowing which of the virtually infinite variety of possible proteins one could manufacture might have some useful function.

Consider, for example, a pharmaceutical company that wanted to manufacture a therapeutic protein that would bind to the surface of the AIDS or influenza virus. Assume that computer simulation programs could predict the shape such a protein should have to bind to the viral surface. What sequence of amino acids strung together would produce such a protein? The answer requires detailed insight into the rules governing the complex relationship between a protein's primary structure and its tertiary structure. Figure 2.51 illustrates that protein biochemists now have the knowledge that allows them to construct a protein capable of binding to the surface of another protein, in this case the hemagglutinin (HA) protein that was

Figure 2.51 The computational design of a protein that is capable of binding specifically to the surface of another protein. (a) The computationally designed protein is shown in green and its target protein (the HA protein from the H1N1 1918 influenza virus) is shown on the left in multiple colors. The predicted structure of the designed protein fits closely with that of the actual protein that was generated from the predicted sequence. (b) The actual interface of the targeted hydrophobic helix of the HA protein (gray) and the designed protein (purple). Side chains of the designed protein are seen to interact with sites on the HA helix. (A: FROM SAREL J. FLEISHMAN, ET AL., SCIENCE 332:820, 2011, IMAGE COURTESY OF DAVID BAKER; (B) FROM BRYAN S. DER AND BRIAN KUHLMAN, SCIENCE 332:801, 2011, BOTH © 2011, REPRINTED WITH PERMISSION OF AAAS.)

present in the reconstructed 1918 influenza virus (page 25). Figure 2.51a shows the HA protein in proximity to a small engineered protein (in green). This engineered protein is capable of binding to a hydrophobic patch on the surface of the HA protein with high affinity. Figure 2.51b shows a closer view of the interface between the targeted portion of the HA protein (gray) and the binding surface of the designed protein (purple). It can be seen that side chains from the designed protein interact in highly specific ways with sites on the α helix of HA.

You might think that designing a protein from “scratch” that is capable of catalyzing a given chemical reaction—that is, designing an enzyme—would be far beyond the capability of present-day biotechnology. Given the magnitude of the task, it came as a surprise when researchers reported in 2008 that they had successfully designed and produced artificial proteins that were capable of catalyzing two different organic reactions, neither of which was catalyzed by any known natural enzyme. One of the reactions involved breaking a carbon–carbon bond, and the other the transfer of a proton from a carbon atom. These protein architects began by choosing a catalytic mechanism that might accelerate each chosen reaction and then used computer-based calculations to construct an idealized space in which amino acid side chains were positioned (forming an *active site*) to accomplish the task. They then searched among known protein structures to find ones that might serve as a framework or scaffold that could hold the active site they had designed. To transform the computer models into an actual protein, they used computational techniques to generate DNA sequences that had the potential to encode such a protein. The proposed DNA molecules were synthesized and introduced into bacterial cells where the proteins were manufactured. The catalytic activities of the proteins were then tested. Those proteins that showed the greatest promise were then subjected to a process of test-tube evolution; the proteins were mutated to create a new generation of altered proteins, which could in turn be screened for enhanced activity. Eventually, the team obtained proteins that could accelerate the rates of reaction as much as one million times that of the uncatalyzed reaction. While this is not a rate of enhancement that would fill a natural enzyme with pride, it is a remarkable accomplishment for a team of biochemists. It suggests, in fact, that scientists will ultimately be able to construct proteins from scratch that will be capable of catalyzing virtually any chemical reaction.

An alternate approach to the production of novel proteins has been to modify those that are already produced by cells. Recent advances in DNA technology have allowed investigators to isolate an individual gene from human chromosomes, to alter its information content in a precisely determined way, and to synthesize the modified protein with its altered amino acid sequence. This technique, which is called **site-directed mutagenesis** (Section 18.17), has many different uses, both in basic research and in applied biology. If, for example, an investigator wants to know about the role of a particular residue in the folding or function of a polypeptide, the gene can be mutated in a way that substitutes an amino acid with different charge, hydrophobic character, or hydrogen-bonding properties. The effect of the substitution on the structure and function of the modified protein can then be determined. As we will see throughout this textbook, site-directed mutagenesis has

(a)

(b)

(c)

(d)

proven invaluable in the analysis of the specific functions of minute parts of virtually every protein of interest to biologists.

Site-directed mutagenesis is also used to modify the structure of clinically useful proteins to bring about various physiological effects. For example, the drug Somavert, which was approved by the FDA in 2003, is a modified version of human growth hormone (GH) containing several alterations. GH normally acts by binding to a receptor on the surface of target cells, which triggers a physiological response. Somavert competes with GH in binding to the GH receptor, but interaction between drug and receptor fails to trigger the cellular response. Somavert is prescribed for the treatment of acromegaly, a disorder that results from excess production of growth hormone.

Structure-Based Drug Design The production of new proteins is one clinical application of recent advances in molecular biology; another is the development of new drugs that act by binding to known proteins, thereby inhibiting their activity. Drug companies have access to chemical “libraries” that contain millions of different organic compounds that have been either isolated from plants or microorganisms or chemically synthesized. One way to search for potential drugs is to expose the protein being targeted to combinations of these compounds and determine which compounds, if any, happen

Figure 2.52 Development of a protein-targeting drug, such as

Gleevec. (a) Typical steps in drug development. In step 1, a protein (e.g., ABL) has been identified that plays a causative role in the disease. This protein is a likely target for a drug that inhibits its enzymatic activity. In step 2, the protein is incubated with thousands of compounds in a search for ones that bind with reasonable affinity and inhibit its activity. In step 3, one such compound (e.g., 2-phenylaminopyrimidine in the case of ABL) has been identified. In step 4, knowledge of the structure of the target protein is used to make derivatives of the compound (e.g., Gleevec) that have greater binding affinity and thus can be used at lower concentrations. In step 5, the compound in question is tested in preclinical experiments for toxicity and efficacy (level of effectiveness) in vivo. Preclinical experiments are typically carried out on cultured human cells (step 5a) (e.g., those from patients with CML) and laboratory animals (step 5b) (e.g., mice carrying transplants of human CML cells). If the drug appears safe and effective in animals, the drug is tested in clinical trials (step 6) as discussed on page 68. (b) The structure of the molecule indicates the structure of the compound 2-phenylaminopyrimidine that was initially identified as an ABL kinase inhibitor. (c,d) The structure of the catalytic domain of ABL in complex (c) with Gleevec (shown in yellow) and (d) with a second-generation inhibitor called Sprycel. Gleevec binds to the inactive conformation of the protein, whereas Sprycel binds to the active conformation. Both binding events block the activity that is required for the cell’s cancerous phenotype. Sprycel is effective against most cancer cells that have become resistant to the action of Gleevec. (C,D: FROM ELLEN WEISBERG ET AL., COURTESY OF JAMES D. GRIFFIN, NATURE REVIEWS CANCER 7:353, 2007 © 2007 REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LIMITED.)

to bind to the protein with reasonable affinity. An alternate approach, called *structure-based drug design*, relies upon knowledge of the structure of the protein target. If the tertiary structure of a protein has been determined, researchers can use computers to design “virtual” drug molecules whose size and shape might allow them to fit into the apparent cracks and crevices of the protein, rendering it inactive.

We can illustrate both of these approaches by considering the development of the drug Gleevec, as depicted in Figure 2.52a. Introduction of Gleevec into the clinic has revolutionized the treatment of a number of relatively rare cancers, most notably that of chronic myelogenous leukemia (CML). As discussed at length in Chapters 15 and 16, a group of enzymes called tyrosine kinases are often involved in the transformation of normal cells into cancer cells. Tyrosine kinases catalyze a reaction in which a phosphate group is added to specific tyrosine residues within a target protein, an event that may activate or inhibit the target protein. The development of CML is driven almost single-handedly by the presence of an overactive tyrosine kinase called ABL.

During the 1980s researchers identified a compound called 2-phenylaminopyrimidine that was capable of inhibiting tyrosine kinases. This compound was discovered by randomly screening a large chemical library for compounds that exhibited this particular activity (Figure 2.52a). As is usually the case in these types of blind screening experiments, 2-phenylaminopyrimidine would not have made a very effective drug. For one reason, it was only a weak enzyme inhibitor, which meant it would have had to be used in very large quantities. 2-Phenylaminopyrimidine is described as a *lead* compound, a starting point from which usable drugs might be developed. Beginning with this lead molecule, compounds of greater potency and specificity were synthesized using structure-based drug design. One of the compounds to emerge from this process was Gleevec (Figure 2.52b), which was found to bind tightly to the inactive form of the ABL tyrosine kinase and prevent the enzyme from becoming activated, which is a necessary step if the cell is to become cancerous. The complementary nature of the interaction between the drug and its enzyme target is shown in Figure 2.52c. Preclinical studies demonstrated that Gleevec strongly inhibited the growth in the laboratory of cells from CML patients and that the compound showed no harmful effects in tests in animals. In the very first clinical trial of Gleevec, virtually all of the CML patients went into remission after taking once-daily doses of the compound. Gleevec has gone on to become the primary drug prescribed for treatment of CML, but this is not the end of the story. Many patients taking Gleevec experience a recurrence of their cancer as the ABL kinase becomes resistant to the drug. In such cases, the cancer can continue to be suppressed by treatment with more recently designed drugs that are capable of inhibiting Gleevec-resistant forms of the ABL kinase. One of these newer (second-generation) ABL kinase inhibitors is shown bound to the protein in Figure 2.52d.

Protein Adaptation and Evolution Adaptations are traits that improve the likelihood that an organism will survive in a particular environment. Proteins are biochemical adaptations that are subject to natural selection and evolutionary change in the same way as other types of characteristics, such as eyes or skeletons. This is best revealed by comparing evolutionarily related (*homologous*) proteins in organisms living in very different environments. For example, the proteins of halophilic (salt-loving) archaeobacteria possess amino acid substitutions that allow them to maintain their solubility and function at very high cytosolic salt concentrations (up to 4 M KCl). Unlike its counterpart in other organisms, the surface of the halophilic version of the protein malate dehydrogenase, for example, is coated with aspartic and glutamic acid residues whose carboxyl groups can compete with the salt for water molecules (Figure 2.53).

Homologous proteins isolated from different organisms can exhibit virtually identical shapes and folding patterns, but show strikingly divergent amino acid sequences. The greater the evolutionary distance between two organisms, the greater the difference in the amino acid sequences of their proteins. In some cases, only a few key amino acids located in a critical portion of the protein will be present in all of the organisms from which that protein has been studied. In one comparison of 226 globin sequences, only two residues were found to be absolutely

Figure 2.53 Distribution of polar, charged amino acid residues in the enzyme malate dehydrogenase from a halophilic archaeobacterium. Red balls represent acidic residues, and blue balls represent basic residues. The surface of the enzyme is seen to be covered with acidic residues, which gives the protein a net charge of -156 , and promotes its solubility in extremely salty environments. For comparison, a homologous protein from the dogfish, an ocean-dwelling shark, has a net charge of $+16$. (FROM O. DYM, M. MEVARECH, AND J. L. SUSSMAN, SCIENCE 267:1345, © 1995, REPRINTED WITH PERMISSION OF AAAS.)

conserved in all of these polypeptides; one is a histidine residue that plays a key role in the binding and release of O_2 . These observations indicate that the secondary and tertiary structures of proteins change much more slowly during evolution than their primary structures. This does not mean that the conformation of a protein cannot be affected in a major way by simple changes in primary structure. An example of such a change is shown in Figure 2.54. In this case, an amino acid substitution was experimentally introduced into a protein that completely altered the conformation of a small domain within a large protein molecule. The polypeptide on the left, which has a leucine at position 45, has a conformation consisting of a bundle of three α helices, whereas the polypeptide on the right, which has a tyrosine at this position, has a conformation that contains a single α helix and a four-stranded β -sheet. If a mutation having an effect of this magnitude happened to occur in nature, it might result in the formation of a protein with new functional properties and thus could be responsible for generating the ancestral form of an entirely new family of proteins.

We have seen how evolution has produced different versions of proteins in different organisms, but it has also produced different versions of proteins in individual organisms. Take a particular protein with a given function, such as globin or collagen. Several different versions of each of these proteins are encoded by the human genome. In most cases, different versions of a protein, which are known as **isoforms**, are adapted to function in different tissues or at different stages of development. For example, humans possess six different genes encoding isoforms of the contractile protein actin. Two of these isoforms are found in smooth muscle, one in skeletal muscle, one in heart muscle, and two in virtually all other types of cells.

Figure 2.54 The dramatic effect on conformation that can result from a single amino acid substitution. In this case the switch between a leucine and a tyrosine at a critical position within this 56-amino acid polypeptide chain results in a transformation of the entire fold of the backbone of this polypeptide. This single substitution causes 85 percent of the amino acid residues to change their secondary structure. The spatial disposition of the two alternate side chains, which brings about this conformational shift, is shown in red in the model structures. The N-terminal amino acids are shown in orange and the C-terminal amino acids in blue. (FROM PATRICK A. ALEXANDER ET AL., COURTESY OF PHILIP N. BRYAN, PROC. NAT'L ACAD. SCI. U.S.A. 106:21153, 2009, FIG. 6. © 2009 NATIONAL ACADEMY OF SCIENCES.)

As more and more amino acid sequences and tertiary structures of proteins were reported, it became apparent that most proteins are members of much larger **families** (or *superfamilies*) of related molecules. The genes that encode the various members of a protein family are thought to have arisen from a single ancestral gene that underwent a series of duplications during the course of evolution (see Figure 10.23). Over long periods of time, the nucleotide sequences of the various copies diverge from one another to generate proteins with related structures. Many protein families contain a remarkable variety of proteins that have evolved diverse functions. The expansion of protein families is responsible for much of the protein diversity encoded in the genomes of today's complex plants and animals.

Nucleic Acids

Nucleic acids are macromolecules constructed out of long chains (**strands**) of monomers called **nucleotides**. Nucleic acids function primarily in the storage and transmission of genetic information, but they may also have structural or catalytic roles. There are two types of nucleic acids found in living organisms, **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA)**. DNA serves as the genetic material of all cellular organisms, though RNA carries out that role for many viruses. In cells, information stored in DNA is used to govern cellular activities through the formation of RNA messages. In the present discussion, we will examine the basic structure of nucleic acids using single-stranded RNA as the representative molecule. We will

look at the structure of DNA in Chapter 10, where it can be tied to its central role in the chemical basis of life.

Each nucleotide in a strand of RNA consists of three parts (Figure 2.55a): (1) a five-carbon sugar, ribose; (2) a nitrogenous base (so called because nitrogen atoms form part of the rings of the molecule); and (3) a phosphate group. The

(a)

(b)

Figure 2.55 Nucleotides and nucleotide strands of RNA. (a) Nucleotides are the monomers from which strands of nucleic acid are constructed. A nucleotide consists of three parts: a sugar, a nitrogenous base, and a phosphate. The nucleotides of RNA contain the sugar ribose, which has a hydroxyl group bonded to the second carbon atom. In contrast, the nucleotides of DNA contain the sugar deoxyribose, which has a hydrogen atom rather than a hydroxyl group attached to the second carbon atom. Each nucleotide is polarized, having a 5' end (corresponding to the 5' side of the sugar) and a 3' end. (b) Nucleotides are joined together to form a strand by covalent bonds that link the 3' hydroxyl group of one sugar with the 5' phosphate group of the adjoining sugar.

Figure 2.56 Nitrogenous bases in nucleic acids. Of the four standard bases found in RNA, adenine and guanine are purines, and uracil and cytosine are pyrimidines. In DNA, the pyrimidines are cytosine and thymine, which differs from uracil by a methyl group attached to the ring.

sugar and nitrogenous base together form a *nucleoside*, so that the nucleotides of an RNA strand are also known as ribonucleoside monophosphates. The phosphate is linked to the 5' carbon of the sugar, and the nitrogenous base is attached to the sugar's 1' carbon. During the assembly of a nucleic acid strand, the hydroxyl group attached to the 3' carbon of the sugar of one nucleotide becomes linked by an ester bond to the phosphate group attached to the 5' carbon of the next nu-

cleotide in the chain. Thus the nucleotides of an RNA (or DNA) strand are connected by sugar-phosphate linkages (Figure 2.55*b*), which are described as 3'-5'-*phosphodiester bonds* because the phosphate atom is esterified to two oxygen atoms, one from each of the two adjoining sugars.

A strand of RNA (or DNA) contains four different types of nucleotides distinguished by their nitrogenous base. Two types of bases occur in nucleic acids: pyrimidines and purines (Figure 2.56). **Pyrimidines** are smaller molecules, consisting of a single ring; **purines** are larger, consisting of two rings. RNAs contain two different purines, **adenine** and **guanine**, and two different pyrimidines, **cytosine** and **uracil**. In DNA, uracil is replaced by **thymine**, a pyrimidine with an extra methyl group attached to the ring (Figure 2.56).

Although RNAs consist of a continuous single strand, they often fold back on themselves to produce molecules having extensive double-stranded segments and complex three-dimensional structures. This is illustrated by the two RNAs shown in Figure 2.57. The RNA whose secondary structure is shown in Figure 2.57*a* is a component of the small subunit of the bacterial ribosome (see Figure 2.58). Ribosomal RNAs are not molecules that carry genetic information; rather, they serve as structural scaffolds on which the proteins of the ribosome can be attached and as elements that recognize and bind various soluble components required for protein synthesis. One of the ribosomal RNAs of the large subunit acts as the catalyst for the reaction by which amino acids are covalently joined during protein synthesis. RNAs having a catalytic role are called RNA enzymes, or **ribozymes**. Figure 2.57*b* depicts the tertiary

Figure 2.57 RNAs can assume complex shapes. (a) This ribosomal RNA is an integral component of the small ribosomal subunit of a bacterium. In this two-dimensional profile, the RNA strand is seen to be folded back on itself in a highly ordered pattern so that most of the molecule is double-stranded. (b) This hammerhead ribozyme, as it is

called, is a small RNA molecule from a viroid (page 26). The helical nature of the double-stranded portions of this RNA can be appreciated in this three-dimensional model of the molecule. (B: FROM WILLIAM G. SCOTT ET AL., CELL 81:993, © 1995, WITH PERMISSION FROM ELSEVIER.)

structure of the so-called hammerhead ribozyme, which is able to cleave its own RNA strand. In both examples shown in Figure 2.57, the double-stranded regions are held together by hydrogen bonds between the bases. This same principle is responsible for holding together the two strands of a DNA molecule.

Nucleotides are not only important as building blocks of nucleic acids, they also have important functions in their own right. Most of the energy being put to use at any given moment in any living organism is derived from the nucleotide **adenosine triphosphate (ATP)**. The structure of ATP and its key role in cellular metabolism are discussed in the following chapter. **Guanosine triphosphate (GTP)** is another nucleotide of enormous importance in cellular activities. GTP binds to a variety of proteins (called G proteins) and acts as a switch to turn on their activities (see Figure 11.49 for an example).

REVIEW

1. Which macromolecules are polymers? What is the basic structure of each type of monomer? How do the various monomers of each type of macromolecule vary among themselves?
2. Describe the structure of nucleotides and the manner in which these monomers are joined to form a polynucleotide strand. Why would it be overly simplistic to describe RNA as a single-stranded nucleic acid?
3. Name three polysaccharides composed of polymers of glucose. How do these macromolecules differ from one another?
4. Describe the properties of three different types of lipid molecules. What are their respective biological roles?
5. What are the major properties that distinguish different amino acids from one another? What roles do these differences play in the structure and function of proteins?
6. What are the properties of glycine, proline, and cysteine that distinguish these amino acids?
7. How are the properties of an α helix different from a β strand? How are they similar?
8. Given that proteins act as molecular machines, explain why conformational changes are so important in protein function.

2.6 | The Formation of Complex Macromolecular Structures

To what degree can the lessons learned from the study of protein architecture be applied to more complex structures in the cell? Can structures, such as membranes, ribosomes, and cytoskeletal elements, which consist of different types of subunits, also assemble by themselves? How far can subcellular organization be explained simply by having the pieces fit together to form the most stable arrangement? The assembly of cellular organelles is poorly understood, but it is apparent from the following examples that different types of subunits can self-assemble to form higher-order arrangements.

The Assembly of Tobacco Mosaic Virus Particles and Ribosomal Subunits

The most convincing evidence that a particular assembly process is self-directed is the demonstration that the assembly can occur outside the cell (in vitro) under physiologic conditions when the only macromolecules present are those that make up the final structure. In 1955, Heinz Fraenkel-Conrat and Robley Williams of the University of California, Berkeley, demonstrated that TMV particles, which consist of one long RNA molecule (approximately 6600 nucleotides) wound within a helical capsule made of 2130 identical protein subunits (see Figure 1.20), were capable of self-assembly. In their experiments, they purified TMV RNA and protein separately, mixed them together under suitable conditions, and recovered mature, infective particles after a short period of incubation. Clearly the two components contain all the information necessary for particle formation.

Ribosomes, like TMV particles, are made of RNA and protein. Unlike the simpler TMV, ribosomes contain several different types of RNA and a considerable collection of different proteins. All ribosomes, regardless of their source, are composed of two subunits of different size. Although ribosomal subunits are often depicted in drawings as symmetric structures, in fact they have a highly irregular shape, as indicated in Figure 2.58. The large (or 50S) ribosomal subunit of bacteria contains two molecules of RNA and approximately 32 different proteins. The small (or 30S) ribosomal subunit of bacteria contains one molecule of RNA and 21 different proteins. The structure and function of the ribosome are discussed in detail in Section 11.8.

Figure 2.58 Reconstruction of a ribosome from the cytoplasm of a wheat germ cell. This reconstruction is based on high-resolution electron micrographs and shows the two subunits of this eukaryotic ribosome, the small (40S) subunit on the left and the large (60S) subunit on the right. The internal structure of a ribosome is discussed in Section 11.8. (FROM ADRIANA VERSCHOOR, ET AL., J. CELL BIOL. VOL. 133 (COVER #3), 1996; BY COPYRIGHT PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

One of the milestones in the study of ribosomes came in the mid-1960s, when Masayasu Nomura and his co-workers at the University of Wisconsin succeeded in reconstituting complete, fully functional 30S bacterial subunits by mixing the 21 purified proteins of the small subunit with purified small-subunit ribosomal RNA. Apparently, the components of the small subunit contain all the information necessary for the assembly of the entire particle. Analysis of the intermediates that form at different stages during reconstitution *in vitro* indicates that subunit assembly occurs in a sequential step-by-step manner that closely parallels the process *in vivo*. At least one of the proteins of the small subunit (S16) appears to function solely in ribosome assembly; deletion of this protein from the reconstitution mixture greatly slowed the assembly process but did not block the formation of fully functional ribosomes. Reconstitution of the large subunit of the bacterial ribosome was accomplished in the following decade. It should be kept in mind that although it takes approximately 2 hours at 50°C to reconstitute the ribosome *in vitro*, the bacterium can assemble the same structure in a few minutes at temperatures as low as 10°C. It may be that the bacterium uses something that

is not available to the investigator who begins with purified components. Assembly of the ribosome within the cell, for example, may include the participation of accessory factors that function in protein folding, such as the chaperones described in the Experimental Pathways. In fact, the formation of ribosomes within a *eukaryotic* cell requires the transient association of many proteins that do not end up in the final particle, as well as the removal of approximately half the nucleotides of the large ribosomal RNA precursor (Section 11.3). As a result, the components of the mature eukaryotic ribosome no longer possess the information to reconstitute themselves *in vitro*.

2. What evidence would indicate that a particular ribosomal protein had a role in ribosome function but not assembly?

EXPERIMENTAL PATHWAYS

Chaperones: Helping Proteins Reach Their Proper Folded State

In 1962, F. M. Ritossa, an Italian biologist studying the development of the fruit-fly *Drosophila*, reported a curious finding.¹ When the temperature at which fruit-fly larvae were developing was raised from the normal 25°C to 32°C, a number of new sites on the giant chromosomes of the larval cells became activated. As we will see in Chapter 10, the giant chromosomes of these insect larvae provide a visual exhibit of gene expression (see Figure 10.8). The results suggested that increased temperature induced the expression of new genes, a finding that was confirmed a decade later with the characterization of several proteins that appeared in larvae following temperature elevation.² It was soon found that this response, called the **heat-shock response**, was not confined to fruit flies, but can be initiated in many different cells from virtually every type of organism—from bacteria to plants and mammals. Closer examination revealed that the proteins produced during the response were found not only in heat-shocked cells, but also at lower concentration in cells under normal conditions. What is the function of these so-called *heat-shock proteins* (*hsp*s)? The answer to this question was gradually revealed by a series of seemingly unrelated studies.

We saw on page 79 that some complex, multisubunit structures, such as a bacterial ribosome or a tobacco mosaic virus particle, can self-assemble from purified subunits. It was demonstrated in the 1960s that the proteins that make up bacteriophage particles (see Figure 1.21c) also possess a remarkable ability to self-assemble, but they are generally unable to form a complete, functional virus particle by themselves *in vitro*. Experiments on phage assembly in bacterial cells confirmed that phages require bacterial help. It was shown in 1973, for example, that a certain mutant strain of bacteria, called *GroE*, could not support the assembly of normal phages. Depending on the type of phage, the head or the tail of the phage particle was assembled incorrectly.^{3,4} These studies suggested that a protein encoded by the bacterial chromosome participated in the assembly of viruses, even though this host protein was not a component of the

final virus particles. As it obviously did not evolve as an aid for virus assembly, the bacterial protein required for phage assembly had to play some role in the cell's normal activities, but the precise role remained obscure. Subsequent studies revealed that the *GroE* site on the bacterial chromosome actually contains two separate genes, *GroEL* and *GroES*, that encode two separate proteins GroEL and GroES. Under the electron microscope, the purified GroEL protein appeared as a cylindrical assembly consisting of two disks. Each disk was composed of seven subunits arranged symmetrically around the central axis (Figure 1).^{5,6}

Several years later, a study on pea plants hinted at the existence of a similar assembly-promoting protein in the chloroplasts of plants.⁷ Rubisco is a large protein in chloroplasts that catalyzes the reaction in which CO₂ molecules taken up from the atmosphere are covalently linked to organic molecules during photosynthesis (Section 6.6). Rubisco comprises 16 subunits: 8 small subunits (molecular mass of 14,000 daltons) and 8 large subunits (55,000 daltons). It was found that large Rubisco subunits, synthesized inside the chloroplast, are not present in an independent state, but are associated with a huge protein assembly consisting of identical subunits of 60,000 daltons (60 kDa) molecular mass. In their paper, the researchers considered the possibility that the complex formed by the large Rubisco subunits and the 60-kDa polypeptides was an intermediate in the assembly of a complete Rubisco molecule.

A separate line of investigation on mammalian cells also revealed the existence of proteins that appeared to assist the assembly of multisubunit proteins. Like Rubisco, antibody molecules consist of a complex of two different types of subunits, smaller light chains and larger heavy chains. Just as the large subunits of Rubisco become associated with another protein not found in the final complex, so too do the heavy chains of an antibody complex.⁸ This protein, which associates with newly synthesized heavy chains, but not with heavy chains that are already bound to light chains, was named *bind-*

Figure 1 A model of the GroEL complex built according to data from electron microscopy and molecular-weight determination. The complex is seen to consist of two disks, each composed of seven identical subunits arranged symmetrically around a central axis. Subsequent studies showed the complex contains two internal chambers. (FROM T. HOHN ET AL., *J. MOL. BIOL.* 129:371, © 1979, WITH PERMISSION OF ELSEVIER.)

ing protein, or BiP. BiP was subsequently found to have a molecular mass of 70,000 daltons (70 kDa).

To this point, we have been discussing two lines of investigation: one concerned with the heat-shock response and the other with proteins that promote protein assembly. These two fields came together in 1986, when it was shown that one of the proteins that figures most prominently in the heat-shock response, a protein that had been named *heat-shock protein 70* (*hsp70*) because of its molecular mass, was identical to BiP, the protein implicated in the assembly of antibody molecules.⁹

Even before the discovery of the heat-shock response, the structure of proteins was known to be sensitive to temperature, with a small rise in temperature causing these delicate molecules to begin to unfold. Unfolding exposes hydrophobic residues that were previously buried in the protein's core. Just as fat molecules in a bowl of soup are pushed together into droplets, so too are proteins with hydrophobic patches on their surface. Consequently, when a cell is heat shocked, soluble proteins become denatured and form aggregates. A report in 1985 demonstrated that, following temperature elevation, newly synthesized *hsp70* molecules enter cell nuclei and bind to aggregates of nuclear proteins, where they act like molecular crowbars to promote disaggregation.¹⁰ Because of their role in assisting the assembly of proteins by preventing undesirable interactions, *hsp70* and related molecules were named **molecular chaperones**.¹¹

It was soon demonstrated that the bacterial heat-shock protein GroEL and the Rubisco assembly protein in plants were homologous proteins. In fact, the two proteins share the same amino acids at nearly half of the more than 500 residues in their respective molecules.¹² The fact that the two proteins—both members of the *Hsp60 chaperone family*—have retained so many of the same amino acids reflects their similar and essential function in the two types of cells. But what was that essential function? At this point it was thought that their primary function was to mediate the assembly of multisubunit complexes, such as Rubisco. This view was changed in 1989 by experiments studying molecular chaperones in mitochondria by Arthur Horwich of Yale University and F.-Ulrich Hartl, Walter Neupert, and their colleagues at the University of Munich.^{13,14} It was known that newly made mitochondrial proteins produced in the

cytosol had to cross the outer mitochondrial membranes in an unfolded, extended, monomeric form. A mutant was found that altered the activity of another member of the Hsp60 chaperone family that resided inside mitochondria. In cells containing this mutant chaperone, proteins that were transported into mitochondria failed to fold into their active forms. Even proteins that consisted of a single polypeptide chain failed to fold into their native conformation. This finding changed the perception of chaperone function from a notion that they assist assembly of already-folded subunits into larger complexes, to our current understanding that they assist polypeptide chain folding within the crowded confines of the cell.

The results of these and other studies indicated the presence in cells of at least two major families of molecular chaperones: the Hsp70 chaperones, such as BiP, and the Hsp60 chaperones (which are also called *chaperonins*), such as Hsp60, GroEL, and the Rubisco assembly protein. We will focus on the Hsp60 chaperonins, such as GroEL, which are best understood.

As first revealed in 1979, GroEL is a huge molecular complex of 14 polypeptide subunits arranged in two stacked rings resembling a double doughnut.^{5,6} Fifteen years after these first electron micrographs were taken, the three-dimensional structure of the GroEL complex was determined by X-ray crystallography.¹⁵ The study revealed the presence of a central cavity within the GroEL cylinder. Subsequent studies demonstrated that this cavity was divided into two separate chambers. Each chamber was situated within the center of one of the rings of the GroEL complex and was large enough to enclose a polypeptide undergoing folding.

Electron microscopic studies also provided information about the structure and function of a second protein, GroES, which acts in conjunction with GroEL. Like GroEL, GroES is a ring-like protein with seven subunits arrayed symmetrically around a central axis. GroES, however, consists of only one ring, and its subunits are much smaller (10,000 daltons) than those of GroEL (60,000 daltons). GroES is seen as a cap or dome that fits on top of either end of a GroEL cylinder (Figure 2). The attachment of GroES to one end of GroEL causes a dramatic conformational change in the GroEL

Figure 2 Reconstructions of GroEL based on high-resolution electron micrographs taken of specimens that had been frozen in liquid ethane and examined at -170°C . The image on the left shows the GroEL complex, and that on the right shows the GroEL complex with GroES, which appears as a dome on one end of the cylinder. It is evident that the binding of the GroES is accompanied by a marked change in conformation of the apical end of the proteins that make up the top GroEL ring (arrow), which results in a marked enlargement of the upper chamber. (FROM S. CHEN ET AL., COURTESY OF HELEN R. SAIBIL, *NATURE* 371:263, © 1994, REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LIMITED.)

protein that markedly increases the volume of the enclosed chamber at that end of the complex.¹⁶

The importance of this conformational change has been revealed in remarkable detail by X-ray crystallographic studies in the laboratories of Arthur Horwich and Paul Sigler at Yale University.¹⁷ As shown in Figure 3, the binding of the GroES cap is accompanied by a 60° rotation of the apical (red) domain of the subunits that make up the GroEL ring at that end of the GroEL cylinder. The attachment of GroES does more than trigger a conformational change that enlarges the GroEL chamber. Before attachment of GroES, the inner wall of the GroEL chamber has exposed hydrophobic residues that give the lining a hydrophobic character. Nonnative polypeptides also have exposed hydrophobic residues that become buried in the interior of the native polypeptide. Because hydrophobic surfaces tend to interact, the hydrophobic lining of the GroEL cavity binds to the surface of nonnative polypeptides. Binding of GroES to GroEL buries the hydrophobic residues of the GroEL wall and ex-

Figure 3 Conformational change in GroEL. (a) The model on the left shows a surface view of the two rings that make up the GroEL chaperonin. The drawing on the right shows the tertiary structure of one of the subunits of the top GroEL ring. The polypeptide chain can be seen to fold into three domains. (b) When a GroES ring (arrow) binds to the GroEL cylinder, the apical domain of each GroEL subunit of the adjacent ring undergoes a dramatic rotation of approximately 60° with the intermediate domain (shown in green) acting like a hinge. The effect of this shift in parts of the polypeptide is a marked elevation of the GroEL wall and enlargement of the enclosed chamber. (FROM Z. XU, A. L. HORWICH, AND P. B. SIGLER, NATURE 388:744, 1997. © 1997, REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS, LTD.)

poses a number of polar residues, thereby changing the character of the chamber wall. As a result of this change, a nonnative polypeptide that had been bound to the GroEL wall by hydrophobic interactions is displaced into the space within the chamber. Once freed from its attachment to the chamber wall, the polypeptide is given the opportunity to continue its folding in a protected environment. After about 15 seconds, the GroES cap dissociates from the GroEL ring, and the polypeptide is ejected from the chamber. If the polypeptide has not reached its native conformation by the time it is ejected, it can rebind to the same or another GroEL, and the process is repeated. A model depicting some of the steps thought to occur during GroEL-GroES-assisted folding is shown in Figure 4.

Approximately 250 of the roughly 2400 proteins present in the cytosol of an *E. coli* cell normally interact with GroEL.¹⁸ How is it possible for a chaperone to bind so many different polypeptides? The GroEL binding site consists of a hydrophobic surface formed largely by two α helices of the apical domain that is capable of binding virtually any sequence of hydrophobic residues that might be accessible in a partially folded or misfolded polypeptide.¹⁹ A comparison of the crystal structure of the unbound GroEL molecule with that of GroEL bound to several different peptides revealed that the binding site on the apical domain of a GroEL subunit can locally adjust its positioning when bound to different partners. This finding indicates that the binding site has structural flexibility that allows it to adjust its shape to fit the shape of the particular polypeptide with which it has to interact.

A number of studies have also suggested that GroEL does more than simply provide a passive chamber in which proteins can fold without outside interference. In one study, site-directed mutagenesis was utilized to modify a key residue, Tyr71 of GroES, whose side chain hangs from the ceiling of the folding chamber.²⁰ Because of its aromatic ring, tyrosine is a modestly hydrophobic residue (Figure 2.26). When Tyr71 was replaced by a positively or negatively charged amino acid, the resulting GroEL-GroES variant exhibited an increased ability to assist the folding of one specific foreign polypeptide, the green fluorescent protein (GFP). However, substitutions for Tyr71 that improved the ability of GroES-GroEL to increase GFP folding made the chaperonin less competent to help its natural substrates fold. Thus as the chaperonin became more and more specialized to interact with GFP, it lost its general ability to assist folding of proteins having an unrelated structure. This finding suggests that individual amino acids in the wall of the folding chamber may participate somehow in the folding reaction. Data from another study has suggested that binding of a nonnative protein to GroEL is followed by a forced unfolding of the substrate protein.²¹ FRET (fluorescence resonance energy transfer) is a technique (discussed in Section 18.1) that allows researchers to determine the distance between different parts of a protein molecule at different times during a given process. In this study, investigators found that the protein undergoing folding, in this case Rubisco, bound to the apical domain of the GroEL ring in a relatively compact state. The compact nature of the bound protein was revealed by the close proximity to one another of the FRET tags, which were attached to amino acids located at opposite ends of the Rubisco chain. Then, during the conformational change that enlarges the volume of the GroEL cavity (Figure 3), the bound Rubisco protein was forcibly unfolded, as evidenced by the increased distance between the two tagged ends of the molecule. This study suggests that the Rubisco polypeptide is taken completely back to the unfolded state, where it is given the opportunity to refold from scratch. This action should help prevent the nonnative protein from becoming trapped permanently in a misfolded state. In other words, each individual visit to a GroEL-GroES chamber provides an all-or-none attempt to reach the native

Figure 4 A schematic illustration of the proposed steps that occur during the GroEL-GroES-assisted folding of a polypeptide. The GroEL is seen to consist of two chambers that have equivalent structures and functions and that alternate in activity. Each chamber is located within one of the two rings that make up the GroEL complex. The nonnative polypeptide enters one of the chambers (step 1) and binds to hydrophobic sites on the chamber wall. Binding of the GroES cap produces a conformational change in the wall of the top chamber, causing the enlargement of the chamber and release of the nonnative polypeptide from the wall into the encapsulated space (step 2). After about 15 seconds have elapsed, the

GroES dissociates from the complex and the polypeptide is ejected from the chamber (step 3). If the polypeptide has achieved its native conformation, as has the molecule on the left, the folding process is complete. If, however, the polypeptide is only partially folded, or is misfolded, it will rebind the GroEL chamber for another round of folding. (*Note:* As indicated, the mechanism of GroEL action is driven by the binding and hydrolysis of ATP, an energy-rich molecule whose function is discussed at length in the following chapter.) (A. L. HORWICH, ET AL., PROC. NAT'L. ACAD. SCI. U.S.A. 96:11037, 1999.)

state, rather than just one stage in a series of steps in which the protein moves closer to the native state with each round of folding. Recent reviews of molecular chaperones can be found in References 22–23.

Keep in mind that molecular chaperones do not convey information for the folding process but instead prevent proteins from veering off their correct folding pathway and finding themselves in misfolded or aggregated states. Just as Anfinsen discovered decades ago, the three-dimensional structure of a protein is determined by its amino acid sequence.

Synopsis

Covalent bonds hold atoms together to form molecules. Covalent bonds are stable partnerships formed when atoms share their outer-shell electrons, each participant gaining a filled shell. Covalent bonds can be single, double, or triple depending on the number of pairs of shared electrons. If electrons in a bond are shared unequally by the component atoms, the atom with the greater attraction for electrons (the more electronegative atom) bears a partial negative charge, whereas the other atom bears a partial positive charge. Molecules that lack polarized bonds have a nonpolar, or hydrophobic, character, which makes them insoluble in water. Molecules that have polarized bonds have a polar, or hydrophilic, character, which makes them water soluble. Polar molecules of biological importance contain atoms other than just carbon and hydrogen, usually O, N, S, or P. (p. 33)

Noncovalent bonds are formed by weak attractive forces between positively and negatively charged regions within the same molecule or between two nearby molecules. Noncovalent bonds play a key role in maintaining the structure of biological molecules and mediating their dynamic activities. Noncovalent bonds include ionic bonds, hydrogen bonds, and van der Waals forces. Ionic bonds form between fully charged positive and negative groups; hydrogen bonds form between a covalently bonded hydrogen atom (which bears a partial positive charge) and a covalently bonded nitrogen or oxygen atom (which bears a partial negative charge); van der Waals forces form between two atoms exhibiting a transient charge due to a momentary asymmetry in the distribution of electrons around the atoms. Nonpolar molecules or nonpolar portions of larger molecules tend to associate with one another in aqueous environments to form hydrophobic interactions. Examples of these various types of noncovalent interactions include the association of DNA and proteins by ionic bonds, the association of pairs of DNA strands by hydrogen bonds, and the formation of the hydrophobic core of soluble proteins as the result of hydrophobic interactions and van der Waals forces. (p. 34)

Water has unique properties on which life depends. The covalent bonds that make up a water molecule are highly polarized. As a result, water is an excellent solvent capable of forming hydrogen bonds with virtually all polar molecules. Water is also a major determinant of the structure of biological molecules and the types of interactions in which they can engage. The pH of a solution is a measure of the concentration of hydrogen (or hydronium) ions. Most biological processes are acutely sensitive to pH because changes in hydrogen ion concentration alter the ionic state of biological molecules. Cells are protected from pH fluctuations by buffers—compounds that react with hydrogen or hydroxyl ions. (p. 37)

Carbon atoms play a pivotal role in the formation of biological molecules. Each carbon atom is able to bond with up to four other atoms, including other carbon atoms. This property allows the formation of large molecules whose backbone consists of a chain of carbon atoms. Molecules consisting solely of hydrogen and carbon are called hydrocarbons. Most of the molecules of biological importance contain functional groups that include one or more electronegative atoms, making the molecule more polar, more water soluble, and more reactive. (p. 40)

Biological molecules are members of four distinct types: carbohydrates, lipids, proteins, and nucleic acids. Carbohydrates include simple sugars and larger molecules (polysaccharides) constructed of sugar monomers. Carbohydrates function primarily as a storehouse of chemical energy and as durable building materials for biological construction. Simple biological sugars consist of a backbone of three to seven carbon atoms, with each carbon linked to a hydroxyl group except one, which bears a carbonyl. Sugars with five or more carbon atoms self-react to form a ring-shaped molecule. Those

carbon atoms along the sugar backbone that are linked to four different groups are sites of stereoisomerism, generating pairs of isomers that cannot be superimposed. The asymmetric carbon farthest from the carbonyl determines whether the sugar is D or L. Sugars are linked to one another by glycosidic bonds to form disaccharides, oligosaccharides, and polysaccharides. In animals, sugar is stored primarily as the branched polysaccharide glycogen, which provides a readily available energy source. In plants, glucose reserves are stored as starch, which is a mixture of unbranched amylose and branched amylopectin. Most of the sugars in both glycogen and starch are joined by $\alpha(1 \rightarrow 4)$ linkages. Cellulose is a structural polysaccharide manufactured by plant cells that serves as a major component of the cell wall. Glucose monomers in cellulose are joined by $\beta(1 \rightarrow 4)$ linkages, which are cleaved by cellulase, an enzyme that is absent in virtually all animals. Chitin is a structural polysaccharide composed of *N*-acetylglucosamine monomers. (p. 42)

Lipids are a diverse array of hydrophobic molecules having widely divergent structures and functions. Fats consist of a glycerol molecule esterified to three fatty acids. Fatty acids differ in chain length and the number and position of double bonds (sites of unsaturation). Fats are very rich in chemical energy; a gram of fat contains over twice the energy content of a gram of carbohydrate. Steroids are a group of lipids containing a characteristic four-ringed hydrocarbon skeleton. Steroids include cholesterol as well as numerous hormones (e.g., testosterone, estrogen, and progesterone) that are synthesized from cholesterol. Phospholipids are phosphate-containing lipid molecules that contain both a hydrophobic end and a hydrophilic end and play a pivotal role in the structure and function of cell membranes. (p. 47)

Proteins are macromolecules of diverse function consisting of amino acids linked by peptide bonds into polypeptide chains. Included among the diverse array of proteins are enzymes, structural materials, membrane receptors, gene regulatory factors, hormones, transport agents, and antibodies. The order in which the 20 different amino acids are incorporated into a protein is encoded in the sequence of nucleotides in DNA. All 20 amino acids share a common structural organization consisting of an α -carbon bonded to an amino group, a carboxyl group, and a side chain of varying structure. In the present scheme, the side chains are classified into four categories: those that are fully charged at physiologic pH; those that are polar, but uncharged and capable of forming hydrogen bonds; those that are nonpolar and interact by means of van der Waals forces; and three amino acids (proline, cysteine, and glycine) that possess unique properties. (p. 50)

The structure of a protein can be described at four levels of increasing complexity. Primary structure is described by the amino acid sequence of a polypeptide; secondary structure by the three-dimensional structure (conformation) of sections of the polypeptide backbone; tertiary structure by the conformation of the entire polypeptide; and quaternary structure by the arrangement of the subunits if the protein consists of more than one polypeptide chain. The α helix and β -pleated sheet are both stable, maximally hydrogen-bonded secondary structures that are common in many proteins. The tertiary structure of a protein is highly complex and unique to each individual type of protein. Most proteins have an overall globular shape in which the polypeptide is folded to form a compact molecule in which specific residues are strategically situated to allow the protein to carry out its specific function. Most proteins consist of two or more domains that maintain a structural and functional independence from one another. Using the technique of site-directed mutagenesis, researchers can learn about the role of specific amino acid residues by making specific substitutions. In recent years, a new field of proteomics has emerged that uses advanced technologies such as mass spectrometry and high-

speed computation to study various properties of proteins on a comprehensive, large scale. For example, the various interactions among thousands of proteins encoded by the fruit-fly genome have been analyzed by such large-scale techniques. (p. 54)

The information required for a polypeptide chain to achieve its native conformation is encoded in its primary structure. Some proteins fold into their final conformation by themselves; others require the assistance of nonspecific chaperones, which prevent aggregation of partially folded intermediates. (p. 63)

Nucleic acids are primarily informational molecules that consist of strands of nucleotide monomers. Each nucleotide in a strand

consists of a sugar, phosphate, and nitrogenous base. The nucleotides are linked by bonds between the 3' hydroxyl group of the sugar of one nucleotide and the 5' phosphate group of the adjoining nucleotide. Both RNA and DNA are assembled from four different nucleotides; nucleotides are distinguished by their bases, which can be a pyrimidine (cytosine or uracil/thymine) or a purine (adenine or guanine). DNA is a double-stranded nucleic acid, and RNA is generally single stranded, though the single strand is often folded back on itself to form double-stranded sections. Information in nucleic acids is encoded in the specific sequence of nucleotides that constitute a strand. (p. 77)

Analytic Questions

- Sickle cell anemia results from a substitution of a valine for a glutamic acid. What do you expect the effect might be if the mutation were to have placed a leucine at that site? An aspartic acid?
- Of the following amino acids, glycine, isoleucine, and lysine, which would you expect to be the most soluble in an acidic aqueous solution? Which the least?
- How many structural isomers could be formed from a molecule with the formula C_5H_{12} ? C_4H_8 ?
- Glyceraldehyde is the only three-carbon aldotetrose, and it can exist as two stereoisomers. What is the structure of dihydroxyacetone, the only ketotriose? How many stereoisomers does it form?
- Bacteria are known to change the kinds of fatty acids they produce as the temperature of their environment changes. What types of changes in fatty acids would you expect as the temperature drops? Why would this be adaptive?
- In the polypeptide backbone $—C—C—N—C—C—N—C—C—NH_2$, identify the α -carbons.
- Which of the following are true? Increasing the pH of a solution would (1) suppress the dissociation of a carboxylic acid, (2) increase the charge on an amino group, (3) increase the dissociation of a carboxylic acid, (4) suppress the charge on an amino group.
- Which of the four classes of amino acids has side chains with the greatest hydrogen-bond-forming potential? Which has the greatest potential to form ionic bonds? Hydrophobic interactions?
- If the three enzymes of the pyruvate dehydrogenase complex existed as physically separate proteins rather than as a complex, what effect might this have on the rate of reactions catalyzed by these enzymes?
- Would you agree that neither ribonuclease nor myoglobin had quaternary structure? Why or why not?
- How many different tripeptides are possible? How many carboxyl terminals of polypeptide chains are present in a molecule of hemoglobin?
- You have isolated a pentapeptide composed of four glycine residues and one lysine residue that resides at the C-terminus of the peptide. Using the information provided in the legend of Figure 2.27, if the pK of the side chain of lysine is 10 and the pK of the terminal carboxyl group is 4, what is the structure of the peptide at pH 7? At pH 12?
- The side chains of glutamic acid (pK 4.3) and arginine (pK 12.5) can form an ionic bond under certain conditions. Draw the relevant portions of the side chains and indicate whether or not an ionic bond could form at the following: (a) pH 4; (b) pH 7; (c) pH 12; (d) pH 13.
- Would you expect a solution of high salt to be able to denature ribonuclease? Why or why not?
- You have read in the Human Perspective that (1) mutations in the *PRNP* gene can make a polypeptide more likely to fold into the PrP^{Sc} conformation, thus causing CJD and (2) exposure to the PrP^{Sc} prion can lead to an infection that also causes CJD. How can you explain the occurrence of rare sporadic cases of the disease in persons who have no genetic propensity for it?
- Persons who are born with Down syndrome have an extra (third) copy of chromosome #21 in their cells. Chromosome #21 contains the gene that encodes the APP protein. Why do you suppose that individuals with Down syndrome typically develop Alzheimer's disease at an early age?
- We saw on page 76 how evolution has led to the existence of protein families composed of related molecules with similar functions. A few examples are also known where proteins with very similar functions have primary and tertiary structures that show no evidence of evolutionary relationship. Subtilisin and trypsin, for example, are two protein-digesting enzymes (proteases) that show no evidence they are homologous despite the fact that they utilize the same mechanism for attacking their substrates. How can this coincidence be explained?
- Would you agree with the statement that many different amino acid sequences can fold into the same basic tertiary structure? What data can you cite as evidence for your position.
- In the words of one scientist: "The first question any structural biologist asks upon being told that a new [protein] structure has been solved is no longer 'What does it look like?'; it is now 'What does it look like?'" What do you suppose he meant by this statement?
- It was noted in the Human Perspective that persons with arthritis who had taken certain NSAIDs over a long period of time exhibited a lower incidence of Alzheimer's disease, yet double-blinded clinical trials on these same drugs did not appear to benefit patients with AD. These would appear to be contradictory findings. The first type of study is referred to as a *retrospective* study in that researchers look backwards from a correlation that is made at the present time, in this case a conclusion that taking NSAIDs over a period of time may prevent the development of AD. The second type of study is referred to as a *prospective* study in that it looks forward to future results based on an experimental plan to give some patients a drug and others a placebo. Can you give a reason why these two different approaches might lead to differing conclusions about the use of these drugs?

Bioenergetics, Enzymes, and Metabolism

3.1 Bioenergetics

3.2 Enzymes as Biological Catalysts

3.3 Metabolism

THE HUMAN PERSPECTIVE: The Growing Problem of Antibiotic Resistance

The interrelationship between structure and function is evident at all levels of biological organization from the molecular to the organismal. We saw in the last chapter that proteins have an intricate three-dimensional structure that depends on particular amino acid residues being present in precisely the correct place. In this chapter, we will look more closely at one large group of proteins, the enzymes, and see how their complex architecture endows them with the capability to vastly increase the rate of biological reactions. To understand how enzymes are able to accomplish such feats, it is necessary to consider the flow of energy during a chemical reaction, which brings us to the subject of thermodynamics. A brief survey of the principles of thermodynamics also helps explain many of the cellular processes that will be discussed in this and following chapters, including the movement of ions across membranes, the synthesis of macromolecules, and the assembly of cytoskeletal networks. As we will see, the thermodynamic analysis of a particular system can reveal whether or not the events can occur spontaneously and, if not, provide a measure of the energy a cell must expend for the process to be accomplished. In the final section of this chapter, we will see how individual chemical reactions are linked together to form metabolic pathways and how the flow of energy and raw materials through certain pathways can be controlled.

The electrostatic character of the surface is indicated by color (red, acidic; blue, basic). (FROM ZHENG RONG WU ET AL., SCIENCE 276:417, 1997, COURTESY OF MICHAEL F. SUMMERS, UNIVERSITY OF MARYLAND, BALTIMORE COUNTY; © 1997 REPRINTED WITH PERMISSION FROM AAAS.)

3.1 | Bioenergetics

A living cell bustles with activity. Macromolecules of all types are assembled from raw materials, waste products are produced and excreted, genetic instructions flow from the nucleus to the cytoplasm, vesicles are moved along the secretory pathway, ions are pumped across cell membranes, and so forth. To maintain such a high level of activity, a cell must acquire and expend energy. The study of the various types of energy transformations that occur in living organisms is referred to as **bioenergetics**.

The Laws of Thermodynamics and the Concept of Entropy

Energy is defined as the capacity to do work, that is, the capacity to change or move something. **Thermodynamics** is the study of the changes in energy that accompany events in the universe. In the following pages, we will focus on a set of concepts that allow us to predict the direction that events will take and whether or not an input of energy is required to cause the event to happen. However, thermodynamic measurements provide no help in determining how rapidly a specific process will occur or the mechanism used by the cell to carry out the process.

The First Law of Thermodynamics The first law of thermodynamics is the law of conservation of energy. It states that energy can neither be created nor destroyed. Energy can, however, be converted (*transduced*) from one form to another. The **transduction** of electric energy to mechanical energy occurs when we plug in a clock (Figure 3.1a), and chemical energy is converted to thermal energy when fuel is burned in an oil heater. Cells are also capable of energy transduction. As discussed in later chapters, the chemical energy stored in certain biological molecules, such as ATP, is converted to me-

chanical energy when organelles are moved from place to place in a cell, to electrical energy when ions flow across a membrane, or to thermal energy when heat is released during muscle contraction (Figure 3.1b). The most important energy transduction in the biological world is the conversion of sunlight into chemical energy—the process of photosynthesis—which provides the fuel that directly or indirectly powers the activities of nearly all forms of life.¹ A number of animals, including fireflies and luminous fish, are able to convert chemical energy back into light (Figure 3.1c). Regardless of the transduction process, however, the total amount of energy in the universe remains constant.

To discuss energy transformations involving matter, we need to divide the universe into two parts: the *system* under study and the remainder of the universe, which we will refer to as the *surroundings*. A system can be defined in various ways: it may be a certain space in the universe or a certain amount of matter. For example, the system may be a living cell. The changes in a system's energy that occur during an event are manifested in two ways—as a change in the heat content of the system and in the performance of work. Even though the system may lose or gain energy, the first law of thermodynamics indicates that the loss or gain must be balanced by a corresponding gain or loss in the surroundings, so that the amount in the universe as a whole remains constant. The energy of the system is termed the *internal energy* (E), and its change during a transformation is ΔE (delta E). One way to describe the first law of thermodynamics is that $\Delta E = Q - W$, where Q is the heat energy and W is the work energy.

Depending on the process, the internal energy of the system at the end can be greater than, equal to, or less than its internal

¹Several communities of organisms are known that are independent of photosynthesis. These include communities that reside in the hydrothermal vents at the bottom of the ocean floor that depend on energy obtained by bacterial chemosynthesis.

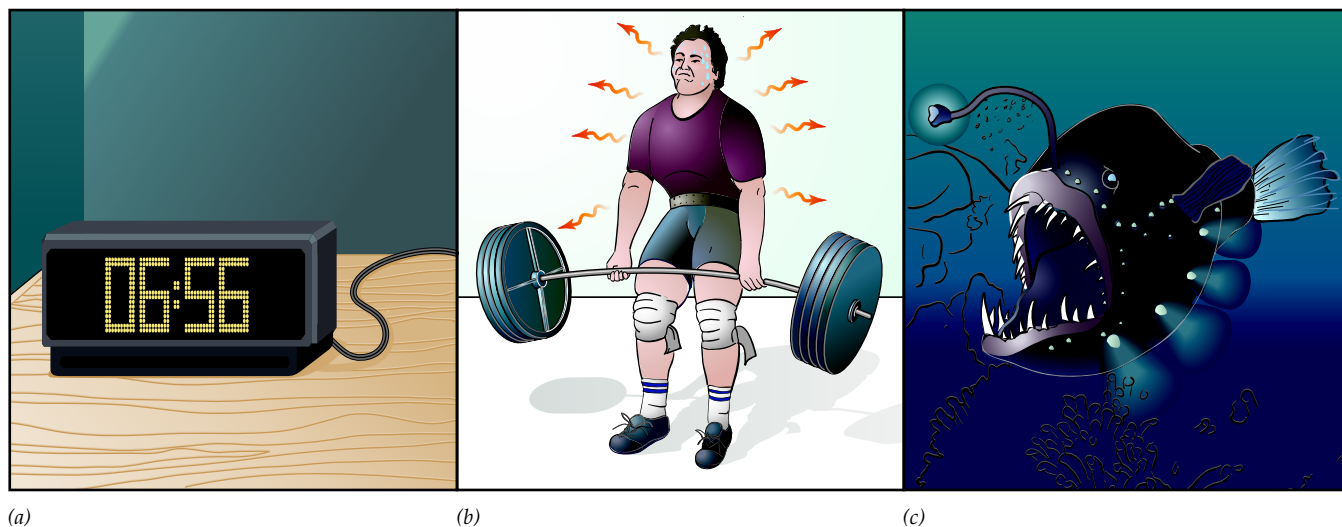

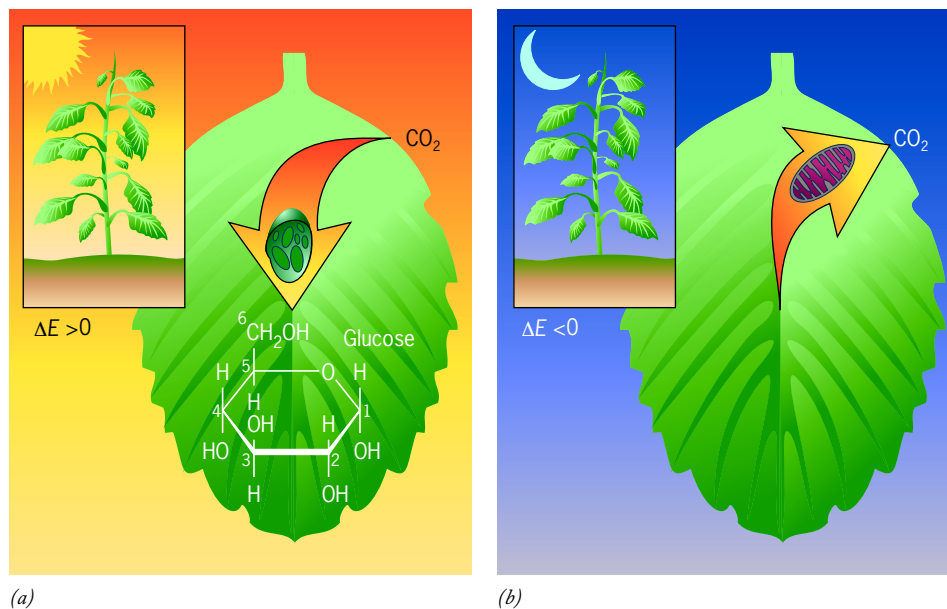

Figure 3.1 Examples of energy transduction. (a) Conversion of electrical energy to mechanical energy, (b) conversion of chemical

energy to mechanical and thermal energy, (c) conversion of chemical energy to light energy.

Figure 3.2 A change in a system's internal energy. In this example, the system will be defined as a particular leaf of a plant. (a) During the day, sunlight is absorbed by photosynthetic pigments in the leaf's chloroplasts and used to convert CO_2 into carbohydrates, such as the glucose molecule shown in the drawing (which is subsequently incorporated into sucrose or starch). As the cell absorbs light, its internal energy increases; the energy present in the remainder of the universe has to decrease. (b) At night, the energy relationship between the cell and its surroundings is reversed as the carbohydrates produced during the day are oxidized to CO_2 in the mitochondria and the energy is used to run the cell's nocturnal activities.

energy at the start, depending on its relationship to its surroundings (Figure 3.2). In other words, ΔE can be positive, zero, or negative. Consider a system to be the contents of a reaction vessel. As long as there is no change in pressure or volume of the contents, there is no work being done by the system on its surroundings, or vice versa. In that case, the internal energy at the end of the transformation will be greater than that at the beginning if heat is absorbed and less if heat is released. Reactions that lose heat are termed **exothermic**, and ones that gain heat are **endothermic**, and there are many reactions of both types. Because ΔE for a particular reaction can be positive or negative, it gives us no information as to the likelihood that a given event will occur. To determine the likelihood of a particular transformation, we need to consider some additional concepts.

The Second Law of Thermodynamics The second law of thermodynamics expresses the concept that events in the universe have direction; they tend to proceed “downhill” from a state of higher energy to a state of lower energy. Thus, in any energy transformation, there is a decreasing availability of energy for doing additional work. Rocks fall off cliffs to the ground below, and once at the bottom, their ability to do additional work is reduced; it is very unlikely that they will lift themselves back to the top of the cliff. Similarly, opposite charges normally move together, not apart, and heat flows from a warmer to a cooler body, not the reverse. Such events are said to be **spontaneous**, a term that indicates they are thermodynamically favorable and can occur *without the input of external energy*.

The concept of the second law of thermodynamics was formulated originally for heat engines, and the law carried with it the idea that it is thermodynamically impossible to construct a perpetual-motion machine. In other words, it is impossible for a machine to be 100 percent efficient, which would be required if it were to continue functioning without the input of external energy. Some of the energy is inevitably lost as the machine carries out its activity. A similar relationship holds true for living organisms. For example, when a giraffe browses on the leaves of a tree or a lion preys on the

giraffe, much of the chemical energy in the food never becomes available to the animal having the meal.

The loss of available energy during a process is a result of a tendency for the randomness, or disorder, of the universe to increase every time there is a transfer of energy. This gain in disorder is measured by the term **entropy**, and the loss of available energy is equal to $T\Delta S$, where ΔS is the change in entropy between the initial and final states. Entropy is associated with the *random* movements of particles of matter, which, because they are random, cannot be made to accomplish a *directed* work process. According to the second law of thermodynamics, every event is accompanied by an increase in the entropy of the universe. When a sugar cube is dropped into a cup of hot water, for example, there is a spontaneous shift of the molecules from an ordered state in the crystal to a much more disordered condition when the sugar molecules are spread throughout the solution (Figure 3.3a). As the molecules of the sugar cube dissolve into solution, their freedom of movement increases, as does the entropy of the system. The change from a concentrated to a dispersed state results from the random movements of the molecules. The sugar molecules eventually spread themselves equally through the available volume because the state of uniform distribution is the most probable state.

The release of heat, for example, from the oxidation of glucose within a cell or from the friction generated as blood flows through a vessel, is another example of an increase in entropy. The release of thermal energy by living organisms increases the rate of random movements of atoms and molecules; it cannot be redirected to accomplish additional work. Since the energy of molecular and atomic movements increases with temperature, so too does the entropy. It is only at absolute zero (0 K), when all movements cease, that the entropy is zero.

As with other spontaneous events, we must distinguish between the system and its surroundings. The second law of thermodynamics indicates only that the total entropy in the universe must increase; the disorder within one part of the universe (the system) can decrease at the greater expense of its surroundings. The dissolved sugar in Figure 3.3a can decrease

Figure 3.3 Events are accompanied by an increase in the entropy of the universe. (a) A sugar cube contains sucrose molecules in a highly ordered arrangement in which their freedom of movement is restricted. As the cube dissolves, the freedom of movement of the sucrose molecules is greatly increased, and their random movement causes them to become equally distributed throughout the available space. Once this occurs, there will be no further tendency for redistribution, and the entropy of the system is at a maximum. (b) Sugar molecules spread randomly through a solution can be returned to an ordered state, but only if the entropy of the surroundings is increased, as occurs when the more ordered water molecules of the liquid phase become disordered following evaporation.

in entropy; it can be recrystallized by evaporating off the water (Figure 3.3*b*). The consequence of this process, however, is an even greater increase in the entropy of the surroundings. The increased freedom of movement of the water molecules in the gaseous phase more than balances the decrease in freedom of the molecules of the sugar crystals.

Life operates on a similar principle. Living organisms are able to decrease their own entropy by increasing the entropy of their environment. Entropy is decreased in an organism when relatively simple molecules, such as amino acids, are ordered into more complex molecules, such as the protein myoglobin in a muscle cell. For this to occur, however, the entropy of the environment must increase, which is accomplished as complex, ordered molecules such as glycogen stored in liver or muscle tissue are converted into heat and smaller, less ordered compounds (such as CO_2 and H_2O) are released to the environment. It is this feature of metabolism that allows living organisms to maintain such a highly ordered and improbable state—at least for a while.

Another measure of the energy state of a living organism is provided by the information content of its macromolecules. Information is a subject that is difficult to define but easy to recognize. Information can be measured in terms of the ordered arrangement of a structure's subunits. For example, proteins and nucleic acids, in which the specific linear sequence of the subunits is highly ordered, are low in entropy and high in information content. Maintaining a state of high information content (low entropy) requires the input of energy. Consider just one molecule of DNA located in one cell in your liver. That cell has dozens of different proteins whose sole job is to

patrol the DNA, looking for damage and repairing it (discussed in Section 13.2). Nucleotide damage in an active cell can be so great that, without this expenditure of energy, the information content of DNA would rapidly deteriorate.

Free Energy

Together, the first and second laws of thermodynamics indicate that the energy of the universe is constant, but the entropy continues to increase toward a maximum. The concepts inherent in the first two laws were combined by the American chemist, J. Willard Gibbs, in 1878 into the expression $\Delta H = \Delta G + T\Delta S$, where ΔG (delta G) is the change in **free energy**, that is, the change during a process in the energy available to do work; ΔH is the change in *enthalpy* or total energy content of the system (equivalent to ΔE for our purposes), T is the absolute temperature ($\text{K} = ^\circ\text{C} + 273$), and ΔS is the change in the entropy of the system. The equation states that the total energy change is equal to the sum of the changes in useful energy (ΔG) and energy that is unavailable to do further work ($T\Delta S$).

When rearranged and written as $\Delta G = \Delta H - T\Delta S$, the above equation provides a measure of the spontaneity of a particular process. It allows one to predict the direction in which a process will proceed and the extent to which that process will occur. All *spontaneous* energy transformations must have a negative ΔG ; that is, the process must proceed toward a state of lower free energy. The magnitude of ΔG indicates the maximum amount of energy that can be passed on for use in another process but tells us nothing about how rapidly the process will occur. Processes that can occur spontaneously,

Figure 3.4 When water freezes, its entropy decreases because the water molecules of ice exist in a more ordered state with less freedom of movement than in a liquid state. The decrease in entropy is particularly apparent in the formation of a snowflake. (© NURIDSANY AND PERENNOU/PHOTO RESEARCHERS, INC.)

that is, processes that are thermodynamically favored (have a $-\Delta G$), are described as **exergonic**. In contrast, if the ΔG for a given process is positive, then it cannot occur spontaneously. Such processes are thermodynamically unfavorable and are described as **endergonic**. As we will see, reactions that are normally endergonic can be made to occur by coupling them to energy-releasing processes.

The signs of ΔH and ΔS for a given transformation can be positive or negative, depending on the relation between the system and its surroundings. (Hence, ΔH will be positive if heat is gained by the system and negative if heat is lost; ΔS will be positive if the system becomes more disordered and negative if it becomes more ordered.) The counterplay between ΔH and ΔS is illustrated by the ice–water transformation. The conversion of water from the liquid to the solid state is accompanied by a decrease in entropy (ΔS is negative, as illustrated in Figure 3.4) and a decrease in enthalpy (ΔH is negative). In order for this transformation to occur (i.e., for ΔG to be negative), ΔH must be more negative than $T\Delta S$, a condition that occurs only below 0°C . This relationship can be seen from Table 3.1, which indicates the values for the different terms if one mole of water were to be converted to ice at 10°C , 0°C , or -10°C . In all cases, regardless of the temperature, the energy level of the ice is less than that of the liquid (the ΔH is negative). However, at the higher temperature, the entropy term of the equation ($T\Delta S$) is more negative than the enthalpy term; therefore, the free-energy change is positive, and the process cannot occur spontaneously. At 0°C , the system is in equilibrium; at -10°C , the solidification process is favored, that is, the ΔG is negative.

Free-Energy Changes in Chemical Reactions Now that we have discussed the concept of free energy in general terms, we can apply the information to chemical reactions within the cell. All chemical reactions within the cell are

Table 3.1 Thermodynamics of the Ice–Water Transformation

Temp. (°C)	ΔE (cal/mol)	ΔH (cal/mol)	ΔS (cal/mol · °C)	$T\Delta S$ (cal/mol)	ΔG (cal/mol)
-10	-1343	-1343	-4.9	-1292	-51
0	-1436	-1436	-5.2	-1436	0
+10	-1529	-1529	-5.6	-1583	+54

reversible, and therefore we must consider two reactions occurring simultaneously, one forward and the other in reverse. According to the law of mass action, the rate of a reaction is proportional to the concentration of the reactants. Consider, for example, the following reaction:

The rate of the forward reaction is directly proportional to the product of the molar concentrations of A and B. The rate of the forward reaction can be expressed as $k_1[A][B]$, where k_1 is a rate constant for the forward reaction. The rate of the backward reaction equals $k_2[C][D]$. All chemical reactions proceed, however slowly, toward a state of equilibrium, that is, toward a point at which the rates of the forward and backward reactions are equal. At equilibrium, the same number of A and B molecules are converted into C and D molecules per unit time as are formed from them. At equilibrium, therefore,

$$k_1[A][B] = k_2[C][D]$$

which can be rearranged to

$$\frac{k_1}{k_2} = \frac{[C][D]}{[A][B]}$$

In other words, at equilibrium there is a predictable ratio of the concentration of products to the concentration of reactants. This ratio, which is equal to k_1/k_2 , is termed the **equilibrium constant**, K_{eq} .

The equilibrium constant allows one to predict the direction (forward or reverse) in which the reaction is favored under a given set of conditions. Suppose, for example, that we are studying the above reaction, and we have just mixed the four components (A, B, C, D) so that each is present at an initial concentration of 0.5 M.

$$\frac{[C][D]}{[A][B]} = \frac{[0.5][0.5]}{[0.5][0.5]} = 1$$

The direction in which this reaction will proceed depends on the equilibrium constant. If the K_{eq} is greater than 1, the reaction will proceed at a greater rate toward the formation of the products C and D than in the reverse direction. For example, if the K_{eq} happens to be 9.0, then the concentration of the reactants and products at equilibrium in this particular reaction mixture will be 0.25 M and 0.75 M, respectively.

$$\frac{[C][D]}{[A][B]} = \frac{[0.75][0.75]}{[0.25][0.25]} = 9$$

If, on the other hand, the K_{eq} is less than 1, the reverse reaction

will proceed at a greater rate than the forward reaction, so that the concentration of A and B will rise at the expense of C and D. It follows from these points that the net direction in which the reaction is proceeding at any moment depends on the relative concentrations of all participating molecules and can be predicted from the K'_{eq} .

Let us return to the subject of energetics. The ratio of reactants to products present at equilibrium is determined by the relative free-energy levels of the reactants and products. As long as the total free energy of the reactants is greater than the total free energy of the products, then ΔG has a negative value and the reaction proceeds in the direction of formation of products. The greater the ΔG , the farther the reaction is from equilibrium and the more work that can be performed by the system. As the reaction proceeds, the difference in free-energy content between the reactants and products decreases (ΔG becomes less negative), until at equilibrium the difference is zero ($\Delta G = 0$) and no further work can be obtained.

Because ΔG for a given reaction depends on the reaction mixture present at a given time, it is not a useful term to compare the energetics of various reactions. To place reactions on a comparable basis and to allow various types of calculations to be made, a convention has been adopted to consider the free-energy change that occurs during a reaction under a set of *standard conditions*. For biochemical reactions, the conditions are arbitrarily set at 25°C (298 K) and 1 atm of pressure, with all the reactants and products present at 1.0 M concentration, except for water, which is present at 55.6 M, and H^+ at 10^{-7} M (pH 7.0).² The **standard free-energy change ($\Delta G^{\circ'}$)** describes the free energy released when reactants are converted to products under these standard conditions. It must be kept in mind that standard conditions do not prevail in the cell, and therefore one must be cautious in the use of values for standard free-energy differences in calculations of cellular energetics.

The relationship between the equilibrium constant and standard free-energy change is given by the equation

$$\Delta G^{\circ'} = -RT \ln K'_{eq}$$

When the natural log (ln) is converted to \log_{10} , the equation becomes

$$\Delta G^{\circ'} = -2.303RT \log K'_{eq}$$

where R is the gas constant (1.987 cal/mol · K) and T is the absolute temperature (298 K).³ Recall that the log of 1.0 is zero. Consequently, it follows from the above equation that reactions having equilibrium constants greater than 1.0 have negative $\Delta G^{\circ'}$ values, which indicates that they can occur spontaneously under *standard conditions*. Reactions having equilibrium constants of less than 1 have positive $\Delta G^{\circ'}$ values and cannot occur spontaneously under standard conditions. In other words, given the reaction written as follows: $A + B \rightleftharpoons C + D$, if the $\Delta G^{\circ'}$ is negative, the reaction will go

² $\Delta G^{\circ'}$ indicates standard conditions include pH 7, whereas ΔG° indicates standard conditions in 1.0 M H^+ (pH 0.0). The designation K'_{eq} also indicates a reaction mixture at pH 7.

³The right-hand side of this equation is equivalent to the amount of free energy lost as the reaction proceeds from standard conditions to equilibrium.

Table 3.2 Relation between $\Delta G^{\circ'}$ and K'_{eq} at 25°C

K'_{eq}	$\Delta G^{\circ'}$ (kcal/mol)
10^6	-8.2
10^4	-5.5
10^2	-2.7
10^1	-1.4
10^0	0.0
10^{-1}	1.4
10^{-2}	2.7
10^{-4}	5.5
10^{-6}	8.2

to the right when reactants and products are all present at 1.0 M concentration at pH 7. The greater the negative value, the farther to the right the reaction will proceed before equilibrium is reached. Under the same conditions, if the $\Delta G^{\circ'}$ is positive, the reaction will proceed to the left; that is, the reverse reaction is favored. The relation between $\Delta G^{\circ'}$ and K'_{eq} is shown in Table 3.2.

Free-Energy Changes in Metabolic Reactions One of the most important chemical reactions in the cell is the hydrolysis of ATP (Figure 3.5). In the reaction,

the standard free-energy difference between the products and reactants is -7.3 kcal/mol. Based on this information, it is evident that the hydrolysis of ATP is a highly favorable (exergonic) reaction, that is, one that tends toward a large $[ADP]/[ATP]$ ratio at equilibrium. There are several reasons why this reaction is so favorable, one of which is evident in Figure 3.5. The electrostatic repulsion created by four closely spaced negative charges on ATP^{4-} is partially relieved by formation of ADP^{3-} .

It is important that the difference between ΔG and $\Delta G^{\circ'}$ be kept clearly in mind. The $\Delta G^{\circ'}$ is a fixed value for a given reaction and indicates the direction in which that reaction would proceed were the system at standard conditions. Since standard conditions do not prevail within a cell, $\Delta G^{\circ'}$ values cannot be used to predict the direction in which a particular reaction is proceeding at a given moment within a particular cellular compartment. To do this, one must know the ΔG , which is determined by the concentrations of the reactants and products that are present at the time. At 25°C

$$\Delta G = \Delta G^{\circ'} + 2.303RT \log \frac{[C][D]}{[A][B]}$$

$$\Delta G = \Delta G^{\circ'} + 2.303(1.987 \text{ cal/mol} \cdot \text{K})(298 \text{ K})$$

$$\log \frac{[C][D]}{[A][B]}$$

$$\Delta G = \Delta G^{\circ'} + (1.4 \text{ kcal/mol}) \log \frac{[C][D]}{[A][B]}$$

where $[A]$, $[B]$, $[C]$, and $[D]$ are the actual concentrations at the time. Calculation of the ΔG reveals the direction in which

Figure 3.5 ATP hydrolysis. Adenosine triphosphate (ATP) is hydrolyzed as part of many biochemical processes. In most reactions, as shown here, ATP is hydrolyzed to ADP and inorganic phosphate (P_i), but in some cases (not shown) it is hydrolyzed to AMP, a compound

with only one phosphate group, and pyrophosphate (PP_i). Both of these reactions have essentially the same $\Delta G^{\circ'}$ of -7.3 kcal/mol (-30.5 kJ/mol).

the reaction in the cell is proceeding and how close the particular reaction in question is to equilibrium. For example, typical cellular concentrations of the reactants and products in the reaction for ATP hydrolysis might be $[ATP] = 10$ mM; $[ADP] = 1$ mM; $[P_i] = 10$ mM. Substituting these values into the equation,

$$\Delta G = \Delta G^{\circ'} + 2.303RT \log \frac{[ADP][P_i]}{[ATP]}$$

$$\Delta G = -7.3 \text{ kcal/mol} + (1.4 \text{ kcal/mol}) \log \frac{[10^{-3}][10^{-2}]}{[10^{-2}]}$$

$$\Delta G = -7.3 \text{ kcal/mol} + (1.4 \text{ kcal/mol})(-3)$$

$$\Delta G = -11.5 \text{ kcal/mol (or } -46.2 \text{ kJ/mol)}$$

Thus, even though the $\Delta G^{\circ'}$ for the hydrolysis of ATP is -7.3 kcal/mol, the typical ΔG in the cell for this reaction is about -12 kcal/mol because a cell maintains a high $[ATP]/[ADP]$ ratio.

Cells carry out many reactions with positive $\Delta G^{\circ'}$ values because the relative concentrations of reactants and products favor the progress of the reactions. This can happen in two ways. The first illustrates the important difference between ΔG and $\Delta G^{\circ'}$, and the second reveals the manner in which reactions with positive $\Delta G^{\circ'}$ values can be driven in the cell by the input of stored chemical energy.

Consider the reaction of glycolysis (see Figure 3.24) in which dihydroxyacetone phosphate is converted to glyceraldehyde 3-phosphate. The $\Delta G^{\circ'}$ for this reaction is $+1.8$ kcal/mol, yet the formation of the product of this reaction takes place in the cell. The reaction proceeds because other cellular reactions maintain the ratio of the reactant to product above that defined by the equilibrium constant. As long as this condition holds, the ΔG will be negative and the reaction will continue spontaneously in the direction of formation of glyceraldehyde 3-phosphate. This brings up an important characteristic of cellular metabolism, namely, that specific reactions cannot be considered independently as if they were occurring in isolation in a test tube. Hundreds of reactions occur simultaneously in a cell. All these reactions are interrelated because a product of

one reaction becomes a reactant for the next reaction in the sequence and so on throughout one metabolic pathway and into the next. To maintain the production of glyceraldehyde 3-phosphate at the expense of dihydroxyacetone phosphate, the reaction is situated within a metabolic pathway in such a way that the product is removed by the next reaction in the sequence at a sufficiently rapid rate that a favorable ratio of the concentrations of these two molecules is retained.

Coupling Endergonic and Exergonic Reactions Reactions with large positive $\Delta G^{\circ'}$ values are typically driven by the input of energy. Consider the formation of the amino acid glutamine from glutamic acid by the enzyme glutamine synthetase:

This endergonic reaction takes place in the cell because glutamic acid is actually converted to glutamine in two sequential reactions, both of which are exergonic:

The formation of glutamine is said to be *coupled* to the hydrolysis of ATP. As long as the ΔG for ATP hydrolysis is more negative than the ΔG for glutamine synthesis from glutamic acid is positive, the “downhill” ATP hydrolysis reaction can be used to drive the “uphill” synthesis of glutamine. To couple the two chemical reactions, the product of the first reaction becomes the reactant for the second. The bridge between the two reactions—glutamyl phosphate in this case—is called the

FIGURE IN FOCUS

common intermediate. What happens, in essence, is that the exergonic hydrolysis of ATP is taking place in two steps. In the first step, glutamic acid acts as an acceptor of the phosphate group, which is displaced by NH_3 in the second step.

The hydrolysis of ATP can be used in the cell to drive reactions leading to the formation of molecules such as glutamine because ATP levels are maintained at much higher levels (relative to those of ADP) than they would be at equilibrium. This can be demonstrated by the following calculation. As noted above, a typical cellular concentration of P_i might be 10 mM. To calculate the equilibrium ratio of $[\text{ATP}]/[\text{ADP}]$ under these conditions, we can set ΔG at the equilibrium value of 0 and solve the following equation (taken from page 91) for $[\text{ADP}]/[\text{ATP}]$:

$$\Delta G = \Delta G^{\circ'} + (1.4 \text{ kcal/mol}) \log \frac{[\text{ADP}][\text{P}_i]}{[\text{ATP}]}$$

$$0 = -7.3 \text{ kcal/mol} + (1.4 \text{ kcal/mol}) \log \frac{[\text{ADP}][10^{-2}]}{[\text{ATP}]}$$

$$0 = -7.3 \text{ kcal/mol} + (1.4 \text{ kcal/mol}) \left(\log 10^{-2} + \log \frac{[\text{ADP}]}{[\text{ATP}]} \right)$$

$$+ 7.3 \text{ kcal/mol} = (1.4 \text{ kcal/mol})(-2) + (1.4 \text{ kcal/mol}) \log \frac{[\text{ADP}]}{[\text{ATP}]}$$

$$\log \frac{[\text{ADP}]}{[\text{ATP}]} = \frac{10.1 \text{ kcal/mol}}{1.4 \text{ kcal/mol}} = 7.2$$

$$\frac{[\text{ADP}]}{[\text{ATP}]} = 1.6 \times 10^7$$

Thus, at equilibrium, the ADP concentration would be expected to be more than 10^7 times that of ATP, but in fact, the ATP concentrations in most cells are 10 to 100 times that of ADP. This is a crucial point because it's the relative concentrations of ATP and ADP that matter. If a cell were to contain an equilibrium mixture of ATP, ADP, and P_i , it wouldn't matter how much ATP was present, the cell would have no capacity to perform work.

ATP hydrolysis is used to drive most endergonic processes within the cell, including chemical reactions such as the one just described, the separation of charge across a membrane, the concentration of a solute, the movement of filaments in a muscle cell, and the properties of proteins (Figure 3.6). ATP can be used for such diverse processes because its terminal phosphate group can be transferred to a variety of different types of molecules, including amino acids, sugars, lipids, and proteins. In most coupled reactions, the phosphate group is transferred in an initial step from ATP to one of these acceptors and is subsequently removed in a second step (see Figure 4.46 as an example).

Equilibrium versus Steady-State Metabolism As reactions tend toward equilibrium, the free energy available to do work decreases toward a minimum and the entropy increases toward a maximum. Thus, the farther a reaction is kept from its equilibrium state, the less its capacity to do work is lost to the increase in entropy. Cellular metabolism is essentially nonequilibrium metabolism; that is, it is characterized by nonequilibrium ratios of products to reactants. This does not mean that some reactions do not occur at or near equilibrium within cells. In fact, many of the reactions of a metabolic pathway may be near equilibrium (see Figure 3.25). However, at least one and

often several reactions in a pathway are poised far from equilibrium, making them essentially irreversible. These are the reactions that keep the pathway going in a single direction. These are also the reactions that are subject to cellular regulation because the flow of materials through the entire pathway can be greatly increased or decreased by stimulating or inhibiting the activity of the enzymes that catalyze these reactions.

The basic principles of thermodynamics were formulated using nonliving, *closed* systems (no exchange of matter between the system and its surroundings) under reversible equilibrium conditions. The unique features of cellular metabolism require a different perspective. Cellular metabolism can maintain itself at irreversible, nonequilibrium conditions because unlike the environment within a test tube, the cell is an *open* system. Materials and energy are continually flowing into the cell from the bloodstream or culture medium. The extent of this input into cells from the outside becomes apparent if you simply hold your breath. We depend from minute to minute on an external source of oxygen because oxygen is a very important reactant in cellular metabolism. The continual flow of oxygen and other materials into and out of cells allows cellular metabolism to exist in a **steady state** (Figure 3.7). In a steady state, the concentrations of reactants and products remain relatively constant, even though the individual reac-

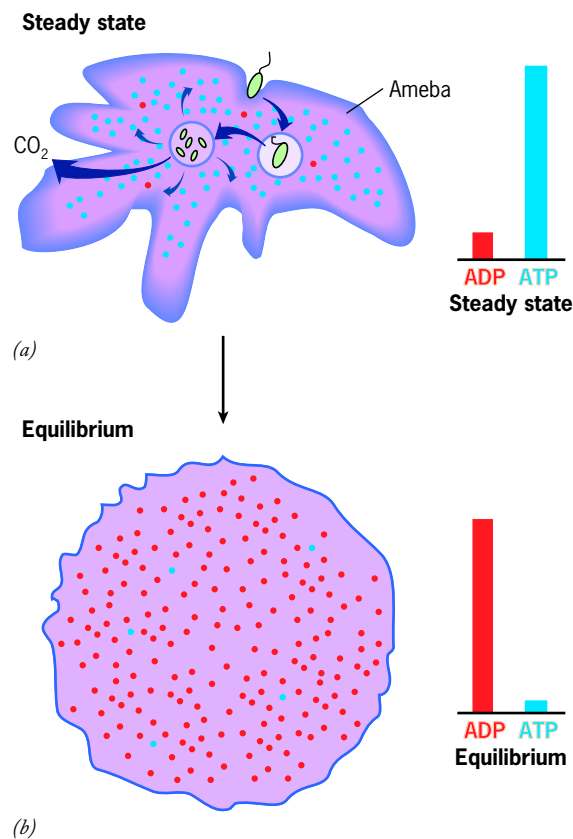

Figure 3.7 Steady state versus equilibrium. (a) As long as this amoeba can continue to take in nutrients from the outside world, it can harvest the energy necessary to maintain concentrations of compounds at a steady state, which may be far from equilibrium. The steady-state concentrations of ATP and ADP are indicated by the colored dots and the histogram. (b) When the amoeba dies, the concentrations of ATP and ADP (as well as other biochemicals) shift toward their equilibrium ratios.

tions are not necessarily at equilibrium. This is not to suggest that the concentrations of cellular metabolites do not change. Cells are capable of continually adjusting the concentration of key substances in response to changing conditions. A rise or fall in the level of regulatory substances, such as the hormone insulin, for example, can cause a dramatic surge or decline in the production of sugars, amino acids, or fats. Cells, in other words, exist in a state of *dynamic* nonequilibrium, in which the rates of forward and reverse reactions can be increased or decreased instantaneously in response to changing conditions.

REVIEW

1. Describe the differences between the first and second laws of thermodynamics and how, when taken together, they are able to describe the direction of events that take place in the universe.
2. How is the maintenance of the ordered living state consistent with the second law of thermodynamics?
3. Describe two examples in which the entropy of a system decreases and two examples in which the entropy of a system increases.
4. Discuss the differences between ΔG and ΔG° ; between the relative rates of the forward and reverse reactions when ΔG is negative, zero, or positive. What is the relationship between ΔG° and K'_{eq} ? How can a cell carry out a reaction that has a $+\Delta G^\circ$?
5. How is it possible for a cell to maintain an $[\text{ATP}]/[\text{ADP}]$ ratio greater than one? How does this ratio differ from that expected at equilibrium?
6. How is it that ice formation does not take place at temperatures above 0°C ?

3.2 | Enzymes as Biological Catalysts

At the end of the nineteenth century, a debate was raging as to whether or not the process of ethanol formation required the presence of intact yeast cells. On one side of the debate was the organic chemist Justus von Liebig, who argued that the reactions of fermentation that produced the alcohol were no different from the types of organic reactions he had been studying in the test tube. On the other side was the biologist Louis Pasteur, who argued that the process of fermentation could only occur within the confines of an intact, highly organized, living cell.

In 1897, two years after Pasteur's death, Hans Büchner, a bacteriologist, and his brother Eduard, a chemist, were preparing "yeast juice"—an extract made by grinding yeast cells with sand grains and then filtering the mixture through filter paper. They wanted to preserve the yeast juice for later use. After trying to preserve the extract with antiseptics and failing, they attempted to protect the preparation from spoilage by adding sugar, the same procedure used to preserve jams and jellies. Instead of preserving the solution, the yeast juice produced gas from the sugar, and it bubbled continuously for days. After further analysis, Eduard discovered that

fermentation was producing ethanol and bubbles of carbon dioxide. Büchner had shown that fermentation did not require the presence of intact cells.

It was soon found, however, that fermentation was very different from the types of reactions carried out by organic chemists. Fermentation required the presence of a unique set of catalysts that had no counterpart in the nonliving world. These catalysts were called **enzymes** (after the Greek for “in yeast”). Enzymes are the mediators of metabolism, responsible for virtually every reaction that occurs in a cell. Without enzymes, metabolic reactions would proceed so slowly as to be imperceptible.

The first evidence that enzymes are proteins was obtained in 1926 by James Sumner of Cornell University, when he crystallized the enzyme urease from jack beans and determined its composition. Though this finding was not greeted with much positive acclaim at the time, several other enzymes were soon shown to be proteins, and it became accepted for the next few decades that all biological catalysts were proteins. Eventually, it became evident that certain biological reactions are catalyzed by RNA molecules. For the sake of clarity, the term *enzyme* is still generally reserved for protein catalysts, while the term *ribozyme* is used for RNA catalysts. We will restrict the discussion in the present chapter to protein catalysts and discuss the properties of RNA catalysts in Chapter 11.

Even though enzymes are proteins, many of them are conjugated proteins; that is, they contain nonprotein components, called **cofactors**, which may be inorganic (metals) or organic (**coenzymes**). Vitamins and their derivatives often function as coenzymes. When present, cofactors are important participants in the functioning of the enzyme, often carrying out activities for which amino acids are not suited. In myoglobin, for example, as discussed in the previous chapter, the iron atom of a heme group is the site where oxygen is bound and stored until required by cellular metabolism.

The Properties of Enzymes

As is true of all catalysts, enzymes exhibit the following properties: (1) they are required only in small amounts; (2) they are

not altered irreversibly during the course of the reaction, and therefore each enzyme molecule can participate repeatedly in individual reactions; and (3) they have no effect on the thermodynamics of the reaction. This last point is particularly important. Enzymes do not supply energy for a chemical reaction and therefore do not determine whether a reaction is thermodynamically favorable or unfavorable. Similarly, enzymes do not determine the ratio of products to reactants at equilibrium. These are inherent properties of the reacting chemicals. As catalysts, enzymes can only accelerate the rate at which a favorable chemical reaction proceeds.

There is no necessary relationship between the magnitude of the ΔG for a particular reaction and the rate at which that reaction takes place. The magnitude of ΔG informs us only of the difference in free energy between the beginning state and equilibrium. It is totally independent of the pathway or the time it takes to reach equilibrium. The oxidation of glucose, for example, is a very favorable process, as can be determined by the amount of energy released during its combustion. However, glucose crystals can be left out in room air virtually indefinitely without a noticeable conversion into less energetic materials. Glucose, in other words, is *kinetically* stable, even if it is *thermodynamically* unstable. Even if the sugar were to be dissolved, as long as the solution were kept sterile, it would not rapidly deteriorate. However, if one were to add a few bacteria, within a short period of time the sugar would be taken up by the cells and enzymatically degraded.

Enzymes are remarkably adept catalysts. Catalysts employed by organic chemists in the lab, such as acid, metallic platinum, and magnesium, generally accelerate reactions a hundred to a thousand times over the noncatalyzed rate. In contrast, enzymes typically increase the velocity of a reaction 10^8 to 10^{13} fold or greater (Table 3.3). On the basis of these numbers, enzymes can accomplish in one second what would require from 3 years to 300,000 years if the enzyme were absent. Even more remarkably, they accomplish this feat at the mild temperature and pH found within a cell. In addition, unlike the inorganic catalysts used by chemists, enzymes are highly specific in the reactants they can bind and the reaction

Table 3.3 Catalytic Activity of a Variety of Enzymes

Enzyme	Nonenzymatic $t_{1/2}$ ¹	Turnover number ²	Rate enhancement ³
OMP decarboxylase	78,000,000 yr	39	1.4×10^{17}
Staphylococcal nuclease	130,000 yr	95	5.6×10^{14}
Adenosine deaminase	120 yr	370	2.1×10^{12}
AMP nucleosidase	69,000 yr	60	6.0×10^{12}
Cytidine deaminase	69 yr	299	1.2×10^{12}
Phosphotriesterase	2.9 yr	2,100	2.8×10^{11}
Carboxypeptidase A	7.3 yr	578	1.9×10^{11}
Ketosteroid isomerase	7 wk	66,000	3.9×10^{11}

¹The time that would elapse for half the reactants to be converted to product in the absence of enzyme.

²The number of reactions catalyzed by a single enzyme molecule per second when operating at a saturating substrate concentration.

³The increase in reaction rate achieved by the enzyme-catalyzed reaction over the noncatalyzed reaction.

they can catalyze. The reactants bound by an enzyme are called **substrates**. If, for example, the enzyme hexokinase is present in solution with a hundred low-molecular-weight compounds in addition to its substrate, glucose, only the glucose molecules will be recognized by the enzyme and undergo reaction. For all practical purposes, the other compounds may as well be absent. This type of specificity, whether between enzymes and substrates or other types of proteins and the substances that they bind, is crucial for maintaining the order required to sustain life.

In addition to their high level of activity and specificity, enzymes act as metabolic traffic directors in the sense that enzyme-catalyzed reactions are very orderly—the only products formed are the appropriate ones. This is very important because the formation of chemical by-products would rapidly take its toll on the life of a fragile cell. Finally, unlike other catalysts, the activity of enzymes can be regulated to meet the particular needs of the cell at a particular time. As will be evident in this chapter and the remainder of the text, the enzymes of a cell are truly a wondrous collection of miniature molecular machines.

Overcoming the Activation Energy Barrier

How are enzymes able to accomplish such effective catalysis? The first question to consider is why thermodynamically favorable reactions do not proceed on their own at relatively rapid rates in the absence of enzymes. Even ATP, whose hydrolysis is so favorable, is stable in a cell until broken down in a controlled enzymatic reaction. If this weren't the case, ATP would have little biological use.

Chemical transformations require that certain covalent bonds be broken within the reactants. For this to occur, the reactants must contain sufficient kinetic energy (energy of mo-

tion) that they overcome a barrier, called the **activation energy** (E_A). This is expressed diagrammatically in Figure 3.8, where the activation energy is represented by the height of the curves. The reactants in a chemical reaction are often compared to an object resting on top of a cliff ready to plunge to the bottom. If left to itself, the object in all likelihood would remain there indefinitely. However, if someone were to come along and provide the object with sufficient energy to overcome the friction or other small barrier in its way and cause it to reach the edge of the cliff, it would spontaneously drop to the bottom. The object has the potential to fall to a lower energy state once the kinetic barriers have been removed.

In a solution at room temperature, molecules exist in a state of random movement, each possessing a certain amount of kinetic energy at a given instant. Among a population of molecules, their energy is distributed in a bell-shaped curve (Figure 3.9), some having very little energy and others much more. Molecules of high energy (activated molecules) remain as such only for a brief time, losing their excess energy to other molecules by collision. Let us consider a reaction in which one reactant molecule is split into two product molecules. If a given reactant molecule acquires sufficient energy to overcome the activation barrier, then the possibility exists that it will split into the two product molecules. The rate of the reaction depends on the number of reactant molecules that contain the necessary kinetic energy at any given time. One way to increase the reaction rate is to increase the energy of the reactants. This is most readily done in the laboratory by heating the reaction mixture (Figure 3.9). In contrast, applying heat to an enzyme-mediated reaction leads to the rapid inactivation of the enzyme due to its denaturation.

Reactants, when they are at the crest of the energy hump and ready to be converted to products, are said to be at the **transition state** (Figure 3.8). At this point, the reactants have

Figure 3.8 Activation energy and enzymatic reactions. Even though the formation of glucose 6-phosphate is a thermodynamically favored reaction ($\Delta G^{\circ} = -4$ kcal/mol), the reactants must possess sufficient energy to achieve an activated state in which the atomic rearrangements necessary for the reaction can occur. The amount of energy required is called the activation energy (E_A) and is represented by the height of the curve. The activation energy is not a fixed value, but varies with the particular reaction pathway. E_A is greatly reduced when the reactants combine with an enzyme catalyst. (This diagram depicts a simple, one-step reaction mechanism. Many enzymatic reactions take place in two or more steps leading to the formation of intermediates (as in Figure 3.13). Each step in the reaction has a distinct E_A and a separate transition state.)

Figure 3.9 The effect of lowering activation energy on the rate of a reaction. The bell-shaped curves indicate the energy content of a population of molecules present in a reaction mixture at two different temperatures. The number of reactant molecules containing sufficient energy to undergo reaction is increased by either heating the mixture or adding an enzyme catalyst. Heat increases the rate of reaction by increasing the energy content of the molecules, while the enzyme does so by lowering the activation energy required for the reaction to occur.

formed a fleeting, activated complex in which bonds are being formed and broken. We can illustrate the nature of a transition state structure by examining the interconversion of D and L stereoisomers of proline, a reaction catalyzed by the bacterial enzyme proline racemase.

This reaction proceeds in either direction through the loss of a proton from the α -carbon of the proline molecule. As a result, the transition state structure contains a negatively charged carbanion in which the three bonds formed by the carbon atom are all in the same plane.

Unlike the difference in standard free energy for a reaction, the activation energy required to reach the transition state is not a fixed value but varies with the particular reaction mechanism utilized. Enzymes catalyze reactions by decreasing the magnitude of the activation energy barrier. Consequently, unlike catalysis by heat, enzymes cause their substrates to be very reactive without having to be raised to particularly high energy levels. A comparison between the percentage of molecules able to react in an enzyme-catalyzed reaction versus a noncatalyzed reaction is shown in Figure 3.9. Enzymes are able to lower activation energies by binding more tightly to the transition state than to the reactants,

which stabilizes this activated complex, thereby decreasing its energy. As a result, differences in the geometry and bonding properties between the reactants and the transition state are a focus of research in enzymatic mechanisms. The importance of the transition state can be demonstrated in numerous ways. For example:

- Compounds that resemble the transition state of a reaction tend to be very effective inhibitors of that reaction because they are able to bind so tightly to the catalytic region of the enzyme.
- Antibodies normally do not behave like enzymes but, rather, simply bind to molecules with high affinity. However, antibodies that bind to a compound that resembles a transition state for a reaction are often able to act like enzymes and catalyze the breakdown of that compound.

As the transition state is converted to products, the affinity of the enzyme for the bound molecule(s) decreases and the products are expelled.

The Active Site

As catalysts, enzymes accelerate bond-breaking and bond-forming processes. To accomplish this task, enzymes become intimately involved in the activities that are taking place among the reactants. Enzymes do this by forming a complex with reactants, called an **enzyme-substrate (ES) complex**. An ES complex is illustrated schematically in Figure 3.10 and the image in Figure 3.14. In most cases, the association between

Figure 3.10 Formation of an enzyme-substrate complex. Schematic drawing of the reaction catalyzed by pyruvate kinase (see Figure 3.24) in which the two substrates, phosphoenolpyruvate (PEP) and ADP, bind to the enzyme to form an enzyme-substrate (ES) complex, which leads to the formation of the products, pyruvate and ATP.

enzyme and substrate is noncovalent, though many examples are known in which a transient covalent bond is formed.

That part of the enzyme molecule that is directly involved in binding the substrate is termed the **active site**. The active site and the substrate(s) have complementary shapes, enabling them to bind together with a high degree of precision. The binding of substrate to enzyme is accomplished by the same types of noncovalent interactions (ionic bonds, hydrogen bonds, hydrophobic interactions) that determine the structure of the protein itself. For example, the enzyme depicted in Figure 3.11*a* contains a number of positively charged residues strategically located to bind negatively charged atoms of the substrate. In addition to binding the substrate, the active site contains a particular array of amino acid side chains that influence the substrate and lower the activation energy of the reaction. The importance of individual side chains of the active site can be evaluated by site-directed mutagenesis (page 74), a technique in which one particular amino acid is replaced by another amino acid having different properties.

The active site is typically buried in a cleft or crevice that leads from the aqueous surroundings into the depths of the protein. When a substrate enters the active site cleft, it typically gives up its bound water molecules (desolvation) and enters a hydrophobic environment within the enzyme. The reactivity of the active-site side chains may be much greater in this protected environment as compared to the aqueous solvent of the cell. The amino acids that make up the active site are usually situated at distant points along the length of the extended polypeptide chain, but they are brought into close proximity to one another as the polypeptide folds into its final tertiary structure (Figure 3.11*b,c*). The structure of the active site accounts not only for the catalytic activity of the enzyme, but also for its *specificity*. As noted above, most enzymes are capable of binding only one or a small number of closely related biological molecules.

Mechanisms of Enzyme Catalysis

How is it that an enzyme can cause a reaction to occur hundreds of times a second when that same reaction might occur at undetectable rates in the enzyme's absence? The answer lies in the formation of the enzyme–substrate complex, which allows the substrate(s) to be taken out of solution and held onto the surface of the large catalyst molecule. Once there, the physical and chemical properties of the substrate can be affected in a number of ways, several of which are described in the following sections.

Substrate Orientation Suppose you were to place a handful of nuts and bolts into a bag and shake the bag for 5 minutes. It is very unlikely that any of the bolts would have a nut firmly attached to its end when you were finished. In contrast, if you were to pick up a bolt in one hand and a nut in the other, you could rapidly guide the bolt into the nut. By holding the nut and bolt in the proper orientation, you have greatly decreased the entropy of the system. Enzymes lower the entropy of their substrates in a similar manner.

Substrates bound to the surface of an enzyme are brought very close together in precisely the correct orientation to undergo reaction (Figure 3.12*a*). In contrast, when reactants are present in solution, they are free to undergo translational and rotational movements, and even those possessing sufficient energy do not necessarily undergo a collision that results in the formation of a transition-state complex.

Changing Substrate Reactivity Enzymes are composed of amino acids having a variety of different types of side chains, from fully charged to highly nonpolar. When a substrate is bound to the surface of an enzyme, the distribution of electrons within that substrate molecule is influenced by the neighboring side chains of the enzyme (Figure 3.12*b*). This influence increases the reactivity of the substrate and stabilizes the transition-state complex formed during the reaction. These effects are accomplished without the input of external energy, such as heat.

There are several general mechanisms whereby the reactivity of substrates is increased by association with enzymes. Basically, these mechanisms are similar to those characterized by organic chemists studying the mechanisms of organic reactions in a test tube. For example, the rate of reactions can be greatly affected by changes in pH. Although enzymes cannot change the pH of their medium, they do contain numerous amino acids with acidic or basic side chains. These groups are capable of donating or accepting protons to and from the substrate, thereby altering the electrostatic character of the substrate, making it more reactive.

The active sites of many enzymes contain side chains with a partial positive or negative charge. Such groups are capable of interacting with a substrate to alter its electrostatic properties (Figure 3.12*b*) and hence its reactivity. Such groups are also capable of reacting with a substrate to produce a temporary, covalent enzyme–substrate linkage. Chymotrypsin, an enzyme that digests food proteins within the small intestine, acts in this way. The series of reactions that take place as chy-

Figure 3.12 Three mechanisms by which enzymes accelerate reactions: (a) maintaining precise substrate orientation, (b) changing substrate reactivity by altering its electrostatic configuration, (c) exerting physical stress on bonds in the substrate to be broken.

motrypsin hydrolyzes a peptide bond in a substrate protein is shown in Figure 3.13. The reaction in Figure 3.13 is divided into two steps. In the first step, the electronegative oxygen atom of the side chain of a serine of the enzyme “attacks” a carbon atom of the substrate. As a result, the peptide bond of the substrate is hydrolyzed, and a covalent bond is formed between the serine and the substrate, displacing the remainder of the substrate as one of the products. As discussed in the figure legend, the ability of serine to carry out this reaction depends on a nearby histidine residue, which attracts the proton of serine’s hydroxyl group, increasing the nucleophilic power of the group’s oxygen atom. Enzymes are also adept at utilizing water molecules in the reactions they catalyze. In the second step shown in Figure 3.13*b*, the covalent bond between enzyme and substrate is cleaved by a water molecule, returning the enzyme to its original unbonded state and releasing the remainder of the substrate as the second product.

Although amino acid side chains can engage in a variety of reactions, they are not well suited to donate or accept electrons. As we will see in the following section (and more fully in Chapters 5 and 6), the transfer of electrons is the central

Figure 3.13 Diagrammatic representation of the catalytic mechanism of chymotrypsin. The reaction is divided into two steps. (a) The electronegative oxygen atom of a serine residue (Ser 195) in the enzyme, which carries a partial negative charge, carries out a nucleophilic attack on the carbonyl carbon atom of the substrate, which carries a partial positive charge, splitting the peptide bond. The polypeptide substrate is shown in blue. The serine is made more reactive by a closely applied histidine residue (His 57) that draws the proton from the serine and subsequently donates the proton to the nitrogen atom of the cleaved peptide bond. Histidine is able to do this because its side chain is a weak base that is capable of gaining and losing a proton at physiologic pH. (A stronger base, such as lysine, would remain fully protonated at this pH.) Part of the substrate forms a transient covalent bond with the enzyme by means of the serine side chain, while the remainder of the substrate is released as the first product. (It can be noted that the serine and histidine residues are situated 138 amino acids away from each other in the primary sequence but are brought together within the enzyme by the folding of the polypeptide. An aspartic acid, residue 102, which is not shown, also plays a role in catalysis by influencing the ionic state of the histidine.) (b) In the second step, the electronegative oxygen atom of a water molecule displaces the covalently linked substrate from the enzyme, regenerating the unbound enzyme molecule. As in the first step, the histidine plays a role in proton transfer; in this step, the proton is removed from water, making it a much stronger nucleophile. The proton is subsequently donated to the serine residue of the enzyme.

event in the oxidation–reduction reactions that play such a vital role in cellular metabolism. To catalyze these reactions, enzymes contain cofactors (metal ions or coenzymes) that increase the reactivity of substrates by removing or donating electrons. In a number of cases, enzymes create their own electron-accepting cofactor by chemically modifying one of the amino acid residues situated in their active site.

Inducing Strain in the Substrate Although the active site of an enzyme may be complementary to its substrate(s), various studies reveal a shift in the relative positions of certain of the atoms of the enzyme once the substrate has bound. In many cases, the conformation shifts so that the complementary fit between the enzyme and reactants is improved (an **induced fit**), and the proper reactive groups of the enzyme move into place. An example of induced fit is shown in Figure 3.14. These types of movements within an enzyme molecule provide a good example of a protein acting as a molecular machine. As these conformational changes occur, mechanical work is performed, allowing the enzyme to exert a physical force on certain bonds within a substrate molecule. This has the effect of destabilizing the substrate, causing it to adopt the transition state in which the strain is relieved (Figure 3.12c).

Studying Conformational Changes and Catalytic Intermediates To fully understand the mechanism by which an enzyme catalyzes a particular reaction, it is necessary to describe the various changes in atomic and electronic structure in both the enzyme and the substrate(s) as the reaction proceeds. We saw in the last chapter how X-ray crystallographic techniques can reveal details of the structure of a large enzyme molecule. Since 40 to 60 percent of the volume of a typical protein crystal consists of trapped solvent, most crystallized enzymes retain a high level of enzymatic activity. It should be possible, therefore, to use X-ray diffraction techniques to study reaction mechanisms. There is one major limitation, namely, time. In a standard crystallographic study, enzyme crystals must be subjected to an X-ray beam for a period of hours or days while the necessary data are collected. The portrait that emerges from such studies captures the structure of the molecule averaged out over time. Recent innovations, however, have made it possible to use X-ray crystallographic techniques to observe the fleeting structural changes that take place in the active site while an enzyme is catalyzing a single reaction cycle. This approach, which is called *time-resolved crystallography*, can include:

- Use of ultra-high-intensity X-ray beams generated by a synchrotron, an instrument used by nuclear physicists to study subatomic particles. This can cut the X-ray exposure period to a matter of picoseconds, which is the same time scale required for an enzyme to catalyze a single chemical transformation.
- Cooling the enzyme crystals to temperatures within 20 to 40 degrees of absolute zero, which slows the reaction by a factor as high as 10 billion, greatly increasing the lifetime of transient intermediates.
- Use of techniques to simultaneously trigger a reaction throughout an entire crystal so that all of the enzyme molecules in the crystal are in the same stage of the reaction at

the same time. For example, in the case of a reaction in which ATP is a substrate, the enzyme crystals can be infiltrated with ATP molecules that have been made nonreactive by linking them to an inert group (e.g., a nitrophenyl group) by a photosensitive bond. When the crystals are exposed to a brief pulse of light, all of the “caged” ATP molecules are released, initiating the reaction simultaneously in active sites throughout the crystal.

- Use of enzymes bearing site-directed mutations (page 74) that impose kinetic barriers at specific stages of the reaction, leading to an increased lifetime for particular intermediates.
- Determination of the structure at ultra-high (atomic) resolution (e.g., 0.8 Å), which allows visualization of individual hydrogens that may be present in hydrogen bonds or associated with acidic groups in the protein; the presence or absence of bound water molecules; the precise conformation of catalytic side chains; and the subtle strain that appears in

(a)

(b)

parts of the substrate during catalysis. The remarkable detail that can be extracted from these high-resolution images is illustrated by the hydrogen bond in Figure 3.15.

By combining these techniques, researchers have been able to determine the three-dimensional structure of an

Figure 3.15 Electron density map of a single hydrogen bond (green-dotted line). This map shows a very small part of the proteolytic enzyme subtilisin at atomic (0.78 Å) resolution. The hydrogen atom (yellow) is seen to be shared between a nitrogen atom on the ring of a histidine residue and an oxygen atom of an aspartic acid residue. enzyme at successive stages during a single catalyzed reaction. When these individual “snapshots” are put together in sequence, they produce a “movie” showing the various catalytic intermediates that appear and disappear as the reaction proceeds. An example of the data that can be collected using several of these approaches is shown in Figure 3.16.

While the spotlight has been focused on the conformational changes that occur as an enzyme transforms its substrates into products, considerable attention has also been paid in recent years to the conformational changes that occur within the protein itself. As shown in Figure 2.37, proteins are dynamic molecules that are capable of built-in (intrinsic) motion that can have important functional relevance. In the case depicted in Figure 2.37, this motion allows entry of substrate to the enzyme’s active site. Analysis of this type of intrinsic motion by various experimental techniques has suggested that proteins—even in the absence of substrate—are capable of many of the same movements that can be detected during the protein’s catalytic cycle. If true, this suggests that evolution has selected for protein structures that are capable of intrinsic motions that can be useful for potential functions that a protein might serve. Rather than inducing a specific conformational

change, the substrate(s) might simply be “waiting” for a protein to assume a conformation to which it can bind effectively.

Enzyme Kinetics

Enzymes vary greatly in their ability to catalyze reactions. The catalytic activity of an enzyme is revealed by studying its **kinetics**, that is, the rate at which it catalyzes a reaction under various experimental conditions. In 1913, Leonor Michaelis and Maud Menten reported on the mathematical relationship between substrate concentration and the velocity of enzyme reactions as measured by the amount of product formed (or substrate consumed) in a given amount of time. This relationship can be expressed by an equation (given on p. 103) that generates a hyperbola, as shown in Figure 3.17. Rather than considering the theoretical aspects of enzyme kinetics, we can obtain the same curve in a practical manner, as it is done for each enzyme studied. To determine the velocity of a reaction, an incubation mixture is set up at the desired temperature, containing all the ingredients required except one, which when added initiates the reaction. If, at the time the reaction begins, no product is present in the mixture, then the amount

Figure 3.16 Myoglobin: the movie. In this example of time-resolved X-ray crystallography, the structure of myoglobin (Mb) was determined with a molecule of CO bound to the heme group and at various times after the CO molecule was released. (CO binds to the same site on Mb as O₂ but is better suited for these types of studies.) Release of CO was induced simultaneously throughout the crystal by exposure to a flash of laser light (photolysis). Each of the structures was determined following a single, intense X-ray pulse from a synchrotron. The myoglobin molecule being studied had a single amino acid substitution that made it a better subject for analysis. (a) A 6.5 Å-thick slice through a Mb molecule showing the changes that occur by 100 picoseconds (1 ps = one-trillionth of a second) following the release of CO from its binding site. The structure of Mb prior to the laser flash is shown in magenta, and the structure of the protein 100 ps after the laser flash is shown in green. Those parts of the molecule that did not change in structure over this time period appear white. Three large-scale displacements near the CO-binding site can be seen (indicated by the yellow arrows). (b) An enlarged view of the boxed region in part a. The released CO (solid circle) is situated about 2 Å from its original binding site (dashed circle). Movement of CO is accommodated by the rotation of Phe29, which pushes His64 outward, which in turn dislodges a bound water molecule. (c) By 3.16 nanoseconds after the laser flash, the CO molecule has migrated to either of the two positions shown (labeled 2 and 3), Phe29 and His64 have relaxed toward their initial states, and the heme group has undergone considerable displacement as indicated by the increased amount of green shading in the region of the heme. Figure 3.17 The relationship between the rate (velocity) of an enzyme-catalyzed reaction and the substrate concentration. Since each enzyme molecule is only able to catalyze a certain number of reactions in a given amount of time, the velocity of the reaction (typically expressed as moles of product formed per second) approaches a maximal rate as the substrate concentration increases. The substrate concentration at which the reaction is at half-maximal velocity ($V_{\max}/2$) is called the Michaelis constant, or K_M .

of product that appears over time provides a measure of the velocity of the reaction. There are complicating factors in this procedure. If the incubation time is too great, the substrate concentration becomes measurably reduced. In addition, as product appears, it can be converted back to substrate by the reverse reaction, which is also catalyzed by the enzyme. Ideally, what we want to determine is the *initial* velocity, that is, the velocity at the instant when no product has yet been formed. To accurately measure the initial reaction velocity, brief incubation times and sensitive measuring techniques are employed.

To generate a curve such as that shown in Figure 3.17, the initial velocity is determined for a series of incubation mixtures that contain the same amount of enzyme but an increasing concentration of substrate. It is evident from this curve that the initial reaction velocity varies markedly with substrate concentration. At low substrate concentrations, enzyme molecules are subjected to relatively few collisions with substrate in a given amount of time. Consequently, the enzyme has “idle time”; that is, substrate molecules are rate limiting. At high substrate concentrations, enzymes are colliding with substrate molecules more rapidly than they can be converted to product. Thus, at high substrate concentrations, individual enzyme molecules are working at their maximal capacity; that is, enzyme molecules are rate limiting. Thus, as a greater and greater concentration of substrate is present in the reaction mixture, the enzyme approaches a state of *saturation*. The initial velocity at this theoretical saturation point is termed the **maximal velocity** (V_{\max}).

The simplest measure of the catalytic activity of an enzyme is provided by its **turnover number**, which can be calculated from the V_{\max} . The turnover number (or *catalytic constant*, k_{cat} , as it is also called) is the maximum number of

molecules of substrate that can be converted to product by one enzyme molecule per unit time. A turnover number (per second) of 1 to 10^3 is typical for enzymes, although values as great as 10^6 are known (see Table 3.3). It is apparent from these values that a few molecules of enzyme can rapidly convert a large number of substrate molecules into product.

The value of V_{\max} is only one useful term obtained from a plot such as that in Figure 3.17; another is the **Michaelis constant** (K_M), which is equal to the substrate concentration when the reaction velocity is one-half of V_{\max} . As its name implies, the K_M is constant for a given enzyme and, thus, independent of substrate or enzyme concentration. The relationship between V_{\max} and K_M is best appreciated by considering the Michaelis-Menten equation, which can be used to generate the plot shown in Figure 3.17.

$$V = V_{\max} \frac{[S]}{[S] + K_M}$$

According to the equation, when the substrate concentration $[S]$ is set at a value equivalent to K_M , then the velocity of the reaction (V) becomes equal to $V_{\max}/2$, or one-half the maximal velocity. Thus, $K_M = [S]$, when $V = V_{\max}/2$.

To generate a hyperbolic curve such as that in Figure 3.17 and make an accurate determination of the values for V_{\max} and K_M , a considerable number of points must be plotted. An easier and more accurate description is gained by plotting the reciprocals of the velocity and substrate concentration against one another, as formulated by Hans Lineweaver and Dean Burk. When this is done, the hyperbola becomes a straight line (Figure 3.18) whose x intercept is equal to $-1/K_M$, y intercept is equal to $1/V_{\max}$, and slope is equal to K_M/V_{\max} . The values of K_M and V_{\max} are, therefore, readily determined by extrapolation of the line drawn from a relatively few points.

In most cases, the value for K_M provides a measure of the affinity of the enzyme for the substrate. The higher the K_M , the greater the substrate concentration that is required to reach one-half V_{\max} and, thus, the lower the affinity of the

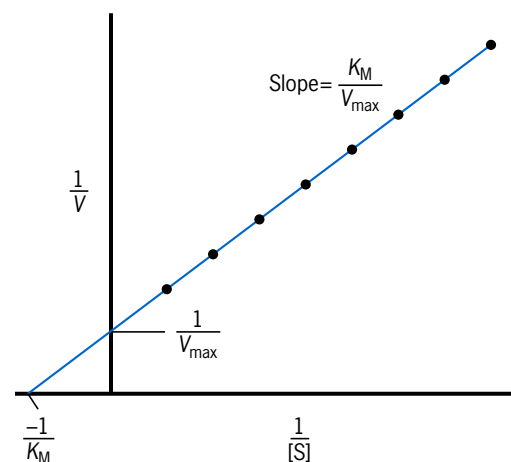

Figure 3.18 A Lineweaver-Burk plot of the reciprocals of velocity and substrate concentration from which the values for the V_{\max} and K_M are readily calculated.

Figure 3.19 Dependence of the rate of an enzyme-catalyzed reaction on (a) pH, and (b) temperature. The shape of the curves and the optimal pH and temperature vary with the particular reaction. (a) Changes in pH affect the ionic properties of the substrate and the enzyme as well as the enzyme's conformation. (b) At lower temperatures, reaction rates rise with increasing temperature due to the increased energy of the reactants. At higher temperatures, this positive effect is offset by enzyme denaturation. (A: FROM E. A. MOELWYN-HUGHES, IN THE ENZYMES, J. B. SUMNER AND K. MYRBACK, EDs., VOL. 1, ACADEMIC PRESS, 1950. B: FROM K. HAYASHI ET AL., JOURNAL BIOCHEM. 64:93, 1968, BY PERMISSION OF OXFORD UNIVERSITY PRESS.)

enzyme for that substrate. The K_M for most enzymes ranges between 10^{-1} and 10^{-7} , with a typical value about 10^{-4} M. Other factors that strongly influence enzyme kinetics are the pH and temperature of the incubation medium. Each enzyme has an optimal pH and temperature at which it operates at maximal activity (Figure 3.19). The influence of temperature on enzyme activity is illustrated by the striking effect of refrigeration in slowing the growth of microorganisms.

Enzyme Inhibitors **Enzyme inhibitors** are molecules that are able to bind to an enzyme and decrease its activity. The cell depends on inhibitors to regulate the activity of many of its enzymes; biochemists use inhibitors to study the properties of enzymes; and many pharmaceutical companies produce enzyme inhibitors that act as drugs. Enzyme inhibitors can be divided into two types: reversible or irreversible.

Irreversible inhibitors are those that bind very tightly to an enzyme, often by forming a covalent bond to one of its amino acid residues. A number of nerve gases, such as diisopropylphosphofluoridate and the organophosphate pesticides, act as irreversible inhibitors of acetylcholinesterase, an enzyme that plays a crucial role in destroying acetylcholine, the neurotransmitter responsible for causing muscle contraction. With the enzyme inhibited, the muscle is stimulated continuously and remains in a state of permanent contraction. As discussed in the accompanying Human Perspective, the antibiotic penicillin acts as an irreversible inhibitor of a key enzyme in the formation of the bacterial cell wall.

Reversible inhibitors, on the other hand, bind only loosely to an enzyme, and thus are readily displaced. For the sake of simplicity, we will discuss the simplest cases of reversible inhibitors, namely competitive and noncompetitive types.

Competitive inhibitors are reversible inhibitors that compete with a substrate for access to the active site of an enzyme. Since substrates have a complementary structure to the active site to which they bind, competitive inhibitors must resemble the substrate to compete for the same binding site, but differ in a way that prevents them from being transformed into product (Figure 3.20). Analysis of the types of molecules that can compete with the substrate for a binding site on the enzyme provides insight into the structure of the active site and the nature of the interaction between a substrate and its enzyme.

Competitive enzyme inhibition forms the basis of action of many common drugs, as illustrated in the following example. Angiotensin converting enzyme (ACE) is a proteolytic enzyme that acts on a 10-residue peptide (angiotensin I) to produce an 8-residue peptide (angiotensin II). Elevated levels of angiotensin II are a major risk factor in the development of high blood pressure (*hypertension*). In the 1960s John Vane and his colleagues at the Eli Lilly Company began a search for compounds that could inhibit ACE. Previous studies had found that the venom of a Brazilian pit viper contained inhibitors of proteolytic enzymes, and it was found that one of the components of this venom, a peptide called teprotide

was a potent competitive inhibitor of ACE. Although teprotide was shown to lower blood pressure in hypertensive patients, it was not a very useful drug because it had a peptide structure and thus was rapidly degraded if taken orally. Subsequent efforts to develop nonpeptide inhibitors of the enzyme led researchers to synthesize a compound called captopril,

which became the first useful antihypertensive drug that acted by binding to ACE.

The effectiveness of a competitive inhibitor depends on its relative affinity for the enzyme. Regardless, competitive inhibition can be overcome if the substrate/inhibitor ratio is great enough. In other words, if the number of collisions between the enzyme and inhibitor becomes insignificant relative to those between the enzyme and its substrate, then the effect of the inhibitor becomes minimal. Given a sufficient substrate concentration, it remains theoretically possible to achieve the enzyme's maximal velocity even in the presence of the competitive inhibitor.

Figure 3.20 Competitive inhibition. Because of their molecular similarity, competitive inhibitors are able to compete with the substrate for a binding site on the enzyme. The effect of a competitive inhibitor depends on the relative concentrations of the inhibitor and substrate.

In **noncompetitive inhibition**, the substrate and inhibitor do not compete for the same binding site; generally, the inhibitor acts at a site other than the enzyme's active site. The level of inhibition depends only on the concentration of the inhibitor, and increasing the concentration of the substrate cannot overcome it. Since, in the presence of a noncompetitive inhibitor, a certain fraction of the enzyme molecules are necessarily inactive at a given instant, the maximal velocity of the population of enzyme molecules cannot be reached. Tipranavir is a potent noncompetitive inhibitor of the protease produced by HIV when it infects a white blood cell. Unlike other inhibitors of this enzyme, such as ritonavir, tipranavir does not resemble the peptide substrate of the enzyme, nor does it compete with the substrate. The effects on the kinetics of enzymes in the presence of noncompetitive and competitive inhibitors are shown in Figure 3.21. In one case, the V_{\max} is lowered, and in the other, the K_M is increased. In both types, the slope (K_M/V_{\max}) is increased relative to the uninhibited reaction. As we will see on page 115, cells utilize a version of noncompetitive inhibition to regulate the activity of key enzymes of metabolic pathways.

REVIEW

1. How is it possible to have a reaction characterized by a large ΔG and a small E_A ? a large E_A and a small ΔG ?
2. Explain how enzymes can be so specific toward the substrates they bind.
3. Examine Figure 3.13 illustrating the steps in an enzymatically catalyzed reaction and describe what is occurring without reading the legend.
4. Distinguish between turnover number and V_{\max} .

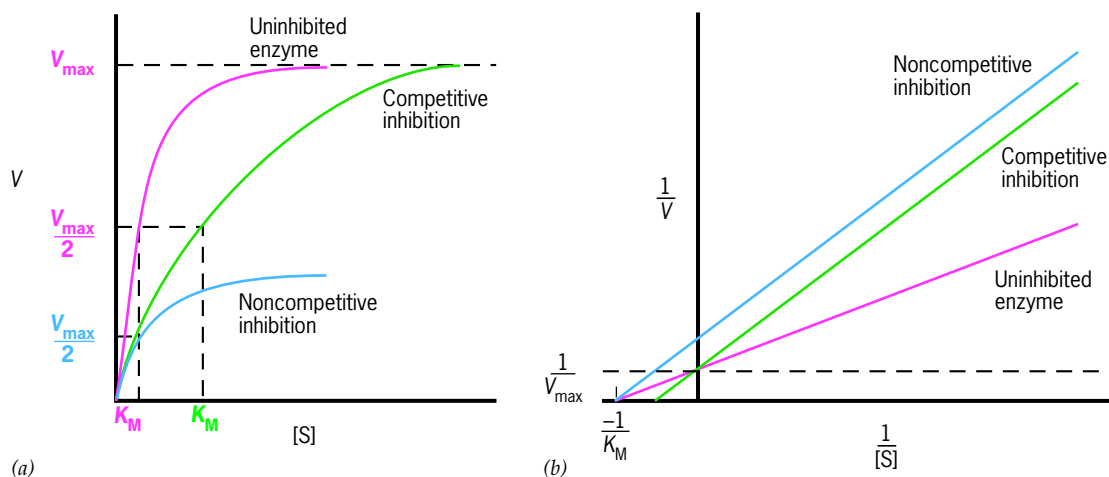

Figure 3.21 The effects of inhibitors on enzyme kinetics. The effect of both competitive and noncompetitive inhibitors is shown when the kinetics of the reaction are plotted as velocity of reaction versus substrate concentration (a) or its reciprocal (b). The noncompetitive

inhibitor reduces V_{\max} without affecting K_M , whereas the competitive inhibitor increases K_M without affecting V_{\max} . (The more complex cases of uncompetitive and mixed inhibitors are not discussed.)

THE HUMAN PERSPECTIVE

The Growing Problem of Antibiotic Resistance

Not too long ago, it was widely believed that human health would no longer be threatened by serious bacterial infections. Bacterial diseases such as leprosy, pneumonia, gonorrhea, and dozens of others were being cured by administration of any one of a number of antibiotics—compounds that selectively kill bacteria without harming the human host in which they grow. This state of affairs has changed dramatically in the past couple of decades as pathogenic bacteria have become increasingly resistant to these “wonder drugs,” leading to the deaths of many people who would once have been successfully treated. Even tuberculosis, which had virtually disappeared from developed countries, has reemerged around the world in a form referred to as XDR (extremely drug resistant) that is virtually untreatable. It is feared that XDR-TB is on the verge of becoming a major global health crisis. To make matters worse, the pharmaceutical industry has drastically cut resources devoted to the development of new antibiotics. This change of action by the drug industry is generally attributed to a lack of financial incentives: (1) Antibiotics are taken only for a short period of time (as opposed to drugs prescribed for chronic conditions such as diabetes or depression). (2) Unlike other types of drugs that retain their effectiveness (*efficacy*), new antibiotics run the risk of having a relatively short lifetime in the marketplace as bacteria become resistant to each successive product. (3) The most effective antibiotics are held back from widespread use and are kept instead as weapons of last resort when other drugs have failed. Ideas for the formation of nonprofit institutions for the development of new antibiotics have been widely discussed.

Here, we will look briefly at the mechanism of action of antibiotics—particularly those that target enzymes, which are the subjects of this chapter—and the development of bacterial resistance. Most antibiotics are derived from natural products that are produced by microorganisms living in the soil and readily cultivated in the lab. Table 1 lists the major classes of antibiotics, examples of each class, the targets in the bacterial cells on which these compounds act, and the mechanism by which bacteria have developed resistance to that class of compounds. We will first look at several of the main types of targets:

1. *Enzymes involved in the synthesis of the bacterial cell wall.* Penicillin and its derivatives (e.g., methicillin) are structural analogues of the substrates of a family of transpeptidases that catalyze the final cross-linking reactions that give the cell wall its rigidity. If these reactions do not occur, a rigid cell wall fails to develop. Penicillin is an irreversible inhibitor of the transpeptidases; the antibiotic fits into the active site of these enzymes, forming a covalently bound complex that cannot be dislodged. The antibiotic vancomycin inhibits transpeptidation by binding to the peptide substrate of the transpeptidase, rather than to the enzyme itself. Normally, the transpeptidase substrate terminates in a D-alanine–D-alanine dipeptide. To become resistant to vancomycin, a bacterial cell must synthesize an alternate terminus that doesn't bind the drug, which is a roundabout process that requires the acquisition of several new enzymatic activities. As a result, vancomycin is the antibiotic to which bacteria have proven least able to develop resistance and thus is usually given as a last resort when other antibiotics have failed. Unfortunately, vancomycin-resistant strains of several pathogenic bacteria, including *Staphylococcus aureus*, have emerged in recent years. *S. aureus* is a common inhabitant of the skin and nasal passages. Although it is usually relatively harmless, this organism is the most frequent cause of life-

threatening infections that develop in hospitalized patients who have open wounds or invasive tubes. For years, methicillin-resistant *S. aureus* (MRSA) strains, which are also resistant to many other antibiotics, have created havoc in hospital wards. Infections by this one pathogen kill approximately 20,000 patients every year in the United States alone, which is greater than the number of deaths in the United States from AIDS. MRSA infections have also begun to appear in community settings, such as high school gyms or children's daycare centers, where there is a lot of contact between individuals. In many cases, vancomycin is the only drug that can stop these infections. Consequently, it was alarming to discover that MRSA can become resistant to vancomycin by acquiring a cluster of vancomycin-resistance genes from another bacterium (*E. faecium*), which is also a common cause of hospital-based infections. So far, no known vancomycin-resistant MRSA have been able to gain a foothold in either a hospital or community setting, but it may only be a matter of time. For this reason, infectious disease specialists have urged hospitals to institute better hygiene programs and to isolate patients at the first sign of infection. These practices have been proven to reduce the incidence of lethal infections where they have been put into place.

2. *Components of the system by which bacteria duplicate, transcribe, and translate their genetic information.* Although bacterial and eukaryotic cells have a similar system for storing and utilizing genetic information, there are many differences between the two types of cells that pharmacologists can take advantage of. Streptomycin and the tetracyclines, for example, bind to bacterial ribosomes, but not eukaryotic ribosomes. Quinolones, such as ciprofloxacin (brand name Cipro), are a rare example of wholly synthetic antibiotics (i.e., they are not based on natural products). Quinolones inhibit the enzyme DNA gyrase, which is required for bacterial DNA replication.

3. *Enzymes that catalyze metabolic reactions specifically in bacteria.* Sulfa drugs, for example, are effective antibiotics because they closely resemble the compound *p*-aminobenzoic acid (PABA),

which bacteria convert enzymatically to the essential coenzyme folic acid. Since humans lack a folic acid-synthesizing enzyme, they must obtain this essential coenzyme in their diet and, consequently, sulfa drugs have no effect on human metabolism.

Nearly all of the “new” antibiotics approved for use in recent years are derivatives of existing compounds that have been modified chemically in the laboratory. In other words, these compounds possess the same core or scaffold as the compound from which they are derived and thus can be considered members of the same chemical class. Existing drugs are chemically modified in an attempt to make them less vulnerable to the mechanisms of resistance employed by the bacteria they target. It was hoped that the sequencing of the genomes of pathogenic bacteria beginning in 1995 would lead to the identification of a host of new drug targets, but this has not been the case. Remarkably, there have only been two new classes of antibiotics developed and approved since 1963. One of these two new classes includes the antibiotic linezolid (brand name Zyvox), introduced in 2000, which acts specifically on bacterial ribosomes and in-

Table 1 Antibiotics in Clinical Use and Modes of Resistance

Antibiotic class	Examples	Target	Mode of resistance
β -lactams	Penicillins (ampicillin) Cephalosporins (cephamycin) Penems (meropenem) Monobactams (aztreonam)	Peptidoglycan biosynthesis	Hydrolysis Efflux Altered target
Aminoglycosides	Getamycin Streptomycin Spectinomycin	Translation	Phosphorylation Acetylation Nucleotidylation Efflux Altered target
Glycopeptides	Vancomycin Teicoplanin	Peptidoglycan biosynthesis	Reprogramming of peptidoglycan biosynthesis
Tetracyclines	Minocycline Tigecycline	Translation	Monoxygenation Efflux Altered target
Macrolides	Erythromycin Azithromycin	Translation	Hydrolysis Glycosylation Phosphorylation Efflux Altered target
Lincosamides	Clindamycin	Translation	Nucleotidylation Efflux Altered target
Streptogramins	Synercid	Translation	C—O lyase (Type B streptogramins) Acetylation (Type A streptogramins) Efflux Altered target

terferes with protein synthesis. The other new class of antibiotics, introduced in 2003 and represented by daptomycin (brand name Cubicin), are cyclic lipopeptides, which disrupt bacterial membrane function. Many researchers are hoping that Zyvox and Cubicin will be used sparingly so that resistance can be kept to a minimum.

Bacteria become resistant to antibiotics through a number of distinct mechanisms, many of which can be illustrated using penicillin as an example. Penicillin is a β -lactam; that is, it contains a four-membered β -lactam ring (shown in color).

By the 1940s, researchers had discovered that certain bacteria possess an enzyme called β -lactamase (or penicillinase) that can open the lactam ring, rendering the compound harmless to the bacterium. At the time when penicillin was first introduced as an antibiotic during World War II, none of the major disease-causing bacteria possessed a gene for β -lactamase. This can be verified by examining the DNA of bacteria descended from laboratory cultures that were started in the preantibiotic era. Today, the β -lactamase gene is present in a wide variety of infectious bacteria, and the production of β -lactamase by these cells is the primary cause of penicillin resistance. How did these species acquire the gene?

The widespread occurrence of the β -lactamase gene illustrates how readily genes can spread from one bacterium to another, not only among the cells of a given species, but between species. There are several ways this can happen, including conjugation (shown in Figure 1.13), in which DNA is passed from one bacterial cell to another; transduction, in which a bacterial gene is carried from cell to cell by a virus; and transformation, in which a bacterial cell is able to pick up naked DNA from its surrounding medium. Pharmacologists have attempted to counter the spread of β -lactamase by synthesizing penicillin derivatives that are more resistant to the hydrolytic enzyme. Methicillin, which is no longer in use, was first produced in 1959 as a β -lactamase-resistant antibiotic. As might be expected, natural selection leads rapidly to the evolution of bacteria whose β -lactamase can hydrolyze new forms of the antibiotic.

Not all penicillin-resistant bacteria have acquired a β -lactamase gene. Some are resistant because they possess modifications in their cell walls that block entry of the antibiotic; others are resistant because they possess an *efflux pump* that allows them to export the an-

tibiotic once it has entered the cell; still others are resistant because they possess an altered target, such as a modified transpeptidase that fails to bind the antibiotic. Bacterial meningitis, for example, is caused by the bacterium *Neisseria meningitidis*, which has yet to display evidence it has acquired β -lactamase. Yet these bacteria are becoming resistant to penicillin because their transpeptidases have lost an affinity for the antibiotics as the result of mutations in the gene that encodes the enzyme.

The problem of drug resistance is not restricted to bacterial diseases, but has also become a major issue in the treatment of AIDS. Unlike bacteria, whose DNA-replicating enzymes operate at a very high level of accuracy, the replicating enzyme of the AIDS virus (HIV), called *reverse transcriptase*, makes a large number of mistakes, which leads to a high rate of mutation. This high error rate (about 1 mistake for every 10,000 bases duplicated), combined with the high rate of virus production ($>10^8$ virus particles produced in a person per day), makes it very likely that drug-resistant variants will emerge within an individual as the infection progresses. This problem is being combatted:

- By having patients take several different drugs targeted at different viral enzymes. This greatly reduces the likelihood that a variant will emerge that is resistant to all of the drugs.
- By designing drugs that interact with the most highly conserved portions of each targeted enzyme, that is, those portions where mutations are most likely to produce a defective enzyme. This point underscores the importance of knowing the structure and function of the target enzyme and the manner in which potential drugs interact with that target.

3.3 | Metabolism

Metabolism is the collection of biochemical reactions that occur within a cell, which includes a tremendous diversity of molecular conversions. Most of these reactions can be grouped into **metabolic pathways** containing a sequence of chemical reactions in which each reaction is catalyzed by a specific enzyme, and the product of one reaction is the substrate for the next. The enzymes constituting a metabolic pathway are usually confined to a specific region of the cell, such as the mitochondria or the cytosol. Increasing evidence suggests that the enzymes of a metabolic pathway are often physically linked to one another, a feature that allows the product of one enzyme to be delivered directly as a substrate to the active site of the next enzyme in the reaction sequence.

The compounds formed in each step along the pathway are **metabolic intermediates** (or *metabolites*) that lead ultimately to the formation of an end product. End products are molecules with a particular role in the cell, such as an amino acid that can be incorporated into a polypeptide, or a sugar that can be consumed for its energy content. The metabolic pathways of a cell are interconnected at various points so that a compound generated by one pathway may be shuttled in a number of directions depending on the requirements of the cell at the time. We will concentrate in this section on aspects

of metabolism that lead to the transfer and utilization of chemical energy, for this topic is one we will draw on throughout the book.

An Overview of Metabolism

Metabolic pathways can be divided into two broad types. **Catabolic pathways** lead to the disassembly of complex molecules to form simpler products. Catabolic pathways serve two functions: they make available the raw materials from which other molecules can be synthesized, and they provide chemical energy required for the many activities of a cell. As will be discussed at length, energy released by catabolic pathways is stored temporarily in two forms: as high-energy phosphates (primarily ATP) and as high-energy electrons (primarily in NADPH). **Anabolic pathways** lead to the synthesis of more complex compounds from simpler starting materials. Anabolic pathways are energy-requiring and utilize chemical energy released by the exergonic catabolic pathways.

Figure 3.22 shows a greatly simplified profile of the ways in which the major anabolic and catabolic pathways are interconnected. Macromolecules are first disassembled (hydrolyzed) into the building blocks of which they are made (stage I, Figure 3.22). Once macromolecules have been hydrolyzed into their components—amino acids, sugars, and

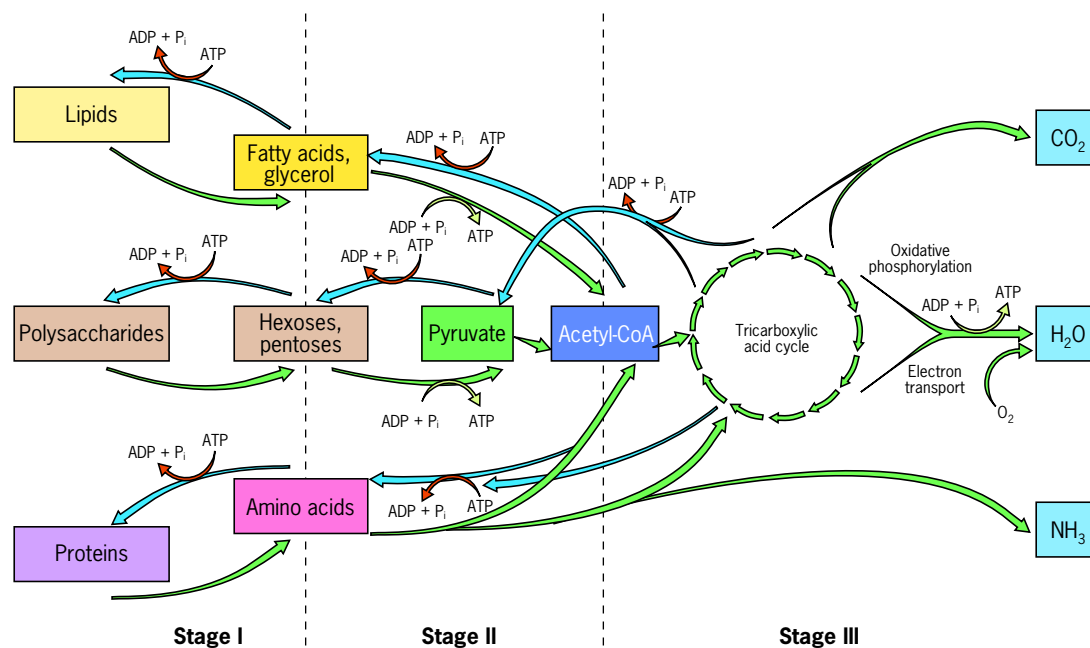

Figure 3.22 Three stages of metabolism. The catabolic pathways (green arrows rightward) converge to form common metabolites and lead to ATP synthesis in stage III. The anabolic pathways (blue arrows

leftward) start from a few precursors in stage III and utilize ATP to synthesize a large variety of cellular materials. Metabolic pathways for nucleic acids are more complex and are not shown here.

fatty acids—the cell can reutilize the building blocks directly to (1) form other macromolecules of the same class (stage I), (2) convert them into different compounds to make other products, or (3) degrade them further (stages II and III, Figure 3.22) and extract a measure of their free-energy content.

The pathways for degradation of the diverse building blocks of macromolecules vary according to the particular compound being catabolized. Ultimately, however, all of these molecules are converted into a small variety of compounds that can be metabolized similarly. Thus, even though substances begin as macromolecules having a very different structure, they are converted by catabolic pathways to the same low-molecular-weight metabolites. For this reason, catabolic pathways are said to be convergent.

Remarkably, the chemical reactions and metabolic pathways described in this chapter are found in virtually every living cell, from the simplest bacterium to the most complex plant or animal. It is evident that these pathways appeared very early in, and have been retained throughout, the course of biological evolution.

Oxidation and Reduction: A Matter of Electrons

Both catabolic and anabolic pathways include key reactions in which electrons are transferred from one reactant to another. Reactions that involve a change in the electronic state of the reactants are called **oxidation–reduction** (or **redox**) **reactions**. Changes of this type involve the gain or loss of electrons. Consider the conversion of metallic iron (Fe^0) to the ferrous state (Fe^{2+}), in which the iron atom loses a pair of electrons, thereby attaining a more positive state. When an atom loses one or more electrons, it is said to be *oxidized*. The

reaction is reversible, meaning ferrous ions can be converted to metallic iron, a more negative state, by the acquisition of a pair of electrons. When an atom gains one or more electrons, it is said to be *reduced*.

For metallic iron to be oxidized, there must be some substance to accept the electrons that are released. Conversely, for ferrous ions to be reduced, there must be some substance to donate the necessary electrons. In other words, the oxidation of one reactant must be accompanied by the simultaneous reduction of some other reactant, and vice versa. One possible reaction involving iron might be

The substance that is oxidized during a redox reaction, that is, the one that loses electrons, is called a **reducing agent**, and the one that is reduced, that is, the one that gains electrons, is called an **oxidizing agent**.

The oxidation or reduction of metals, such as iron or copper, involves the complete loss or gain of electrons. The same cannot occur with most organic compounds for the following reason: the oxidation and reduction of organic substrates during cellular metabolism involve carbon atoms that are covalently bonded to other atoms. As discussed in Chapter 2, when a pair of electrons is shared by two different atoms, the electrons are attracted more strongly to one of the two atoms of the polarized bond. In a C—H bond, the carbon atom has the strongest pull on the electrons; thus it can be said that the carbon atom is in a reduced state. In contrast, if a carbon atom is bonded to a more electronegative atom, as in a C—O or C—N bond, the electrons are pulled away from the carbon atom, which is thus in an oxidized state. Since carbon has four outer-shell electrons it can share with other atoms, it can exist

Figure 3.23 The oxidation state of a carbon atom depends on the other atoms to which it is bonded. Each carbon atom can form a maximum of four bonds with other atoms. This series of simple, one-carbon molecules illustrates the various oxidation states in which the

carbon atom can exist. In its most reduced state, the carbon is bonded to four hydrogens (forming methane); in its most oxidized state, the carbon atom is bonded to two oxygens (forming carbon dioxide).

in a variety of oxidation states. This is illustrated by the carbon atom in a series of one-carbon molecules (Figure 3.23) ranging from the fully reduced state in methane (CH₄) to the fully oxidized state in carbon dioxide (CO₂). The relative oxidation state of an organic molecule can be roughly determined by counting the number of hydrogen versus oxygen and nitrogen atoms per carbon atom. As we will see shortly, the oxidation state of the carbon atoms in an organic molecule provides a measure of the molecule's free-energy content.

The Capture and Utilization of Energy

The compounds that we use as chemical fuels to run our furnaces and automobiles are highly reduced organic compounds, such as natural gas (CH₄) and petroleum derivatives. Energy is released when these molecules are burned in the presence of oxygen, converting the carbons to more oxidized states, as in carbon dioxide and carbon monoxide gases. The degree of reduction of a compound is also a measure of its ability to perform chemical work within the cell. The more hydrogen atoms that can be stripped from a "fuel" molecule, the more ATP that ultimately can be produced. Carbohydrates are rich in chemical energy because they contain strings

of $\begin{array}{c} | \\ \text{H}-\text{C}-\text{OH} \\ | \end{array}$ units. Fats contain even greater energy per unit weight because they contain strings of more reduced $\begin{array}{c} | \\ \text{H}-\text{C}-\text{H} \\ | \end{array}$ units. In the following discussion we will concentrate on carbohydrates.

As the sole building block of both starch and glycogen, glucose is a key molecule in the energy metabolism of both plants and animals. The free energy released by the complete oxidation of glucose is very large:

By comparison, the free energy required to convert ADP to ATP is relatively small:

It is evident from these numbers that the complete oxidation of a molecule of glucose to CO₂ and H₂O can release enough energy to produce a large number of ATPs. As we will see in Chapter 5, up to about 36 molecules of ATP are formed per molecule of glucose oxidized under conditions that exist within most cells. For this many ATP molecules to be produced, the sugar molecule is disassembled in many small steps. Those steps in which the free-energy difference between the reactants and products is relatively large can be coupled to reactions that lead to the formation of ATP.

There are basically two stages in the catabolism of glucose, and they are virtually identical in all aerobic organisms. The first stage, **glycolysis**, occurs in the soluble phase of the cytoplasm (the cytosol) and leads to the formation of pyruvate. The second stage is the **tricarboxylic acid** (or **TCA**) **cycle**, which occurs within the mitochondria of eukaryotic cells and the cytosol of prokaryotes and leads to the final oxidation of the carbon atoms to carbon dioxide. Most of the chemical energy of glucose is stored in the form of high-energy electrons, which are removed as substrate molecules are oxidized during both glycolysis and the TCA cycle. It is the energy of these electrons that is ultimately used to synthesize ATP. We will concentrate in the following pages on the steps during glycolysis, the first stage in the oxidation of glucose, which occurs without the involvement of oxygen. This is presumably the pathway of energy capture utilized by our early anaerobic ancestors and remains the major anabolic pathway utilized by anaerobic organisms living today. We will complete the story of glucose oxidation in Chapter 5 when we discuss the mitochondrion and its role in aerobic respiration.

Glycolysis and ATP Formation The reactions of glycolysis and the enzymes that catalyze them are shown in Figure 3.24. Before discussing the specific reactions, an important

Figure 3.24 The steps of glycolysis.

point concerning the thermodynamics of metabolism can be made. In an earlier discussion, the difference between ΔG and $\Delta G^{\circ'}$ was stressed; it is the ΔG for a particular reaction that determines its direction in the cell. Actual measurements of the concentrations of metabolites in the cell can reveal the value for ΔG of a reaction at any given time. Figure 3.25 shows the typical ΔG values measured for the reactions of glycolysis. In contrast to the $\Delta G^{\circ'}$ values of Figure 3.24, all but three reactions have ΔG values of nearly zero; that is, they are near equilibrium. The three reactions that are far from equilibrium, which makes them essentially irreversible in the cell, provide the driving force that moves the metabolites through the glycolytic pathway in a directed manner.

In 1905, two British chemists, Arthur Harden and William Young, were studying glucose breakdown by yeast cells, a process that generates bubbles of CO_2 gas. Harden and Young noted that the bubbling eventually slowed and stopped, even though there was plenty of glucose left to metabolize. Apparently, some other essential component of the broth was being exhausted. After experimenting with a number of substances, the chemists found that adding inorganic phosphates started the reaction going again. They concluded that the reaction was exhausting phosphate, the first clue that phosphate groups played a role in metabolic pathways. The importance of the phosphate group is illustrated by the initial reactions of glycolysis.

Glycolysis begins with the linkage of the sugar to a phosphate group (step 1, Figure 3.24) at the expense of one molecule

of ATP. The use of ATP at this stage can be considered an energy investment—the cost of getting into the glucose oxidation business. Phosphorylation activates the sugar, making it capable of participating in subsequent reactions whereby phosphate groups are moved around and transferred to other

Figure 3.25 Free-energy profile of glycolysis in cardiac muscle tissue. The step numbers correspond to the reactions of glycolysis shown in Figure 3.24. All reactions are at or near equilibrium except those catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase (reactions 1, 3, and 10), which exhibit large differences in free energy. (FROM VOET, VOET, PRATT, *FUND OF BIOCHEMISTRY 4E*. THIS MATERIAL IS REPRODUCED WITH PERMISSION OF JOHN WILEY & SONS, INC.)

acceptors. Phosphorylation also lowers the cytoplasmic concentration of glucose, which promotes continued diffusion of the sugar from the blood into the cell. Glucose 6-phosphate is converted to fructose 6-phosphate and then to fructose 1,6-bisphosphate at the expense of a second molecule of ATP (steps 2, 3). The six-carbon bisphosphate is split into two three-carbon monophosphates (step 4), which sets the stage for the first exergonic reaction to which the formation of ATP can be coupled. Let us turn now to the formation of ATP.

ATP is formed in two basically different ways, both illustrated by one chemical reaction of glycolysis: the conversion of glyceraldehyde 3-phosphate to 3-phosphoglycerate (steps 6, 7). The overall reaction is an oxidation of an aldehyde to a carboxylic acid (as in Figure 3.23), and it occurs in two steps catalyzed by two different enzymes (Figure 3.24). The first of these enzymes requires a nonprotein cofactor (a coenzyme), called nicotinamide adenine dinucleotide (NAD), to catalyze the reaction. As will be evident in this and following chapters, NAD plays a key role in energy metabolism by accepting and donating electrons. The first reaction (Figure 3.26*a,b*) is an oxidation–reduction in which two electrons and a proton (equivalent to a hydride ion, :H^-) are transferred from glyceraldehyde 3-phosphate (which becomes oxidized) to NAD^+ (which becomes reduced). The reduced form of the coenzyme is NADH (Figure 3.27). An enzyme that catalyzes this type of reaction is termed a **dehydrogenase**; the enzyme catalyzing the

above reaction is *glyceraldehyde 3-phosphate dehydrogenase*. The NAD^+ molecule, which is derived from the vitamin niacin, acts as a loosely associated coenzyme to the dehydrogenase in position to accept the hydride ion (i.e., both the electrons and the proton). The NADH formed in the reaction is then released from the enzyme in exchange for a fresh molecule of NAD^+ .

We will return to this reaction in a moment, but first we will continue with the consequences of the formation of NADH. NADH is considered a high-energy compound because of the ease with which it is able to transfer electrons to other electron-attracting molecules. (NADH is said to have a high electron-transfer potential relative to other electron acceptors in the cell; see Table 5.1). Electrons are usually transferred from NADH through a series of membrane-embedded electron carriers that constitute an *electron-transport chain*. As the electrons move along this chain, they move to a lower and lower free-energy state and are ultimately passed to molecular oxygen, reducing it to water. The energy released during electron transport is utilized to form ATP by a process called *oxidative phosphorylation*. Electron transport and oxidative phosphorylation will be explored in detail in Chapter 5.

In addition to the indirect route for ATP formation involving NADH and an electron-transport chain, the conversion of glyceraldehyde 3-phosphate to 3-phosphoglycerate includes a direct route for ATP formation. In the second step of this overall reaction (step 7, Figures 3.24 and 3.26*c*), a phosphate group is transferred from 1,3-bisphosphoglycerate

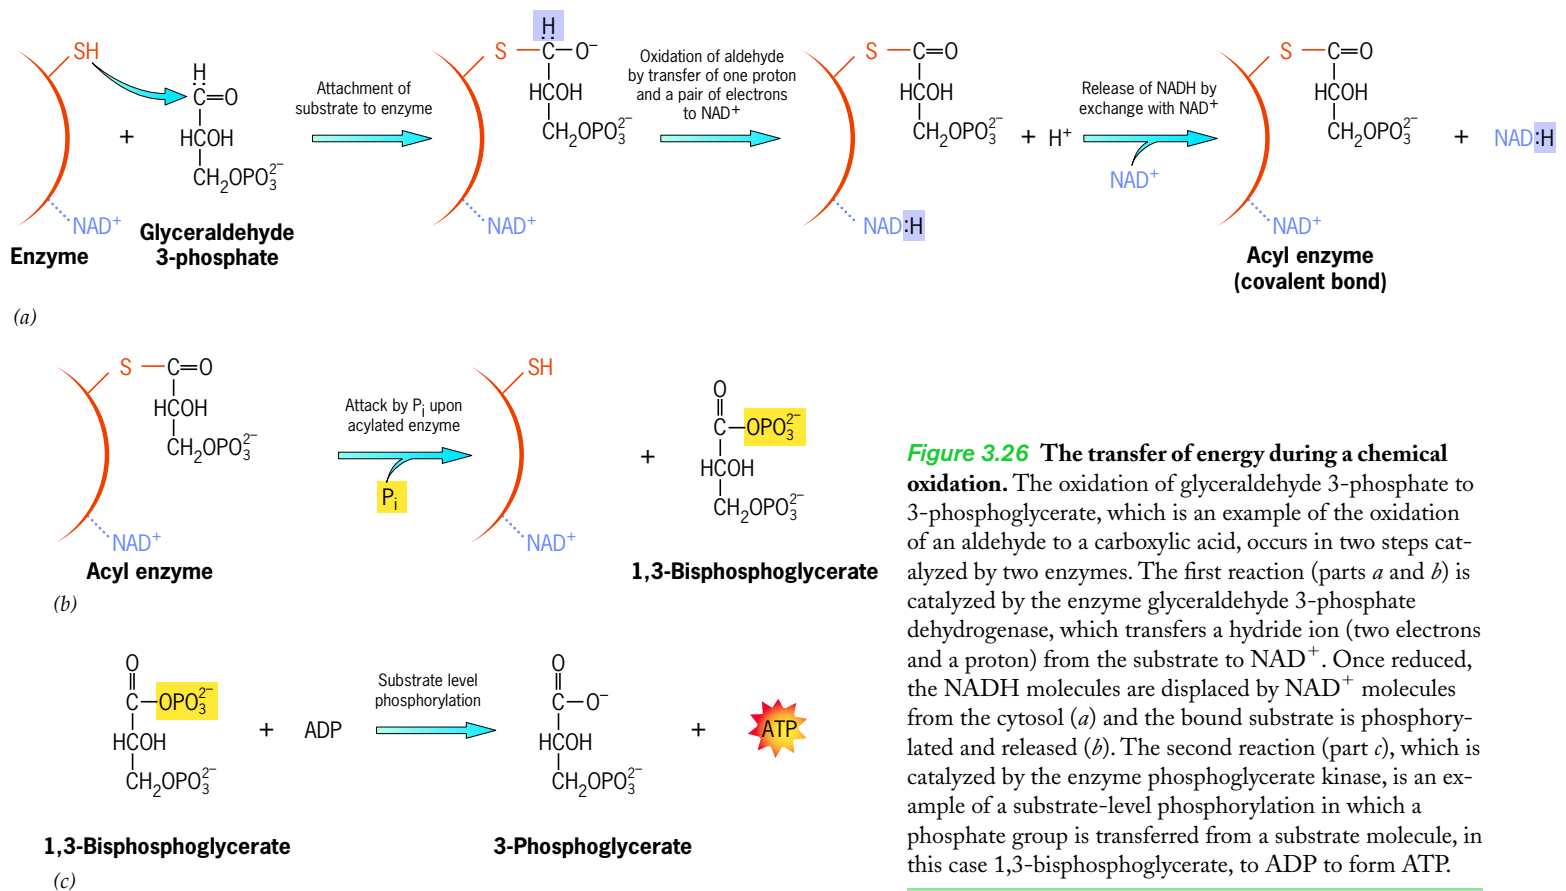

Figure 3.26 The transfer of energy during a chemical oxidation. The oxidation of glyceraldehyde 3-phosphate to 3-phosphoglycerate, which is an example of the oxidation of an aldehyde to a carboxylic acid, occurs in two steps catalyzed by two enzymes. The first reaction (parts *a* and *b*) is catalyzed by the enzyme glyceraldehyde 3-phosphate dehydrogenase, which transfers a hydride ion (two electrons and a proton) from the substrate to NAD^+ . Once reduced, the NADH molecules are displaced by NAD^+ molecules from the cytosol (*a*) and the bound substrate is phosphorylated and released (*b*). The second reaction (part *c*), which is catalyzed by the enzyme phosphoglycerate kinase, is an example of a substrate-level phosphorylation in which a phosphate group is transferred from a substrate molecule, in this case 1,3-bisphosphoglycerate, to ADP to form ATP.

Figure 3.27 The structure of NAD^+ and its reduction to NADH . When the 2' OH of the ribose moiety (indicated by the purple colored screen) is covalently bonded to a phosphate group, the molecule is $\text{NADP}^+/\text{NADPH}$, whose function is discussed later in the chapter.

to ADP to form a molecule of ATP. The reaction is catalyzed by the enzyme *phosphoglycerate kinase*. This direct route of ATP formation is referred to as **substrate-level phosphorylation** because it occurs by transfer of a phosphate group from one of the substrates (in this case, 1,3-bisphosphoglycerate) to ADP. The remaining reactions of glycolysis (steps 8–10), which includes a second substrate-level phosphorylation of ADP (step 10), are indicated in Figure 3.24.

The substrate-level phosphorylation of ADP illustrates an important point about ATP. Its formation is not *that* endergonic. In other words, ATP can be readily formed by metabolic reactions. There are numerous phosphorylated molecules whose hydrolysis has a more negative ΔG° than that of ATP. Figure 3.28 illustrates the relative ΔG° 's for the hydrolysis of several phosphorylated compounds. Any donor higher on the scale can be used to phosphorylate any molecule lower on the scale, and the ΔG° of this reaction will be equal to the difference between the two values given in the figure. For example, the ΔG° for the transfer of a phosphate group from 1,3-bisphosphoglycerate to ADP to form ATP is equal to -4.5 kcal/mol ($-11.8 \text{ kcal/mol} + 7.3 \text{ kcal/mol}$). This concept of **transfer potential** is useful for comparing any series of donors and acceptors regardless of the group being transferred, whether protons, electrons, oxygen, or phosphate groups. Those molecules higher on the scale, that is, ones with greater free energy (larger $-\Delta G^{\circ}$'s), are molecules with less affinity for the group being transferred than are ones lower on the scale. The less the affinity, the better the donor; the greater the affinity, the better the acceptor.

An important feature of glycolysis is that it can generate a limited number of ATP molecules in the absence of oxygen. Neither the substrate-level phosphorylation of ADP by 1,3-bisphosphoglycerate nor a later one by phosphoenolpyruvate

Figure 3.28 Ranking compounds by phosphate transfer potential. Those phosphorylated compounds higher on the scale (ones with a more negative ΔG° of hydrolysis) have a lower affinity for their phosphate group than those compounds lower on the scale. As a result, compounds higher on the scale readily transfer their phosphate group to form compounds that are lower on the scale. Thus, phosphate groups can be transferred from 1,3-bisphosphate or phosphoenolpyruvate to ADP during glycolysis.

(step 10, Figure 3.24) requires molecular oxygen. Thus, glycolysis can be considered an **anaerobic pathway** to ATP production, indicating that it can proceed in the absence of molecular oxygen to continue to provide ATP. Two molecules of ATP are produced by substrate-level phosphorylation during glycolysis from each molecule of glyceraldehyde 3-phosphate oxidized to pyruvate. Since each molecule of glucose produces two molecules of glyceraldehyde 3-phosphate, four ATP molecules are generated per molecule of glucose oxidized to pyruvate. On the other hand, two molecules of ATP must be hydrolyzed to initiate glycolysis, leaving a net profit for the cell of two molecules of ATP per glucose oxidized. The net equation for the reactions of glycolysis can be written

Pyruvate, the end product of glycolysis, is a key compound because it stands at the junction between anaerobic (oxygen-independent) and aerobic (oxygen-dependent) pathways. In the absence of molecular oxygen, pyruvate is subjected to fermentation, as discussed in the following section. When oxygen is available, pyruvate is further catabolized by aerobic respiration, as discussed in Chapter 5.

Anaerobic Oxidation of Pyruvate: The Process of Fermentation We have seen that glycolysis is able to provide a cell with a small net amount of ATP for each molecule of glucose converted to pyruvate. However, glycolytic reactions

occur at rapid rates so that a cell is able to produce a significant amount of ATP using this pathway. In fact, a number of cells, including yeast cells, tumor cells, and muscle cells, rely heavily on glycolysis as a means of ATP formation. There is, however, a problem that must be confronted by such cells. One of the products of the oxidation of glyceraldehyde 3-phosphate is NADH. The formation of NADH occurs at the expense of one of the reactants, NAD^+ , which is in short supply in cells. Since NAD^+ is a required reactant in this important step of glycolysis, it must be regenerated from NADH. If not, the oxidation of glyceraldehyde 3-phosphate can no longer take place, nor can any of the succeeding reactions of glycolysis. However, without oxygen, NADH cannot be oxidized to NAD^+ by means of the electron-transport chain because oxygen is the final electron acceptor of the chain. Cells are able, however, to regenerate NAD^+ by **fermentation**, the transfer of electrons from NADH to pyruvate, the end product of glycolysis, or to a compound derived from pyruvate (Figure 3.29). Like glycolysis, fermentation takes place in the cytosol. For most organisms, which depend on O_2 , fermentation is a stopgap measure to regenerate NAD^+ when O_2 levels are low, so that glycolysis can continue and ATP production can be maintained.

The product of fermentation varies from one type of cell or organism to another. When muscle cells are required to con-

Figure 3.29 Fermentation. Most cells carry out aerobic respiration, which depends on molecular oxygen. If oxygen supplies should diminish, as occurs in a skeletal muscle cell undergoing strenuous contraction or a yeast cell living under anaerobic conditions, these cells are able to regenerate NAD^+ by fermentation. Muscle cells accomplish fermentation by formation of lactate, whereas yeast cells do so by formation of ethanol. Aerobic oxidation of pyruvate by means of the TCA cycle is discussed at length in Chapter 5.

tract repeatedly, the oxygen level becomes too low to keep pace with the cell's metabolic demands. Under these conditions, skeletal muscle cells regenerate NAD^+ by converting pyruvate to lactate. When oxygen once again becomes available in sufficient amounts, the lactate can be converted back to pyruvate for continued oxidation. Yeast cells have faced the challenges of anaerobic life with a different metabolic solution: they convert pyruvate to ethanol, as illustrated in Figure 3.29.

Although fermentation is a necessary adjunct to metabolism in many organisms, and the sole source of metabolic energy in some anaerobes, the energy gained by glycolysis alone is meager when compared with the complete oxidation of glucose to carbon dioxide and water. When a mole of glucose is completely oxidized, 686 kilocalories are released. In contrast, only 57 kilocalories are released when this same amount of glucose is converted to ethanol under standard conditions, and only 47 kilocalories are released when it is converted to lactate. In any case, only two molecules of ATP are formed per glucose oxidized by glycolysis and fermentation; over 90 percent of the energy is simply discarded in the fermentation product (as evidenced by the flammability of ethyl alcohol).

During the early stages of life on Earth, when oxygen had not yet appeared, glycolysis and fermentation were probably the primary metabolic pathways by which energy was extracted from sugars by primitive prokaryotic cells. Following the appearance of cyanobacteria, the oxygen of the atmosphere rose dramatically, and the evolution of an aerobic metabolic strategy became possible. As a result, the products of glycolysis could be completely oxidized, and much more ATP could be harvested. We will see how this is accomplished in Chapter 5 when we discuss the structure and function of the mitochondrion.

Reducing Power The energy required to synthesize complex biological molecules, such as proteins, fats, and nucleic acids, is derived largely from the ATP generated by glycolysis and electron transport. But many of these materials, particularly fats and other lipids, are more reduced than the metabolites from which they are built. Synthesis of fats requires the reduction of metabolites, which is accomplished by the transfer of high-energy electrons from NADPH, a compound similar in structure to NADH, but containing an additional phosphate group (described in the legend to Figure 3.27). A cell's reservoir of NADPH represents its **reducing power**, which is an important measure of the cell's usable energy content. The use of NADPH can be illustrated by one of the key reactions of photosynthesis:

In this reaction, a pair of electrons (together with a proton) are

transferred from NADPH to the substrate 1,3-bisphosphoglycerate, reducing a carbon atom (indicated in red).

The oxidized form of NADPH, NADP^+ , is formed from NAD^+ in the following reaction:

NADPH can then be formed by the reduction of NADP^+ . Like NADH, NADPH is a high-energy compound because of its high electron-transfer potential. The transfer of free energy in the form of these electrons raises the acceptor to a more reduced, more energetic state.

The separation of reducing power into two distinct but related molecules, NADH and NADPH, reflects a separation of their primary metabolic roles. NADH and NADPH are recognized as coenzymes by different enzymes. Enzymes having a reductive role in anabolic pathways utilize NADPH as their coenzyme, whereas enzymes acting as dehydrogenases in catabolic pathways utilize NAD^+ . Even though they are used differently, one coenzyme can reduce the other in the following reaction, which is catalyzed by the enzyme *transhydrogenase*:

When energy is abundant, the production of NADPH is favored, providing a supply of electrons needed for biosynthesis of new macromolecules that are essential for growth. When energy resources are scarce, however, most of the high-energy electrons of NADH are “cashed in” for ATP, and only enough NADPH is generated to meet the cell’s minimal biosynthetic requirements.

Metabolic Regulation

The amount of ATP present in a cell at a given moment is surprisingly small. A bacterial cell, for example, contains approximately one million molecules of ATP, whose half-life is very brief (on the order of a second or two). With so limited a supply, it is evident that ATP is not a molecule in which a large total amount of free energy is stored. The energy reserves of a cell are stored instead as polysaccharides and fats. When the levels of ATP start to fall, reactions are set in motion to increase ATP formation at the expense of the energy-rich storage forms. Similarly, when ATP levels are high, reactions that would normally lead to ATP production are inhibited. Cells regulate these important energy-releasing reactions by controlling certain key enzymes in a number of metabolic pathways.

The function of a protein is closely related to its structure (i.e., conformation). It is not surprising, therefore, that cells regulate protein activity by modifying the conformation of key protein molecules. In the case of enzymes, regulation of catalytic activity is centered on the modification of the structure of the active site. Two common mechanisms for altering the shape of an enzyme’s active site are covalent modification and allosteric modulation, both of which play key roles in regulating glucose oxidation.⁴

⁴Metabolism is also regulated by controlling the concentrations of enzymes. The relative rates at which enzymes are synthesized and degraded are considered in subsequent chapters.

Altering Enzyme Activity by Covalent Modification

During the mid-1950s, Edmond Fischer and Edwin Krebs of the University of Washington were studying glycogen phosphorylase, an enzyme found in muscle cells that disassembles glycogen into its glucose subunits. The enzyme could exist in either an inactive or an active state. Fischer and Krebs prepared a crude extract of muscle cells and found that inactive enzyme molecules in the extract could be converted to active ones simply by adding ATP to the test tube. Further analysis revealed a second enzyme in the extract—a “converting enzyme,” as they called it—that transferred a phosphate group from ATP to one of the 841 amino acids that make up the glycogen phosphorylase molecule. The presence of the phosphate group altered the shape of the active site of the enzyme molecule and increased its catalytic activity.

Subsequent research has shown that covalent modification of enzymes, as illustrated by the addition (or removal) of phosphates, is a general mechanism for changing the activity of enzymes. Enzymes that transfer phosphate groups to other proteins are called **protein kinases** and regulate such diverse activities as hormone action, cell division, and gene expression. The “converting enzyme” discovered by Krebs and Fischer was later named phosphorylase kinase, and its regulation is discussed in Section 15.3. There are two basically different types of protein kinases: one type adds phosphate groups to specific tyrosine residues in a substrate protein; the other type adds phosphates to specific serine or threonine residues in the substrate. The importance of protein kinases is reflected in the fact that approximately 2 percent of all the genes of a yeast cell (113 out of about 6200) encode members of this class of enzymes.

Altering Enzyme Activity by Allosteric Modulation

Allosteric modulation is a mechanism whereby the activity of an enzyme is either inhibited or stimulated by a compound that binds to a site, called the **allosteric site**, that is spatially distinct from the enzyme’s active site. According to one view, the binding of a compound to the allosteric site sends a “ripple” through the protein, producing a defined change in the shape of the active site, which may be located on the opposite side of the enzyme or even on a different polypeptide within the protein molecule. Depending on the particular enzyme and the particular allosteric modulator, the change in shape of the active site may either stimulate or inhibit its ability to catalyze the reaction. Allosteric modulation illustrates the intimate relationship between molecular structure and function. Very small changes in the structure of the enzyme induced by the allosteric modulator can cause marked changes in enzyme activity.

Cells are highly efficient manufacturing plants that do not waste energy and materials producing compounds that are not utilized. One of the primary mechanisms cells use to shut down anabolic assembly lines is a type of allosteric modulation called **feedback inhibition**, in which the enzyme catalyzing the first committed step in a metabolic pathway is temporarily inactivated when the concentration of the end product of that pathway—an amino acid, for example—reaches a certain level. This is illustrated by the simple pathway depicted in

Figure 3.30 in which two substrates, A and B, are converted to the end product E. As the concentration of the product E rises, it binds to the allosteric site of enzyme BC, causing a conformational change in the active site that decreases the enzyme's activity. Feedback inhibition exerts immediate, sensitive control over a cell's anabolic activity.

Separating Catabolic and Anabolic Pathways A brief consideration of the anabolic pathway leading to the synthesis of glucose (**gluconeogenesis**) will illustrate a few important aspects about synthetic pathways. Most cells are able to synthesize glucose from pyruvate at the same time they are oxidizing glucose as their major source of chemical energy. How are cells able to utilize these two opposing pathways? The first important point is that, even though enzymes can catalyze a reaction in both directions, the reactions of gluconeogenesis cannot proceed simply by the reversal of the reactions of glycolysis. The glycolytic pathway contains three thermodynamically irre-

Figure 3.30 Feedback inhibition. The flow of metabolites through a metabolic pathway stops when the first enzyme of the pathway (enzyme BC) is inhibited by the end product of that pathway (compound E), which binds to an allosteric site on the enzyme. Feedback inhibition prevents a cell from wasting resources by continuing to produce compounds that are no longer required.

versible reactions (Figure 3.25), and these steps must somehow be bypassed. Even if all the reactions of glycolysis could be reversed, it would be a very undesirable way for the cell to handle its metabolic activities, since the two pathways could not be controlled independently of one another. Thus, a cell could not shut down glucose synthesis and crank up glucose breakdown because the same enzymes would be active in both directions.

If one compares the pathway by which glucose is degraded to the pathway by which glucose is synthesized, it is apparent that some of the reactions are identical, although they are running in opposite directions, while others are very different (steps 1 to 3, Figure 3.31). By using different enzymes to catalyze different key reactions in the two opposing pathways, a cell can solve both the thermodynamic and the regulatory problems inherent in being able to manufacture and degrade the same molecules.

We can see this better by looking more closely at key enzymes of both glycolysis and gluconeogenesis. As indicated in

Figure 3.31 Glycolysis versus gluconeogenesis. Whereas most of the reactions are the same in the two pathways, even though they run in opposite directions, the three irreversible reactions of glycolysis (steps 1 to 3 here) are replaced in the gluconeogenic pathway by different, thermodynamically favored reactions.

step 2 of Figure 3.31, *phosphofructokinase*, an enzyme of glycolysis, catalyzes the reaction

which has a ΔG° of -3.4 kcal/mol, making it essentially irreversible. The reaction has such a large $-\Delta G^{\circ}$ because it is coupled to the hydrolysis of ATP. In gluconeogenesis, the formation of fructose 6-phosphate is catalyzed by the enzyme *fructose 1,6-bisphosphatase* by a simple hydrolysis:

The particular enzymes of glycolysis and gluconeogenesis described above are key enzymes in their respective pathways. These enzymes are regulated, in part, by AMP and ATP. Keep in mind that the concentration of AMP within cells is inversely related to the concentration of ATP; when ATP levels are low, AMP levels are high, and vice versa. Consequently, elevated AMP concentrations signal to a cell that its ATP fuel reserves are becoming depleted. Even though ATP happens to be a substrate of phosphofructokinase, ATP is also an allosteric inhibitor, while AMP is an allosteric activator. When ATP levels are high, the activity of the enzyme is decreased so that no additional ATP is formed by glycolysis. Conversely, when ADP and AMP levels are high relative to ATP, the activity of the enzyme is increased, which promotes the synthesis of ATP. In contrast, the activity of fructose 1,6-bisphosphatase, a key enzyme of gluconeogenesis, is inhibited by elevated levels of AMP.

The importance of allosteric modulation in metabolic control is illustrated by recent studies on the enzyme AMP-activated protein kinase (AMPK). Like phosphorylase kinase discussed above, AMPK controls the activity of other enzymes by adding phosphate groups to specific serine or threonine residues within their structure. AMPK activity is itself controlled by posttranslational modifications; the enzyme is activated by addition of a phosphate group and inhibited by removal of that phosphate group. More importantly for the present discussion, AMPK is also activated by both AMP and ADP, the two alternate products of ATP hydrolysis. AMP activates AMPK by binding to an allosteric site on the enzyme, and ADP activates AMPK by blocking removal of the above-mentioned phosphate group. As AMP or ADP concentrations rise, AMPK is activated, causing it to phosphorylate and inhibit key enzymes involved in anabolic pathways while at the same time phosphorylating and activating key enzymes in

catabolic pathways. The end result of AMPK activation is a decrease in the activity of pathways that consume ATP and an increase in the activity of pathways that produce ATP, leading to an elevation in the concentration of ATP within the cell.

AMPK is involved not only in cellular energy regulation but, at least in mammals, in regulation of energy balance within the whole body. In mammals, appetite is controlled by centers within the hypothalamus of the brain that respond to the levels of certain nutrients and hormones within the blood. A drop in blood glucose levels, for example, acts on the hypothalamus to stimulate appetite, which appears to be mediated through activation of AMPK in hypothalamic nerve cells. Conversely, the feeling of being “full” that we experience after eating a meal is thought to be triggered by certain hormones (e.g., leptin secreted by fat cells) that inhibit the activity of AMPK in these same brain cells. Because of its role as an “energy thermostat,” AMPK has become a prime target in the development of drugs to treat both obesity and diabetes. The diabetes drug metformin activates AMPK, leading to the suppression of gluconeogenesis in the liver and a consequent decrease in blood glucose levels.

REVIEW

1. Why are catabolic pathways described as convergent, whereas anabolic pathways are described as divergent?
2. Compare the energy obtained by a cell that oxidizes glucose anaerobically and aerobically. What is the difference in the end products of these two types of metabolism?
3. Explain what is meant by phosphate transfer potential. How does the phosphate transfer potential of phosphoenolpyruvate compare with that of ATP? What does this mean thermodynamically (i.e., in terms of relative ΔG° 's of hydrolysis)? What does it mean in terms of affinity for phosphate groups?
4. Why is reducing power considered a form of energy?
5. In the reaction in which glyceraldehyde 3-phosphate is oxidized to 3-phosphoglycerate, which compound is acting as the reducing agent? Which as the oxidizing agent? Which compound is being oxidized? Which is being reduced?
6. Which reactions of glycolysis are coupled to ATP hydrolysis? Which reactions involve substrate-level phosphorylation? Which reactions depend on either fermentation or aerobic respiration to continue?

Synopsis

Energy is the capacity to do work. Energy can occur in various forms, including chemical, mechanical, light, electrical, and thermal energy, which are interconvertible. Whenever energy is exchanged, the total amount of energy in the universe remains constant, but there is a loss of free energy, that is, energy available to do additional

work. The usable energy lost to entropy results from an increase in the randomness and disorder of the universe. Living organisms are systems of low entropy, maintained by the constant input of external energy that is ultimately derived from the sun. (p. 87)

All spontaneous (exergonic) energy transformations proceed from a state of higher free energy to a state of lower free energy; the ΔG must be negative. In a chemical reaction, ΔG is equivalent to the difference in the free-energy content between the reactants and products. The greater the ΔG , the farther the reaction is from equilibrium. As the reaction proceeds, ΔG decreases and reaches 0 at equilibrium. To compare the energy changes during different chemical reactions, free-energy differences between reactants and products are determined for a set of standard conditions and denoted as $\Delta G^{\circ'}$, in which $\Delta G^{\circ'} = -2.303 RT \log K'_{\text{eq}}$. Reactions having equilibrium constants greater than one have negative $\Delta G^{\circ'}$ values. It must be kept in mind that $\Delta G^{\circ'}$ is a fixed value that describes the direction in which a reaction proceeds when the reaction mixture is at standard conditions. It is of no value in determining the direction of a reaction at a particular moment in the cell; this is governed by ΔG , which is dependent on the concentrations of reactants and products at the time. Reactions that have positive $\Delta G^{\circ'}$ values (such as the reaction in which dihydroxyacetone phosphate is converted to glyceraldehyde 3-phosphate) can occur in the cell because the ratio of reactants to products is kept at a value greater than that predicted by K'_{eq} . (p. 89)

The hydrolysis of ATP is a highly favorable reaction ($\Delta G^{\circ'} = -7.3$ kcal/mol) and can be used to drive reactions that would otherwise be unfavorable. The use of ATP hydrolysis to drive unfavorable reactions is illustrated by glutamine synthesis from glutamic acid and NH_3 ($\Delta G^{\circ'} = +3.4$ kcal/mol). The reaction is driven through the formation of a common intermediate, glutamyl phosphate. ATP hydrolysis can play a role in such processes because the cell maintains an elevated $[\text{ATP}]/[\text{ADP}]$ ratio that is far above that at equilibrium, which illustrates that cellular metabolism operates under nonequilibrium conditions. This does not mean that every reaction is kept from equilibrium. Rather, certain key reactions in a metabolic pathway occur with large negative ΔG values, which makes them essentially irreversible within the cell and allows them to drive the entire pathway. The concentrations of reactants and products can be maintained at relatively constant nonequilibrium (steady state) values within a cell because materials are continually flowing into the cell from the external medium and waste products are continually being removed. (p. 91)

Enzymes are proteins that vastly accelerate the rate of specific chemical reactions by binding to the reactant(s) and increasing the likelihood that they will be converted to products. Like all true catalysts, enzymes are present in small amounts; they are not altered irreversibly during the course of the reaction; and they have no effect on the thermodynamics of the reaction. Enzymes, therefore, cannot cause an unfavorable reaction (one with a $+\Delta G$) to proceed in the forward direction, nor can they change the ratio of products to reactants at equilibrium. As catalysts, enzymes can only accelerate the rate of favorable reactions, which they accomplish under conditions of mild temperature and pH found in the cell. Enzymes are also characterized by specificity toward their substrates, highly efficient catalysis with virtually no undesirable by-products, and the opportunity for their catalytic activity to be regulated. (p. 94)

Enzymes act by lowering the activation energy (E_A)—the kinetic energy required by reactants to undergo reaction. As a result, a much greater percentage of reactant molecules possess the necessary energy to be converted to products in the presence of an enzyme. Enzymes lower E_A through the formation of an enzyme–substrate complex. The part of the enzyme that binds the substrate(s) is called

the active site, which also contains the necessary amino acid side chains and/or cofactors to influence the substrates so as to facilitate the chemical transformation. Among the mechanisms that facilitate catalysis, enzymes are able to hold reactants in the proper orientation; they are able to make the substrates more reactive by influencing their electronic character; and they are able to exert physical stress that weakens certain bonds within the substrate. (p. 96)

Metabolism is the collection of biochemical reactions that occur within the cell. These reactions can be grouped into metabolic pathways containing a sequence of chemical reactions in which each reaction is catalyzed by a specific enzyme. Metabolic pathways are divided into two broad types: catabolic pathways, in which compounds are disassembled and energy is released, and anabolic pathways that lead to the synthesis of more complex compounds using energy stored in the cell. Macromolecules of diverse structure are degraded by catabolic pathways into a relatively small number of low-molecular-weight metabolites that provide the raw materials from which anabolic pathways diverge. Both types of pathways include oxidation–reduction reactions in which electrons are transferred from one substrate to another, increasing the state of reduction of the recipient and increasing the state of oxidation of the donor. (p. 108)

The state of reduction of an organic molecule, as measured by the number of hydrogens per carbon atom, provides a rough measure of the molecule's energy content. A mole of glucose releases 686 kcal when completely oxidized to CO_2 and H_2O , whereas the conversion of a mole of ADP to ATP requires only 7.3 kcal. Thus, the oxidation of a molecule of glucose can produce enough energy to generate a large number of ATP molecules. The first stage in the catabolism of glucose is glycolysis, during which glucose is converted to pyruvate with a net gain of two molecules of ATP and two molecules of NADH. The ATP molecules are produced by substrate-level phosphorylation in which a phosphate group is transferred from a substrate to ADP. The NADHs are produced by oxidation of an aldehyde to a carboxylic acid with the accompanying transfer of a hydride ion (a proton and two electrons) from the substrate to NAD^+ . In the presence of O_2 , most cells oxidize the NADH by means of an electron-transport chain, forming ATP by aerobic respiration. In the absence of O_2 , NAD^+ is regenerated by fermentation in which the high-energy electrons of NADH are used to reduce pyruvate. NAD^+ regeneration is required for glycolysis to continue. (p. 110)

An enzyme's activity is commonly regulated by two mechanisms: covalent modification and allosteric modulation. Covalent modification is most often accomplished by transfer of a phosphate group from ATP to one or more serine, threonine, or tyrosine residues of the enzyme in a reaction catalyzed by a protein kinase. Allosteric modulators act by binding noncovalently to a site on the enzyme that is removed from the active site. Binding of the modulator alters the conformation of the active site, increasing or decreasing the enzyme's catalytic activity. A common example of allosteric modulation is feedback inhibition, in which the end product of a pathway allosterically inhibits the first enzyme that is unique to that pathway. The same compound degraded by a catabolic pathway may serve as the end product of an anabolic pathway. Glucose, for example, is degraded by glycolysis and synthesized by gluconeogenesis. While most of the enzymes are shared by the two pathways, three key enzymes are unique to each pathway, which allows the cell to regulate the two pathways independently and to overcome what would otherwise be irreversible reactions. (p. 115)

Analytic Questions

- How would you expect a drop in pH to affect a reaction catalyzed by chymotrypsin? How might an increase in pH affect this reaction?
- Feedback inhibition typically alters the activity of the first enzyme of a metabolic pathway rather than one of the latter enzymes of the pathway. Why is this adaptive?
- After reviewing the reactions of glutamine formation on page 92, explain why each of the following statements concerning the third (or overall) reaction is either true or false.
 - If the reaction were written in reverse, its $\Delta G^{\circ'}$ would be +3.9 kcal/mol.
 - If all reactants and products were at standard conditions at the beginning of an experiment, after a period of time, the $[\text{NH}_3]/[\text{ADP}]$ ratio would decrease.
 - As the reaction proceeds, the $\Delta G^{\circ'}$ moves closer to zero.
 - At equilibrium, the forward and reverse reactions are equal and the $[\text{ATP}]/[\text{ADP}]$ ratio becomes one.
 - In the cell, it is possible for glutamine to be formed when the $[\text{glutamine}]/[\text{glutamic acid}]$ ratio is greater than one.
- You have just isolated a new enzyme and have determined the velocity of reaction at three different substrate concentrations. You find that the slope of the product versus time curve is the same for all three concentrations. What can you conclude about the conditions in the reaction mixture?
- Lysozyme is a slow-acting enzyme, requiring approximately two seconds to catalyze a single reaction. What is the turnover number of lysozyme?
- In the reaction $\text{R} \rightleftharpoons \text{P}$, if one mole of product (P) has the same free energy as one mole of reactant (R), what is the value for the K'_{eq} of this reaction? What is the value of the $\Delta G^{\circ'}$?
- What is meant in terms of concentration ratios when it is said that the ΔG of ATP hydrolysis in the cell is approximately -12 kcal/mol, whereas the $\Delta G^{\circ'}$ is -7.3 kcal/mol?
- The enzymes under cellular regulation are those whose reactions typically proceed under nonequilibrium conditions. What would be the effect of allosteric inhibition of an enzyme that operated close to equilibrium?
- In the reaction $\text{A} \rightleftharpoons \text{B}$, if the K'_{eq} is 10^3 , what is the $\Delta G^{\circ'}$? What is the $\Delta G^{\circ'}$ if the K'_{eq} had been determined to be 10^{-3} ? What is the K'_{eq} of the hexokinase reaction indicated in Figure 3.24 (step 1)?
- In 1926, James Sumner concluded that urease was a protein based on the fact that crystals of the enzyme tested positive for reagents that reacted with proteins and negative for reagents that reacted with fats, carbohydrates, and other substances. His conclusion was attacked by other enzymologists, who found that their highly active enzyme solutions failed to contain evidence of protein. How can these seemingly opposing findings be reconciled?
- If the reaction $\text{XA} + \text{Y} \rightleftharpoons \text{XY} + \text{A}$ has a $\Delta G^{\circ'}$ of +7.3 kcal/mol, could this reaction be driven in the cell by coupling it to ATP hydrolysis? Why or why not?
- In a series of reactions, $\text{A} \rightarrow \text{B} \rightarrow \text{C} \rightarrow \text{D}$, it was determined that the equilibrium constant for the second reaction ($\text{B} \rightarrow \text{C}$) is 0.1. You would expect the concentration of C in a living cell to be: (1) equal to B, (2) one-tenth of B, (3) less than one-tenth of B, (4) 10 times that of B, (5) more than 10 times that of B. (Circle any correct answer.)
- The reaction of compound X with compound Y to produce compound Z is an unfavorable reaction ($\Delta G^{\circ'} = +5$ kcal/mol). Draw the chemical reactions that would occur if ATP was utilized to drive the reaction.
- ATP has evolved as the central molecule in energy metabolism. Could 1,3-bisphosphoglycerate serve the same function? Why or why not?
- Calculate the ΔG for ATP hydrolysis in a cell in which the $[\text{ATP}]/[\text{ADP}]$ ratio had climbed to 100:1, while the P_i concentration remained at 10 mM. How does this compare to the ratio of $[\text{ATP}]/[\text{ADP}]$ when the reaction is at equilibrium and the P_i concentration remains at 10 mM? What would be the value for ΔG when the reactants and products were all at standard conditions (1 M)?
- Consider the reaction:

$$\text{Glucose} + \text{P}_i \rightleftharpoons \text{glucose 6-phosphate} + \text{H}_2\text{O}$$

$$\Delta G^{\circ'} = +3 \text{ kcal/mol}$$
 What is the equilibrium constant, K'_{eq} , for this reaction? (*Note:* the concentration of water is ignored.) Does the positive $\Delta G^{\circ'}$ in the above reaction mean that the reaction can never go spontaneously from left to right?
- Under physiologic conditions, $[\text{Glucose}] = 5$ mM, $[\text{Glucose 6-phosphate}] = 83$ mM, and $[\text{P}_i] = 1$ mM. Under these conditions, will the reaction of problem 16 go spontaneously from left to right? If not, what would the concentration of glucose need to be for the reaction to go from left to right, if the concentrations of the other reactants and products are as stated above?
- Consider the reaction:

$$\text{Glutamate} + \text{ammonia} \rightleftharpoons \text{glutamine} + \text{H}_2\text{O}$$

$$\Delta G^{\circ'} = +3.4 \text{ kcal/mol}$$
 If the concentration of ammonia (NH_3) is 10 mM, what is the ratio of glutamate/glutamine required for the reaction to proceed spontaneously from left to right at 25°C?
- It should be clear that the synthesis of glutamine cannot occur in a cell by the reaction described in Problem 18. The actual reaction couples glutamine synthesis to ATP hydrolysis:

$$\text{Glutamate} + \text{ammonia} + \text{ATP} \rightleftharpoons \text{glutamine} + \text{ADP} + \text{P}_i$$
 What is the $\Delta G^{\circ'}$ for this reaction? Suppose that all reactants and products, except ammonia, are present at 10 mM. What concentration of ammonia would be required to drive the reaction to the right, that is, to drive the net synthesis of glutamine?
- A noncompetitive inhibitor does not prevent the enzyme from binding its substrate. What will be the effect of increasing the substrate concentration in the presence of a noncompetitive inhibitor? Do you expect a noncompetitive inhibitor to affect the enzyme V_{max} ? K_M ? Explain briefly.

The outer walls of a house or car provide a strong, inflexible barrier that protects its human inhabitants from an unpredictable and harsh external world. You might expect the outer boundary of a living cell to be constructed of an equally tough and impenetrable barrier because it must also protect its delicate internal contents from a nonliving, and often inhospitable, environment. Yet cells are separated from the external world by a thin, fragile structure called the **plasma membrane** that is only 5 to 10 nm wide. It would require about five thousand plasma membranes stacked one on top of the other to equal the thickness of a single page of this book.

Because it is so thin, no hint of the plasma membrane is detected when a section of a cell is examined under a light microscope. In fact, it wasn't until the late 1950s that techniques for preparing and staining tissue had progressed to the point where the plasma membrane could be resolved in the electron

Three-dimensional, X-ray crystallographic structure of a β_2 -adrenergic receptor (β_2 -AR), which is a member of the G protein-coupled receptor (GPCR) superfamily. These integral membrane proteins are characterized as containing seven transmembrane helices. The β_2 -AR is a resident of the plasma membrane of a variety of cells, where it normally binds the ligand epinephrine and mediates such responses as increased heart rate and relaxation of smooth muscle cells. Until recently, GPCRs had been very difficult to crystallize so that high-resolution structures of these important proteins have been lacking. This situation is now rapidly changing as the result of recent advances in crystallization technology. The image shown here depicts two β_2 -ARs, which were crystallized in the presence of cholesterol and palmitic acid (yellow) and a receptor-binding ligand (green). The crystals used to obtain this image were selected from more than 15,000 trials. (FROM VADIM CHEREZOV ET AL., COURTESY OF RAYMOND C. microscope. These early electron micrographs, such as those taken by J. D. Robertson of Duke University (Figure 4.1 a), portrayed the plasma membrane as a three-layered structure, consisting of darkly staining inner and outer layers and lightly staining middle layer. All membranes that were examined closely—whether they were plasma, nuclear, or cytoplasmic membranes (Figure 4.1 b), or taken from plants, animals, or microorganisms—showed this same ultrastructure. In addition to providing a visual image of this critically important cellular structure, these electron micrographs touched off a vigorous debate

as to the molecular composition of the various layers of a membrane, an argument that went to the very heart of the subject of membrane structure and function. As we will see shortly, cell membranes contain a lipid bilayer, and the two dark-staining layers in the electron micrographs of Figure 4.1 correspond primarily to the inner and outer polar surfaces of the bilayer. We will return to the structure of membranes below, but first we will survey some of the major functions of membranes in the life of a cell (Figure 4.2).

4.1 | An Overview of Membrane Functions

1. **Compartmentalization.** Membranes are continuous, unbroken sheets and, as such, inevitably enclose compartments. The plasma membrane encloses the contents of the entire cell, whereas the nuclear and cytoplasmic membranes enclose diverse intracellular spaces. The various membrane-bounded compartments of a cell possess markedly different contents. Membrane compartmentalization allows specialized activities to proceed without external interference and enables cellular activities to be regulated independently of one another.
2. **Scaffold for biochemical activities.** Membranes not only enclose compartments but are also a distinct compartment themselves. As long as reactants are present in solution, their relative positions cannot be stabilized and their interactions are dependent on random collisions. Because of their construction, membranes provide the cell with an extensive framework or scaffolding within which components can be ordered for effective interaction.
3. **Providing a selectively permeable barrier.** Membranes prevent the unrestricted exchange of molecules from one side to the other. At the same time, membranes provide the means of communication between the compartments they separate. The plasma membrane, which encircles a

Figure 4.2 A summary of membrane functions in a plant cell. (1) An example of membrane compartmentalization in which hydrolytic enzymes (acid hydrolases) are sequestered within the membrane-bounded vacuole. (2) An example of the role of cytoplasmic membranes as a site of enzyme localization. The fixation of CO_2 by the plant cell is catalyzed by an enzyme that is associated with the outer surface of the thylakoid membranes of the chloroplasts. (3) An example of the role of membranes as a selectively permeable barrier. Water molecules are able to penetrate rapidly through the plasma membrane, causing the plant cell to fill out the available space and exert pressure against its cell wall. (4) An example of solute transport. Hydrogen ions, which are produced by various metabolic processes in the cytoplasm, are pumped out of plant cells into the extracellular space by a transport protein located in the plasma membrane. (5) An example of the involvement of a membrane in the transfer of information from one side to another (signal transduction). In this case, a hormone (e.g., abscisic acid) binds to the outer surface of the plasma membrane and triggers the release of a chemical message (such as IP_3) into the cytoplasm. In this case, IP_3 causes release of Ca^{2+} ions from a cytoplasmic warehouse. (6) An example of the role of membranes in cell-cell communication. Openings between adjoining plant cells, called plasmodesmata, allow materials to move directly from the cytoplasm of one cell into its neighbors. (7) An example of the role of membranes in energy transduction. The conversion of ADP to ATP occurs in close association with the inner membrane of the mitochondrion.

cell, can be compared to a moat around a castle: both serve as a general barrier, yet both have gated “bridges” that promote the movement of select elements into and out of the enclosed living space.

- Transporting solutes.** The plasma membrane contains the machinery for physically transporting substances from one side of the membrane to another, often from a region where the solute is present at low concentration into a region where that solute is present at much higher concentration. The membrane’s transport machinery allows a cell to accumulate substances, such as sugars and amino acids, that are necessary to fuel its metabolism and build its macromolecules. The plasma membrane is also able to transport specific ions, thereby establishing ionic gradients across itself. This capability is especially critical for nerve and muscle cells.
- Responding to external stimuli.** The plasma membrane plays a critical role in the response of a cell to external stimuli, a process known as **signal transduction**. Membranes possess **receptors** that combine with specific molecules (**ligands**) or respond to other types of stimuli such as light or mechanical tension. Different types of cells have membranes with different receptors and are, therefore, capable of recognizing and responding to different environmental stimuli. The interaction of a plasma membrane receptor with an external stimulus may cause the membrane to generate a signal that stimulates or inhibits internal activities. For example, signals generated at the plasma membrane may tell a cell to manufacture more glycogen, to prepare for cell division, to move toward a higher concentration of a particular compound, to release calcium from internal stores, or possibly to commit suicide.
- Intercellular interaction.** Situated at the outer edge of every living cell, the plasma membrane of multicellular organisms mediates the interactions between a cell and its neighbors. The plasma membrane allows cells to recognize and signal one another, to adhere when appropriate, and to exchange materials and information. Proteins within the plasma membrane may also facilitate the interaction between extracellular materials and the intracellular cytoskeleton.
- Energy transduction.** Membranes are intimately involved in the processes by which one type of energy is converted to another type (energy transduction). The most fundamental energy transduction occurs during photosynthesis when energy in sunlight is absorbed by membrane-bound pigments, converted into chemical energy, and stored in carbohydrates. Membranes are also involved in the transfer of chemical energy from carbohydrates and fats to ATP. In eukaryotes, the machinery for these energy conversions is contained within membranes of chloroplasts and mitochondria.

We will concentrate in this chapter on the structure and functions of the plasma membrane, but remember that the principles discussed here are common to all cell membranes. Specialized aspects of the structure and functions of mitochondrial, chloroplast, cytoplasmic, and nuclear membranes will be discussed in Chapters 5, 6, 8, and 12, respectively.

4.2 | A Brief History of Studies on Plasma Membrane Structure

The first insights into the chemical nature of the outer boundary layer of a cell were obtained by Ernst Overton of the University of Zürich during the 1890s. Overton knew that nonpolar solutes dissolved more readily in nonpolar solvents than in polar solvents, and that polar solutes had the opposite solubility. Overton reasoned that a substance entering a cell from the medium would first have to dissolve in the outer boundary layer of that cell. To test the permeability of the outer boundary layer, Overton placed plant root hairs into hundreds of different solutions containing a diverse array of solutes. He discovered that the more lipid-soluble the solute, the more rapidly it would enter the root hair cells (see p. 149). He concluded that the dissolving power of the outer boundary layer of the cell matched that of a fatty oil.

The first proposal that cellular membranes might contain a lipid bilayer was made in 1925 by two Dutch scientists, E. Gorter and F. Grendel. These researchers extracted the lipid from human red blood cells and measured the amount of surface area the lipid would cover when spread over the surface of water (Figure 4.3*a*). Since mature mammalian red blood cells lack both nuclei and cytoplasmic organelles, the plasma membrane is the only lipid-containing structure in the cell. Consequently, all of the lipids extracted from the cells can be assumed to have resided in the cells' plasma membranes. The

ratio of the surface area of water covered by the extracted lipid to the surface area calculated for the red blood cells from which the lipid was extracted varied between 1.8 to 1 and 2.2 to 1. Gorter and Grendel speculated that the actual ratio was 2:1 and concluded that the plasma membrane contained a bimolecular layer of lipids, that is, a **lipid bilayer** (Figure 4.3*b*). They also suggested that the polar groups of each molecular layer (or *leaflet*) were directed outward toward the aqueous environment, as shown in Figure 4.3*b,c*. This would be the thermodynamically favored arrangement, because the polar head groups of the lipids could interact with surrounding water molecules, just as the hydrophobic fatty acyl chains would be protected from contact with the aqueous environment (Figure 4.3*c*). Thus, the polar head groups would face the cytoplasm on one edge and the blood plasma on the other. Even though Gorter and Grendel made several experimental errors (which fortuitously canceled one another out), they still arrived at the correct conclusion that membranes contain a lipid bilayer.

In the 1920s and 1930s, cell physiologists obtained evidence that there must be more to the structure of membranes than simply a lipid bilayer. It was found, for example, that lipid

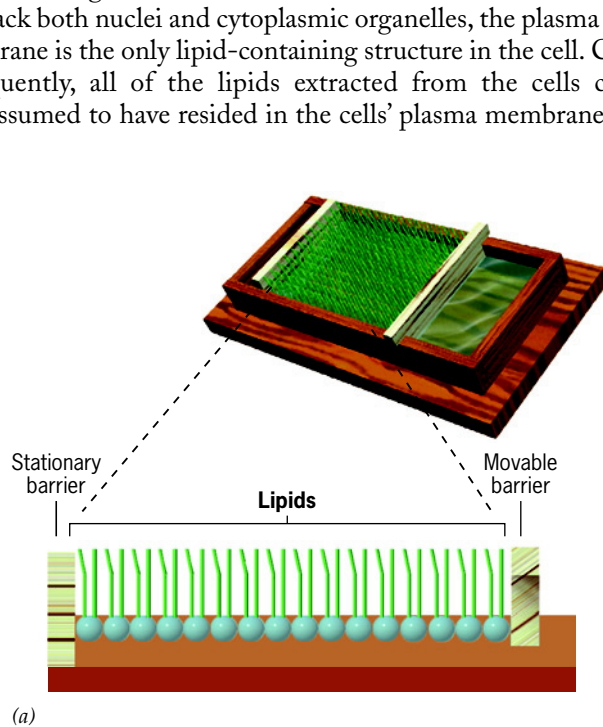

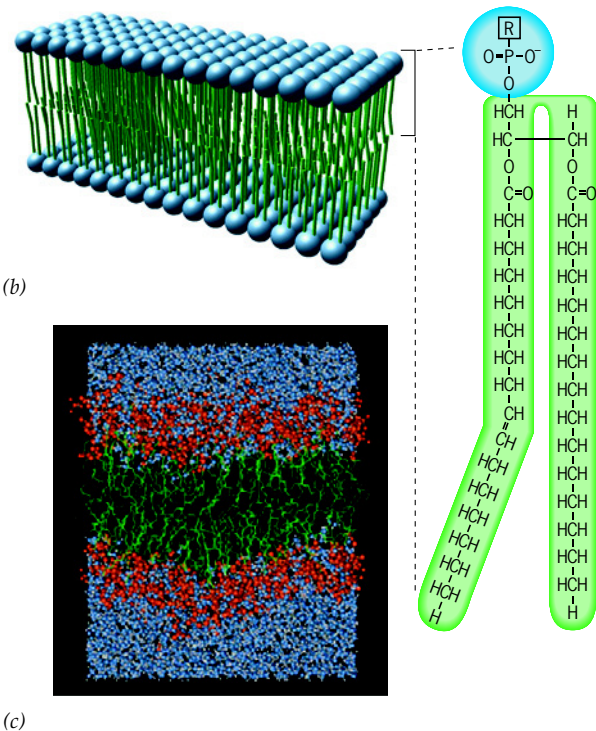

Figure 4.3 The plasma membrane contains a lipid bilayer. (a) Calculating the surface area of a lipid preparation. When a sample of phospholipids is dissolved in an organic solvent, such as hexane, and spread over an aqueous surface, the phospholipid molecules form a layer over the water that is a single molecule thick: a monomolecular layer. The molecules in the layer are oriented with their hydrophilic groups bonded to the surface of the water and their hydrophobic chains directed into the air. To estimate the surface area the lipids would cover if they were part of a membrane, the lipid molecules can be compressed into the smallest possible area by means of movable barriers. Using this type of apparatus, which is called a Langmuir trough after its inventor, Gorter and Grendel concluded that red

blood cells contained enough lipid to form a layer over their surface that was two molecules thick: a bilayer. (b) As Gorter and Grendel first proposed, the core of a membrane contains a bimolecular layer of phospholipids oriented with their water-soluble head groups facing the outer surfaces and their hydrophobic fatty acid tails facing the interior. The structures of the head groups are given in Figure 4.6*a*. (c) Simulation of a fully hydrated lipid bilayer composed of the phospholipid phosphatidylcholine. Phospholipid head groups are orange, water molecules are blue and white, fatty acid chains are green. (C: FROM S.-W. CHIU, TRENDS IN BIOCHEM. SCI. 22:341, © 1997, WITH PERMISSION FROM ELSEVIER.)

solubility was not the sole determining factor as to whether or not a substance could penetrate the plasma membrane. Similarly, the surface tensions of membranes were calculated to be much lower than those of pure lipid structures. This decrease in surface tension could be explained by the presence of protein in the membrane. In 1935, Hugh Davson and James Danielli proposed that the plasma membrane was composed of a lipid bilayer that was lined on both its inner and outer surface by a layer of globular proteins. They revised their model in the early 1950s to account for the selective permeability of

the membranes they had studied. In the revised version (Figure 4.4*a*), Davson and Danielli suggested that, in addition to the outer and inner protein layers, the lipid bilayer was also penetrated by protein-lined pores, which could provide conduits for polar solutes and ions to enter and exit the cell.

Experiments conducted in the late 1960s led to a new concept of membrane structure, as detailed in the fluid-mosaic model proposed in 1972 by S. Jonathan Singer and Garth Nicolson of the University of California, San Diego (Figure 4.4*b*). In the **fluid-mosaic model**, which has served as

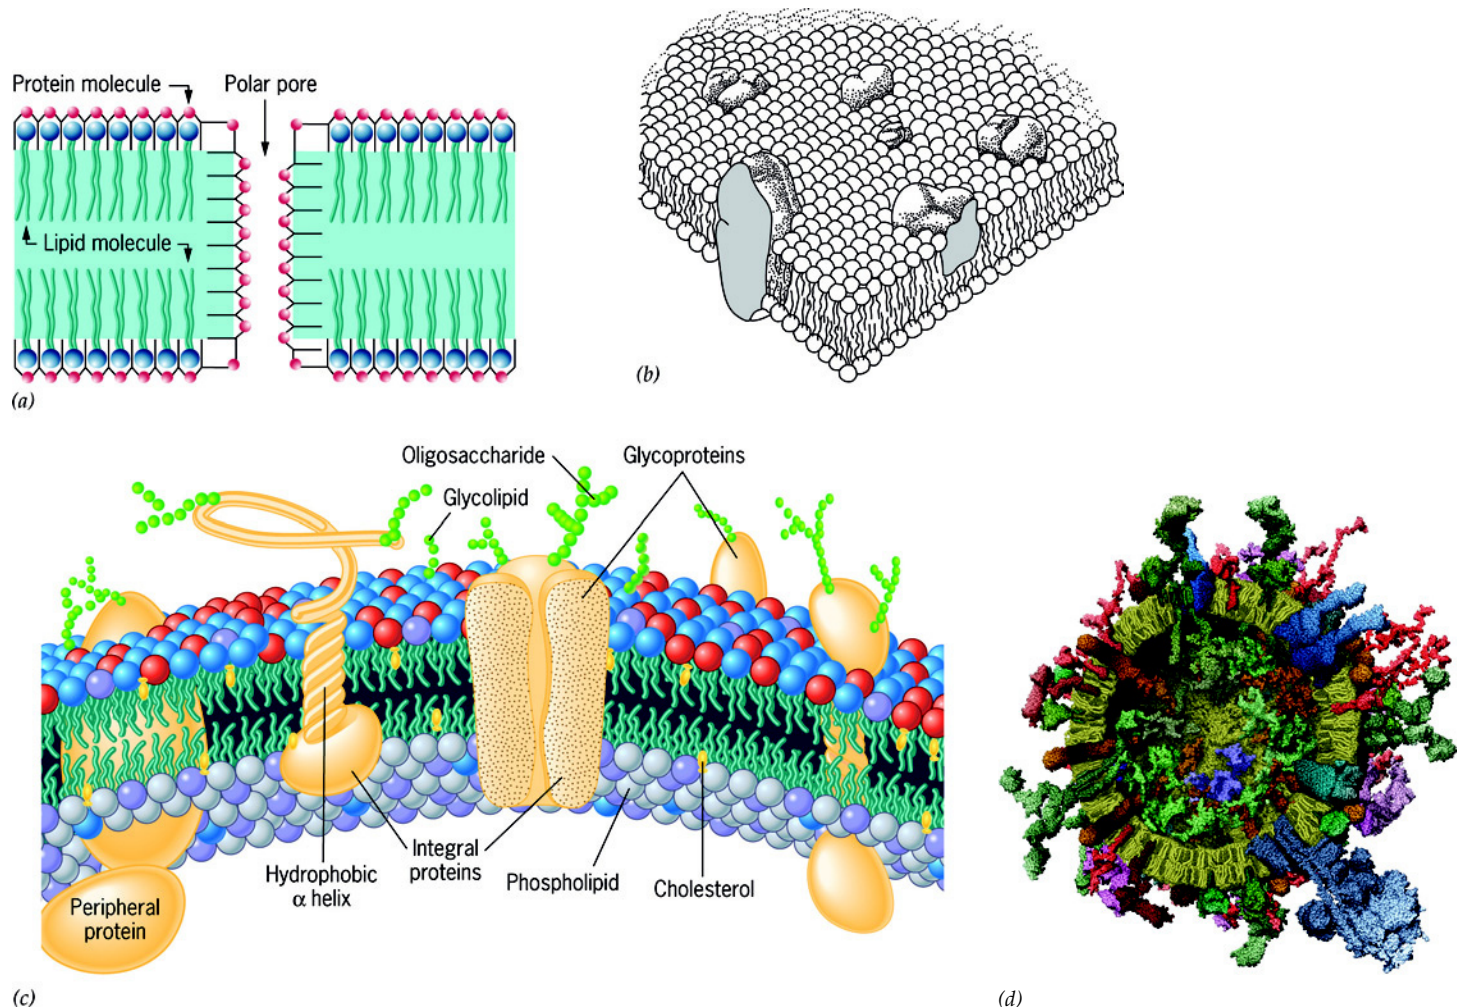

Figure 4.4 A brief history of the structure of the plasma membrane. (a) A revised 1954 version of the Davson–Danielli model showing the lipid bilayer, which is lined on both surfaces by a monomolecular layer of proteins that extends through the membrane to form protein-lined pores. (b) The fluid-mosaic model of membrane structure as initially proposed by Singer and Nicolson in 1972. Unlike previous models, the proteins penetrate the lipid bilayer. Although the original model shown here depicted a protein that was only partially embedded in the bilayer, lipid-penetrating proteins that have been studied span the entire bilayer. (c) A current representation of the plasma membrane showing the same basic organization as that proposed by Singer and Nicolson. The external surface of most membrane proteins, as well as a small percentage of the phospholipids, contain short chains of sugars, making them glycoproteins and glycolipids. Those portions of the polypeptide chains that extend through the lipid bilayer typically occur as α helices composed of hydrophobic amino acids. The two leaflets of the bilayer

contain different types of lipids as indicated by the differently colored head groups. (d) Molecular model of the membrane of a synaptic vesicle constructed using known structures of the various proteins along with information on their relative numbers obtained from the analysis of purified synaptic vesicles. The high protein density of the membrane is apparent. Most of the proteins in this membrane are required for the interaction of the vesicle with the plasma membrane. The large blue protein at the lower right pumps H^+ ions into the vesicle. (A: FROM J. F. DANIELLI, COLLSTON PAPERS 7:8, 1954A; REPRINTED WITH PERMISSION FROM S. J. SINGER AND G. L. NICOLSON, SCIENCE 175:720, 1972; COPYRIGHT 1972 REPRINTED WITH PERMISSION FROM AAAS. B: REPRINTED WITH PERMISSION FROM S. J. SINGER AND G. L. NICOLSON, SCIENCE 175:720, 1972; COPYRIGHT 1972, AAAS; D: FROM SHIGEO TAKAMORI, ET AL., COURTESY OF REINHARD JAHN, CELL 127:841, 2006, REPRINTED WITH PERMISSION FROM ELSEVIER.)

the “central dogma” of membrane biology for more than three decades, the lipid bilayer remains the core of the membrane, but attention is focused on the physical state of the lipid. Unlike previous models, the bilayer of a fluid-mosaic membrane is present in a fluid state, and individual lipid molecules can move laterally within the plane of the membrane.

The structure and arrangement of membrane proteins in the fluid-mosaic model differ from those of previous models in that they occur as a “mosaic” of discontinuous particles that penetrate the lipid sheet (Figure 4.4*b*). Most importantly, the fluid-mosaic model presents cellular membranes as dynamic structures in which the components are mobile and capable of coming together to engage in various types of transient or semipermanent interactions. In the following sections, we will examine some of the evidence used to formulate and support this dynamic portrait of membrane structure and look at some of the recent data that bring the model up to date (Figure 4.4*c,d*).

REVIEW

1. Describe some of the important roles of membranes in the life of a eukaryotic cell. What do you think might be the effect of a membrane that was incapable of performing one or another of these roles?
2. Summarize some of the major steps leading to the current model of membrane structure. How does each new model retain certain basic principles of earlier models?

4.3 | The Chemical Composition of Membranes

Membranes are lipid–protein assemblies in which the components are held together in a thin sheet by noncovalent bonds. As noted above, the core of the membrane consists of a sheet of lipids arranged in a bimolecular layer (Figure 4.3*b,c*). The lipid bilayer serves primarily as a structural backbone of the membrane and provides the barrier that prevents random movements of water-soluble materials into and out of the cell. The proteins of the membrane, on the other hand, carry out most of the specific functions summarized in Figure 4.2. Each type of differentiated cell contains a unique complement of membrane proteins, which contributes to the specialized activities of that cell type (see Figure 4.32*d* for an example).

The ratio of lipid to protein in a membrane varies, depending on the type of cellular membrane (plasma vs. endoplasmic reticulum vs. Golgi), the type of organism (bacterium vs. plant vs. animal), and the type of cell (cartilage vs. muscle vs. liver). For example, the inner mitochondrial membrane has a very high ratio of protein/lipid in comparison to the red blood cell plasma membrane, which is high in comparison to the membranes of the myelin sheath that form a multilayered wrapping around a nerve cell (Figure 4.5). To a large degree, these differences can be correlated with the basic functions of these membranes. The inner mitochondrial membrane contains the protein carriers of the electron-transport chain, and

Figure 4.5 The myelin sheath. Electron micrograph of a nerve cell axon surrounded by a myelin sheath consisting of concentric layers of plasma membrane that have an extremely low protein/lipid ratio. The myelin sheath insulates the nerve cell from the surrounding environment, which increases the velocity at which impulses can travel along the axon (discussed on page 167). The perfect spacing between the layers is maintained by interlocking protein molecules (called P_0) that project from each membrane. (FROM LEONARD NAPOLITANO, FRANCIS LEBARON, AND JOSEPH SCALETTI, *J. CELL BIOL.* 34:820, 1967; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

relative to other membranes, lipid is diminished. In contrast, the myelin sheath acts primarily as electrical insulation for the nerve cell it encloses, a function that is best carried out by a thick lipid layer of high electrical resistance with a minimal content of protein. Membranes also contain carbohydrates, which are attached to the lipids and proteins as indicated in Figure 4.4*c*.

Membrane Lipids

Membranes contain a wide diversity of lipids, all of which are **amphipathic**; that is, they contain both hydrophilic and hydrophobic regions. There are three main types of membrane lipids: phosphoglycerides, sphingolipids, and cholesterol.

Phosphoglycerides Most membrane lipids contain a phosphate group, which makes them **phospholipids**. Because most membrane phospholipids are built on a glycerol backbone, they are called **phosphoglycerides** (Figure 4.6*a*). Unlike triglycerides, which have three fatty acids (page 47) and are not amphipathic, membrane glycerides are **diglycerides**—only two of the hydroxyl groups of the glycerol are esterified to fatty acids; the third is esterified to a hydrophilic phosphate group. Without any additional substitutions beyond the phosphate

and the two fatty acyl chains, the molecule is called *phosphatidic acid*, which is virtually absent in most membranes. Instead, membrane phosphoglycerides have an additional group linked to the phosphate, most commonly either choline (forming *phosphatidylcholine*, PC), ethanolamine (forming *phosphatidylethanolamine*, PE), serine (forming *phosphatidylserine*, PS), or inositol (forming *phosphatidylinositol*, PI). Each of these groups is small and hydrophilic and, together with the negatively charged phosphate to which it is attached, forms a highly water-soluble domain at one end of the molecule, called the **head group**. At physiologic pH, the head groups of PS and PI have an overall negative charge, whereas those of PC and PE are neutral. In contrast, the fatty acyl chains are hydrophobic, unbranched hydrocarbons approximately 16 to 22 carbons in length (Figure 4.6). A membrane fatty acid may be fully saturated (i.e., lack double bonds), monounsaturated (i.e., possess one double bond), or polyunsaturated (i.e., possess more than one double bond). Phosphoglycerides often contain one unsaturated and one saturated fatty acyl chain. Recent interest has focused on the apparent health benefits of two highly unsaturated fatty acids (EPA and DHA) found at high concentration in fish oil. EPA and DHA contain five and six double bonds, respectively, and are incorporated primarily into PE and PC molecules of certain membranes, most notably in the brain and retina. EPA and DHA are described as omega-3 fatty acids because their last double bond is situated 3 carbons from the omega (CH₃) end of the fatty acyl chain. With fatty acid chains at one end of the molecule and a polar head group at the other end, all of the phosphoglycerides exhibit a distinct amphipathic character.

Sphingolipids A less abundant class of membrane lipids, called **sphingolipids**, are derivatives of sphingosine, an amino alcohol that contains a long hydrocarbon chain (Figure 4.6*b*). Sphingolipids consist of sphingosine linked to a fatty acid (R of Figure 4.6*b*) by its amino group. This molecule is a *ceramide*. The various sphingosine-based lipids have additional groups esterified to the terminal alcohol of the sphingosine moiety. If the substitution is phosphorylcholine, the molecule is *sphingomyelin*, which is the only phospholipid of the membrane that is not built with a glycerol backbone. If the substitution is a carbohydrate, the molecule is a **glycolipid**. If the carbohydrate is a simple sugar, the glycolipid is called a *cerebroside*; if it is a small cluster of sugars that includes sialic acid, the glycolipid is called a *ganglioside*. Hundreds of different gangliosides have been identified by differences in their carbohydrate chains. Since all sphingolipids have two long, hydrophobic hydrocarbon chains at one end and a hydrophilic

Figure 4.6 The chemical structures of membrane lipids. (a) The structures of phosphoglycerides (see also Figure 2.22). (b) The structures of sphingolipids. Sphingomyelin is a phospholipid; cerebroside and gangliosides are glycolipids. A third membrane lipid is cholesterol, which is shown in the next figure. (R = fatty acyl chain). [The green portion of each lipid, which represents the hydrophobic tail(s) of the molecule, is actually much longer than the hydrophilic head group (see Figure 4.23).]

region at the other, they are also amphipathic and basically similar in overall structure to the phosphoglycerides. The fatty acyl chains of sphingolipids, however, tend to be longer and more highly saturated than those of phosphoglycerides.

Glycolipids are interesting membrane components. Relatively little is known about them, yet tantalizing hints have emerged to suggest they play crucial roles in cell function. The nervous system is particularly rich in glycolipids. The myelin sheath pictured in Figure 4.5 contains a high content of a particular glycolipid, called galactocerebroside (shown in Figure 4.6*b*), which is formed when a galactose is added to ceramide. Mice lacking the enzyme that carries out this reaction exhibit severe muscular tremors and eventual paralysis. Similarly, humans who are unable to synthesize a particular ganglioside (G_{M3}) suffer from a serious neurological disease characterized by severe seizures and blindness. Glycolipids also play a role in certain infectious diseases; the toxins that cause cholera and botulism both enter their target cell by first binding to cell-surface gangliosides, as does the influenza virus.

Cholesterol Another lipid component of certain membranes is the sterol **cholesterol** (see Figure 2.21), which in certain animal cells may constitute up to 50 percent of the lipid molecules in the plasma membrane. Plant cells contain cholesterol-like sterols, but biologists disagree as to whether or not they completely lack cholesterol. Cholesterol molecules are oriented with their small hydrophilic hydroxyl group toward the membrane surface and the remainder of the molecule embedded in the lipid bilayer (Figure 4.7). The hydrophobic rings of a cholesterol molecule are flat and rigid, and they interfere with the movements of the fatty acid tails of the phospholipids (page 138).

The Nature and Importance of the Lipid Bilayer Each type of cellular membrane has its own characteristic lipid composition, differing from one another in the types of lipids, the nature of the head groups, and the particular species of fatty acyl chain(s). Because of this structural variability, it is estimated that some biological membranes contain hundreds of chemically distinct species of phospholipids, which can be catalogued by mass spectrometry. The biological significance of this remarkable diversity of lipid species remains the subject of interest and speculation.

The percentages of some of the major types of lipids of a variety of membranes are given in Table 4.1. The lipids of a membrane are more than simple structural elements; they can have important effects on the biological properties of a membrane. Lipid composition can determine the physical state of the membrane (page 138) and influence the activity of particular membrane proteins. Membrane lipids also provide the precursors for highly active chemical messengers that regulate cellular function (Section 15.3).

Various types of measurements indicate that the combined fatty acyl chains of both leaflets of the lipid bilayer span a width of about 30 Å and that each row of head groups (with its adjacent shell of water molecules) adds another 15 Å. Thus, the entire lipid bilayer is only about 60 Å (6 nm) thick. The presence in membranes of this thin film of amphipathic

Figure 4.7 The cholesterol molecules (shown in green) of a lipid bilayer are oriented with their small hydrophilic end facing the external surface of the bilayer and the bulk of their structure packed in among the fatty acid tails of the phospholipids. The placement of cholesterol molecules interferes with the flexibility of the lipid hydrocarbon chains, which tends to stiffen the bilayer while maintaining its overall fluidity. Unlike other lipids of the membrane, cholesterol is often rather evenly distributed between the two layers (leaflets). (FROM H. L. SCOTT, CURR. OPIN. STRUCT. BIOL. 12:499, 2002, FIGURE 3; © 2002, WITH PERMISSION FROM ELSEVIER.)

lipid molecules has remarkable consequences for cell structure and function. Because of thermodynamic considerations, the hydrocarbon chains of the lipid bilayer are never exposed to the surrounding aqueous solution. Consequently, membranes are never seen to have a free edge; they are always continuous, unbroken structures. As a result, membranes form extensive interconnected networks within the cell. Because of the flexibility of the lipid bilayer, membranes are deformable and their overall shape can change, as occurs during locomotion

Table 4.1 Lipid Compositions of Some Biological Membranes*

Lipid	Human erythrocyte	Human myelin	Beef heart mitochondria	<i>E. coli</i>
Phosphatidic acid	1.5	0.5	0	0
Phosphatidylcholine	19	10	39	0

(Figure 4.8a) or cell division (Figure 4.8b). The lipid bilayer is thought to facilitate the regulated fusion or budding of membranes. For example, the events of secretion, in which cytoplasmic vesicles fuse to the plasma membrane (Figure 4.8c), or of fertilization, where two cells fuse to form a single cell, involve processes in which two separate membranes come together to become one continuous sheet (see Figure 8.32). The importance of the lipid bilayer in maintaining the proper internal composition of a cell, in separating electric charges across the plasma membrane, and in many other cellular activities will be apparent throughout this and subsequent chapters.

Another important feature of the lipid bilayer is its ability to self-assemble, which can be demonstrated more easily within a test tube than a living cell. If, for example, a small amount of phosphatidylcholine is dispersed in an aqueous solution, the phospholipid molecules assemble spontaneously to form the walls of fluid-filled spherical vesicles, called **liposomes**. The walls of these liposomes consist of a continuous lipid bilayer that is organized in the same manner as that of the lipid bilayer of a natural membrane. Liposomes have proven invaluable in membrane research. Membrane proteins can be inserted into liposomes and their function studied in a much simpler environment than that of a natural membrane. Liposomes have also been developed as vehicles to deliver drugs or DNA molecules within the body. The drugs or DNA can be linked to the wall of the liposome or contained at high concentration within its lumen (Figure 4.9). In these studies, the walls of the liposomes are constructed to contain specific proteins (such as antibodies or hormones) that allow the liposomes to bind selectively to the surfaces of particular target cells where the drug or DNA is intended to go. Most of the early clinical studies with liposomes met with failure

because the injected vesicles were rapidly removed by phagocytic cells of the immune system. This obstacle has been overcome with the development of so-called stealth liposomes (e.g., Caelyx) that contain an outer coating of a synthetic polymer that protects the liposomes from immune destruction (Figure 4.9).

The Asymmetry of Membrane Lipids

The lipid bilayer consists of two distinct leaflets that have a distinctly different lipid composition. One line of experiments that has led to this conclusion takes advantage of the fact that lipid-digesting enzymes cannot penetrate the plasma membrane and, consequently, are only able to digest lipids that reside in the outer leaflet of the bilayer. If intact human red blood cells are treated with a lipid-digesting phospholipase, approximately 80 percent of the phosphatidylcholine (PC) of the membrane is hydrolyzed, but only about 20 percent of the membrane's phosphatidylethanolamine (PE) and less than 10 percent of its phosphatidylserine (PS) are attacked. These data indicate that, compared to the inner leaflet, the outer leaflet has a relatively high concentration of PC (and sphingomyelin) and a low concentration of PE and PS (Figure 4.10). It follows that the lipid bilayer can be thought of as composed of two more-or-less stable, independent monolayers having different physical and chemical properties.

The different classes of lipids in Figure 4.10 exhibit different properties. All the glycolipids of the plasma membrane are in the outer leaflet where they often serve as receptors for extracellular ligands. Phosphatidylethanolamine, which is concentrated in the inner leaflet, tends to promote the curvature of

Figure 4.9 Liposomes. A schematic diagram of a stealth liposome containing a hydrophilic polymer (such as polyethylene glycol) to protect it from destruction by immune cells, antibody molecules that target it to specific body tissues, a water-soluble drug enclosed in the fluid-filled interior chamber, and a lipid-soluble drug in the bilayer.

the membrane, which is important in membrane budding and fusion. Phosphatidylserine, which is concentrated in the inner leaflet, has a net negative charge at physiologic pH, which makes it a candidate for binding positively charged lysine and arginine residues, such as those adjacent to the membrane-spanning α helix of glycophorin A in Figure 4.18. The appearance of PS on the outer surface of aging lymphocytes marks the cells for destruction by macrophages, whereas its appearance on the outer surface of platelets leads to blood coagulation. Phosphatidylinositol (PI), which is concentrated in the inner leaflet, can be phosphorylated at different sites on the inositol ring, which converts the lipid into a phosphoinositide. As discussed in Chapter 15, phosphoinositides play a key role in the transfer of stimuli from the plasma membrane

Figure 4.10 The asymmetric distribution of phospholipids (and cholesterol) in the plasma membrane of human erythrocytes. (SM, sphingomyelin; PC, phosphatidylcholine; PS, phosphatidylserine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; CI, cholesterol.)

to the cytoplasm (Section 15.3) and the recruitment of proteins to the cytosolic face of the plasma membrane.

Membrane Carbohydrates

The plasma membranes of eukaryotic cells also contain carbohydrate. Depending on the species and cell type, the carbohydrate content of the plasma membrane ranges between 2 and 10 percent by weight. More than 90 percent of the membrane's carbohydrate is covalently linked to proteins to form glycoproteins; the remaining carbohydrate is covalently linked to lipids to form glycolipids, which were discussed on page 126. As indicated in Figure 4.4c, all of the carbohydrate of the plasma membrane faces outward into the extracellular space.¹ The carbohydrate of internal cellular membranes also faces away from the cytosol (the basis for this orientation is illustrated in Figure 8.14).

The modification of proteins was discussed briefly on page 54. The addition of carbohydrate, or **glycosylation**, is the most complex of these modifications. The carbohydrate of glycoproteins is present as short, branched hydrophilic **oligosaccharides**, typically having fewer than about 15 sugars per chain. In contrast to most high-molecular-weight carbohydrates (such as glycogen, starch, or cellulose), which are polymers of a single sugar, the oligosaccharides attached to membrane proteins and lipids can display extensive variability in composition and structure. Even the same protein can display different chains of sugars in different cells and tissues. Oligosaccharides may be attached to several different amino acids by two major types of linkages (Figure 4.11). These

¹It can be noted that even though phosphatidylinositol contains a sugar group (Figure 4.6), it is not considered to be part of the carbohydrate portion of the membrane in this discussion.

Figure 4.11 Two types of linkages that join sugars to a polypeptide chain. The *N*-glycosidic linkage between asparagine and *N*-acetylglucosamine is more common than the *O*-glycosidic linkage between serine or threonine and *N*-acetylgalactosamine.

Figure 4.12 Blood-group antigens. Whether a person has type A, B, AB, or O blood is determined by a short chain of sugars covalently attached to membrane lipids and proteins of the red blood cell membrane. The oligosaccharides attached to membrane lipids (forming a ganglioside) that produce the A, B, and O blood types are shown here. A person with type AB blood has gangliosides with both the A and B structure. (Gal, galactose; GlcNAc, *N*-acetylglucosamine; Glu, glucose; Fuc, fucose; GalNAc, *N*-acetylgalactosamine.)

carbohydrate projections play an important role in mediating the interactions of a cell with its environment (Chapter 7) and sorting of membrane proteins to different cellular compartments (Chapter 8). The carbohydrates of the glycolipids of the red blood cell plasma membrane determine whether a person's blood type is A, B, AB, or O (Figure 4.12). A person having blood type A has an enzyme that adds an *N*-acetylgalactosamine to the end of the chain, whereas a person with type B blood has an enzyme that adds galactose to the chain terminus. These two enzymes are encoded by alternate versions of the same gene, yet they recognize different substrates. People with AB blood type possess both enzymes, whereas people with O blood type lack enzymes capable of attaching either terminal sugar. The function of the ABO blood-group antigens remains a mystery.

REVIEW

1. Draw the basic structure of the major types of lipids found in cellular membranes. How do sphingolipids differ from glycerolipids? Which lipids are phospholipids? Which are glycolipids? How are these lipids organized into a bilayer? How is the bilayer important for membrane activities?
2. What is a liposome? How are liposomes used in medical therapies?
3. What is an oligosaccharide? How are they linked to membrane proteins? How are they related to human blood types?

4.4 | The Structure and Functions of Membrane Proteins

Depending on the cell type and the particular organelle within that cell, a membrane may contain hundreds of different proteins. Each membrane protein has a defined orientation relative to the cytoplasm, so that the properties of one surface of a membrane are very different from those of the other surface (as in Figure 4.4*d*). This asymmetry is referred to as membrane “sidedness.” In the plasma membrane, for example, those parts of membrane proteins that interact with other cells or with extracellular substances are exposed to the extracellular space, whereas those parts of membrane proteins that interact with cytoplasmic molecules are exposed to the cytosol. Membrane proteins can be grouped into three distinct classes distinguished by the intimacy of their relationship to the lipid bilayer (Figure 4.13). These are

1. **Integral proteins** that penetrate the lipid bilayer. Integral proteins are **transmembrane proteins**; that is, they pass entirely through the lipid bilayer and thus have domains that protrude from both the extracellular and cytoplasmic sides of the membrane. Some integral proteins have only one membrane-spanning segment, whereas others are multispanning. Genome-sequencing studies suggest that integral proteins constitute 25–30 percent of all encoded proteins and roughly 60 percent of all current drug targets.
2. **Peripheral proteins** that are located entirely outside of the lipid bilayer, on either the cytoplasmic or extracellular side, yet are associated with the surface of the membrane by noncovalent bonds.
3. **Lipid-anchored proteins** that are located outside the lipid bilayer, on either the extracellular or cytoplasmic surface, but are covalently linked to a lipid molecule that is situated within the bilayer.

Integral Membrane Proteins

Most integral membrane proteins function in the following capacities: as receptors that bind specific substances at the membrane surface, as channels or transporters involved in the movement of ions and solutes across the membrane, or as agents that transfer electrons during the processes of photosynthesis and respiration. Like the phospholipids of the bilayer, integral membrane proteins are also amphipathic, having both hydrophilic and hydrophobic portions. As discussed below, those portions of an integral membrane protein that reside within the lipid bilayer—the transmembrane domains—tend to have a hydrophobic character. Amino acid residues in transmembrane domains form van der Waals interactions with the fatty acyl chains of the bilayer, which seals the protein into the lipid “wall” of the membrane. As a result, the permeability barrier of the membrane is preserved, the protein is anchored within the bilayer, and the protein is brought into direct contact with surrounding lipid molecules (Figure 4.14*a*). According to current consensus, most of the lipid molecules that make contact with a transmembrane

Figure 4.13 Three classes of membrane protein. (a) Integral proteins typically contain one or more transmembrane helices (see Figure 5.4 for an exception). (b) Peripheral proteins are noncovalently bonded to the polar head groups of the lipid bilayer and/or to an integral membrane protein. (c) Lipid-anchored proteins are covalently bonded to a lipid group that resides within the membrane. The lipid can be phosphatidylinositol, a fatty acid, or a prenyl group (a long-chain hydrocarbon built from five-carbon isoprenoid units). I, inositol; GlcNAc, *N*-acetylglucosamine; Man, mannose; Etn, ethanolamine; GPI, glycosylphosphatidylinositol.

Figure 4.14 The interactions between membrane proteins and lipids. (a) Aquaporin is a membrane protein containing four subunits (colored differently in the illustration) with each subunit containing an aqueous channel. Analysis of the protein's structure revealed the presence of a surrounding layer of bound lipid molecules. In this case, these lipid molecules are not likely to play a role in the function of aquaporin because the protein retains its function as a water channel in bilayers containing nonnative lipids. (b) Two views of another tetrameric membrane protein, in this case the bacterial K^+ channel, KcsA. Anionic phosphatidylglycerol molecules (red/gray) are seen in each crevice between the subunits and are thought to be required for normal channel function. A K^+ ion (purple sphere) is seen in transit through the pore. (A: FROM CAROLA HUNTE AND SEBASTIAN RICHERS, CURR. OPIN. STRUCT. BIOL. 18:407, © 2008; B: FROM ANTHONY G. LEE, TRENDS BIOCHEM. SCI. 36:497, 2011, © BOTH WITH PERMISSION FROM ELSEVIER SCIENCE.)

domain, such as those shown in Figure 4.14a, are simply passive bystanders and are rapidly exchanged with other lipid molecules in the bilayer. There is increasing evidence, however, that certain sites on the surface of many membrane proteins do form important functional interactions with specific lipid molecules. An example of this is shown in Figure 14.4b, where anionic lipid molecules are seen to bind in the crevice at the interfaces between the subunits of a tetrameric KcsA K^+

channel. The channel does not open normally in a bilayer that lacks these specific lipid molecules.

Those portions of an integral membrane protein that project into either the cytoplasm or extracellular space tend to be more like the globular proteins discussed in Section 2.5. These nonembedded domains tend to have hydrophilic surfaces that interact with water-soluble substances (low-molecular-weight substrates, hormones, and other proteins) at the edge of the membrane. In some membrane proteins, the transmembrane domains are essentially devoid of water molecules, whereas others allow the aqueous solvent to penetrate deep into the protein's membrane-embedded regions. Several large families of membrane proteins contain an interior channel that provides an aqueous passageway through the lipid bilayer. The linings of these channels typically contain key hydrophilic residues at strategic locations. As will be discussed later, integral proteins need not be fixed structures but may be able to move laterally within the membrane.

Distribution of Integral Proteins: Freeze-Fracture Analysis The concept that proteins penetrate through membranes, rather than simply remaining external to the bilayer, was derived primarily from the results of a technique called **freeze-fracture replication** (see Section 18.2). In this procedure, tissue is frozen solid and then struck with a knife blade, which fractures the block into two pieces. As this occurs, the fracture plane often takes a path between the two leaflets of the lipid bilayer (Figure 4.15*a*). Once the membranes are split in this manner, metals are deposited on their exposed surfaces to form a shadowed *replica*, which is viewed in the electron microscope (see Figure 18.17). As shown in Figure 4.15*b*, the replica resembles a road strewn with pebbles, which are called *membrane-associated particles*. Since the fracture plane passes through the center of

the bilayer, most of these particles correspond to integral membrane proteins that extend at least halfway through the lipid core. When the fracture plane reaches a given particle, it goes around it rather than cracking it in half. Consequently, each protein (particle) separates with one half of the plasma membrane (Figure 4.15*c*), leaving a corresponding pit in the other half (see Figure 7.30*c*). One of the great values of the freeze-fracturing technique is that it allows an investigation of the microheterogeneity of the membrane. Localized differences in parts of the membrane stand out in these replicas and can be identified (as illustrated by the replica of a gap junction shown in Figure 7.32*d*). Biochemical analyses, in contrast, average out such differences.

Studying the Structure and Properties of Integral Membrane Proteins

Because of their hydrophobic transmembrane domains, integral membrane proteins are difficult to isolate in a soluble form. Removal of these proteins from the membrane normally

0.2 μm

(c)

0.3 μm

Figure 4.15 Freeze fracture: a technique for investigating cell membrane structure. (a) When a block of frozen tissue is struck by a knife blade, a fracture plane runs through the tissue, often following a path that leads it through the middle of the lipid bilayer. The fracture plane goes around the proteins rather than cracking them in half, and they segregate with one of the two halves of the bilayer. The exposed faces within the center of the bilayer can then be covered with a metal deposit to form a metallic replica. These exposed faces are referred to as the E, or ectoplasmic face, and the P, or protoplasmic face. (b) Replica of a freeze-fractured human erythrocyte. The P fracture face is seen to be covered with particles approximately 8 nm in diameter. A small ridge (arrow) marks the junction of the particulate face with the surrounding ice. (c) This micrograph shows the surface of an erythrocyte that was frozen and then fractured, but rather than preparing a replica, the cell was thawed, fixed, and labeled with a marker for the carbohydrate groups that project from the external surface of the integral protein glycoporphin (Figure 4.18). Thin sections of the labeled, fractured cell reveal that glycoporphin molecules (black particles) have preferentially segregated with the outer half of the membrane. The red line shows the path of the fracture plane. (B: FROM THOMAS W. TILLACK AND VINCENT T. MARCHESI, *J. CELL BIOL.* 45:649, 1970; C: FROM PEDRO PINTO DA SILVA AND MARIA R. TORRISI, *J. CELL BIOL.* 93:467, 1982; B,C: REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

Figure 4.16 Solubilization of membrane proteins with detergents.

The nonpolar ends of the detergent molecules associate with the nonpolar residues of the protein that had previously been in contact with the fatty acyl chains of the lipid bilayer. In contrast, the polar ends of the detergent molecules interact with the surrounding water molecules, keeping the protein in solution. Nonionic detergents, as shown here, solubilize membrane proteins without disrupting their structure.

requires the use of a detergent, such as the ionic (charged) detergent SDS (which denatures proteins) or the nonionic (uncharged) detergent Triton X-100 (which generally does not alter a protein's tertiary structure).

Like membrane lipids, detergents are amphipathic, being composed of a polar end and a nonpolar hydrocarbon chain (see Figure 2.20). As a consequence of their structure, detergents can substitute for phospholipids in stabilizing integral proteins while rendering them soluble in aqueous solution (Figure 4.16). Once the proteins have been solubilized by the detergent, various analyses can be carried out to determine the protein's amino acid composition, molecular mass, amino acid sequence, and so forth.

Researchers have had great difficulty obtaining crystals of most integral membrane proteins for use in X-ray crystallography. In fact, fewer than 1 percent of the known high-resolution protein structures represent integral membrane proteins (see http://blanco.biomol.uci.edu/MemPro_resources.html for a discussion of principles of protein structure and http://blanco.biomol.uci.edu/Membrane_Proteins_xtal.html for an updated gallery).² Furthermore, most of these structures repre-

²Many integral membrane proteins have a substantial portion that is present in the cytoplasm or extracellular space. In many cases, this soluble portion has been cleaved from its transmembrane domain, crystallized, and its tertiary structure determined. While this approach provides valuable data about the protein, it fails to provide information about the protein's orientation within the membrane. Another crystallographic approach to the study of membrane proteins, which uses the electron microscope rather than X-ray diffraction, is discussed in the Experimental Pathways on page 173.

sent prokaryotic versions of a particular protein, which are often smaller than their eukaryotic homologues and easier to obtain in large quantity. Once the structure of one member of a membrane protein family is determined, researchers can usually apply a strategy called *homology modeling* to learn about the structure and activity of other members of the family. For example, solution of the structure of the bacterial K^+ channel KcsA (shown in Figure 4.39) provided a wealth of data that could be applied to the structure and mechanism of action of the much more complex eukaryotic K^+ channels (Figure 4.42).

One of the first membrane proteins whose entire three-dimensional structure was determined by X-ray crystallography is shown in Figure 4.17. This protein—the bacterial photosynthetic reaction center—consists of three subunits containing 11 membrane-spanning α helices. Most membrane proteins have not been as amenable to crystallization as the photosynthetic reaction center. Among the obstacles, many membrane proteins (1) are present at low numbers per cell, (2) are unstable in the detergent-containing solutions required for their extraction, (3) are prone to aggregation, and (4) are heavily modified by glycosylation and cannot be expressed as recombinant proteins in other types of cells. Some of the technical difficulties in preparing membrane protein crystals have been overcome using new methodologies and laborious efforts. In one study, for example researchers were able to obtain high-quality crystals of a bacterial transporter after testing and refining more than 95,000 different conditions for crystallization. In some cases, mutant versions of a membrane protein are found to be better suited to forming the ordered arrays of molecules that make up a crystal lattice. In many other cases, crystallization has been achieved by covalently linking the membrane protein to other molecules, often small soluble proteins. These added elements stabilize

Figure 4.17 An integral protein as it resides within the plasma membrane. Tertiary structure of the photosynthetic reaction center of a bacterium as determined by X-ray crystallography. The protein contains three different membrane-spanning polypeptides, shown in yellow, light blue, and dark blue. The helical nature of each of the transmembrane segments is evident. (FROM G. FEHER, J. P. ALLEN, M. Y. OKAMURA, AND D. C. REES, NATURE 339:113, © 1989; REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD.)

the structure of the target protein and increase the number of sites on the surface of the protein that can participate in intermolecular contacts required for lattice formation. For example, the crystal structure of the β_2 -adrenergic receptor shown in the chapter opening image on page 120 was obtained by inserting a T4-lysozyme molecule (derived from a T4 bacteriophage) into one of the intracellular loops of the receptor. Crystallization of the β_2 -adrenergic receptor was also facilitated by the presence of a specific ligand bound to the receptor and the use of cholesterol in the lipid-phase medium in which the crystals were grown. Despite increasing success in protein crystallization, researchers still rely largely on indirect approaches for determining the three-dimensional organization of most membrane proteins. We will examine some of these approaches in the following paragraphs.

Identifying Transmembrane Domains A great deal can be learned about the structure of a membrane protein and its orientation within the lipid bilayer from a computer-based (computational) analysis of its amino acid sequence, which is readily deduced from the nucleotide sequence of an isolated gene. The first question one might ask is: Which segments of the polypeptide chain are actually embedded in the lipid bilayer? Those segments of a protein embedded within the membrane, which are described as the **transmembrane domains**, have a simple structure; they consist of a string of about 20 predominantly nonpolar amino acids that span the core of the lipid bilayer as an α helix.³ The chemical structure

³It was noted on page 55 that the α helix is a favored conformation because it allows for a maximum number of hydrogen bonds to be formed between atoms of the polypeptide backbone, thereby creating a highly stable (low-energy) configuration. This is particularly important for a membrane-spanning polypeptide that is surrounded by fatty acyl chains and, thus, cannot form hydrogen bonds with an aqueous solvent. Transmembrane helices are at least 20 amino acids in length, because this is the minimum stretch of polypeptide capable of spanning the hydrocarbon core of a lipid bilayer of 30 Å width. A few integral membrane proteins have been found to contain loops or helices that penetrate but do not span the bilayer. An example is the P helix in Figure 4.39.

Figure 4.18 Glycophorin A, an integral protein with a single transmembrane domain. The single α helix that passes through the membrane consists predominantly of hydrophobic residues (brown-colored circles). The four positively charged amino acid residues of the cytoplasmic domain of the membrane protein form ionic bonds with negatively charged lipid head groups. Carbohydrates are attached to a number of amino acid residues on the outer surface of the protein (shown in the inset). All but one of the 16 oligosaccharides are small *O*-linked chains (the exception is a larger oligosaccharide linked to the asparagine residue at position 26). Glycophorin molecules are present as homodimers within the erythrocyte membrane (Figure 4.32*d*). The two helices of the dimer cross over one another in the region between residues 79 and 83. This Gly-X-X-Gly sequence is commonly found where transmembrane helices come into close proximity.

of a single transmembrane helix is shown in Figure 4.18, which depicts the two-dimensional structure of glycophorin A, the major integral protein of the erythrocyte plasma membrane. Of the 20 amino acids that make up the lone α helix of a glycophorin monomer (amino acids 73 to 92 of Figure 4.18), all but three have hydrophobic side chains (or an H atom in the case of the glycine residues). The exceptions are serine and threonine, which are noncharged, polar residues (Figure 2.26). Figure 4.19*a* shows a portion of a transmembrane helix with a threonine residue, not unlike those of glycophorin A. The hydroxyl group of the residue's side chain can form a hydrogen bond with one of the oxygen atoms of the peptide backbone. Fully charged residues may also appear in transmembrane helices, but they tend to be near one of the ends of the helix and to be accommodated in ways that allow them to fit into their hydrophobic environment. This is illustrated in the model transmembrane helices shown in Figures 4.19*b* and *c*. Each of the helices in these figures contains a pair of charged residues whose side chains are able to reach out and interact with the innermost polar regions of the membrane, even if it requires distorting the helix to do so. Figure 4.19*d* shows two tyrosine residues with their hydrophobic aromatic side chains; each aromatic ring is oriented parallel with the hydrocarbon chains of the bilayer with which it has become integrated.

Knowing the amino acid sequence of an integral membrane protein, we can usually identify the transmembrane segments using a *hydropathy plot*, in which each site along a polypeptide is assigned a value that provides a measure of the *hydrophobicity* of the amino acid at that site as well as that of its neighbors. This approach provides a "running average" of the hydrophobicity of short sections of the polypeptide, and guarantees that one or a few polar amino acids in a sequence do not alter the profile of the entire stretch. Hydrophobicity of

Figure 4.19 Accommodating various amino acid residues within transmembrane helices. (a) In this portrait of a small portion of a transmembrane helix, the hydroxyl group of the threonine side chain (arrow) is able to form a (shared) hydrogen bond with a backbone oxygen within the lipid bilayer. Hydrogen bonds are indicated by the dashed lines and their distances are shown in angstroms. (b) The side chains of the two lysine residues of this transmembrane helix are sufficiently long and flexible to form bonds with the head groups and water

molecules of the polar face of the lipid bilayer. (c) The side chains of the two aspartic acid residues of this transmembrane helix can also reach the polar face of the bilayer but introduce distortion in the helix to do so. (d) The aromatic side chains of the two tyrosine residues of this transmembrane helix are oriented perpendicular to the axis of the membrane and parallel to the fatty acyl chains with which they interact. (FROM ANNA C. V. JOHANSSON AND ERIK LINDAHL, *BIOPHYS. J.* 91:4459, 4453, 2006, © 2006, WITH PERMISSION FROM ELSEVIER.)

amino acids can be determined using various criteria, such as their lipid solubility or the energy that would be required to transfer them from a nonpolar medium into an aqueous medium. A hydrophathy plot for glycoporphin A is shown in Figure 4.20. Transmembrane segments are usually identified as a jagged peak that extends well into the hydrophobic side of the spectrum. A reliable prediction concerning the orientation of the transmembrane segment within the bilayer can usually be made by examining the flanking amino acid residues. In most cases, as illustrated by glycoporphin in Figure 4.18, those parts of the polypeptide at the cytoplasmic flank of a

Figure 4.20 Hydrophathy plot for glycoporphin A, a single membrane-spanning protein. Hydrophobicity is measured by the free energy required to transfer each segment of the polypeptide from a nonpolar solvent to an aqueous medium. Values above the 0 line are energy-requiring ($+\Delta G$ s), indicating they consist of stretches of amino acids that have predominantly nonpolar side chains. Peaks that project above the red-colored line are interpreted as a transmembrane domain.

transmembrane segment tend to be more positively charged than those at the extracellular flank.

Not all integral membrane proteins contain transmembrane α helices. A number of membrane proteins contain a relatively large channel positioned within a circle of membrane-spanning β strands organized into a barrel as illustrated in Figure 5.4. To date, aqueous channels constructed of β barrels have only been found in the outer membranes of bacteria, mitochondria, and chloroplasts.

Experimental Approaches to Identifying Conformational Changes within an Integral Membrane Protein Suppose you have isolated a gene for an integral membrane protein and, based on its nucleotide sequence, determined that it contains 12 apparent membrane-spanning α helices. You might want to know which sites within these transmembrane domains are accessible to the aqueous environment and how this changes as the protein carries out its function. This type of information is particularly important when working with a membrane channel or transporter that functions in the movement of hydrophilic substances across the membrane. Although these determinations are difficult to make without detailed structural models, considerable insight can be gained by site-directed mutagenesis, that is, by introducing specific changes into the gene that encodes the protein (Section 18.17). An experiment of this type, which was conducted on lactose permease, a sugar-transporting protein in bacterial cell membranes, is shown in Figure 4.21. In this experiment, researchers prepared different versions of the permease in which nearly all of the individual amino acids of the protein were replaced, one at a time, by a cysteine residue. Each mutated membrane protein was then incubated with a water-soluble reagent (NEM) that is capable of adding an alkyl group to the cysteine side chain—as long as it has access to that side chain. The incubations with NEM were carried out

Figure 4.21 An experiment employing site-directed mutagenesis to learn about dynamic changes in the conformation of a membrane protein as it carries out its activity. The experimental strategy of the experiment and its results are discussed in the text. The cytoplasmic surface of the protein (lactose permease) is at the top. (a) The red spheres indicate the residues of the membrane protein that reacted with the alkylating agent NEM in the absence of a sugar to be transported. (b) The gold spheres denote the residues that are much more accessible to the alkylating agent when the protein is incubated with the sugar. The gold spheres in *b* are seen to cluster in a portion of the protein near the external medium (the periplasm in bacteria). The authors concluded

that the gold spheres correspond to residues that line an outward-facing cavity, i.e., one that is open to the external medium. The results support a model of alternating access to the medium as depicted in part *c*. (Note the structure that is depicted in parts *a–b* is that of the inward-facing conformation as determined by X-ray crystallography. The structure of the outward-facing conformation has not been directly determined, which is why these types of labeling experiments remain important.) (A–B: FROM H. RONALD KABACK, ET AL., PNAS 104:492, 2007, © 2007 NATIONAL ACADEMY OF SCIENCES, U. S. A.) C: REPRINTED FROM CURRENT OPINION IN STRUCTURAL BIOLOGY 14:414, 2004 FIG. 1 BY H. R. KABACK, WITH PERMISSION FROM ELSEVIER.

under two different conditions: either in the presence of the sugar to be transported or in its absence. The image in Figure 4.21*a* shows those residues (depicted as red spheres) of the protein that become alkylated by NEM *in the absence of the sugar*. Many of these accessible residues are thought to line an inward-facing hydrophilic cavity in the permease that is open to the cytoplasm. Those cysteine residues that are not labeled, most notably on helices VI and XII, are presumed to either face the fatty acyl chains of the phospholipids or to be located in tightly packed regions of the molecule, thus making them inaccessible to NEM.

The image in Figure 4.21*b* shows those residues (depicted as gold spheres) that show a significant *increase* in reactivity to NEM when the permease is incubated with the sugar to be transported. The difference in NEM reactivity of the residues between the protein in the absence of the sugar (*a*) and the presence of the sugar (*b*) indicates that different parts of the protein are accessible to the aqueous medium under these two conditions. The results, in other words, suggest that addition of the sugar induces a conformational change in the permease. Careful analysis of the positions of the residues that become labeled in these two conformations supports the model shown in Figure 4.21*c*. According to this model of alternating access, the sugar-binding site is open to the cytoplasm of the bacterial cell in one conformation and is open to the extracellular space in the other conformation. Alternation between the two conformations brings about transport of the sugar across the membrane. This type of ion-driven transport system is discussed further on page 159.

Determining spatial relationships between specific amino acids in a membrane protein is another approach to learning about dynamic events that occur as a protein carries out its function. One way to learn about the distance between selected residues in a protein is to introduce chemical groups whose properties are sensitive to the distance that separates them. *Nitroxides* are chemical groups that contain an unpaired electron, which produces a characteristic spectrum when monitored by a technique called *electron paramagnetic resonance (EPR) spectroscopy*. A nitroxide group can be introduced at any site in a protein by first mutating that site to a cysteine and then attaching the nitroxide to the —SH group of the cysteine residue. Figure 4.22 shows how this technique was used to discover the conformational changes that occur in a membrane protein as its channel is opened in response to changes in the pH of the medium. The protein in question, a bacterial K^+ channel, is a tetramer composed of four identical subunits. The cytoplasmic opening to the channel is bounded by four transmembrane helices, one from each subunit of the protein. Figure 4.22*a* shows the EPR spectra that were obtained when a nitroxide was introduced near the cytoplasmic end of each transmembrane helix. The red line shows the spectrum obtained at pH 6.5 when the channel is in the closed state, and the blue line shows the spectrum at pH 3.5 when the channel is open. The shape of each line depends on the proximity of the nitroxides to one another. The spectrum is broader at pH 6.5 because the nitroxide groups on the four subunits are closer together at this pH, which decreases the intensity of their EPR signals. These results indicate that the

Figure 4.22 Use of EPR spectroscopy to monitor changes in conformation of a bacterial K^+ ion channel as it opens and closes. (a) EPR spectra from nitroxides that have been attached to cysteine residues near the cytoplasmic end of the four transmembrane helices that line the channel. The cysteine residue in each helix replaces a glycine residue that is normally at that position. The shapes of the spectra depend on the distances between unpaired electrons in the nitroxides on

different subunits. (Nitroxides are described as “spin-labels,” and this technique is known as site-directed spin labeling.) (b) A highly schematic model of the ion channel in the open and closed states based on the data from part a. Opening of the channel is accompanied by the movement of the four nitroxide groups apart from one another. (A: REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD; FROM E. PEROZO ET AL., NATURE STRUCT. BIOL. 5:468, 1998.)

activation of the channel is accompanied by an increased separation between the labeled residues of the four subunits (Figure 4.22b). An increase in diameter of the channel opening allows ions in the cytoplasm to reach the actual permeation pathway (shown in red) within the channel, which allows only the passage of K^+ ions (discussed on page 153). An alternate technique, called FRET, that can also be used to measure changes in the distance between labeled groups within a protein, is illustrated in Figure 18.8.

Peripheral Membrane Proteins

Peripheral proteins are associated with the membrane by weak electrostatic bonds (refer to Figure 4.13b). Peripheral proteins can usually be solubilized by extraction with high-concentration salt solutions that weaken the electrostatic bonds holding peripheral proteins to a membrane. In actual fact, the distinction between integral and peripheral proteins is blurred because many integral membrane proteins consist of several polypeptides, some that penetrate the lipid bilayer and others that remain on the periphery.

The best studied peripheral proteins are located on the internal (cytosolic) surface of the plasma membrane, where they form a fibrillar network that acts as a membrane “skeleton” (see Figure 4.32d). These proteins provide mechanical support for the membrane and function as an anchor for integral membrane proteins. Other peripheral proteins on the internal

plasma membrane surface function as enzymes, specialized coats (see Figure 8.24), or factors that transmit transmembrane signals (see Figure 15.19). Peripheral proteins typically have a dynamic relationship with the membrane, being recruited to the membrane or released from the membrane depending on prevailing conditions.

Lipid-Anchored Membrane Proteins

Several types of lipid-anchored membrane proteins can be distinguished. Numerous proteins present on the external face of the plasma membrane are bound to the membrane by a small, complex oligosaccharide linked to a molecule of phosphatidylinositol that is embedded in the outer leaflet of the lipid bilayer (refer to Figure 4.13c). Peripheral membrane proteins containing this type of glycosyl-phosphatidylinositol linkage are called **GPI-anchored proteins**. They were discovered when it was shown that certain membrane proteins could be released by a phospholipase that specifically recognized and cleaved inositol-containing phospholipids. The normal cellular scrapie protein PrP^C (page 66) is a GPI-linked molecule, as are various receptors, enzymes, and cell-adhesion proteins. A rare type of anemia, paroxysmal nocturnal hemoglobinuria, results from a deficiency in GPI synthesis that makes red blood cells susceptible to lysis.

Another group of proteins present on the *cytoplasmic* side of the plasma membrane is anchored to the membrane by one

or more long hydrocarbon chains embedded in the inner leaflet of the lipid bilayer (refer to Figure 4.13c and accompanying legend). At least two proteins associated with the plasma membrane in this way (Src and Ras) have been implicated in the transformation of a normal cell to a malignant state.

REVIEW

1. Why are detergents necessary to solubilize membrane proteins? How might one determine the diversity of integral proteins that reside in a purified membrane fraction?
2. How can one determine: (1) the location of transmembrane segments in the amino acid sequence or (2) the relative locations of transmembrane helices with access to the external medium?
3. What is meant by the statement that the proteins of a membrane are distributed asymmetrically? Is this also true of the membrane's carbohydrate?
4. Describe the properties of the three classes of membrane proteins (integral, peripheral, and lipid-anchored), how they differ from one another, and how they vary among themselves.

4.5 | Membrane Lipids and Membrane Fluidity

The physical state of the lipid of a membrane is described by its fluidity (or viscosity).⁴ Consider a simple artificial bilayer composed of phosphatidylcholine and phosphatidylethanolamine, whose fatty acids are largely unsaturated. If the temperature of the bilayer is kept relatively warm

⁴Fluidity and viscosity are inversely related; fluidity is a measure of the ease of flow, and viscosity is a measure of the resistance to flow.

(a)

Figure 4.23 The structure of the lipid bilayer depends on the temperature. The bilayer shown here is composed of two phospholipids: phosphatidylcholine and phosphatidylethanolamine. (a) Above the transition temperature, the lipid molecules and their hydrophobic tails are free to move in certain directions, even though they retain a

(e.g., 37°C), the lipid exists in a relatively fluid state (Figure 4.23a). At this temperature, the lipid bilayer is best described as a two-dimensional liquid crystal. As in a crystal, the molecules still retain a specified orientation; in this case, the long axes of the molecules tend toward a parallel arrangement, yet individual phospholipids can rotate around their axis or move laterally within the plane of the bilayer. If the temperature is slowly lowered, a point is reached where the bilayer distinctly changes (Figure 4.23b). The lipid is converted from a liquid crystalline phase to a frozen crystalline gel in which the movement of the phospholipid fatty acid chains is greatly restricted. The temperature at which this change occurs is called the **transition temperature**.

The transition temperature of a particular bilayer depends on the ability of the lipid molecules to be packed together, which depends in turn on the particular lipids of which it is constructed. Saturated fatty acids have the shape of a straight, flexible rod. *Cis*-unsaturated fatty acids, on the other hand, have crooks in the chain at the sites of a double bond (Figures 2.19 and 4.23). Consequently, phospholipids with saturated chains pack together more tightly than those containing unsaturated chains. The greater the degree of unsaturation of the fatty acids of the bilayer, the *lower* the temperature before the bilayer gels. The introduction of one double bond in a molecule of stearic acid lowers the melting temperature almost 60°C (Table 4.2).⁵ Another factor that influences bilayer fluidity is fatty acid chain length. The shorter the fatty acid chains of a phospholipid, the lower its melting temperature. The physical state of the membrane is also affected by cholesterol. Because of their orientation within the bilayer (Figure 4.7), cholesterol molecules disrupt the close packing of fatty

⁵The effect of fatty acid saturation on melting temperature is illustrated by familiar food products. Vegetable oils remain a liquid in the refrigerator, whereas margarine is a solid. Vegetable oils contain polyunsaturated fatty acids, whereas the fatty acids of margarine have been saturated by a chemical process that hydrogenates the double bonds of the vegetable oils used as the starting material.

(b)

considerable degree of order. (b) Below the transition temperature, the movement of the molecules is greatly restricted, and the entire bilayer can be described as a crystalline gel. (A–B: R. N. ROBERTSON, *THE LIVELY MEMBRANES*, CAMBRIDGE UNIV. PRESS; 1983, REPRINTED WITH PERMISSION OF CAMBRIDGE UNIV. PRESS.)

acyl chains and interfere with their mobility. The presence of cholesterol tends to abolish sharp transition temperatures and creates a condition of intermediate fluidity. In physiologic terms, cholesterol tends to increase the durability while decreasing the permeability of a membrane.

The Importance of Membrane Fluidity

What effect does the physical state of the lipid bilayer have on the biological properties of the membrane? Membrane fluidity provides a perfect compromise between a rigid, ordered structure in which mobility would be absent and a completely fluid, nonviscous liquid in which the components of the membrane could not be oriented and structural organization and mechanical support would be lacking. In addition, fluidity allows for interactions to take place within the membrane. For example, membrane fluidity makes it possible for clusters of membrane proteins to assemble at particular sites within the membrane and form specialized structures, such as intercellular junctions, light-capturing photosynthetic complexes, and synapses. Because of membrane fluidity, molecules that interact can come together, carry out the necessary reaction, and move apart.

Fluidity also plays a key role in membrane assembly, a subject discussed in Chapter 8. Membranes arise only from preexisting membranes, and their growth is accomplished by the insertion of lipids and proteins into the fluid matrix of the membranous sheet. Many of the most basic cellular processes, including cell movement, cell growth, cell division, formation of intercellular junctions, secretion, and endocytosis, depend on the movement of membrane components and would probably not be possible if membranes were rigid, nonfluid structures.

Maintaining Membrane Fluidity

The internal temperature of most organisms (other than birds and mammals) fluctuates with the temperature of the external environment. Since it is essential for many activities that the membranes of a cell remain in a fluid state, cells respond to changing conditions by altering the types of phospholipids of which they are made. Maintenance of membrane fluidity is an example of homeostasis at the cellular level and can be demonstrated in various ways. For example, if the temperature of a culture of cells is lowered, the cells respond metabolically.

The initial “emergency” response is mediated by enzymes that remodel membranes, making the cell more cold resistant. Remodeling is accomplished by (1) desaturating single bonds in fatty acyl chains to form double bonds, and (2) reshuffling the chains between different phospholipid molecules to produce ones that contain two unsaturated fatty acids, which greatly lowers the melting temperature of the bilayer. Desaturation of single bonds to form double bonds is catalyzed by enzymes called *desaturases*. Reshuffling is accomplished by *phospholipases*, which split the fatty acid from the glycerol backbone, and *acyltransferases*, which transfer fatty acids between phospholipids. In addition, the cell changes the types of phospholipids being synthesized in favor of ones containing more unsaturated fatty acids. As a result of the activities of these various enzymes, the physical properties of a cell’s membranes are matched to the prevailing environmental conditions. Maintenance of fluid membranes by adjustments in fatty acyl composition has been demonstrated in a variety of organisms, including hibernating mammals, pond-dwelling fish whose body temperature changes markedly from day to night, cold-resistant plants, and bacteria living in hot springs. Prokaryotic cells that live at very high temperatures have plasma membranes that contain highly unusual lipids.

Lipid Rafts

Every so often an issue emerges that splits the community of cell biologists into believers and nonbelievers. The issue of lipid rafts falls into this category. When membrane lipids are extracted from cells and used to prepare *artificial* lipid bilayers, cholesterol and sphingolipids tend to self-assemble into microdomains that are more gelled and highly ordered than surrounding regions consisting primarily of phosphoglycerides. Because of their distinctive physical properties, such microdomains tend to float within the more fluid and disordered environment of the artificial bilayer (Figure 4.24a). As a result, these patches of cholesterol and sphingolipid are referred to as **lipid rafts**. When added to these artificial bilayers, certain proteins tend to become concentrated in the lipid rafts, whereas others tend to remain outside their boundaries. GPI-anchored proteins show a particular fondness for the ordered regions of the bilayer (Figure 4.24a).

The controversy arises over whether similar types of sphingolipid- and cholesterol-rich lipid rafts, such as that illustrated in Figure 4.24b, exist within living cells. Most of the evidence in favor of lipid rafts is derived from studies that employ unnatural treatments, such as detergent extraction or cholesterol depletion, which makes the results difficult to interpret. Attempts to demonstrate the presence of lipid rafts in living cells have generally been unsuccessful, which can either mean that such rafts do not exist or they are so small (5 to 25 nm diameter) and short-lived as to be difficult to detect with current techniques. The concept of lipid rafts is very appealing because it provides a means to introduce order into a seemingly random sea of lipid molecules. Lipid rafts are postulated to serve as floating platforms that concentrate particular proteins, thereby organizing the membrane into functional compartments (Figure 4.24b). For example, lipid rafts are thought

(a)

(b)

Figure 4.24 Lipid rafts. (a) Image of the upper surface of an artificial lipid bilayer containing phosphatidylcholine, which appears as the black background, and sphingomyelin molecules, which organize themselves spontaneously into the orange-colored rafts. The yellow peaks show the positions of a GPI-anchored protein, which is almost exclusively raft-associated. This image is provided by an atomic force microscope, which measures the height of various parts of the specimen at the molecular level. (b) Schematic model of a lipid raft within a cell. The outer leaflet of the raft consists primarily of cholesterol (yellow) and sphingolipids (red head groups). Phosphatidylcholine molecules (blue head groups) with long saturated fatty acids also tend to concentrate in this region. GPI-anchored proteins are thought to

become concentrated in lipid rafts. The lipids in the outer leaflet of the raft have an organizing effect on the lipids of the inner leaflet. As a result, the inner-leaflet raft lipids consist primarily of cholesterol and glycerophospholipids with long saturated fatty acyl tails. The inner leaflet tends to concentrate lipid-anchored proteins, such as Src kinase, that are involved in cell signaling. (The controversy over the existence of lipid rafts is discussed in *Nature Revs. Mol. Cell Biol.* 11:688, 2010 and *Science* 334:1046, 2011.) (A: FROM D. E. SASLOWSKY, ET AL., *J. BIOL. CHEM.* 277, COVER OF #30, JULY 26, 2002; COURTESY OF J. MICHAEL EDWARDSON © 2002 THE AMERICAN SOCIETY FOR BIOCHEMISTRY AND MOLECULAR BIOLOGY.)

to provide a favorable local environment for cell-surface receptors to interact with other membrane proteins that transmit signals from the extracellular space to the cell interior.

REVIEW

1. What is the importance of fatty acid unsaturation for membrane fluidity? Of enzymes that are able to desaturate fatty acids?
2. What is meant by a membrane's transition temperature, and how is it affected by the degree of saturation or length of fatty acyl chains? How are these properties important in the formation of lipid rafts?
3. Why is membrane fluidity important to a cell?
4. How can the two sides of a lipid bilayer have different ionic charges?

4.6 | The Dynamic Nature of the Plasma Membrane

It is apparent from the previous discussion that the lipid bilayer can exist in a relatively fluid state. As a result, a phospholipid can move laterally within the same leaflet with con-

siderable ease. The mobility of individual lipid molecules within the bilayer of the plasma membrane can be directly observed under the microscope by linking the polar heads of the lipids to gold particles or fluorescent compounds (see Figure 4.29). It is estimated that a phospholipid can diffuse from one end of a bacterium to the other end in a second or two. In contrast, it takes a phospholipid molecule a matter of hours to days to move across to the other leaflet. Thus, of all the possible motions that a phospholipid can make, its flip-flop to the other side of the membrane is the most restricted (Figure 4.25). This finding is not surprising. For flip-flop to occur, the hydrophilic head group of the lipid must pass through the internal hydrophobic sheet of the membrane, which is thermodynamically unfavorable. However, cells contain enzymes that actively move certain phospholipids from one leaflet to the other. These enzymes play a role in establishing lipid asymmetry and may also reverse the slow rate of passive transmembrane movement.

Because lipids provide the matrix in which integral proteins of a membrane are embedded, the physical state of the lipid is an important determinant of the mobility of integral proteins. The demonstration that integral proteins can move within the plane of the membrane was a cornerstone in the formulation of the fluid-mosaic model. The dynamic properties of membrane proteins have been revealed in several ways.

Figure 4.25 The possible movements of phospholipids in a membrane. The types of movements in which membrane phospholipids can engage and the approximate time scales over which they occur. Whereas phospholipids move from one leaflet to another at a very slow rate, they diffuse laterally within a leaflet rapidly. Lipids lacking polar groups, such as cholesterol, can move across the bilayer quite rapidly.

The Diffusion of Membrane Proteins after Cell Fusion

Cell fusion is a technique whereby two different types of cells, or cells from two different species, can be fused to produce one cell with a common cytoplasm and a single, continuous plasma membrane. Cells are induced to fuse with one another by making the outer surface of the cells “sticky” so that their plasma membranes adhere to one another. Cells can be induced to fuse by addition of certain inactivated viruses that attach to the surface membrane, by adding the compound polyethylene glycol, or by a mild electric shock. Cell fusion

has played an important role in cell biology and is currently used in an invaluable technique to prepare specific antibodies (Section 18.18).

The first experiments to demonstrate that membrane proteins could move within the plane of the membrane utilized cell fusion, and they were reported in 1970 by Larry Frye and Michael Edidin of Johns Hopkins University. In their experiments, mouse and human cells were fused, and the locations of specific proteins of the plasma membrane were followed once the two membranes had become continuous. To follow the distribution of either the mouse membrane proteins or the human membrane proteins at various times after fusion, antibodies against one or the other type of protein were prepared and covalently linked to fluorescent dyes. The antibodies against the mouse proteins were complexed with a dye that fluoresces green and the antibodies against human proteins with one that fluoresces red. When the antibodies were added to fused cells, they bound to the human or mouse proteins and could be located under a fluorescence light microscope (Figure 4.26*a*). At the time of fusion, the plasma membrane appeared half human and half mouse; that is, the two protein types remained segregated in their own hemisphere (step 3, Figure 4.26*a,b*). As the time after fusion increased, the membrane proteins were seen to move laterally within the membrane into the opposite hemisphere. By about 40 minutes, each species’ proteins were uniformly distributed around the entire hybrid cell membrane (step 4, Figure 4.26*a*). If the same experiment was performed at lower temperature, the viscosity of the lipid bilayer increased, and the mobility of the membrane proteins decreased. These early cell fusion experiments gave the impression that integral membrane proteins were capable of virtually unrestricted movements. As we will see shortly, subsequent studies made it apparent that membrane dynamics was a much more complex subject than first envisioned.

Figure 4.26 The use of cell fusion to reveal mobility of membrane proteins. (a) Outline of the experiment in which human and mouse cells were fused (steps 1–2) and the distribution of the proteins on the surface of each cell were followed in the hybrids over time (steps 3–4). Mouse membrane proteins are indicated by solid circles, human membrane proteins by open circles. Locations of human and mouse proteins in the plasma membranes of the hybrid cells were monitored by interaction with fluorescent red and fluorescent green antibodies,

respectively. (b) Micrograph showing a fused cell in which mouse and human proteins are still in their respective hemispheres (equivalent to the hybrid in step 3 of part a). (B: FROM L. D. Restrictions on Protein and Lipid Mobility

Several techniques allow researchers to follow the movements of molecules in the membranes of living cells using the light microscope. In a technique called **fluorescence recovery after photobleaching (FRAP)**, which is illustrated in Figure 4.27*a*, integral membrane components in cultured cells are first labeled by linkage to a fluorescent dye. A particular membrane protein can be labeled using a specific probe, such as a fluorescent antibody. Once labeled, cells are placed under the microscope and irradiated by a sharply focused laser beam that bleaches the fluorescent molecules in its path, leaving a circular spot (typically about 1 μm diameter) on the surface of the cell that is largely devoid of fluorescence. If the labeled proteins in the membrane are mobile, then the random movements of these molecules should produce a gradual reappearance of fluorescence in the irradiated circle. The rate of fluorescence recovery (Figure 4.27*b*) provides a direct measure of the rate of diffusion (expressed as a diffusion coefficient, D) of the mobile molecules. The extent of fluorescence recovery (expressed as a percentage of the original intensity) provides a measure of the percentage of the labeled molecules that are free to diffuse.

Early studies utilizing FRAP suggested that (1) membrane proteins moved much more slowly in a plasma membrane than they would in a pure lipid bilayer and (2) a significant fraction of membrane proteins (30 to 70 percent) were not free to diffuse back into the irradiated circle. But the FRAP technique has its drawbacks. FRAP can only follow the average movement of a relatively large number of labeled molecules (hundreds to thousands) as they diffuse over a relatively large distance (e.g., 1 μm). As a result, researchers using FRAP cannot distinguish between proteins that are truly immobile and ones that can only diffuse over a limited distance in the time allowed. To get around these limitations, alternate techniques have been developed that allow researchers to observe the movements of individual protein molecules over very short distances and to determine how they might be restrained.

In **single-particle tracking (SPT)**, individual membrane protein molecules are labeled, usually with antibody-coated gold particles (approximately 40 nm in diameter), and the movements of the labeled molecules are followed by computer-enhanced video microscopy (Section 18.1). The results of these studies often depend on the particular protein being investigated. For example,

- Some membrane proteins move randomly throughout the membrane (Figure 4.28, protein A), though generally at rates considerably less than would be measured in an artificial lipid bilayer. (If protein mobility were based strictly on physical parameters such as lipid viscosity and protein size, one would expect proteins to migrate with diffusion coefficients of approximately 10^{-8} to 10^{-9} cm^2/sec rather than 10^{-10} to 10^{-12} cm^2/sec , as is observed for molecules of this group.) The reasons for the reduced diffusion coefficient have been debated.
- Some membrane proteins fail to move and are considered to be immobilized (Figure 4.28, protein B).

- In some cases, a protein is found to move in a highly directed (i.e., nonrandom) manner toward one part of the cell or another (Figure 4.28, protein C). For example, a

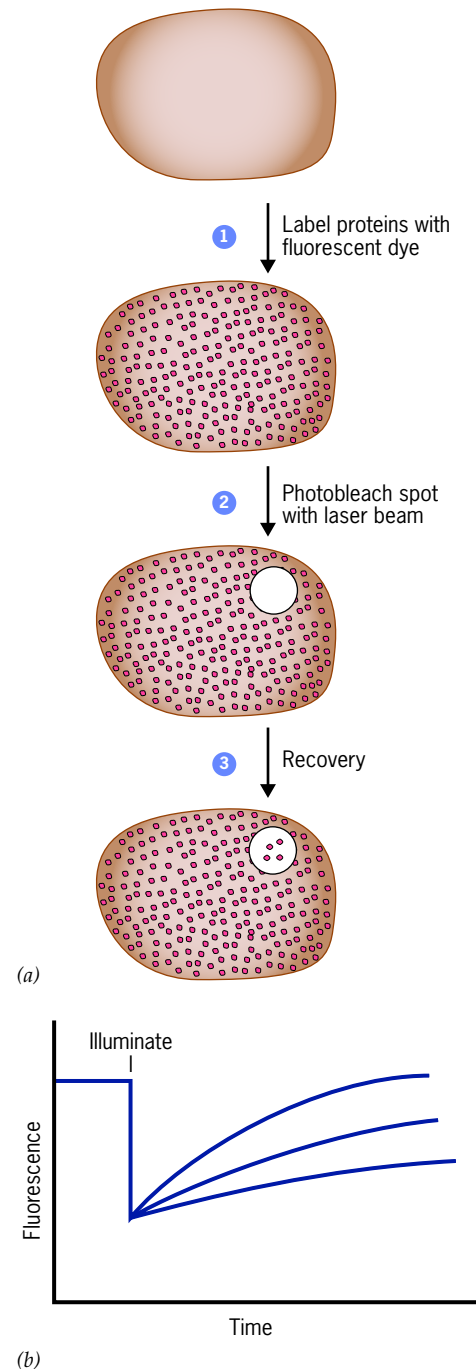

Figure 4.27 Measuring the diffusion rates of membrane proteins by fluorescence recovery after photobleaching (FRAP).

(a) In this technique, a particular component of the membrane is first labeled with a fluorescent dye (step 1). A small region of the surface is then irradiated to bleach the dye molecules (step 2), and the recovery of fluorescence in the bleached region is followed over time (step 3). (b) The rate of fluorescence recovery within the illuminated spot can vary depending on the protein(s) being followed. The rate of recovery is related to the diffusion coefficient of the fluorescently labeled protein.

Figure 4.28 Patterns of movement of integral membrane proteins.

Depending on the cell type and the conditions, integral membrane proteins can exhibit several different types of mobility. Protein A is capable of diffusing randomly throughout the membrane, though its rate of movement may be limited; protein B is immobilized as the result of its interaction with the underlying membrane skeleton; protein C is being moved in a particular direction as the result of its interaction with a motor protein at the cytoplasmic surface of the membrane; movement of protein D is restricted by other integral proteins of the membrane; movement of protein E is restricted by fences formed by proteins of the membrane skeleton, but it can hop into adjacent compartments through transient openings in a fence; movement of protein F is restrained by extracellular materials.

particular membrane protein may tend to move toward the leading or the trailing edge of a moving cell.

- In most studies, the largest fraction of protein species exhibit random (Brownian) movement within the membrane at rates consistent with free diffusion (diffusion coefficients about 5×10^{-9} cm²/sec), but the molecules are unable to migrate freely more than a few tenths of a micrometer. Long-range diffusion occurs but at slower rates, apparently because of the presence of a system of barriers. These barriers are discussed in the following sections.

Control of Membrane Protein Mobility It is apparent that plasma membrane proteins are not totally free to drift around randomly on the lipid “sea.” Instead, this class of proteins is subjected to various influences that affect their mobility and, in doing so, promote intramembrane organization. Some membranes are crowded with proteins, so that the random movements of one molecule can be impeded by its neighbors (Figure 4.28, protein D). The strongest influences on an integral membrane protein are thought to be exerted from just beneath the membrane on its cytoplasmic face. The plasma membranes of many cells possess a fibrillar network, or “mem-

brane skeleton,” consisting of peripheral proteins situated on the cytoplasmic surface of the membrane. A certain proportion of a membrane’s integral protein molecules are either tethered to the membrane skeleton (Figure 4.28, protein B) or otherwise restricted by it.

Information concerning the presence of membrane barriers has been obtained using an innovative technique that allows investigators to trap integral proteins and drag them through the plasma membrane with a known force. This technique, which uses an apparatus referred to as *optical tweezers*, takes advantage of the tiny optical forces that are generated by a focused laser beam. The integral proteins to be studied are tagged with antibody-coated beads, which serve as handles that can be gripped by the laser beam. It is generally found that optical tweezers can drag an integral protein for a limited distance before the protein encounters a barrier that causes it to be released from the laser’s grip. As it is released, the protein typically springs backward, suggesting that the barriers are elastic structures.

One approach to studying factors that affect membrane protein mobility is to genetically modify cells so that they produce altered membrane proteins. Integral proteins whose cytoplasmic portions have been genetically deleted often move much greater *distances* than their intact counterparts, indicating that barriers reside on the cytoplasmic side of the membrane. These findings suggest that the membrane’s underlying skeleton forms a network of “fences” around portions of the membrane, creating compartments that restrict the distance an integral protein can travel (Figure 4.28, protein E). Proteins move across the boundaries from one compartment to another through breaks in the fences. Such openings are thought to appear and disappear along with the dynamic disassembly and reassembly of parts of the meshwork. Membrane compartments may keep specific combinations of proteins in close enough proximity to facilitate their interaction.

Integral proteins lacking that portion that would normally project into the extracellular space typically move at a much faster *rate* than the wild-type version of the protein. This finding suggests that the movement of a transmembrane protein through the bilayer is slowed by extracellular materials that can entangle the external portion of the protein molecule (Figure 4.28, protein F).

Membrane Lipid Mobility Proteins are huge molecules, so it isn’t surprising that their movement within the lipid bilayer might be restricted. Phospholipids, by comparison, are small molecules that make up the very fabric of the lipid bilayer. One might expect their movements to be completely unfettered, yet a number of studies have suggested that phospholipid diffusion is also restricted. When individual phospholipid molecules of a plasma membrane are tagged and followed under the microscope using ultra high-speed cameras, they are seen to be confined for very brief periods and then hop from one confined area to another. Figure 4.29a shows the path taken by an individual phospholipid within the plasma membrane over a period of 56 milliseconds. Computer analysis indicates that the phospholipid diffuses freely within one

Figure 4.29 Experimental demonstration that diffusion of phospholipids within the plasma membrane is confined. (a) The track of a single labeled unsaturated phospholipid is followed for 56 ms as it diffuses within the plasma membrane of a rat fibroblast. Phospholipids diffuse freely within a confined compartment before hopping into a neighboring compartment. The rate of diffusion within a compartment is as rapid as that expected by unhindered Brownian movement. However, the overall rate of diffusion of the phospholipid appears slowed because the molecule must hop a barrier to continue its movement. The movement of the phospholipid within each compartment is represented by a single color. (b) The same experiment shown in a is carried out for 33 ms in an artificial bilayer, which lacks the “picket fences” present in a cellular membrane. The much more open, extended trajectory of the phospholipid can now be explained by simple, unconfined Brownian movement. For the sake of comparison, fake compartments were assigned in b and indicated by different colors. (FROM TAKAHIRO FUJIWARA ET AL., COURTESY OF AKIHIRO KUSUMI, NAGOYA, J. CELL BIOL. 157:1073, 2002; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

compartment (shaded in purple) before it jumps the “fence” into a neighboring compartment (shaded in blue) and then over another fence into an adjacent compartment (shaded in green), and so forth. Treatment of the membrane with agents that disrupt the underlying membrane skeleton removes some of the fences that restrict phospholipid diffusion. But if the membrane skeleton lies beneath the lipid bilayer, how can it interfere with phospholipid movement? The authors of these studies speculate that the fences are constructed of rows of integral membrane proteins whose cytoplasmic domains are attached to the membrane skeleton. This is not unlike the confinement of horses or cows by a picket fence whose posts are embedded in the underlying soil.

Membrane Domains and Cell Polarity For the most part, studies of membrane dynamics, such as those discussed above, are carried out on the relatively homogeneous plasma membrane situated at the upper or lower surface of a cell residing on a culture dish. Most membranes, however, exhibit distinct variations in protein composition and mobility, especially in cells whose various surfaces display distinct functions.

Apical plasma membrane

- regulation of nutrient and water intake
- regulated secretion
- protection

Lateral plasma membrane

- cell contact and adhesion
- cell communication

Basal membrane

- cell-substratum contact
- generation of ion gradients

Figure 4.30 Differentiated functions of the plasma membrane of an epithelial cell. The apical surface of this intestinal epithelial cell contains integral proteins that function in ion transport and hydrolysis of disaccharides, such as sucrose and lactose; the lateral surface contains integral proteins that function in intercellular interaction; and the basal surface contains integral proteins that function in the association of the cell with the underlying basement membrane.

For example, the epithelial cells that line the intestinal wall or make up the microscopic tubules of the kidney are highly polarized cells whose different surfaces carry out different functions (Figure 4.30). Studies indicate that the apical plasma membrane, which selectively absorbs substances from the lumen, possesses different enzymes than the lateral plasma membrane, which interacts with neighboring epithelial cells, or the basal membrane, which adheres to an underlying extracellular substrate (a *basement membrane*). In other examples, the receptors for neurotransmitter substances are concentrated into regions of the plasma membrane located within synapses (see Figure 4.57), and receptors for low-density lipoproteins are concentrated into patches of the plasma membrane specialized to facilitate their internalization (see Figure 8.38).

Of all the various types of mammalian cells, sperm may have the most highly differentiated structure. A mature sperm can be divided into head, midpiece, and tail, each having its own specialized functions. Although divided into a number of distinct parts, a sperm is covered by a *continuous* plasma membrane which, as revealed by numerous techniques, consists of a mosaic of different types of localized domains. For example, when sperm are treated with a variety of antibodies, each antibody combines with the surface of the cell in a unique topographic pattern that reflects the distribution within the plasma membrane of the particular protein antigen recognized by that antibody (Figure 4.31).

Figure 4.31 Differentiation of the mammalian sperm plasma membrane as revealed by fluorescent antibodies. (a–c) Three pairs of micrographs, each showing the distribution of a particular protein at the cell surface as revealed by a bound fluorescent antibody. The three proteins are localized in different parts of the continuous sperm membrane. Each pair of photographs shows the fluorescence pattern of the bound antibody and a phase contrast micrograph of the same cell. (d) Diagram summarizing the distribution of the proteins. The Red Blood Cell: An Example of Plasma Membrane Structure

Of all the diverse types of membranes, the plasma membrane of the human erythrocyte (red blood cell) is the most studied and best understood (Figure 4.32). There are several reasons for the popularity of this membrane. The cells are inexpensive to obtain and readily available in huge numbers from whole blood. They are already present as single cells and need not be dissociated from a complex tissue. The cells are simple by comparison with other cell types, lacking nuclear and cytoplasmic membranes that inevitably contaminate plasma membrane preparations from other cells. In addition, purified, *intact* erythrocyte plasma membranes can be obtained simply by placing the cells in a dilute (hypotonic) salt solution. The cells respond to this osmotic shock by taking up water and swelling, a phenomenon termed *hemolysis*. As the surface area of each cell increases, the cell becomes leaky, and the contents, composed almost totally of dissolved hemoglobin, flow out of the cell leaving behind a plasma membrane “ghost” (Figure 4.32*b*).

Once erythrocyte plasma membranes are isolated, the proteins can be solubilized and separated from one another (fractionated), providing a better idea of the diversity of proteins within the membrane. Fractionation of membrane proteins can be accomplished using polyacrylamide gel electrophoresis (PAGE) in the presence of the ionic detergent

sodium dodecyl sulfate (SDS). (The technique of SDS–PAGE is discussed in Section 18.7.) The SDS keeps the integral proteins soluble and, in addition, adds a large number of negative charges to the proteins with which it associates. Because the number of charged SDS molecules per unit weight of protein tends to be relatively constant, the molecules separate from one another according to their molecular weight. The largest proteins move most slowly through the molecular sieve of the gel. The major proteins of the erythrocyte membrane are separated into about a dozen conspicuous bands by SDS–PAGE (Figure 4.32*c*). Among the proteins are a variety of enzymes (including glyceraldehyde 3-phosphate dehydrogenase, one of the enzymes of glycolysis), transport proteins (for ions and sugars), and skeletal proteins (e.g., spectrin).

Integral Proteins of the Erythrocyte Membrane A model of the erythrocyte plasma membrane showing its major proteins is seen in Figure 4.32*d*. The most abundant integral proteins of this membrane are a pair of carbohydrate-containing, membrane-spanning proteins, called band 3 and glycophorin A. The high density of these proteins within the membrane is evident in the freeze-fracture micrographs of Figure 4.15. Band 3, which gets its name from its position in an electrophoretic gel (Figure 4.32*c*), is present as a dimer composed of two identical subunits (a *homodimer*). Each subunit spans the membrane at least a dozen times and contains a relatively small amount of carbohydrate (6–8 percent of the molecule’s weight). Band 3 protein serves as a channel for the passive exchange of anions across the membrane. As blood circulates through the tissues, carbon dioxide becomes dissolved in the fluid of the bloodstream (the plasma) and undergoes the following reaction:

The bicarbonate ions (HCO_3^-) enter the erythrocyte in exchange for chloride ions, which leave the cell. In the lungs, where carbon dioxide is released, the reaction is reversed and bicarbonate ions leave the erythrocyte in exchange for chloride ions. The reciprocal movement of HCO_3^- and Cl^- occurs through a channel in the center of each band 3 dimer.

Glycophorin A was the first membrane protein to have its amino acid sequence determined. The arrangement of the polypeptide chain of glycophorin A within the plasma membrane is shown in Figure 4.18. (Other related glycophorins, B, C, D, and E, are also present in the membrane at much lower concentrations.) Like band 3, glycophorin A is also present in the membrane as a dimer. Unlike band 3, each glycophorin A subunit spans the membrane only once, and it contains a bushy carbohydrate cover consisting of 16 oligosaccharide chains that together make up about 60 percent of the molecule’s weight. It is thought that the primary function of glycophorin derives from the large number of negative charges borne on sialic acid, the sugar residue at the end of each carbohydrate chain. Because of these charges, red blood cells repel each other, which prevents the cells from clumping as they circulate through the body’s tiny vessels. It is noteworthy that persons who lack both glycophorin A and B in their red blood cells show no ill-effects from their absence. At the same time,

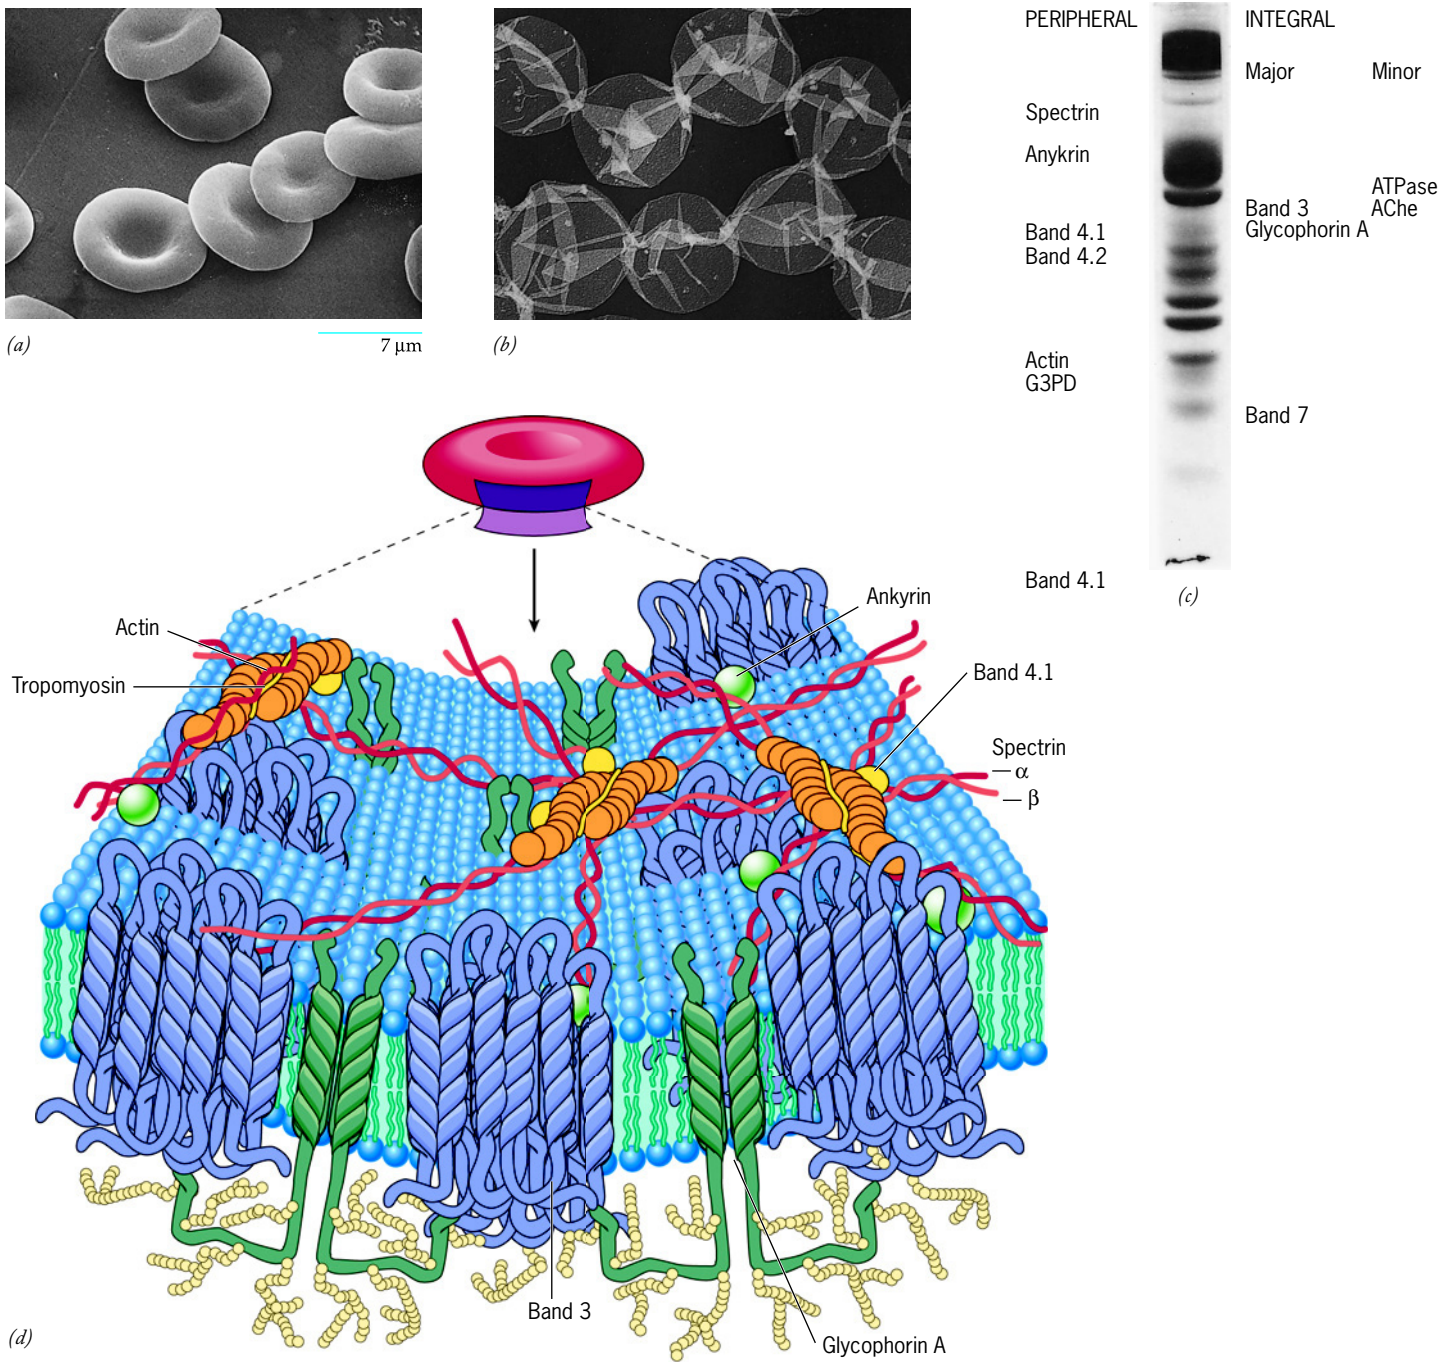

Figure 4.32 The plasma membrane of the human erythrocyte. (a) Scanning electron micrograph of human erythrocytes. (b) Micrograph showing plasma membrane ghosts, which were isolated by allowing erythrocytes to swell and hemolyze as described in the text. (c) The results of SDS-polyacrylamide gel electrophoresis (SDS-PAGE) used to fractionate the proteins of the erythrocyte membrane, which are identified at the sides of the gel. (d) A model of the erythrocyte plasma membrane as viewed from the internal surface, showing the integral proteins embedded in the lipid bilayer and the arrangement of peripheral proteins that make up the membrane's internal skeleton. (e)

the band 3 proteins in these individuals are more heavily glycosylated, which apparently compensates for the otherwise missing negative charges required to prevent cell–cell interaction. Glycophorin also happens to be the receptor utilized by the protozoan that causes malaria, providing a path for entry into the blood cell. Consequently, individuals whose erythrocytes lack glycophorin A and B are thought to be protected from acquiring malaria. Differences in glycophorin amino acid sequence determine whether a person has an MM, MN, or NN blood type.

The Erythrocyte Membrane Skeleton The peripheral proteins of the erythrocyte plasma membrane are located on its internal surface and constitute a fibrillar membrane skeleton (Figure 4.32*d,e*) that plays a major role in determining the biconcave shape of the erythrocyte. As discussed on page 143, the membrane skeleton can establish domains within the membrane that enclose particular groups of membrane proteins and may greatly restrict the movement of these proteins. The major component of the skeleton is an elongated fibrous protein, called *spectrin*. Spectrin is a heterodimer approximately 100 nm long, consisting of an α and β subunit that curl around one another. Two such dimeric molecules are linked at their head ends to form a 200-nm-long filament that is both flexible and elastic. Spectrin is attached to the internal surface of the membrane by means of noncovalent bonds to another peripheral protein, *ankyrin* (the green spheres of Figure 4.32*d*), which in turn is linked noncovalently to the cytoplasmic domain of a band 3 molecule. As is evident in Figures 4.32*d* and *e*, spectrin filaments are organized into hexagonal or pentagonal arrays. This two-dimensional network is constructed by linking both ends of each spectrin filament to a cluster of proteins that include a short filament of *actin* and *tropomyosin*, proteins typically involved in contractile activities. A number of genetic diseases (*hemolytic anemias*) characterized by fragile, abnormally shaped erythrocytes have been traced to mutations in ankyrin or spectrin.

If the peripheral proteins are removed from erythrocyte ghosts, the membrane becomes fragmented into small vesicles, indicating that the inner protein network is required to maintain the integrity of the membrane. Erythrocytes are circulating cells that are squeezed under pressure through microscopic capillaries whose diameter is considerably less than that of the erythrocytes themselves. To traverse these narrow passageways, and to do so day after day, the red blood cell must be highly deformable, durable, and capable of withstanding shearing forces that tend to pull it apart. The spectrin–actin network gives the cell the strength, elasticity, and pliability necessary to carry out its demanding function.

When first discovered, the membrane skeleton of the erythrocyte was thought to be a unique structure suited to the unique shape and mechanical needs of this cell type. However, as other cells were examined, similar types of membrane skeletons containing members of the spectrin and ankyrin families have been revealed, indicating that inner membrane skeletons are widespread. Dystrophin, for example, is a member of the spectrin family that is found in the membrane skeleton of muscle cells. Mutations in dystrophin are respon-

sible for causing muscular dystrophy, a devastating disease that cripples and kills children. As in the case of cystic fibrosis (page 163), the most debilitating mutations are ones that lead to a complete absence of the protein in the cell. The plasma membranes of muscle cells lacking dystrophin are apparently destroyed as a consequence of the mechanical stress exerted on them as the muscle contracts. As a result, the muscle cells die and eventually are no longer replaced.

REVIEW

1. Describe two techniques to measure the rates of diffusion of a specific membrane protein.
2. Compare and contrast the types of protein mobility depicted in Figure 4.28.
3. Discuss two major functions of the integral and peripheral proteins of the erythrocyte membrane.
4. Compare the rate of lateral diffusion of a lipid with that of flip-flop. What is the reason for the difference?

4.7 | The Movement of Substances Across Cell Membranes

Because the contents of a cell are completely surrounded by its plasma membrane, all communication between the cell and the extracellular medium must be mediated by this structure. In a sense, the plasma membrane has a dual function. On one hand, it must retain the dissolved materials of the cell so that they do not simply leak out into the environment, while on the other hand, it must allow the necessary exchange of materials into and out of the cell. The lipid bilayer of the membrane is ideally suited to prevent the loss of charged and polar solutes from a cell. Consequently, some special provision must be made to allow the movement of nutrients, ions, waste products, and other compounds, in and out of the cell. There are basically two means for the movement of substances through a membrane: passively by diffusion or actively by an energy-coupled transport process. Both types of movements lead to the net flux of a particular ion or compound. The term *net flux* indicates that the movement of the substance into the cell (*influx*) and out of the cell (*efflux*) is not balanced, but that one exceeds the other.

Several different processes are known by which substances move across membranes: simple diffusion through the lipid bilayer; simple diffusion through an aqueous, protein-lined channel; diffusion that is facilitated by a protein transporter; and active transport, which requires an energy-driven protein “pump” capable of moving substances against a concentration gradient (Figure 4.33). We will consider each in turn, but first we will discuss the energetics of solute movement.

The Energetics of Solute Movement

Diffusion is a spontaneous process in which a substance moves from a region of high concentration to a region of low concentration, eventually eliminating the concentration

Figure 4.33 Four basic mechanisms by which solute molecules move across membranes. The relative sizes of the letters indicate the directions of the concentration gradients. (a) Simple diffusion through the bilayer, which always proceeds from high to low concentration. (b) Simple diffusion through an aqueous channel formed within an integral membrane protein or a cluster of such proteins. As in *a*, movement is always down a concentration gradient. (c) Facilitated diffusion in which solute molecules bind specifically to a membrane protein carrier (a facilitative transporter). As in *a* and *b*, movement is always from high to low concentration. (d) Active transport by means of a protein transporter with a specific binding site that undergoes a change in affinity driven with energy released by an exergonic process, such as ATP hydrolysis. Movement occurs against a concentration gradient. (e) Examples of each type of mechanism as it occurs in the membrane of an erythrocyte.

difference between the two regions. As discussed on page 88, diffusion depends on the random thermal motion of solutes and is an exergonic process driven by an increase in entropy. We will restrict the following discussion to diffusion of substances across membranes.

The free-energy change when an uncharged solute (a nonelectrolyte) diffuses across a membrane depends on the magnitude of the concentration gradient, that is, the difference in concentration on each side of the membrane. The following relationship describes the movement of a nonelectrolyte *into* the cell:

$$\Delta G = RT \ln \frac{[C_i]}{[C_o]}$$

$$\Delta G = 2.303 RT \log_{10} \frac{[C_i]}{[C_o]}$$

where ΔG is the free-energy change (Section 3.1), R is the gas constant, T is the absolute temperature, and $[C_i]/[C_o]$ is the

ratio of the concentration of the solute on the inside (*i*) and outside (*o*) surfaces of the membrane. At 25°C,

$$\Delta G = 1.4 \text{ kcal/mol} \cdot \log_{10} \frac{[C_i]}{[C_o]}$$

If the ratio of $[C_i]/[C_o]$ is less than 1.0, then the log of the ratio is negative, ΔG is negative, and the net influx of solute is thermodynamically favored (exergonic). If, for example, the external concentration of solute is 10 times the internal concentration, $\Delta G = -1.4 \text{ kcal/mole}$. Thus, the maintenance of a tenfold concentration gradient represents a storage of 1.4 kcal/mol. As solute moves into the cell, the concentration gradient decreases, the stored energy is dissipated, and ΔG decreases until, at equilibrium, ΔG is zero. (To calculate ΔG for movement of a solute out of the cell, the term for concentration ratios becomes $[C_o]/[C_i]$).

If the solute is an electrolyte (a charged species), the overall charge difference between the two compartments must also be considered. As a result of the mutual repulsion of ions of like charges, it is thermodynamically unfavorable for an electrolyte to move across a membrane from one compartment into another compartment having a net charge of the same sign. Conversely, if the charge of the electrolyte is opposite in sign to the compartment into which it is moving, the process is thermodynamically favored. The greater the difference in charge (the potential difference or voltage) between the two compartments, the greater the difference in free energy. Thus, the tendency of an electrolyte to diffuse between two compartments depends on two gradients: a chemical gradient, determined by the concentration difference of the substance between the two compartments, and the electric potential gradient, determined by the difference in charge. Together these differences are combined to form an **electrochemical gradient**. The free-energy change for the diffusion of an electrolyte into the cell is

$$\Delta G = RT \ln \frac{[C_i]}{[C_o]} + zF\Delta E_m$$

where z is the charge of the solute, F is the Faraday constant (23.06 kcal/V · equivalent, where an equivalent is the amount of the electrolyte having one mole of charge), and ΔE_m is the potential difference (in volts) between the two compartments. We saw in the previous example that a tenfold difference in concentration of a nonelectrolyte across a membrane at 25°C generates a ΔG of -1.4 kcal/mol . Suppose the concentration gradient consisted of Na^+ ions, which were present at tenfold higher concentration outside the cell than in the cytoplasm. Because the voltage across the membrane of a cell is typically about -70 mV (page 165), the free-energy change for the movement of a mole of Na^+ ions into the cell under these conditions would be

$$\Delta G = -1.4 \text{ kcal/mol} + zF\Delta E_m$$

$$\Delta G = -1.4 \text{ kcal/mol} + (1)(23.06 \text{ kcal/V} \cdot \text{mol})(-0.07 \text{ V})$$

$$= -3.1 \text{ kcal/mol}$$

Thus under these conditions, the concentration difference and the electric potential make similar contributions to the storage of free energy across the membrane.

The interplay between concentration and potential differences is seen in the diffusion of potassium ions (K^+) out of a cell. The efflux of the ion is favored by the K^+ concentration gradient, which has a higher K^+ concentration inside the cell, but hindered by the electrical gradient that its diffusion creates, which leaves a higher negative charge inside the cell. We will discuss this subject further when we consider the topic of membrane potentials and nerve impulses in Section 4.8.

Diffusion of Substances through Membranes

Two qualifications must be met before a nonelectrolyte can diffuse passively across a plasma membrane. The substance must be present at higher concentration on one side of the membrane than the other, and the membrane must be permeable to the substance. A membrane may be permeable to a given solute either (1) because that solute can pass directly through the lipid bilayer, or (2) because that solute can traverse an aqueous pore that spans the membrane. Let us begin by considering the former route in which a substance must dissolve in the lipid bilayer on its way through the membrane.

Discussion of simple diffusion leads us to consider the polarity of a solute. One simple measure of the polarity (or nonpolarity) of a substance is its **partition coefficient**, which is the ratio of its solubility in a nonpolar solvent, such as octanol or a vegetable oil, to that in water under conditions where the nonpolar solvent and water are mixed together. Figure 4.34 shows the relationship between partition coefficient and membrane permeability of a variety of chemicals and drugs. It is evident that the greater the lipid solubility, the faster the penetration.

Another factor determining the rate of penetration of a compound through a membrane is its size. If two molecules have approximately equivalent partition coefficients, the smaller molecule tends to penetrate the lipid bilayer of a membrane more rapidly than the larger one. Very small, uncharged molecules penetrate very rapidly through cellular membranes. Consequently, membranes are highly permeable to small inorganic molecules, such as O_2 , CO_2 , NO , and H_2O , which are thought to slip between adjacent phospholipids. In contrast, larger polar molecules, such as sugars, amino acids, and phosphorylated intermediates, exhibit poor membrane penetrability. As a result, the lipid bilayer of the plasma membrane provides an effective barrier that keeps these essential metabolites from diffusing out of the cell. Some of these molecules (e.g., sugars and amino acids) must enter cells from the bloodstream, but they cannot do so by simple diffusion. Instead, special mechanisms must be available to mediate their penetration through the plasma membrane. The use of such mechanisms allows a cell to regulate the movement of substances across its surface barrier. We will return to this feature of membranes later.

The Diffusion of Water through Membranes Water molecules move much more rapidly through a cell membrane

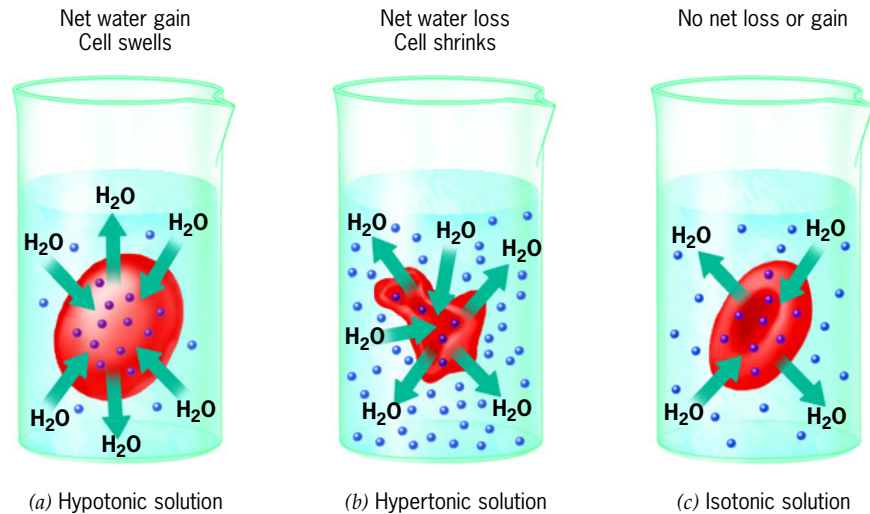

Figure 4.34 The relationship between partition coefficient and membrane permeability. In this case, measurements were made of the penetration of a variety of chemicals and drugs across the plasma membranes of the cells that line the capillaries of the brain. Substances penetrate by passage through the lipid bilayer of these cells. The partition coefficient is expressed as the ratio of solubility of a solute in octanol to its solubility in water. Permeability is expressed as penetrance (P) in cm/sec. For all but a few compounds, such as vinblastine and vincristine, penetrance is directly proportional to lipid solubility. (FROM N. J. ABBOTT AND I. A. ROMERO, MOLEC. MED. TODAY, 2:110, 1996; COPYRIGHT 1996, WITH PERMISSION FROM ELSEVIER SCIENCE.)

than do dissolved ions or small polar organic solutes, which are essentially nonpenetrating. Because of this difference in the penetrability of water versus solutes, membranes are said to be **semipermeable**. Water moves readily through a semipermeable membrane from a region of lower *solute* concentration to a region of higher *solute* concentration. This process is called **osmosis**, and it is readily demonstrated by placing a cell into a solution containing a nonpenetrating solute at a concentration different than that present within the cell itself.

When two compartments of different solute concentration are separated by a semipermeable membrane, the compartment of higher solute concentration is said to be **hypertonic** (or **hyperosmotic**) relative to the compartment of lower solute concentration, which is described as being **hypotonic** (or **hyposmotic**). When a cell is placed into a hypotonic solution, the cell rapidly gains water by osmosis and swells (Figure 4.35*a*). Conversely, a cell placed into a hypertonic solution rapidly loses water by osmosis and shrinks (Figure 4.35*b*). These simple observations show that a cell's volume is controlled by the difference between the solute concentration inside the cell and that in the extracellular medium. The swelling and shrinking of cells in slightly hypotonic and

Figure 4.35 The effects of differences in the concentration of solutes on opposite sides of the plasma membrane. (a) A cell placed in a hypotonic solution (one having a lower solute concentration than the cell) swells because of a net gain of water by osmosis. (b) A cell in a hypertonic solution shrinks because of a net loss of water by osmosis. (c) A cell placed in an isotonic solution maintains a constant volume because the inward flux of water is equal to the outward flux.

hypertonic media are usually only temporary events. Within a few minutes, the cells recover and return to their original volume. In a hypotonic medium, recovery occurs as the cells lose ions, thereby reducing their internal osmotic pressure. In a hypertonic medium, recovery occurs as the cells gain ions from the medium. Once the internal solute concentration (which includes a high concentration of dissolved proteins) equals the external solute concentration, the internal and external fluids are **isotonic** (or **isosmotic**), and no net movement of water into or out of the cells occurs (Figure 4.35c).

Osmosis is an important factor in a multitude of bodily functions. Your digestive tract, for example, secretes several liters of fluid daily, which is reabsorbed osmotically by the cells that line your intestine. If this fluid weren't reabsorbed, as happens in cases of extreme diarrhea, you would face the prospect of rapid dehydration. Plants utilize osmosis in different ways. Unlike animal cells, which are generally isotonic with the medium in which they are bathed, plant cells are generally hypertonic compared to their fluid environment. As a result, there is a tendency for water to enter the cell, causing it to develop an internal (*turgor*) pressure that pushes against its surrounding wall (Figure 4.36a). Turgor pressure provides support for nonwoody plants and for the nonwoody parts of trees, such as the leaves. If a plant cell is placed into a hypertonic medium, its volume shrinks as the plasma membrane pulls away from the surrounding cell wall, a process called **plasmolysis** (Figure 4.36b). The loss of water due to plasmolysis causes plants to lose their support and wilt.

Not all cells are equally permeable to water. In fact, many cells are much more permeable to water than can be explained by simple diffusion through the lipid bilayer. In the early 1990s, Peter Agre and colleagues at Johns Hopkins University were attempting to isolate and purify the membrane proteins responsible for the Rh antigen on the surface of red blood cells. During this pursuit, they identified a protein they thought might be the long-sought water channel of the erythrocyte membrane. To test their hypothesis, they engineered frog oocytes to incorporate the newly discovered protein into their plasma membranes and then placed the oocytes in a

Figure 4.36 The effects of osmosis on a plant cell. (a) Aquatic plants living in freshwater are surrounded by a hypotonic environment. Water therefore tends to flow into the cells, creating turgor pressure. (b) If the plant is placed in a hypertonic solution, such as seawater, the cell loses water, and the plasma membrane pulls away from the cell wall. (ED RESCHKE.)

Figure 4.37 Passage of water molecules through an aquaporin channel.

(a) Snapshot from a molecular dynamics simulation of a stream of water molecules (red and white spheres) passing in single file through the channel in one of the subunits of an aquaporin molecule residing within a membrane. (b) A model describing the mechanism by which water molecules pass through an aquaporin channel with the simultaneous exclusion of protons. Nine water molecules are shown to be lined up in single file along the wall of the channel. Each water molecule is depicted as a red circular O atom with two associated Hs. In this model, the four water molecules at the top and bottom of the channel are oriented, as the result of their interaction with the carbonyl (C=O) groups of the protein backbone (page 51), with their H atoms pointed away from the center of the channel. These water molecules are able to form hydrogen bonds (dashed lines) with their neighbors. In contrast, the single water molecule in the center of the channel is oriented in a position that prevents it from forming hydrogen bonds with other water molecules, which has the effect of interrupting the flow of protons through the channel. Animations of aquaporin channels can be found at www.nobelprize.org/nobel_prizes/chemistry/laureates/2003/animations.html (A: FROM BENOIT ROUX AND KLAUS SCHULTEN, STRUCTURE 12:1344, 2004, WITH PERMISSION FROM ELSEVIER; B: FROM R. M. STROUD ET AL., CURR. OPIN. STRUCT. BIOL. 13:428, © 2003, WITH PERMISSION FROM ELSEVIER.)

(b)

hypotonic medium. Just as predicted, the oocytes swelled due to the influx of water and eventually burst. The team had discovered a family of small integral proteins, called *aquaporins*, that allow the passive movement of water from one side of the plasma membrane to the other. Each aquaporin subunit (in the four-subunit protein) contains a central channel that is lined primarily by hydrophobic amino acid residues and is highly specific for water molecules. A billion or so water molecules can pass—in single file—through each channel every second. At the same time, H^+ ions, which normally hop along a chain of water molecules, are not able to penetrate these open pores. The apparent mechanism by which these channels are able to exclude protons has been suggested by a combination of X-ray crystallographic studies, which has revealed the structure of the protein, and molecular dynamics simulations (page 60), which has put this protein structure into operation. A model based on such simulations is shown in Figure 4.37a. Very near its narrowest point, the wall of an aquaporin channel contains a pair of precisely positioned positive charges (residues N203 and N68 in Figure 4.37b) that attract the oxygen atom of each water molecule as it speeds through the constriction in the protein. This interaction reorients the central water molecule in a position that prevents it from maintaining the hydrogen bonds that normally link it to its neighboring water molecules. This removes the bridge that would normally allow protons to move from one water molecule to the next.

animations.html (A: FROM BENOIT ROUX AND KLAUS SCHULTEN, STRUCTURE 12:1344, 2004, WITH PERMISSION FROM ELSEVIER; B: FROM R. M. STROUD ET AL., CURR. OPIN. STRUCT. BIOL. 13:428, © 2003, WITH PERMISSION FROM ELSEVIER.)

Aquaporins are particularly prominent in cells, such as those of a kidney tubule or plant root, where the passage of water plays a crucial role in the tissue's physiologic activities. The hormone vasopressin, which stimulates water retention by the collecting ducts of the kidney, acts by way of one of these proteins (AQP2). Some cases of the inherited disorder *congenital nephrogenic diabetes insipidus* arise from mutations in this aquaporin channel. Persons suffering from this disease excrete large quantities of urine because their kidneys do not respond to vasopressin.

The Diffusion of Ions through Membranes The lipid bilayer that constitutes the core of biological membranes is highly impermeable to charged substances, including small ions such as Na^+ , K^+ , Ca^{2+} , and Cl^- . Yet the rapid movement (**conductance**) of these ions across membranes plays a critical role in a multitude of cellular activities, including formation and propagation of a nerve impulse, secretion of substances into the extracellular space, muscle contraction, regulation of cell volume, and the opening of stomatal pores on plant leaves.

In 1955, Alan Hodgkin and Richard Keynes of Cambridge University first proposed that cell membranes contain **ion channels**, that is, openings in the membrane that are permeable to specific ions. During the late 1960s and 1970s, Bertil Hille of the University of Washington and Clay

Figure 4.38 Measuring ion channel conductance by patch-clamp recording.

(a) In this technique, a highly polished glass micropipette is placed against a portion of the outer surface of a cell, and suction is applied to seal the rim of the pipette against the plasma membrane. Because the pipette is wired as an electrode (a *microelectrode*), a voltage can be applied across the patch of membrane enclosed by the pipette, and the responding flow of ions through the membrane channels can be measured. As indicated in the figure, the micropipette can enclose a patch of membrane containing a single ion channel, which allows investigators to monitor the opening and closing of a single gated channel, as well as its conductance at different applied voltages. (b) The micrograph shows patch-clamp recordings being made from a single photoreceptor cell of the retina of a salamander. One portion of the cell is drawn into a glass micropipette by suction, while a second micropipette-electrode (lower right) is sealed against a small patch of the plasma membrane on

(a)

another portion of the cell. (B: FROM T. D. LAMB, H. R. MATTHEWS, AND V. TORRE, J. PHYSIOLOGY 372:319, 1986. © 1986, REPRODUCED WITH PERMISSION OF JOHN WILEY & SONS.)

Armstrong of the University of Pennsylvania began to obtain evidence for the existence of such channels. The final “proof” emerged through the work of Bert Sakmann and Erwin Neher at the Max-Planck Institute in Germany in the late 1970s and early 1980s who developed techniques to monitor the ionic current passing through a single ion channel. This is accomplished using very fine micropipette-electrodes made of polished glass that are placed on the outer cell surface and sealed to the membrane by suction. The voltage across the membrane can be maintained (*clamped*) at any particular value, and the current originating in the small patch of membrane surrounded by the pipette can be measured (Figure 4.38). These landmark studies marked the first successful investigations into the activities of individual protein molecules. Today, biologists have identified a bewildering variety of ion channels, each formed by integral membrane proteins that enclose a central aqueous pore. As might be predicted, mutations in the genes encoding ion channels can lead to many serious diseases (see Table 1 of the Human Perspective, page 162).

Most ion channels are highly selective in allowing only one particular type of ion to pass through the pore. As with the passive diffusion of other types of solutes across membranes, the diffusion of ions through a channel is always downhill, that is, from a state of higher energy to a state of lower energy. Most of the ion channels that have been identified can exist in either an open or a closed conformation; such channels are said to be **gated**. The opening and closing of the gates are subject to complex physiologic regulation and can be induced by a variety of factors depending on the particular channel. Three major categories of gated channels are distinguished:

1. **Voltage-gated channels** whose conformational state depends on the difference in ionic charge on the two sides of the membrane.
2. **Ligand-gated channels** whose conformational state depends on the binding of a specific molecule (the ligand),

which is usually not the solute that passes through the channel. Some ligand-gated channels are opened (or closed) following the binding of a molecule to the outer surface of the channel; others are opened (or closed) following the binding of a ligand to the inner surface of the channel. For example, neurotransmitters, such as acetylcholine, act on the outer surface of certain cation channels, while cyclic nucleotides, such as cAMP, act on the inner surface of certain calcium ion channels.

3. **Mechano-gated channels** whose conformational state depends on mechanical forces (e.g., stretch tension) that are applied to the membrane. Members of one family of cation channels, for example, are opened by the movements of stereocilia (see Figure 9.54) on the hair cells of the inner ear in response to sound or motions of the head.

We will focus in the following discussion on the structure and function of voltage-gated potassium ion channels because these are the best understood.

In 1998, Roderick MacKinnon and his colleagues at Rockefeller University provided the first atomic-resolution image of an ion channel protein, in this case, a bacterial K^+ ion channel called KcsA. The relationship between structure and function is evident everywhere in the biological world, but it would be difficult to find a better example than that of the K^+ ion channel depicted in Figure 4.39. As we will see shortly, the formulation of this structure led directly to an understanding of the mechanism by which these remarkable molecular machines are able to select overwhelmingly for K^+ ions over Na^+ ions, yet at the same time allow an incredibly rapid conductance of K^+ ions through the membrane. We will also see that the mechanisms of ion selectivity and conductance in this bacterial channel are virtually identical to those operating in the much larger mammalian channels. Evidently, the basic challenges in operating an ion channel were solved relatively early in evolution, although many refinements appeared over the following one or two billion years.

Figure 4.39 Three-dimensional structure of the bacterial KcsA channel and the selection of K^+ ions. This K^+ ion channel consists of four subunits, two of which are shown here. Each subunit is comprised of M1 and M2 helices joined by a P (pore) segment consisting of a short helix and a nonhelical portion that lines the channel through which the ions pass. A portion of each P segment contains a conserved pentapeptide (GYGVT) whose residues line the selectivity filter that screens for K^+ ions. The oxygen atoms of the carbonyl groups of these residues project into the channel where they can interact selectively with K^+ ions (indicated by the red mesh objects) within the filter. As indicated in the top inset, the selectivity filter contains four rings of carbonyl O atoms and one ring of threonyl O atoms; each of these five rings contains four O atoms, one donated by each subunit. The diameter of the rings is just large enough so that eight O atoms can coordinate a single K^+ ion, replacing its normal water of hydration. Although four K^+ binding sites are shown, only two are occupied at one time. (FROM RODERICK MACKINNON, NATURE MED. 5:1108, © 1999, REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD.)

The KcsA channel consists of four subunits, two of which are shown in Figure 4.39. Each subunit of Figure 4.39 is seen to contain two membrane-spanning helices (M1 and M2) and a pore region (P) at the extracellular end of the channel. P consists of a short pore helix that extends approximately one-third the width of the channel and a nonhelical loop (colored

light brown in Figure 4.39) that forms the lining of a narrow *selectivity filter*, so named because of its role in allowing only the passage of K^+ ions.

The lining of the selectivity filter contains a highly conserved pentapeptide—Gly-Tyr-Gly-Val-Thr (or GYGVT in single-letter nomenclature). The X-ray crystal structure of the KcsA channel shows that the backbone carbonyl (C=O) groups from the conserved pentapeptide (see the backbone structure on page 51) create five successive rings of oxygen atoms (four rings are made up of carbonyl oxygens from the polypeptide backbone, and one ring consists of oxygen atoms from the threonine side chain). Each ring contains four oxygen atoms (one from each subunit) and has a diameter of approximately 3 Å, which is slightly larger than the 2.7 Å diameter of a K^+ ion that has lost its normal shell of hydration. Consequently, the electronegative O atoms that line the selectivity filter can substitute for the shell of water molecules that are displaced as each K^+ ion enters the pore. In this model, the selectivity filter contains four potential K^+ ion binding sites. As indicated in the top inset of Figure 4.39, a K^+ ion bound at any of these four sites would occupy the center of a “box” having four O atoms in a plane above the ion and four O atoms in a plane below the atom. As a result, each K^+ ion in one of these sites could coordinate with eight O atoms of the selectivity filter. Whereas the selectivity filter is a precise fit for a dehydrated K^+ ion, it is much larger than the diameter of a dehydrated Na^+ ion (1.9 Å). Consequently, a Na^+ ion cannot interact optimally with the eight oxygen atoms necessary to stabilize it in the pore. As a result, the smaller Na^+ ions cannot overcome the higher energy barrier required to penetrate the pore.

Although there are four potential K^+ ion binding sites, only two are occupied at any given time. Potassium ions are thought to move, two at a time—from sites 1 and 3 to sites 2 and 4—as indicated in the top inset of Figure 4.39. The entry of a third K^+ ion into the selectivity filter creates an electrostatic repulsion that ejects the ion bound at the opposite end of the line. Studies indicate that there is virtually no energy barrier for an ion to move from one binding site to the next, which accounts for the extremely rapid flow of ions across the membrane. Taken together, these conclusions concerning K^+ ion selectivity and conductance provide a superb example of how much can be learned about biological function through an understanding of molecular structure.

The KcsA channel depicted in Figure 4.39 has a gate, just like eukaryotic channels. The opening of the gate of the KcsA channel in response to very low pH was illustrated in Figure 4.22. The structure of KcsA shown in Figure 4.39 is actually the closed conformation of the protein (despite the fact that it contains ions in its channel). It has not been possible to crystallize the KcsA channel in its open conformation, but the structure of a homologous prokaryotic K^+ channel (called MthK) in the open conformation has been crystallized and its structure determined. Comparison of the open structure of MthK and the closed structure of the homologous protein KcsA strongly suggested that gating of these molecules is accomplished by conformational changes of the cytoplasmic ends of the inner (M2) helices. In the closed conformation, as

Figure 4.40 Schematic illustration of the hinge-bending model for the opening of the bacterial KcsA channel. The M2 helices from each subunit bend outward at a specific glycine residue, which opens the gate at the intracellular end of the channel to K⁺ ions. (REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHER LTD: FROM B. L. KELLY AND A. GROSS, NATURE STRUCT. BIOL. 10:280, 2003; COPYRIGHT 2003.)

seen in Figure 4.39 and Figure 4.40, left drawing, the M2 helices are straight and cross over one another to form a “helix bundle” that seals the cytoplasmic face of the pore. In the model shown in Figure 4.40, the channel opens when the M2 helices bend at a specific hinge point where a glycine residue is located.

Now that we have seen how these prokaryotic K⁺ channels operate, we are in a better position to understand the structure and function of the more complex eukaryotic versions, which are thought to perform in a similar manner. Genes that encode a variety of distinct voltage-gated K⁺ (or Kv) channels have been isolated and the molecular anatomy of their proteins scrutinized. The Kv channels of plants play an important role in salt and water balance and in regulation of cell volume. The Kv channels of animals are best known for their role in muscle and nerve function, which is explored at the end of the chapter. Eukaryotic Kv channel subunits contain six membrane-associated helices, named S1–S6, which are shown two-dimensionally in Figure 4.41. These six helices can be grouped into two functionally distinct domains:

1. a **pore domain**, which has the same basic architecture as that of the entire bacterial channel illustrated in Figure 4.39 and

contains the selectivity filter that permits the selective passage of K⁺ ions. Helices M1 and M2 and the P segment of the KcsA channel of Figure 4.39 are homologous to helices S5 and S6 and the P segment of the voltage-gated eukaryotic channel illustrated in Figure 4.41. Like the four M2 helices of KcsA, the four S6 helices line much of the pore, and their configuration determines whether the gate to the channel is open or closed.

2. a **voltage-sensing domain** consisting of helices S1–S4 that senses the voltage across the plasma membrane (as discussed below).

The three-dimensional crystal structure of a complete eukaryotic Kv channel purified from rat brain is shown in Figure 4.42. Determination of this structure was made possible by use of a mixture of detergent and lipid throughout the purification and crystallization process. The presence of negatively charged phospholipids is thought to be important in maintaining the native structure of the membrane protein and promoting its function as a voltage-gated channel. Like the KcsA channel, a single eukaryotic Kv channel consists of four homologous subunits arranged symmetrically around the central ion-conducting pore. The selectivity filter, and thus the presumed mechanism of K⁺ ion selection, is virtually identical in the prokaryotic KcsA and eukaryotic Kv proteins. The gate leading into a Kv channel is formed by the inner ends of the S6 helices and is thought to open and close in a manner roughly similar to that of the M2 helices of the bacterial channel (shown in Figure 4.40). The protein depicted in Figure 4.42 represents the open state of the channel.⁶

The S4 helix, which contains several positively charged amino acid residues spaced along the polypeptide chain (inset of Figure 4.41), acts as the key element of the voltage sensor. The voltage-sensing domain is seen to be connected to the

⁶Recent studies strongly suggest that K⁺ channels are gated by two distinct mechanisms: one involving the opening and closing of the inner helix bundle as described here and another involving the selectivity filter, which is not discussed (see *PNAS* 107:7623, 2010 and *Nature* 466:203, 2010).

Figure 4.41 The structure of one subunit of a eukaryotic, voltage-gated K⁺ channel. A two-dimensional portrait of a K⁺ channel subunit showing its six transmembrane helices and a portion of the polypeptide (called the pore helix or P) that dips into the protein to form part of the channel’s wall. The inset shows the sequence of amino acids of the positively charged S4 helix of the *Drosophila* K⁺ *Shaker* ion channel, which serves as a voltage sensor. The positively charged side chains are situated at every third residue along the otherwise hydrophobic helix. This member of the Kv family is called a *Shaker* channel because flies with certain mutations in the protein shake vigorously when anesthetized with ether. The *Shaker* channel was the first K⁺ channel to be identified and cloned in 1987.

Figure 4.42 Three-dimensional structure of a voltage-gated mammalian K^+ channel. (a) The crystal structure of the entire tetrameric Kv1.2 channel, a member of the *Shaker* family of K^+ ion channels found in nerve cells of the brain. The transmembrane portion is shown in red, and the cytoplasmic portion in blue. The potassium ion binding sites are indicated in green. (b) Ribbon drawing of the same channel shown in a, with the four subunits that make up the channel shown in different colors. If you focus on the red subunit, you can see (1) the spatial separation between the voltage-sensing and pore domains of the subunit and (2) the manner in which the voltage-sensing domain from each subunit is present on the outer edge of the pore domain of a neighboring subunit. The cytoplasmic portion of this particular channel consists of a T1 domain, which is part of the channel polypeptide itself,

and a separate β polypeptide. (c) Ribbon drawing of a single subunit showing the spatial orientation of the six membrane-spanning helices (S1–S6) and also the presence of the S4–S5 linker helix, which connects the voltage-sensing and pore domains. This linker transmits the signal from the S4 voltage sensor that opens the channel. The inner surface of the channel below the pore domain is lined by the S6 helix (roughly similar to the M2 helix of the bacterial channel shown in Figure 4.39). The channel shown here is present in the open configuration with the S6 helices curved outward (compare to Figure 4.40) at the site marked PVP (standing for Pro–Val–Pro, which is likely the amino acid sequence of the “hinge”). (FROM STEPHEN B. LONG ET AL., SCIENCE 309:867, 899, 2005, COURTESY OF RODERICK MACKINNON; © 2005, REPRINTED WITH PERMISSION FROM AAAS.)

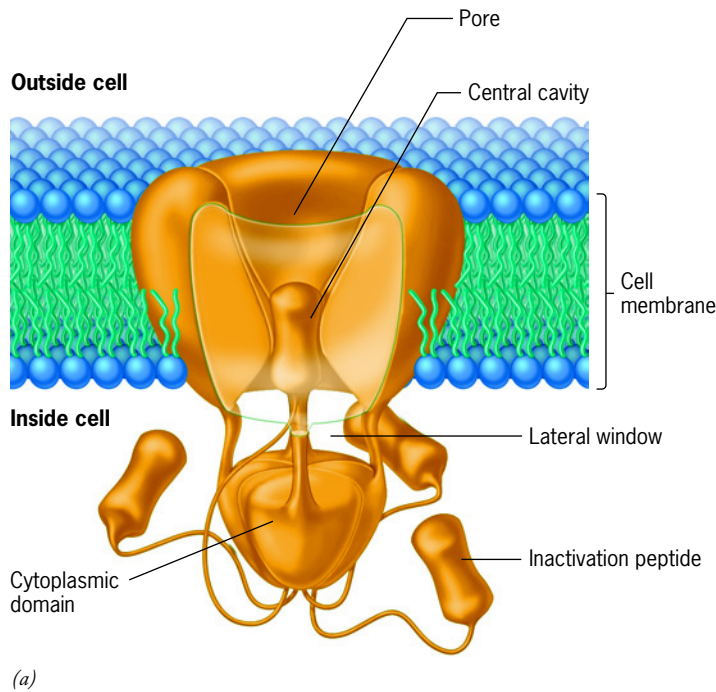

pore domain by a short linker helix denoted as S4–S5 in the model in Figure 4.42. Under resting conditions, the negative potential across the membrane (page 165) keeps the gate closed. A change in the potential to a more positive value (a depolarization, page 166) exerts an electric force on the S4 helix. This force is thought to cause the transmembrane S4 helix to move in such a way that its positively charged residues shift from a position where they were exposed to the cytoplasm to a new position where they are exposed to the outside of the cell. Voltage sensing is a dynamic process whose mechanism cannot be resolved by a single static view of the protein such as that shown in Figure 4.42. In fact, several competing models describing the mechanism of action of the voltage sensor are currently debated. However it occurs, the movement of the S4 helix in response to membrane depolarization initiates a series of conformational changes within the protein that opens the gate at the cytoplasmic end of the channel.

Once opened, more than ten million potassium ions can pass through the channel per second, which is nearly the rate that would occur by free diffusion in solution. Because of the large ion flux, the opening of a relatively small number of K^+ channels has significant impact on the electrical properties of the membrane. After the channel is open for a few millisec-

onds, the movement of K^+ ions is “automatically” stopped by a process known as inactivation. To understand channel inactivation, we have to consider an additional portion of a Kv channel besides the two transmembrane domains discussed above.

Eukaryotic Kv channels typically contain a large cytoplasmic structure whose composition varies among different channels. As indicated in Figure 4.43a inactivation of the channel is accomplished by movement of a small inactivation peptide that dangles from the cytoplasmic portion of the protein. The inactivation peptide is thought to gain access to the cytoplasmic mouth of the pore by snaking its way through one of four “side windows” indicated in the figure. When one of these dangling peptides moves up into the mouth of the pore (Figure 4.43a), the passage of ions is blocked, and the channel is inactivated. At a subsequent stage of the cycle, the inactivation peptide is released, and the gate to the channel is closed. It follows from this discussion that the potassium channel can exist in three different states—open, inactivated, and closed—which are illustrated schematically in Figure 4.43b.

Potassium channels come in many different varieties. It is remarkable that *C. elegans*, a nematode worm whose body consists of only about 1000 cells, contains approximately 80

(a)

different genes that encode K^+ channels. It is evident that a single cell—whether in a nematode, human, or plant—is likely to possess a variety of different K^+ channels that open and close in response to different voltages. In addition, the voltage required to open or close a particular K^+ channel can vary depending on whether or not the channel protein is phosphorylated, which in turn is regulated by hormones and other factors. It is apparent that ion channel function is under the control of a diverse and complex set of regulatory agents. The structure and function of a very different type of ion channel, the ligand-gated nicotinic acetylcholine receptor, is the subject of the Experimental Pathways section at the end of this chapter.

Facilitated Diffusion

Substances always diffuse across a membrane from a region of higher concentration on one side to a region of lower concentration on the other side, but they do not always diffuse through the lipid bilayer or through a channel. In many cases, the diffusing substance first binds selectively to a membrane-spanning protein, called a **facilitative transporter**, that facilitates the diffusion process. The binding of the solute to the facilitative transporter on one side of the membrane is thought to trigger a conformational change in the protein, exposing the solute to the other surface of the membrane, from where it can diffuse down its concentration gradient. This mechanism is illustrated in Figure 4.44. Because they operate passively, that is, without being coupled to an energy-releasing system, facilitated transporters can mediate the movement of solutes equally well in both directions. The direction of net flux depends on the relative concentration of the substance on the two sides of the membrane.

Facilitated diffusion, as this process is called, is similar in many ways to an enzyme-catalyzed reaction. Like enzymes,

Figure 4.43 Conformational states of a voltage-gated K^+ ion channel. (a) Three-dimensional model of a eukaryotic K^+ ion channel. Inactivation of channel activity occurs as one of the inactivation peptides, which dangle from the cytoplasmic portion of the complex, fits into the cytoplasmic opening of the channel. (b) Schematic representation of a view into a K^+ ion channel, perpendicular to the membrane from the cytoplasmic side, showing the channel in the closed (resting), open, and inactivated state. (B: REPRINTED FROM NEURON, VOL. 20, C. M. ARMSTRONG AND B. HILLE, VOLTAGE-GATED ION CHANNELS AND ELECTRICAL ESCITABILITY, P. 377; COPYRIGHT 1998, WITH PERMISSION FROM ELSEVIER SCIENCE.)

facilitative transporters are specific for the molecules they transport, discriminating, for example, between D and L stereoisomers (page 44). In addition, both enzymes and

Figure 4.44 Facilitated diffusion. A schematic model for the facilitated diffusion of glucose depicts the alternating conformation of a carrier that exposes the glucose binding site to either the inside or outside of the membrane. Figure 4.45 The kinetics of facilitated diffusion as compared to that of simple physical diffusion.

transporters exhibit saturation-type kinetics (Figure 4.45). Unlike ion channels, which can conduct millions of ions per second, most facilitative transporters can move only hundreds to thousands of solute molecules per second across the membrane. Another important feature of facilitative transporters is that, like enzymes and ion channels, their activity can be regulated. Facilitated diffusion is particularly important in mediating the entry and exit of polar solutes, such as sugars and amino acids, that do not penetrate the lipid bilayer. This is illustrated in the following section.

The Glucose Transporter: An Example of Facilitated Diffusion Glucose is the body's primary source of direct energy, and most mammalian cells contain a membrane protein that facilitates the diffusion of glucose from the bloodstream into the cell (as depicted in Figures 4.44 and 4.49). A gradient favoring the continued diffusion of glucose into the cell is maintained by phosphorylating the sugar after it enters the cytoplasm, thus lowering the intracellular glucose concentration. Humans have at least five related proteins (isoforms) that act as facilitative glucose transporters. These isoforms, termed GLUT1 to GLUT5, are distinguished by the tissues in which they are located, as well as their kinetic and regulatory characteristics.

Insulin is a hormone produced by endocrine cells of the pancreas and plays a key role in maintaining proper blood sugar levels. An increase in blood glucose levels triggers the secretion of insulin, which stimulates the uptake of glucose into various target cells, most notably skeletal muscle and fat cells (adipocytes). Insulin-responsive cells share a common isoform of the facilitative glucose transporter, specifically GLUT4. When insulin levels are low, these cells contain relatively few glucose transporters on their plasma membrane. Instead, the transporters are present within the membranes of cytoplasmic vesicles. Rising insulin levels act on target cells to stimulate the fusion of the cytoplasmic vesicles to the plasma membrane, which moves transporters to the cell surface where they can bring glucose into the cell (see Figure 15.26).

Active Transport

Life cannot exist under equilibrium conditions (page 93). Nowhere is this more apparent than in the imbalance of ions across the plasma membrane. The differences in concentration of the major ions between the outside and inside of a typical mammalian cell are shown in Table 4.3. The ability of a cell to generate such steep concentration gradients across its plasma membrane cannot occur by either simple or facilitated diffusion. Rather, these gradients must be generated by **active transport**.

Like facilitated diffusion, active transport depends on integral membrane proteins that selectively bind a particular solute and move it across the membrane in a process driven by changes in the protein's conformation. Unlike facilitated diffusion, however, movement of a solute against a gradient requires the coupled input of energy. Consequently, the endergonic movement of ions or other solutes across the membrane against a concentration gradient is coupled to an exergonic process, such as the hydrolysis of ATP, the absorbance of light, the transport of electrons, or the flow of other substances down their gradients. Proteins that carry out active transport are often referred to as "pumps."

Primary Active Transport: Coupling Transport to ATP Hydrolysis In 1957, Jens Skou, a Danish physiologist, discovered an ATP-hydrolyzing enzyme in the nerve cells of a crab that was only active in the presence of both Na^+ and K^+ ions. Skou proposed, and correctly so, that this enzyme, which was responsible for ATP hydrolysis, was the same protein that was active in transporting the two ions; the enzyme was called the Na^+/K^+ -ATPase, or the *sodium-potassium pump*.

Unlike the protein-mediated movement of a facilitated diffusion system, which will carry the substance equally well in either direction, active transport drives the movement of ions in only one direction. It is the Na^+/K^+ -ATPase that is responsible for the large excess of Na^+ ions outside of the cell and the large excess of K^+ ions inside the cell. The positive charges carried by these two cations are balanced by negative charges carried by various anions so that the extracellular and intracellular compartments are, for the most part, electrically neutral. Cl^- ions are present at greater concentration outside of cells, where they balance the extracellular Na^+ ions. The abundance of intracellular K^+ ions is balanced primarily by excess negative charges carried by proteins and nucleic acids.

Table 4.3 Ion Concentrations Inside and Outside of a Typical Mammalian Cell

	Extracellular concentration	Intracellular concentration	Ionic gradient
Na^+	150 mM	10 mM	15×
K^+	5 mM	140 mM	28×
Cl^-	120 mM	10 mM	12×
Ca^{2+}	10^{-3} M	10^{-7} M	10,000×
H^+	$10^{-7.4}$ M (pH of 7.4)	$10^{-7.2}$ M (pH of 7.2)	Nearly 2×

The ion concentrations for the squid axon are given on page 177.

FIGURE IN FOCUS

The ratio of $\text{Na}^+ : \text{K}^+$ pumped by the Na^+/K^+ -ATPase is not 1:1, but 3:2 (see Figure 4.46). In other words, for each ATP hydrolyzed, three sodium ions are pumped out as two potassium ions are pumped in. Because of this pumping ratio, the Na^+/K^+ -ATPase is *electrogenic*, which means that it contributes directly to the separation of charge across the membrane. The Na^+/K^+ -ATPase is an example of a *P-type* ion pump. The “P” stands for phosphorylation, indicating that, during the pumping cycle, the hydrolysis of ATP leads to the transfer of the released phosphate group to an aspartic acid residue of the transport protein. As denoted by the name of the protein, this reaction is catalyzed by the pump itself.

Consider the activity of the protein. It must pick up sodium or potassium ions from a region of low concentration, which means that the protein must have a relatively high affinity for the

ions. Then the protein must release the ions on the other side of the membrane into a much greater concentration of each ion. To do this, the affinity of the protein for that ion must decrease. Thus, the affinity for each ion on the two sides of the membrane must be different. This is achieved by ATP hydrolysis and the subsequent release of ADP, which induces a large conformational change within the protein molecule. The change in protein structure—between the E_1 and E_2 conformations—also serves to alternately expose the ion binding sites to the opposite side of the membrane, as discussed in the following paragraph.

A proposed scheme for the pumping cycle of the Na^+/K^+ -ATPase is shown in Figure 4.46a, which is based on recent X-ray crystallographic structures of P-type ion pumps. In step 1, Figure 4.46a, the pump is in the E_1 conformation, and the ion binding sites are accessible to the inside of the cell. In this step, the

protein has bound three Na^+ ions and an ATP. In step 2, a gate within the protein has closed, shifting the pump into an occluded E_1 state in which the Na^+ ions can no longer flow back into the cytosol. Hydrolysis of the bound ATP (step 2 \rightarrow 3) and release of ADP (step 3 \rightarrow 4) cause the change from the E_1 to the E_2 conformation. In doing so, the binding site becomes accessible to the extracellular compartment, and the protein loses its affinity for Na^+ ions, which are then released outside the cell. Once the three Na^+ ions have been released, the protein picks up two K^+ ions (step 5). The closing of another gate within the protein shifts the pump into an occluded state (step 6), preventing back flow of the K^+ ions into the extracellular space. Occlusion is followed by dephosphorylation (step 6 \rightarrow 7) and ATP binding (step 8), which induces the return of the protein to the original E_1 conformation. In this state, the binding site is open to the internal surface of the membrane and has lost its affinity for K^+ ions, leading to the release of these ions into the cell. The cycle is then repeated. A model of the crystal structure of the Na^+/K^+ -ATPase structure is shown in Figure 4.46*b*. Because they require complex conformational changes, these active transport pumps move ions across membranes at rates that are several orders of magnitude lower than their flow through ion channels.

The sodium–potassium pump is found only in animal cells. This protein is thought to have evolved in primitive animals as the primary means to maintain cell volume and as the mechanism to generate the steep Na^+ and K^+ gradients that play such a key role in the formation of impulses in nerve and muscle cells. These same ionic gradients are used in nonexcitable cells to power the movement of other solutes as discussed below. The importance of the sodium–potassium pump becomes evident when one considers that it consumes approximately one-third of the energy produced by most animal cells and two-thirds of the energy produced by nerve cells. Digitalis, a steroid obtained

from the foxglove plant that has been used for 200 years as a treatment for congestive heart disease, binds to the Na^+/K^+ -ATPase. Digitalis strengthens the heart's contraction by inhibiting the Na^+/K^+ pump, which leads to a chain of events that increases Ca^{2+} availability inside the muscle cells of the heart.

Other Primary Ion Transport Systems The best studied P-type pump is the Ca^{2+} -ATPase whose three-dimensional structure has been determined at several stages of the pumping cycle. The calcium pump is present in the membranes of the endoplasmic reticulum, where it actively transports calcium ions out of the cytosol into the lumen of this organelle. Plant cells have a H^+ -transporting, P-type, plasma membrane pump. In plants, this proton pump plays a key role in the secondary transport of solutes (discussed later), in the control of cytosolic pH, and possibly in control of cell growth by means of acidification of the plant cell wall.

The epithelial lining of the stomach also contains a P-type pump, the H^+/K^+ -ATPase, which secretes a solution of concentrated acid (up to 0.16 N HCl) into the stomach chamber. In the resting state, these pump molecules are situated in cytoplasmic membranes of the parietal cells of the stomach lining and are nonfunctional (Figure 4.47). When food enters the stomach, a hormonal message is transmitted to the parietal cells that causes the pump-containing membranes to move to the apical cell surface, where they fuse with the plasma membrane and begin secreting acid (Figure 4.47). In addition to functioning in digestion, stomach acid can also lead to heartburn. Prilosec and related drugs are widely used to prevent heartburn by inhibiting the stomach's H^+/K^+ -ATPase. Other acid-blocking heartburn medications (e.g., Zantac, Pepcid, and Tagamet) do not inhibit the H^+/K^+ -ATPase directly, but block a receptor on the surface

Figure 4.47 Control of acid secretion in the stomach. In the resting state, the H^+/K^+ -ATPase molecules are present in the walls of cytoplasmic vesicles. Food entering the stomach triggers a cascade of hormone-stimulated reactions in the stomach wall leading to the release of histamine, which binds to a receptor on the surface of the acid-secreting parietal cells. Binding of histamine to its receptor stimulates a response that causes the H^+/K^+ -ATPase-containing vesicles to fuse to the plasma membrane, forming deep folds, or canaliculi. Once

at the surface, the transport protein is activated and pumps protons into the stomach cavity against a concentration gradient (indicated by the size of the letters). The heartburn drugs Prilosec, Nexium, and Prevacid block acid secretion by directly inhibiting the H^+/K^+ -ATPase, whereas several other acid-blocking medications interfere with activation of the parietal cells. Acid-neutralizing medications provide basic anions that combine with the secreted protons.

of the parietal cells, thereby stopping the cells from becoming activated by the hormone.

Unlike P-type pumps, *V-type* pumps utilize the energy of ATP without forming a phosphorylated protein intermediate. V-type pumps actively transport hydrogen ions across the walls of cytoplasmic organelles and vacuoles (hence the designation V-type). They occur in the membranes that line lysosomes, secretory granules, and plant cell vacuoles where they maintain the low pH of the contents. V-type pumps have also been found in the plasma membranes of a variety of cells. For example, a V-type pump in the plasma membranes of kidney tubules helps maintain the body's acid-base balance by secreting protons into the forming urine. V-type pumps are large multi-subunit complexes (shown in Figure 4.4d) and similar in structure to that of the ATP synthase shown in Figure 5.23.

Another diverse group of proteins that actively transport ions is the *ATP-binding cassette (ABC) transporters*, so called because all of the members of this superfamily share a homologous ATP-binding domain. The best studied ABC transporter is described in the accompanying Human Perspective.

Using Light Energy to Actively Transport Ions *Halobacterium salinarium* (or *H. halobium*) is an archaeobacterium that lives in extremely salty environments, such as that found in the Great Salt Lake. When grown under anaerobic conditions, the plasma membranes of these prokaryotes take on a purple color due to the presence of one particular protein, *bacteriorhodopsin*, which acts a light-driven proton pump. As shown in Figure 4.48, bacteriorhodopsin contains retinal, the same prosthetic group present in rhodopsin, the light-absorbing protein of the rods of the vertebrate retina. The absorption of light energy by the retinal group induces a series of conformational changes in the protein that cause a proton to move from the retinal group, through a channel in the protein, to the cell exterior (Figure 4.48). The proton donated by the photoexcited retinal is replaced by another proton transferred to the protein from the cytoplasm. In effect, this process results in the translocation of protons from the cytoplasm to the external environment, thereby generating a steep H^+ gradient across the plasma membrane. This gradient is subsequently used by an ATP-synthesizing enzyme to phosphorylate ADP, as described in the next chapter.

Secondary Active Transport (or Cotransport): Coupling Transport to Existing Ion Gradients The establishment of concentration gradients, such as those of Na^+ , K^+ , and H^+ , provides a means by which free energy can be stored in a cell. The potential energy stored in ionic gradients is utilized by a cell in various ways to perform work, including the transport of other solutes. Consider the physiologic activity of the intestine. Within its lumen, enzymes hydrolyze high-molecular-weight polysaccharides into simple sugars, which are absorbed by the epithelial cells that line the intestine. The movement of glucose across the apical plasma membrane of the epithelial cells, against a concentration gradient, occurs by **cotransport** with sodium ions, as illustrated in Figure 4.49. The Na^+ concentration is kept very low within the cells by the action of a *primary* active transport system (the Na^+/K^+ -ATPase), located in the basal and lateral plasma membrane, which

Figure 4.48 Bacteriorhodopsin: a light-driven proton pump. The protein contains seven membrane-spanning helices and a centrally located retinal group (shown in purple), which serves as the light-absorbing element (chromophore). Absorption of a photon of light causes a change in the electronic structure of retinal, leading to the transfer of a proton from the $-NH^+$ group to a closely associated, negatively charged aspartic acid residue (#85) (step 1). The proton is then released to the extracellular side of the membrane (step 2) by a relay system consisting of several amino acid residues (Asp82, Glu204, and Glu194). The spaces between these residues are filled with hydrogen-bonded water molecules that help shuttle protons along the pathway. The deprotonated retinal is returned to its original state (step 3) when it accepts a proton from an undissociated aspartic acid residue (Asp96) located near the cytoplasmic side of the membrane. Asp96 is then reprotonated by a H^+ from the cytoplasm (step 4). Asp85 is deprotonated (step 5) prior to receiving a proton from retinal in the next pumping cycle. As a result of these events, protons move from the cytoplasm to the cell exterior through a central channel in the protein. (FROM HARTMUT LUECKE ET AL., COURTESY OF JANOS K. LANYI, SCIENCE 286:255, 1999; © 1999, REPRINTED WITH PERMISSION FROM AAAAS.)

pumps sodium ions out of the cell against a concentration gradient. The tendency for sodium ions to diffuse back across the apical plasma membrane down their concentration gradient is “tapped” by the epithelial cells to drive the cotransport of glucose molecules into the cell *against* a concentration gradient. The glucose molecules are said to be driven by *secondary active transport*. In this case, the transport protein, called a *Na^+ /glucose cotransporter*, moves two sodium ions and one glucose molecule with each cycle. Once inside, the glucose molecules diffuse through the cell and are moved across the basal membrane by facilitated diffusion (page 157).

Figure 4.49 Secondary transport: the use of energy stored in an ionic gradient. The Na^+/K^+ -ATPase residing in the plasma membrane of the lateral surface maintains a very low cytosolic concentration of Na^+ . The Na^+ gradient across the plasma membrane represents a storage of energy that can be tapped to accomplish work, such as the transport of glucose by a $\text{Na}^+/\text{glucose}$ cotransporter located in the apical plasma membrane. Once transported across the apical surface into the cell, the glucose molecules diffuse to the basal surface where they are carried by a glucose facilitative transporter out of the cell and into the bloodstream. The relative size of the letters indicates the directions of the respective concentration gradients. Two Na^+ ions are transported for each glucose molecule; the 2:1 $\text{Na}^+/\text{glucose}$ provides a much greater driving force for moving glucose into the cell than a 1:1 ratio.

To appreciate the power of an ion gradient in accumulating other types of solutes in cells, we can briefly consider the energetics of the $\text{Na}^+/\text{glucose}$ cotransporter. Recall from page 148 that the free-energy change for the movement of a mole of Na^+ ions into the cell is equal to -3.1 kcal/mol, and thus 6.2 kcal for two moles of Na^+ ions, which would be available to transport one mole of glucose uphill into the cell. Recall also from page 148 that the equation for the movement of a nonelectrolyte, such as glucose, across the membrane is

$$\Delta G = RT \ln \frac{[C_i]}{[C_o]}$$

$$\Delta G = 2.303 RT \log_{10} \frac{[C_i]}{[C_o]}$$

Using this equation, we can calculate how steep a concentration gradient of glucose (X) that this cotransporter can generate. At 25°C ,

$$-6.2 \text{ kcal/mol} = 1.4 \text{ kcal/mol} \cdot \log_{10} X$$

$$\log_{10} X = -4.43$$

$$X = \frac{1}{23,000}$$

This calculation indicates that the $\text{Na}^+/\text{glucose}$ cotransporter is capable of transporting glucose into a cell against a concentration gradient greater than 20,000-fold.

Plant cells rely on secondary active transport systems to take up a variety of nutrients, including sucrose, amino acids, and nitrate. In plants, uptake of these compounds is coupled to the downhill, inward movement of H^+ ions rather than Na^+ ions. The secondary active transport of glucose into the epithelial cells of the intestine and the transport of sucrose into a plant cell are examples of *symport*, in which the two transported species (Na^+ and glucose or H^+ and sucrose) move in the same direction. Numerous cotransporters have been isolated that engage in *antiport*, in which the two transported species move in opposite directions. For example, cells often maintain a proper cytoplasmic pH by coupling the inward, downhill movement of Na^+ with the outward movement of H^+ . Cotransporters that mediate antiport are usually called *exchangers*. The three-dimensional structures of a number of secondary transporters have been solved in recent years, and, like the Na^+/K^+ -ATPase, they exhibit a transport cycle in which the protein's binding sites gain alternating access to the cytoplasm and the extracellular space. A proposed model of the transport cycle of one of the major families of secondary transporters is shown in Figure 4.50.

Figure 4.50 A schematic model of the transport cycle of a secondary transporter. Four different conformational states during the transport cycle of a bacterial symporter of the LeuT family are shown. The protein actively transports the amino acid leucine into the cell using the established Na^+ ion gradient as its source of energy. In step 1, the outer gate in the protein is open, which allows both Na^+ and leucine to reach their binding sites from the extracellular space. In step 2, the outer gate closes, occluding the substrates within the protein. In step 3, a second leucine molecule binds to another site just outside the outer gate. In step 4, the inner gate opens and the substrates are released into the cytoplasm. The protein returns to its original state when the inner gate is closed and the outer gate is opened. THE HUMAN PERSPECTIVE

Defects in Ion Channels and Transporters as a Cause of Inherited Disease

Several severe, inherited disorders have been traced to mutations in genes that encode ion channel proteins (Table 1). Most of the disorders listed in Table 1 affect the movement of ions across the plasma membranes of excitable cells (i.e., muscle, nerve, and sensory cells), reducing the ability of these cells to develop or transmit impulses (page 167). In contrast, cystic fibrosis, the best studied and most common inherited ion channel disorder, results from a defect in the ion channels of epithelial cells.

On average, 1 out of every 25 persons of Northern European descent carries one copy of the mutant gene that can cause cystic fibrosis. Because they show no symptoms of the mutant gene, most heterozygotes are unaware that they are carriers. Consequently, approximately 1 out of every 2500 infants in this Caucasian population ($1/25 \times 1/25 \times 1/4$) is homozygous recessive at this locus and born with cystic fibrosis (CF). Although cystic fibrosis affects various organs, including the intestine, pancreas, sweat glands, and reproductive tract, the respiratory tract usually exhibits the most severe effects. Victims of CF produce a thickened, sticky mucus that is very hard to propel out of the airways. Afflicted individuals typically suffer from chronic lung infections and inflammation, which progressively destroy pulmonary function.

The gene responsible for cystic fibrosis was isolated in 1989. Once the sequence of the CF gene was determined and the amino acid sequence of the corresponding polypeptide was deduced, it was apparent that the polypeptide was a member of the ABC transporter superfamily. The protein was named *cystic fibrosis transmembrane conductance regulator* (*CFTR*), an ambiguous term that reflected the fact that researchers weren't sure of its precise function. The question was thought to be answered after the protein was purified, incorporated into artificial lipid bilayers, and shown to act as a cyclic AMP-regulated chloride channel, not a transporter. But subsequent studies have added numerous complications to the story as it has been shown

that, in addition to functioning as a chloride channel, CFTR also (1) conducts bicarbonate (HCO_3^-) ions, (2) suppresses the activity of an epithelial Na^+ ion channel (ENaC), and (3) stimulates the activity of a family of epithelial chloride/bicarbonate exchangers. As the role of CFTR has become more complex, it has become difficult to establish precisely how a defect in this protein leads to the development of chronic lung infections. While there is considerable debate, many researchers would agree with the following statements.

Because the movement of water out of epithelial cells by osmosis follows the movement of salts, abnormalities in the flux of Cl^- , HCO_3^- , and/or Na^+ caused by CFTR deficiency leads to a decrease in the fluid that bathes the epithelial cells of the airways (Figure 1). A reduction in volume of the surface liquid, and a resulting increase in viscosity of the secreted mucus, impair the function of the cilia that push mucus and bacteria out of the respiratory tract. Many CF patients are helped by inhaling a mist of hypertonic saline, which helps to draw more water into the airways and reduce the viscosity of the mucus. Clinical trials are also being carried out on compounds that have the potential to increase the volume of surface fluid by altering the movements of ions in and out of the epithelial cells (Figure 1). These compounds include Na^+ -channel inhibitors (e.g., GS-9411) with the potential to reduce Na^+ ion absorption from the airway fluid into the epithelium and activators of Cl^- channels (other than CFTR) (e.g., Moli1901) with the potential to increase Cl^- ion conductance from the epithelium into the airway fluid.

In the past decade, researchers have identified more than 1000 different mutations that give rise to cystic fibrosis. However, approximately 70 percent of the alleles responsible for cystic fibrosis in the United States contain the same genetic alteration (designated ΔF508)—they are all missing three base pairs of DNA that encode a phenylalanine at position 508, within one of the cytoplasmic domains of the CFTR polypeptide. Subsequent research has revealed

Table 1

Inherited disorder	Type of channel	Gene	Clinical consequences
Familial hemiplegic migraine (FHM)	Ca^{2+}	<i>CACNL1A4</i>	Migraine headaches
Episodic ataxia type-2 (EA-2)	Ca^{2+}	<i>CACNL1A4</i>	Ataxia (lack of balance and coordination)
Hypokalemic periodic paralysis	Ca^{2+}	<i>CACNL1A3</i>	Periodic myotonia (muscle stiffness) and paralysis
Episodic ataxia type-1	K^+	<i>KCNA1</i>	Ataxia
Benign familial neonatal convulsions	K^+	<i>KCNQ2</i>	Epileptic convulsions
Nonsyndromic dominant deafness	K^+	<i>KCNQ4</i>	Deafness
Long QT syndrome	K^+	<i>HERG</i> <i>KCNQ1</i> , or <i>SCN5A</i>	Dizziness, sudden death from ventricular fibrillation
Hyperkalemic periodic paralysis	Na^+	<i>SCN4A</i>	Periodic myotonia and paralysis
Liddle Syndrome	Na^+	<i>B-ENaC</i>	Hypertension (high blood pressure)
Myasthenia gravis	Na^+	<i>nAChR</i>	Muscle weakness
Dent's disease	Cl^-	<i>CLCN5</i>	Kidney stones
Myotonia congenita	Cl^-	<i>CLC-1</i>	Periodic myotonia
Bartter's syndrome type IV	Cl^-	<i>CLC-Kb</i>	Kidney dysfunction, deafness
Cystic fibrosis	Cl^-	<i>CFTR</i>	Lung congestion and infections
Cardiac arrhythmias	Na^+ K^+ Ca^{2+}	many different genes	Irregular or rapid heartbeat

Figure 1 An explanation for the debilitating effects on lung function from the absence of the CFTR protein.

In the airway epithelium of a normal individual, water flows out of the epithelial cells in response to the outward movement of ions, thus hydrating the surface mucous layer. The hydrated mucous layer, with its trapped bacteria, is readily moved out of the airways.

In the airway epithelium of a person with cystic fibrosis, the abnormal movement of ions causes water to flow in the opposite direction, thus dehydrating the mucous layer.

trapped bacteria cannot be moved out of the airways, which allows them to proliferate as a biofilm (page 13) and cause chronic infections.

that CFTR polypeptides lacking this particular amino acid fail to be processed normally within the membranes of the endoplasmic reticulum and, in fact, never reach the surface of epithelial cells. As a result, CF patients who are homozygous for the $\Delta F508$ allele completely lack the CFTR channel in their plasma membranes and have a severe form of the disease. When cells from these patients are grown in culture at lower temperature, the mutant protein is transported to the plasma membrane where it functions quite well. This finding has prompted a number of drug companies to screen for small molecules that can bind to these mutant CFTR molecules, preventing their destruction in the cytoplasm and allowing them to reach the cell surface. One of these candidate drugs, VX-809, is in phase II clinical trials. VX-809 is given in combination with another drug, Kalydeco, which can keep the ion channel open if it arrives at the cell surface. Kalydeco has recently been approved as a solo treatment for the approximately 4 percent of CF patients whose CFTR protein carries a single amino acid substitution, G551D. While this mutation does not interfere with the protein reaching the cell surface, it does prevent the ion channel from opening properly.

According to one estimate, the $\Delta F508$ mutation had to have originated more than 50,000 years ago to have reached such a high frequency in the population. The fact that the CF gene has reached this frequency suggests that heterozygotes may receive some selective advantage over those lacking a copy of the defective gene. It has been proposed that CF heterozygotes may be protected from the effects of cholera, a disease that is characterized by excessive fluid secretion by the wall of the intestine. One difficulty with this proposal is that there is no record of cholera epidemics in Europe until the 1820s. An alternate proposal suggests that heterozygotes are protected from typhoid fever because the bacterium responsible for this disease adheres poorly to the wall of an intestine having a reduced number of CFTR molecules.

Ever since the isolation of the gene responsible for CF, the development of a cure by gene therapy—that is, by replacement of the defective gene with a normal version—has been a major goal of CF researchers. Cystic fibrosis is a good candidate for gene therapy because the worst symptoms of the disease result from the defective activities of epithelial cells that line the airways and, therefore, are accessible to agents that can be delivered by inhalation of an aerosol. Clinical trials have been conducted using several different types of delivery systems. In one group of trials, the normal *CFTR* gene was incorporated into the DNA of a defective adenovirus, a type of virus that normally causes upper respiratory tract infections. The recombinant virus particles were then allowed to infect the cells of the airway, delivering the normal gene to the genetically deficient cells. The primary disadvantage in using adenovirus is that the viral DNA (along with the normal *CFTR* gene) does not become integrated into the chromosomes of the infected host cell so that the virus must be readministered frequently. As a result, the procedure often induces an immune response within the patient that eliminates the virus and leads to lung inflammation. Researchers are hesitant to employ viruses that integrate their genomes for fear of initiating the formation of cancers. In other trials, the DNA encoding the normal *CFTR* gene has been linked to positively charged liposomes (page 128) that can fuse with the plasma membranes of the airway cells, delivering their DNA contents into the cytoplasm. Lipid-based delivery has an advantage over viruses in being less likely to stimulate a destructive immune response following repeated treatments, but has the disadvantage of being less effective in achieving genetic modification of target cells. To date, none of the clinical trials of gene therapy has resulted in significant improvement of either physiologic processes or disease symptoms. The development of more effective DNA delivery systems, which are capable of genetically altering a greater percentage of airway cells, will be required if a treatment for CF based on gene therapy is to be achieved.

REVIEW

1. Compare and contrast the four basically different ways that a substance can move across the plasma membrane (as indicated in Figure 4.33).
2. Contrast the energetic difference between the diffusion of an electrolyte versus a nonelectrolyte across the membrane.
3. Describe the relationship between partition coefficient and molecular size with regard to membrane permeability.
4. Explain the effects of putting a cell into a hypotonic, hypertonic, or isotonic medium.

5. Describe two ways in which energy is utilized to move ions and solutes against a concentration gradient.
6. How does the Na^+/K^+ -ATPase illustrate the asymmetry of the plasma membrane?
7. What is the role of phosphorylation in the mechanism of action of the Na^+/K^+ -ATPase?
8. What is the structural relation between the parts of the prokaryotic KcsA K^+ channel and the eukaryotic voltage-regulated K^+ channel? Which part of the channel is involved in ion selectivity, which part in channel gating, and which part in channel inactivation? How does each of these processes (ion selectivity, gating, and inactivation) occur?
9. Because of its smaller size, one would expect Na^+ ions to be able to penetrate any pore large enough for a K^+ ion. How does the K^+ channel select for this specific ion?

4.8 | Membrane Potentials and Nerve Impulses

All organisms respond to external stimulation, a property referred to as *irritability*. Even a single-celled amoeba, if poked with a fine glass needle, responds by withdrawing its pseudopodia, rounding up, and moving off in another direction. Irritability in an amoeba depends on the same basic properties of membranes that lead to the formation and propagation of nerve impulses, which is the subject of the remainder of the chapter.

Nerve cells (or *neurons*) are specialized for the collection, conduction, and transmission of information, which is coded in the form of fast-moving electrical impulses. The basic parts of a typical neuron are illustrated in Figure 4.51. The nucleus of the neuron is located within an expanded region called the *cell body*, which is the metabolic center of the cell and the site where most of its material contents are manufactured. Extending from the cell bodies of most neurons are a number of fine extensions, called **dendrites**, which receive *incoming* information from external sources, typically other neurons. Also emerging from the cell body is a single, more prominent extension, the **axon**, which conducts *outgoing* impulses away from the cell body and toward the target cell(s). Although some axons may be only a few micrometers in length, others extend for many meters in the body of a large vertebrate, such as a giraffe or whale. Most axons split near their ends into smaller processes, each ending in a *terminal knob*—a specialized site where impulses are transmitted from neuron to target cell. Many neurons in the brain end in thousands of terminal knobs, allowing these brain cells to communicate with thousands of potential targets. As discussed on page 167, most neurons in the vertebrate body are wrapped in a lipid-rich **myelin sheath**, whose function is described below.

The Resting Potential

A voltage (or electric potential difference) between two points, such as the inside and outside of the plasma membrane, results when there is an excess of positive ions at one point and an excess of negative ions at the other point. Voltages across plasma

Figure 4.51 The structure of a nerve cell. (a) Schematic drawing of a simple neuron with a myelinated axon. As the inset shows, the myelin sheath comprises individual Schwann cells that have wrapped themselves around the axon. The sites where the axon lacks myelin wrapping are called nodes of Ranvier. (Note: Myelin-forming cells within the central nervous system are called oligodendrocytes rather

(b) A composite micrograph of a single rat hippocampal neuron with cell body and dendrites (purple) and an axon 1 cm in length (red). Motor nerve cells in larger mammals can be 100 times this length. (B: FROM CARLOS F. IBÁÑEZ, TRENDS CELL BIOL. 17:520, 2007, © 2007, WITH PERMISSION FROM ELSEVIER.)

membranes can be measured by inserting one fine glass electrode (or *microelectrode*) into the cytoplasm of a cell, placing another electrode in the extracellular fluid outside the cell, and connecting the electrodes to a voltmeter, an instrument that measures a difference in charge between two points (Figure 4.52). When this experiment was first carried out on a giant axon of the squid, a potential difference of approximately 70 millivolts (mV) was recorded, the inside being negative with respect to the outside (indicated with a minus sign, -70 mV). The presence of a **membrane potential** is not unique to nerve cells; such potentials are present in all types of cells, the magnitude varying between about -15 and -100 mV. When a nerve or muscle cell is in an unexcited state, the membrane potential is referred to as the **resting potential** because it is subject to dramatic change, as discussed in the following section.

The magnitude and direction of the voltage across the plasma membrane are determined by the differences in concentrations of ions on either side of the membrane and their relative permeabilities. As described earlier in the chapter, the Na^+/K^+ -ATPase pumps Na^+ out of the cell and K^+ into the cell, thereby establishing steep gradients of these two ions across the plasma membrane. Because of these gradients, you might expect that potassium ions would leak out of the cell and sodium ions would leak inward through their respective ion channels. However, the vast majority of the ion channels in the plasma membrane of a *resting* nerve cell are closed.

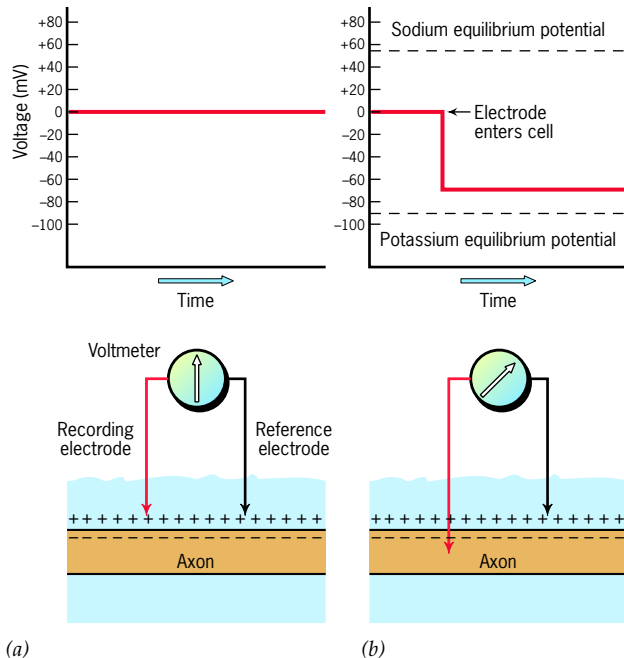

Figure 4.52 Measuring a membrane's resting potential. A potential is measured when a difference in charge is detected between the reference and recording electrodes. In (a), both electrodes are on the outside of the cell, and no potential difference (voltage) is measured. As one electrode penetrates the plasma membrane of the axon in (b), the potential immediately drops to -70 mV (inside negative), which approaches the equilibrium potential for potassium ions, that is, the potential that would result if the membrane were impermeable to all ions except potassium.

Those that are open are selective for K^+ ; they are often referred to as *K^+ leak channels*. K^+ leak channels are members of the K2P family of K^+ channels, which lack the S4 voltage sensor (page 155) and fail to respond to changes in voltage.

Because K^+ ions are the only charged species with significant permeability in a resting nerve cell, their outflow through the membrane leaves an excess of negative charges on the cytoplasmic side of the membrane. Although the concentration gradient across the membrane favors continued efflux of K^+ , the electrical gradient resulting from the excess negative charge on the inside of the membrane favors the retention of K^+ ions inside the cell. When these two opposing forces are balanced, the system is at equilibrium, and there is no further *net* movement of K^+ ions across the membrane. Using the following equation, which is called the Nernst equation, one can calculate the membrane potential (V_m) that would be measured at equilibrium if the plasma membrane of a nerve cell were permeable only to K^+ ions.⁷ In this case, V_m would be equal to the potassium equilibrium potential (E_K):

$$E_K = 2.303 \frac{RT}{zF} \cdot \log_{10} \frac{[\text{K}_o^+]}{[\text{K}_i^+]}$$

For a squid giant axon, the internal $[\text{K}_i^+]$ is approximately 350 mM, while the external $[\text{K}_o^+]$ is approximately 10 mM; thus at 25°C (298 K) and $z = +1$ (for the univalent K^+ ion),

$$E_K = 59 \log_{10} 0.028 = -91 \text{ mV}$$

A similar calculation of the Na^+ equilibrium potential (E_{Na}) would produce a value of approximately $+55$ mV. Because measurements of the voltage across the resting nerve membrane are similar in sign and magnitude (-70 mV) to the potassium equilibrium potential just calculated, the movement of potassium ions across the membrane is considered the most important factor in determining the resting potential. The difference between the calculated K^+ equilibrium potential (-91 mV) and the measured resting potential (-70 mV, Figure 4.52) is due to a slight permeability of the membrane to Na^+ through a recently described Na^+ leak channel.

The Action Potential

Our present understanding of membrane potentials and nerve impulses rests on a body of research carried out on the giant axons of the squid in the late 1940s and early 1950s by a group of British physiologists, most notably Alan Hodgkin, Andrew Huxley, and Bernard Katz. These axons, which are approximately 1 mm in diameter, carry impulses at high speeds, enabling the squid to escape rapidly from predators. If the membrane of a resting squid axon is stimulated by poking it with a fine needle or jolting it with a very small electric current, some of its sodium channels open, allowing a limited number of sodium ions to diffuse into the cell. This opportunity for positively charged ions to move into the cell reduces the membrane

⁷The Nernst equation is derived from the equation provided on page 148, by setting ΔG at zero, which is the case when the movement of the ions is at equilibrium. Walther Nernst was a German physical chemist who won the 1920 Nobel Prize.

potential, making it less negative. Because the positive change in membrane voltage causes a *decrease* in the polarity between the two sides of the membrane, it is called a **depolarization**.

If the stimulus causes the membrane to depolarize by only a few millivolts, say from -70 to -60 mV, the membrane rapidly returns to its resting potential as soon as the stimulus has ceased (Figure 4.53a, left box). If, however, the stimulus depolarizes the membrane beyond a certain point, called the **threshold**, which occurs at about -50 mV, then a new series of events is launched. The change in voltage causes the voltage-gated sodium channels to open. As a result, sodium ions diffuse freely into the cell (Figure 4.53a, middle box) down both their concentration and electric gradients. The increased permeability of the membrane to Na^+ ions and the corresponding movement of positive charge into the cell causes the membrane to reverse potential briefly (Figure 4.53b), becoming positive at about $+40$ mV, which approaches the equilibrium potential for Na^+ (Figure 4.52).

After approximately 1 msec, the sodium channels spontaneously inactivate, blocking further influx of Na^+ ions. According to the prevailing view, inactivation results from the random diffusion of an inactivation peptide into the opening of the channel pore in a manner similar to that described for K^+ channels on page 155. Meanwhile, the change in membrane potential caused by Na^+ influx triggers the opening of the voltage-gated potassium channels (Figure 4.53a, right box) discussed on page 154. As a result, potassium ions diffuse freely out of the cell down their steep concentration gradient. The decreased permeability of the membrane to Na^+ and the increased permeability to K^+ cause the membrane potential to swing back to a negative value of about -80 mV, approaching that of the K^+ equilibrium potential (Figure 4.52). The large negative membrane potential causes the voltage-gated potassium channels to close (see Figure 4.43b), which returns the membrane to its resting state. Collectively, these changes in membrane potential are called an **action potential** (Figure 4.53b). The entire series of changes during an action potential

takes only about 5 msec in the squid axon and less than 1 msec in a myelinated mammalian nerve cell. Following an action potential, the membrane enters a brief *refractory period* during which it cannot be restimulated. The refractory period occurs because the sodium channels that were inactivated during the initial stage of the action potential must close before they can be reopened in response to another stimulus. As depicted in Figure 4.43, the transformation of the ion channel from the inactivated to the closed conformation can only occur after the inactivating peptide has swung out of the opening of the pore.

Although the action potential changes membrane voltage dramatically, only a minute percentage of the ions on the two sides of the membrane are involved in any given action potential. The striking changes in membrane potential seen in Figure 4.53b are not caused by changes in Na^+ and K^+ ion concentra-

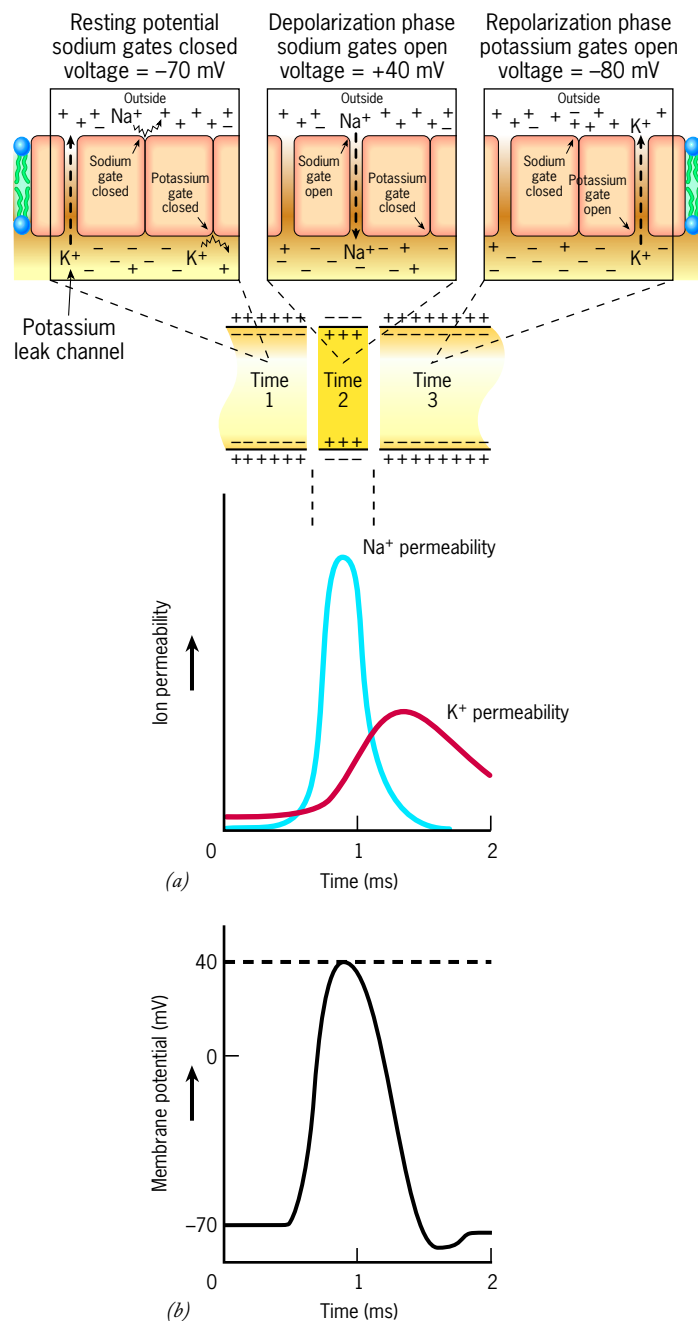

Figure 4.53 Formation of an action potential. (a) Time 1, upper left box: The membrane in this region of the nerve cell exhibits the resting potential, in which only the K^+ leak channels are open and the membrane voltage is approximately -70 mV. Time 2, upper middle box, shows the depolarization phase: The membrane has depolarized beyond the threshold value, opening the voltage-regulated sodium gates, leading to an influx of Na^+ ions (indicated in the permeability change in the lower graph). The increased Na^+ permeability causes the membrane voltage to temporarily reverse itself, reaching a value of approximately $+40$ mV in the squid giant axon (time 2). It is this reversal of membrane potential that constitutes the action potential. Time 3, upper right box, shows the repolarization phase: Within a tiny fraction of a second, the sodium gates are inactivated and the potassium gates open, allowing potassium ions to diffuse across the membrane (lower part of the drawing) and establish an even more negative potential at that location (-80 mV) than that of the resting potential. Almost as soon as they open, the potassium gates close, leaving the potassium leak channels as the primary path of ion movement across the membrane and reestablishing the resting potential. (b) A summary of the voltage changes that occur during an action potential, as described in part a.

tions on the two sides of the membrane (such changes are insignificant). Rather, they are caused by the movements of charge in one direction or the other that result from the fleeting changes in permeability to these ions. Those Na^+ and K^+ ions that do change places across the membrane during an action potential are eventually pumped back by the Na^+/K^+ -ATPase. Even if the Na^+/K^+ -ATPase is inhibited, a neuron can often continue to fire thousands of impulses before the ionic gradients established by the pump's activity are dissipated.

Once the membrane of a neuron is depolarized to the threshold value, a full-blown action potential is triggered without further stimulation. This feature of nerve cell function is known as the *all-or-none law*. There is no in-between; sub-threshold depolarization is incapable of triggering an action potential, whereas threshold depolarization automatically elicits a maximum response. It is also noteworthy that an action potential is not an energy-requiring process, but one that results from the flow of ions down their respective electrochemical gradients. Energy is required by the Na^+/K^+ -ATPase to generate the steep ionic gradients across the plasma membrane, but once that is accomplished, the various ions are poised to flow through the membrane as soon as their ion channels are opened.

The movements of ions across the plasma membrane of nerve cells form the basis for neural communication. Certain *local* anesthetics, such as procaine and novocaine, act by closing ion channels in the membranes of sensory cells and neurons. As long as these ion channels remain closed, the affected cells are unable to generate action potentials and thus unable to inform the brain of events occurring at the skin or teeth.

Propagation of Action Potentials as an Impulse

Up to this point, we have restricted the discussion to events occurring at a particular site on the nerve cell membrane where experimental depolarization has triggered an action potential. Once an action potential has been initiated, it does not remain localized at a particular site but is *propagated* as a **nerve impulse** down the length of the cell to the nerve terminals.

Nerve impulses are propagated along a membrane because an action potential at one site has an effect on the adjacent site. The large depolarization that accompanies an action potential creates a difference in charge along the inner and outer surfaces of the plasma membrane (Figure 4.54). As a result, positive ions move toward the site of depolarization on the outer surface of the membrane and away from that site on the inner surface (Figure 4.54). This local flow of current causes the membrane in the region just ahead of the action potential to become depolarized. Because the depolarization accompanying the action potential is very large, the membrane in the adjacent region is readily depolarized to a level greater than the threshold value, which opens the sodium channels in this adjacent region, generating another action potential. Thus, once triggered, a succession of action potentials passes down the entire length of the neuron without any loss of intensity, arriving at its target cell with the same strength it had at its point of origin.

Because all impulses traveling along a neuron exhibit the same strength, stronger stimuli cannot produce “bigger” im-

Figure 4.54 Propagation of an impulse results from the local flow of ions. An action potential at one site on the membrane depolarizes an adjacent region of the membrane, triggering an action potential at the second site. The action potential can only flow in the forward direction because the portion of the membrane that has just experienced an action potential remains in a refractory period.

pulses than weaker stimuli. Yet, we are clearly capable of detecting differences in the strength of a stimulus. The ability to make sensory discriminations depends on several factors. For example, a stronger stimulus, such as scalding water, activates more nerve cells than does a weaker stimulus, such as warm water. It also activates “high-threshold” neurons that would remain at rest if the stimulus were weaker. Stimulus strength is also encoded in the pattern and frequency by which action potentials are launched down a particular neuron. In most cases, the stronger the stimulus, the greater the number of impulses generated.

Speed Is of the Essence The greater the diameter of an axon, the less the resistance to local current flow and the more rapidly an action potential at one site can activate adjacent regions of the membrane. Some invertebrates, such as squid and tube worms, have evolved giant axons that facilitate the animal's escape from danger. There is, however, a limit to this evolutionary approach. Because the speed of conduction increases with the square root of the increase in diameter, an axon that is 480 μm in diameter can conduct an action potential only four times faster than one that is 30 μm in diameter.

During the evolution of vertebrates, an increase in conduction velocity was achieved when the axon became wrapped in a myelin sheath (see Figures 4.5 and 4.51). Because it is composed of many layers of lipid-containing membranes, the myelin sheath is ideally suited to prevent the passage of ions across the plasma membrane. In addition, nearly all of the Na^+ ion channels of a myelinated neuron reside in the unwrapped gaps, or *nodes of Ranvier*, between adjacent Schwann cells or oligodendrocytes that make up the sheath (see Figure 4.51). Consequently, the nodes of Ranvier are the only sites where action potentials can be generated. An action potential at one node triggers an action potential at the next node (Figure 4.55), causing the impulse to jump from node to node without having to activate the intervening membrane. Propagation of an impulse by this mechanism is called **saltatory conduction**. Impulses are conducted along a myelinated axon at speeds up to 120 meters per second, which is more than

Figure 4.55 Saltatory conduction. During saltatory conduction, only the membrane in the nodal region of the axon becomes depolarized and capable of forming an action potential. This is accomplished as current flows directly from an activated node to the next resting node along the axon.

20 times faster than the speed that impulses travel in an unmyelinated neuron of the same diameter.

The importance of myelination is dramatically illustrated by multiple sclerosis (MS), a disease associated with deterioration of the myelin sheath that surrounds axons in various parts of the nervous system. Manifestations of the disease usually begin in young adulthood; patients experience weakness in their hands, difficulty in walking, and problems with their vision.

Neurotransmission: Jumping the Synaptic Cleft

Neurons are linked with their target cells at specialized junctions called **synapses**. Careful examination of a synapse reveals that the two cells do not make direct contact but are separated from each other by a narrow gap of about 20 to 50 nm. This gap is called the **synaptic cleft**. A **presynaptic cell** (a receptor cell or a neuron) conducts impulses toward a

Figure 4.56 The neuromuscular junction is the site where branches from a motor axon form synapses with the muscle fibers of a skeletal muscle. The left inset shows the synaptic vesicles residing within the terminal knob of the axon and the narrow synaptic cleft between the terminal knob and the postsynaptic target cell. The right inset shows the terminal knob pressed closely against the muscle cell plasma membrane. Neurotransmitter molecules (red) released from synaptic vesicles of the presynaptic neuron are binding to receptors (yellow) on the surface of the muscle cell (blue). (LEFT INSET FROM DON W. FAWCETT/T. REESE/PHOTO RESEARCHERS, INC.)

synapse, and a **postsynaptic cell** (a neuron, muscle, or gland cell) always lies on the receiving side of a synapse. Figure 4.56 shows a number of synapses between the terminal branches of an axon and a skeletal muscle cell; synapses of this type are called **neuromuscular junctions**.

How does an impulse in a presynaptic neuron jump across the synaptic cleft and affect the postsynaptic cell? Studies carried out decades ago indicated that a chemical substance is involved in the transmission of an impulse from one cell to another (page 171). The very tips (terminal knobs) of the branches of an axon appear in the electron microscope to contain large numbers of **synaptic vesicles** (Figure 4.56, left inset) that serve as storage sites for the chemical transmitters that act on postsynaptic cells. Two of the best studied **neurotransmitters** are acetylcholine and norepinephrine,

which transmit impulses to the body's skeletal and cardiac muscles.

The sequence of events during synaptic transmission can be summarized as follows (Figure 4.57). When an impulse reaches a terminal knob (step 1, Figure 4.57), the accompanying depolarization induces the opening of a number of voltage-gated Ca^{2+} channels in the plasma membrane of this part of the presynaptic nerve cell (step 2, Figure 4.57). Calcium ions are normally present at very low concentration within the neuron (about 100 nM), as in all cells. When the gates open, calcium ions diffuse from the extracellular fluid into the terminal knob of the neuron, causing the $[\text{Ca}^{2+}]$ to rise more than a thousandfold within localized microdomains near the channels. The elevated $[\text{Ca}^{2+}]$ triggers the rapid fusion of one or a few nearby synaptic vesicles with the plasma membrane, causing the release of neurotransmitter molecules into the synaptic cleft (step 3, Figure 4.57).

Once released from the synaptic vesicles, the neurotransmitter molecules diffuse across the narrow gap and bind selectively to receptor molecules that are concentrated directly across the cleft in the postsynaptic plasma membrane (step 4, Figure 4.57). A neurotransmitter molecule can have one of two opposite effects depending on the type of receptor on the target cell membrane to which it binds:⁸

1. The bound transmitter can trigger the opening of cation-selective channels in the membrane, leading primarily to an

⁸It is important to note that this discussion ignores an important class of neurotransmitter receptors that are not ion channels and thus do not *directly* affect membrane voltage. This other group of receptors are members of a class of proteins called GPCRs, which are discussed at length in Section 15.3. When a neurotransmitter binds to one of these receptors, it can initiate a variety of responses, which often includes the opening of ion channels by an indirect mechanism.

Figure 4.57 The sequence of events during synaptic transmission with acetylcholine as the neurotransmitter. During steps 1–4, a nerve impulse reaches the terminal knob of the axon, calcium gates open leading to an influx of Ca^{2+} , and acetylcholine is released from synaptic vesicles and binds to receptors on the postsynaptic membrane. If the binding of the neurotransmitter molecules causes a depolarization of the postsynaptic membrane (as in 5a), a nerve im-

pulse may be generated there (6). If, however, the binding of neurotransmitter causes a hyperpolarization of the postsynaptic membrane (5b), the target cell is inhibited, making it more difficult for an impulse to be generated in the target cell by other excitatory stimulation. The breakdown of the neurotransmitter by acetylcholinesterase is not shown.

influx of sodium ions and a less negative (more positive) membrane potential. This depolarization of the postsynaptic membrane *excites* the cell, making the cell more likely to respond to this or subsequent stimuli by generating an action potential of its own (Figure 4.57, steps 5a and 6).

2. The bound transmitter can trigger the opening of anion-selective channels, leading mainly to an influx of chloride ions, and a more negative (hyperpolarized) membrane potential. Hyperpolarization of the postsynaptic membrane makes it less likely the cell will generate an action potential because greater sodium influx is subsequently required to reach the membrane's threshold (Figure 4.57, step 5b).

Most nerve cells in the brain receive both excitatory and inhibitory signals from many different presynaptic neurons. It is the summation of these opposing influences that determine whether or not an impulse will be generated in the postsynaptic neuron.

All terminal knobs of a given neuron release the same neurotransmitter(s). However, a given neurotransmitter may have a stimulatory effect on one particular postsynaptic membrane and an inhibitory effect on another. Acetylcholine, for example, inhibits contractility of the heart but stimulates contractility of skeletal muscle. Within the brain, glutamate serves as the primary excitatory neurotransmitter and gamma-aminobutyric acid (GABA) as the primary inhibitory neurotransmitter. A number of general anesthetics, as well as Valium and its derivatives, act by binding to the GABA receptor and enhancing the activity of the brain's primary "off" switch. As will be evident in the following section, many different drugs affecting disorders, such as anxiety, depression, insomnia, and schizophrenia, exert their action at the synapse.

Actions of Drugs on Synapses It is important that a neurotransmitter has only a short half-life following its release from a presynaptic neuron; otherwise the effect of the neurotransmitter would be extended, and the postsynaptic neuron would not recover. A neurotransmitter is eliminated from the synapse in two ways: by enzymes that destroy neurotransmitter molecules in the synaptic cleft and by proteins that transport neurotransmitter molecules back to the presynaptic terminals—a process called *reuptake*. Because of the destruction or reuptake of neurotransmitter molecules, the effect of each impulse lasts no more than a few milliseconds.

Interfering with the destruction or reuptake of neurotransmitters can have dramatic physiologic and behavioral effects. Acetylcholinesterase is an enzyme localized within the synaptic cleft that hydrolyzes acetylcholine. If this enzyme is inhibited by exposure to the nerve gas DFP, for example, the skeletal muscles of the body undergo violent contraction due to the continued presence of high concentrations of acetylcholine. Milder inhibitors of acetylcholinesterase are used to treat the symptoms of Alzheimer's disease, which is characterized by the loss of acetylcholine-releasing neurons.

Many drugs act by inhibiting the transporters that sweep neurotransmitters out of the synaptic cleft. A number of widely prescribed antidepressants, including Prozac and Zoloft, inhibit the reuptake of serotonin, a neurotransmitter implicated in

mood disorders. Cocaine, on the other hand, interferes with the reuptake of the neurotransmitter dopamine that is released by certain nerve cells in a portion of the brain known as the limbic system. The limbic system contains the brain's "pleasure" or "reward" centers. The sustained presence of dopamine in the synaptic clefts of the limbic system produces a short-lived feeling of euphoria, as well as a strong desire to repeat the activity. Mice that have been genetically engineered to lack the dopamine transporter (DAT)—the protein responsible for dopamine reuptake—show behavior similar to that of normal mice that have been given cocaine or amphetamines. Administration of cocaine or amphetamines has no additional behavioral effects on animals lacking the *DAT* gene. Numerous other drugs act on presynaptic dopamine-releasing or postsynaptic dopamine-responding neurons. Amphetamines are thought to stimulate the excessive release of dopamine from presynaptic terminals and also interfere with the reuptake of the neurotransmitter molecules from the synaptic cleft. A number of antipsychotic drugs bind to certain subtypes of the dopamine receptor on postsynaptic neurons and block their stimulation by dopamine.

The active compound in marijuana (Δ^9 -tetrahydrocannabinol) acts by a totally different mechanism. It binds to cannabinoid (CB1) receptors located on the *presynaptic* terminals of certain neurons of the brain, which reduces the likelihood that these neurons will release neurotransmitters. CB1 receptors normally interact with compounds produced in the body called *endocannabinoids*. Endocannabinoids are produced by postsynaptic neurons following depolarization. These substances diffuse "backwards" across the synaptic cleft to the presynaptic membrane, where they bind to CB1 receptors, suppressing synaptic transmission. CB1 receptors are located in many areas of the brain, including the hippocampus, cerebellum, and hypothalamus, which explains the effects of marijuana on memory, motor coordination, and appetite, respectively. If marijuana increases appetite by binding to CB1 receptors, it follows that blocking these receptors might decrease appetite. This line of reasoning led to the development of a CB1-blocking weight-loss drug called Acomplia, which has been pulled from the market because of side effects.

Synaptic Plasticity Synapses are more than simply connecting sites between adjacent neurons; they are key determinants in the routing of impulses through the nervous system. The human brain is thought to contain at least one hundred trillion synapses. These synapses act like gates stationed along the various pathways, allowing some pieces of information to pass from one neuron to another, while holding back other pieces or rerouting them in another direction. While synapses are often perceived as fixed, unchanging structures, they can display a remarkable dynamic quality known as "synaptic plasticity." Synaptic plasticity is particularly important during infancy and childhood, when the neuronal circuitry of the brain achieves its mature configuration.

Synaptic plasticity is most readily observed in studies on neurons from the hippocampus, a portion of the brain that is vitally important in learning and short-term memory. When hippocampal neurons are repeatedly stimulated over a short period of time, the synapses that connect these neurons to their neigh-

bors become “strengthened” by a process known as long-term potentiation (LTP), which may last for days, weeks, or even longer. Research into LTP has focused on the NMDA receptor, which is one of several receptor types that bind the excitatory neurotransmitter glutamate. When glutamate binds to a postsynaptic NMDA receptor, it opens an internal cation channel within the receptor that allows the influx of Ca^{2+} ions into the postsynaptic neuron, triggering a cascade of biochemical changes that lead to synaptic strengthening. Synapses that have undergone LTP are able to transmit weaker stimuli and evoke stronger responses in postsynaptic cells. These changes are thought to play a major role as newly learned information or memories are encoded in the neural circuits of the brain. When laboratory animals are treated with drugs that inhibit LTP, such as those that interfere with the activity of the NMDA receptor, their ability to learn new information is greatly reduced.

There are numerous other reasons the study of synapses is so important. For example, a number of diseases of the nervous system, including myasthenia gravis, Parkinson’s disease, schizophrenia, and even depression, are thought to have their roots in synaptic dysfunction.

REVIEW

1. What is a resting potential? How is it established as a result of ion flow?
2. What is an action potential? What are the steps that lead to its various phases?
3. How is an action potential propagated along an axon? What is saltatory conduction, and how does such a process occur?
4. What is the role of the myelin sheath in conduction of an impulse?
5. Describe the steps between the time an impulse reaches the terminal knob of a presynaptic neuron and an action potential is initiated in a postsynaptic cell.
6. Contrast the roles of ion pumps and channels in establishing and using ion gradients, particularly as it applies to nerve cells.

EXPERIMENTAL PATHWAYS

The Acetylcholine Receptor

In 1843, at the age of 30, Claude Bernard moved from a small French town, where he had been a pharmacist and an aspiring playwright, to Paris, where he planned to pursue his literary career. Instead, Bernard enrolled in medical school and went on to become the foremost physiologist of the nineteenth century. Among his many interests was the mechanism by which nerves stimulate the contraction of skeletal muscles. His studies included the use of curare, a highly toxic drug isolated from tropical plants and utilized for centuries by native South American hunters to make poisonous darts. Bernard found that curare paralyzed a skeletal muscle without interfering with either the ability of nerves to carry impulses to that muscle or the ability of the muscle to contract on direct stimulation. Bernard concluded that curare somehow acted on the region of contact between the nerve and muscle.

This conclusion was confirmed and extended by John Langley, a physiologist at Cambridge University. Langley was studying the ability of nicotine, another substance derived from plants, to stimulate the contraction of isolated frog skeletal muscles and the effect of curare in inhibiting nicotine action. In 1906, Langley concluded that “the nervous impulse should not pass from nerve to muscle by an electric discharge, but by the secretion of a special substance on the end of the nerve.”¹ Langley proposed that this “chemical transmitter” was binding to a “receptive substance” on the surface of the muscle cells, the same site that bound nicotine and curare. These proved to be farsighted proposals.

Langley’s suggestion that the stimulus from nerve to muscle was transmitted by a chemical substance was confirmed in 1921 in an ingenious experiment by the Austrian-born physiologist, Otto Loewi, the design of which came to Loewi during a dream. The heart rate of a vertebrate is regulated by input from two opposing (antagonistic) nerves. Loewi isolated a frog’s heart with both nerves intact. When he stimulated the inhibitory (*vagus*) nerve, a chemical was released from the heart preparation into a salt solution, which was allowed to drain into the medium bathing a second isolated heart. The

rate of the second heart slowed dramatically, as though its own inhibitory nerve had been activated.² Loewi called the substance responsible for inhibiting the frog’s heart “Vagusstoff.” Within a few years, Loewi had shown that the chemical and physiologic properties of Vagusstoff were identical to acetylcholine, and he concluded that acetylcholine (ACh) was the substance released by the tips of the nerve cells that made up the vagus nerve.

In 1937, David Nachmansohn, a neurophysiologist at the Sorbonne, was visiting the World’s Fair in Paris where he observed several living electric fish of the species *Torpedo marmorata* that were on display. These rays have electric organs that deliver strong shocks (40–60 volts) capable of killing potential prey. At the time, Nachmansohn was studying the enzyme acetylcholinesterase, which acts to destroy ACh after its release from the tips of motor nerves. Nachmansohn was aware that the electric organs of these fish were derived from modified skeletal muscle tissue (Figure 1), and he asked if he could have a couple of the fish for study once the fair had ended. The results of the first test showed the electric organ was an extraordinarily rich source of acetylcholinesterase.³ It was also a very rich source of the nicotinic acetylcholine receptor (nAChR),* the receptor present on the postsynaptic membranes of skeletal muscle cells

*The receptor is described as nicotinic because it can be activated by nicotine as well as by acetylcholine. This contrasts with muscarinic acetylcholine receptors of the parasympathetic nerve synapses, which can be activated by muscarine, but not nicotine, and are inhibited by atropine, but not curare. Smokers’ bodies become accustomed to high levels of nicotine, and they experience symptoms of withdrawal when they stop smoking because the postsynaptic neurons that possess nAChRs are no longer stimulated at their usual level. The drug Chantix, which is marketed as an aid to stop smoking, acts by binding to the most common version of brain nAChR (one with $\alpha 4\beta 2$ subunits). Once bound, the Chantix molecule partially stimulates the receptor while preventing binding of nicotine.

Figure 1 The electric organs of *Torpedo* consist of stacks of modified neuromuscular junctions located on each side of the body. (FROM Z. W. HALL, AN INTRODUCTION TO NEUROBIOLOGY, SINAUER ASSOCIATES, INC., SUNDERLAND, MA © 1992.)

that binds ACh molecules released from the tips of a motor nerve. Finding an ideal system can prove invaluable in the study of a particular aspect of cell structure or function. As will be evident from this discussion, the electric organs of fish have been virtually the sole source of material for the study of the nAChR.

The nAChR is an integral membrane protein, and it wasn't until the 1970s that techniques were developed for the isolation of such

proteins. As discussed in Chapter 18, the purification of a particular protein requires a suitable assay to determine the amount of that protein present in any particular fraction. The ideal assay for nAChR was a compound that bound selectively and tightly to this particular protein. Such a compound was discovered in 1963 by Chen-Yuan Lee and his colleagues of the National Taiwan University. The compound was α -bungarotoxin, a substance present in the venom of a Taiwanese snake. The α -bungarotoxin causes paralysis by binding tightly to the nAChRs on the postsynaptic membrane of skeletal muscle cells, blocking the response of the muscle to ACh.⁴

Equipped with labeled α -bungarotoxin to use in an assay, electric organs as a source, and a detergent capable of solubilizing membrane proteins, a number of investigators were able to isolate the acetylcholine receptors in the early 1970s. In one of these studies,⁵ the membranes containing the nAChR were isolated by homogenizing the electric organs in a blender and centrifuging the suspension to pellet the membrane fragments. Membrane proteins were extracted from the membrane fragments using Triton X-100 (page 133), and the mixture was passed through a column containing tiny beads coated with a synthetic compound whose end bears a structural resemblance to ACh (Figure 2a). As the mixture of dissolved proteins passed through the column, two proteins that have binding sites for acetylcholine, nAChR and acetylcholinesterase (AChE), stuck to the beads. The remaining 90 percent of the protein in the extract failed to bind to the beads and simply passed through the column and was collected (Figure 2b). Once this group of proteins had passed through, a solution of 10^{-3} M flaxedil was passed through the column, which selectively removed the nAChR from the beads, leaving the AChE behind. Using this procedure, the acetylcholine

Figure 2 Steps used in the isolation of the nAChR.

(a) Structure of a synthetic compound, CT5263, that was attached to sepharose beads to form an affinity column. The ends of the compound projecting from the beads resemble acetylcholine, causing both acetylcholinesterase (AChE) and the nicotinic acetylcholine receptor (nAChR) to bind to the beads. (b) When the Triton X-100 extract was passed through the column, both of the acetylcholine-binding proteins stuck to the beads, while the remaining dissolved protein (about 90 percent of the total protein in the extract) passed directly through the column. Subsequent passage of a solution of 10^{-3} M flaxedil through the column released the bound nAChR, without disturbing the bound AChE (which was subsequently eluted with 1 M NaCl). (FROM R. W. OLSEN, J.-C. MEUNIER, AND J.-P. CHANGEUX, FEBS LETT. 28:99, 1972. © 1972, WITH PERMISSION OF ELSEVIER.)

receptor as measured by bungarotoxin binding was purified by more than 150-fold in a single step. This type of procedure is known as *affinity chromatography*, and its general use is discussed in Section 18.7.

The next step was to determine something about the structure of the acetylcholine receptor. Studies in the laboratory of Arthur Karlin at Columbia University determined that the nAChR was a pentamer, a protein consisting of five subunits. Each receptor contained two copies of a subunit called α , and one copy each of three other subunits. The subunits could be distinguished by extracting membrane proteins in Triton X-100, purifying the nAChR by affinity chromatography, and then subjecting the purified protein to electrophoresis through a polyacrylamide gel (SDS-PAGE, as discussed in Section 18.7), which separates the individual polypeptides according to size (Figure 3).⁶ The four different subunits proved to be homologous to one another, each subunit containing four homologous transmembrane helices (M1–M4).

Another important milestone in the study of the nAChR was the demonstration that the purified receptor acted as both a site for binding ACh and a channel for the passage of cations. It had been postulated years earlier by Jean-Pierre Changeux of the Pasteur Institute in Paris that the binding of ACh to the receptor caused a conformational change that opened an ion channel within the protein. The inward flux of Na^+ ions through the channel could then lead to a depolarization of the membrane and the activation of the muscle cell. During the last half of the 1970s, Changeux and his colleagues succeeded in incorporating purified nAChR molecules into artificial lipid vesicles.⁷ Using vesicles containing various concentrations of labeled sodium and potassium ions, they demonstrated that binding of ACh to the receptors in the lipid bilayer initiated a flux of cations through the “mem-

Figure 3 The top portion of the figure shows an SDS-polyacrylamide gel following electrophoresis of a preparation of the purified nAChR. The receptor consists of four different subunits whose molecular weights are indicated. Prior to electrophoresis, the purified receptor preparation was incubated with a radioactive compound (^3H -MBTA) that resembles acetylcholine and binds to the acetylcholine-binding site of the nAChR. Following electrophoresis, the gel was sliced into 1-mm sections and the radioactivity of each slice determined. All of the radioactivity was bound to the 39,000 dalton subunit, indicating this subunit contains the ACh-binding site. The dotted line indicates the light absorbance of each fraction, which provides a measure of the total amount of protein present in that fraction. The heights of the peaks provide a measure of the relative amounts of each of the subunits in the protein. All of the subunits are present in equal numbers except the smallest subunit (the α subunit, which contains the ACh-binding site), which is present in twice the number of copies. (FROM C. L. WEILL, M. G. MCNAMEE, AND A. KARLIN, *BIOCHEM. BIOPHYS. RES. COMMUN.* 61:1002, 1974. REPRODUCED WITH PERMISSION OF ELSEVIER.)

brane.” It was evident that “the pure protein does indeed contain all the structural elements needed for the chemical transmission of an electrical signal—namely, an acetylcholine binding site, an ion channel and a mechanism for coupling their activity.” A personal narrative of the early work on nAChR can be found in Reference 8.

During the past two decades, researchers have focused on determining the structure of the nAChR and the mechanism by which binding of acetylcholine induces the opening of the ion gate. Analysis of the structure has taken several different paths. In one approach, scientists have used purified genes, determination of amino acid sequences, and site-directed mutagenesis to determine the specific parts of the polypeptides that span the membrane, or bind the neurotransmitter, or form the ion channel. These noncrystallographic studies on the molecular anatomy of a protein are similar in principle to those described in Section 4.4.

Another approach employed the electron microscope. The first glimpses of the nAChR were seen in electron micrographs of the membranes of the electric organs (Figure 4).⁹ The receptors appeared to be ring shaped, with a diameter of 8 nm and a central channel of 2-nm diameter, and protruded out from the lipid bilayer into the external space. An increasingly detailed model of the nAChR has been developed by Nigel Unwin and his colleagues of the Medical Research Council of England.^{10–14} These researchers employed the technique of electron crystallography (Section 18.8), which involves a mathematical analysis of large numbers of electron micrographs of frozen membranes containing the proteins being studied. Electric organs are well suited for electron crystallography because they contain highly ordered (crystalline) arrays of the nAChR within the plane of the lipid bilayer. As a result, Unwin was able to analyze the structure of the nAChR as it exists in its native lipid environment. He described the arrangement of the five subunits around a central channel (Figure 5). The ion channel consists of a narrow pore lined by a wall composed of five inner (M2) α helices, one from each of the surrounding subunits. The gate to the pore lies near the middle of the membrane, where each of the M2

Figure 4 Electron micrograph of negatively stained, receptor-rich membranes from the electric organ of an electric fish showing the dense array of nAChR molecules. Each receptor molecule is seen as a small whitish circle with a tiny black dot in its center; the dot corresponds to the central channel, which has collected electron-dense stain. (FROM WERNER SCHIEBLER AND FERDINAND HUCHO, *EUR. J. BIOCHEM.* 85:58, 1978, REPRINTED WITH PERMISSION OF JOHN WILEY & SONS.)

Figure 5 (a) An electron density map of a slice through the nAChR obtained by analyzing electron micrographs of tubular crystals of *Torpedo* membranes embedded in ice. These analyses have allowed researchers to reconstruct the three-dimensional appearance of a single nAChR protein as it resides within the membrane. The continuous contours indicate lines of similar density greater than that of water. The two dark, bar-shaped lines represent the α helices that line the channel at its narrowest point. (b) Schematic diagram of the nAChR showing the arrangement of the subunits and a cross-sectional representation of the protein. Each of the five subunits contains four membrane-spanning helices (M1–M4). Of these, only the inner helix (M2) lines the pore, and is the subject of the remainder of the discussion.

(A: FROM N. UNWIN, J. MOL. BIOL. 229:1118, 1993; © 1993, WITH PERMISSION OF ELSEVIER.)

α helices bends inward (at the apex of the V-shaped bars in Figure 5a) to form a kink in the unactivated receptor. The side chain of a leucine residue projects inward from each kink. In this model, the leucine residues from the five inner helices form a tight hydrophobic ring that prevents the ions from crossing the membrane. The gate opens following the binding of two ACh molecules, one per α subunit. Each ACh binds to a site located within a pocket of an α subunit (Figure 5b).

To study the changes in the nAChR during channel opening, Unwin carried out the following experiment.¹² Preparations of nAChR-rich membranes were applied to a support grid that was allowed to fall into a bath of liquid nitrogen-cooled ethane, which freezes the membranes. Approximately 5 msec before they reached the surface of the freezing bath, the grids were sprayed with a solution of ACh, which bound to the receptors and triggered the conformational change required to open the channel. By comparing electron micrographs of nAChRs trapped in the open versus closed state, Unwin found that ACh binding triggers a small conformational change in the extracellular domains of the receptor subunits near the two ACh binding sites. According to the model depicted in Figure 6, this conformational change is propagated down the protein, causing a small (15°) rotation of the M2 helices that line the ion-conduction pore. The rotation of these inner helices breaks apart the hydrophobic gate, which allows Na^+ ions to enter the cell.^{13,14} Other models for channel opening have been proposed by other laboratories, and a more definitive statement about the mechanism of gating will probably require a high-resolution X-ray crystal structure of the protein in both the open and closed states. Discussion of various models and the bases for them can be found in References 15–17.

Figure 6 Ribbon drawings illustrating the proposed changes that occur within the nAChR upon binding of acetylcholine. Only the two alpha subunits of the receptor are shown. In the closed state (left) the pore is blocked (pink patch) by the close apposition of a ring of hydrophobic residues (the valine and leucine side chains of these residues on the alpha subunits are indicated by the small ball-and-stick models at the site of pore constriction). The diameter of the pore at its narrowest point is about 6 Å, which is not sufficient for a hydrated Na^+ ion to pass. Although it is wide enough for passage of a dehydrated Na^+ ion, the wall of the channel lacks the polar groups that would be required to substitute for the displaced shell of water molecules (as occurs in the selectivity filter of the K^+ channel, Figure 4.39). Following binding of ligand, a conformational change is proposed, which leads to a small rotation of the inner β sheets in the ligand-binding domain of the alpha subunits (curved arrows on left figure). This, in turn, induces a rotational movement of the inner transmembrane helices of the subunits, expanding the diameter of the pore, which allows the flow of Na^+ ions through the open state of the channel (right). The relevant moving parts are shown in blue. (FROM N. UNWIN, FEBS LETT. 555:94, © 2003, WITH PERMISSION FROM ELSEVIER.)

Synopsis

Plasma membranes are remarkably thin, delicate structures, yet they play a key role in many of a cell's most important functions. The plasma membrane separates the living cell from its environment; it provides a selectively permeable barrier that allows the exchange of certain substances, while preventing the passage of others; it contains the machinery that physically transports substances from one side of the membrane to another; it contains receptors that bind to specific ligands in the external space and relay the information to the cell's internal compartments; it mediates interactions with other cells; it provides a framework in which components can be organized; it is a site where energy is transduced from one type to another. (p. 120)

Membranes are lipid–protein assemblies in which the components are held together in a thin sheet by noncovalent bonds. The membrane is held together as a cohesive sheet by a lipid bilayer consisting of a bimolecular layer of amphipathic lipids, whose polar head groups face outward and hydrophobic fatty acyl tails face inward. Included among the lipids are phosphoglycerides, such as phosphatidylcholine; sphingosine-based lipids, such as the phospholipid sphingomyelin and the carbohydrate-containing cerebroside and gangliosides (glycolipids); and cholesterol. The proteins of the membrane can be divided into three groups: integral proteins that penetrate into and through the lipid bilayer, with portions exposed on both the cytoplasmic and extracellular membrane surfaces; peripheral proteins that are present wholly outside the lipid bilayer, but are noncovalently associated with either the polar head groups of the lipid bilayer or with the surface of an integral protein; and lipid-anchored proteins that are outside the lipid bilayer but covalently linked to a lipid that is part of the bilayer. The transmembrane segments of integral proteins occur typically as an α helix, composed predominantly of hydrophobic residues. (p. 125)

Membranes are highly asymmetric structures whose two leaflets have very different properties. As examples, all of the membrane's carbohydrate chains face away from the cytosol; many of the integral proteins bear sites on their external surface that interact with extracellular ligands and sites on their internal surface that interact with peripheral proteins that form part of an inner membrane skeleton; and the phospholipid content of the two halves of the bilayer is highly asymmetric. The organization of the proteins within the

membrane is best revealed in freeze–fracture replicas in which the cells are frozen, their membranes are split through the center of the bilayer by a fracture plane, and the exposed internal faces are visualized by formation of a metal replica. (p. 128)

The physical state of the lipid bilayer has important consequences for the lateral mobility of both phospholipids and integral proteins. The viscosity of the bilayer and the temperature at which it undergoes phase transition depend on the degree of unsaturation and the length of the fatty acyl chains of the phospholipids. Maintaining a fluid membrane is important for many cellular activities, including signal transduction, cell division, and formation of specialized membrane regions. The lateral diffusion of proteins within the membrane was originally demonstrated by cell fusion, and it can be quantitated by techniques that follow the movements of proteins tagged with fluorescent compounds or electron-dense markers. Measurement of the diffusion coefficients of integral proteins suggests that most are subject to restraining influences that inhibit their mobility. Proteins may be restrained by association with other integral proteins or with peripheral proteins located on the membrane surface. Because of these various types of restraint, membranes achieve a considerable measure of organizational stability in which particular membrane regions are differentiated from one another. (p. 138)

The erythrocyte plasma membrane contains two major integral proteins, band 3 and glycophorin A, and a well-defined inner skeleton composed of peripheral proteins. Each band 3 subunit spans the membrane at least a dozen times and contains an internal channel through which bicarbonate and chloride anions are exchanged. Glycophorin A is a heavily glycosylated protein of uncertain function containing a single transmembrane domain consisting of a hydrophobic α helix. The major component of the membrane skeleton is the fibrous protein spectrin, which interacts with other peripheral proteins to provide support for the membrane and restrain the diffusion of its integral proteins. (p. 145)

The plasma membrane is a selectively permeable barrier that allows solute passage by several mechanisms, including simple diffusion through either the lipid bilayer or membrane channels, facilitated diffusion, and active transport. Diffusion is an energy-independent process in which a solute moves down an electrochem-

ical gradient, dissipating the free energy stored in the gradient. Small inorganic solutes, such as O_2 , CO_2 , and H_2O , penetrate the lipid bilayer readily, as do solutes with large partition coefficients (high lipid solubility). Ions and polar organic solutes, such as sugars and amino acids, require special transporters to enter or leave the cell. (p. 147)

Water moves by osmosis through the semipermeable plasma membrane from a region of lower solute concentration (the hypotonic compartment) to a region of higher solute concentration (the hypertonic compartment). Osmosis plays a key role in a multitude of physiologic activities. In plants, for example, the influx of water generates turgor pressure against the cell wall that helps support nonwoody tissues. (p. 149)

Ions diffuse through a plasma membrane by means of special protein-lined channels that are often specific for particular ions. Ion channels are usually gated and are controlled by either voltage or chemical ligands, such as neurotransmitters. Analysis of a bacterial ion channel (KcsA) has revealed how oxygen atoms from the backbone of the polypeptide are capable of replacing the water molecules normally associated with K^+ ions, allowing the protein to selectively conduct K^+ ions through its central channel. Voltage-gated K^+ channels contain a charged helical segment that moves in response to the membrane's voltage leading to the opening or closing of the gate. (p. 151)

Facilitated diffusion and active transport involve integral membrane proteins that combine specifically with the solute to be transported. Facilitative transporters act without the input of energy and move solutes down a concentration gradient in either direction across the membrane. They are thought to act by changing conformation, which alternately exposes the solute binding site to the two sides of the membrane. The glucose transporter is a facilitative transporter whose presence in the plasma membrane is stimulated by increasing levels of insulin. Active transporters require the input of energy and move ions and solutes against a concentration gradient. P-type active transporters, such as the Na^+/K^+ -ATPase,

are driven by the transfer of a phosphate group from ATP to the transporter, changing its affinity toward the transported ion. Secondary active-transport systems tap the energy stored in an ionic gradient to transport a second solute against a gradient. For example, the active transport of glucose across the apical surface of an intestinal epithelial cell is driven by the cotransport of Na^+ down its electrochemical gradient. (p. 156)

The resting potential across the plasma membrane is due largely to the limited permeability of the membrane to K^+ and is subject to dramatic change. The resting potential of a typical nerve or muscle cell is about -70 mV (inside negative). When the membrane of an excitable cell is depolarized past a threshold value, events are initiated that lead to the opening of the gated Na^+ channels and the influx of Na^+ , which is measured as a reversal in the voltage across the membrane. Within milliseconds after they have opened, the Na^+ gates close and gated potassium channels open, which leads to an efflux of K^+ and a restoration of the resting potential. The series of dramatic changes in membrane potential following depolarization constitutes an action potential. (p. 164)

Once an action potential has been initiated, it becomes self-propagating. Action potentials propagate because the depolarization that accompanies an action potential at one site on the membrane is sufficient to depolarize the adjacent membrane, which initiates an action potential at that site. In a myelinated axon, an action potential at one node in the sheath is able to depolarize the membrane at the next node, allowing the action potential to hop rapidly from node to node. When the action potential reaches the terminal knobs of an axon, the calcium gates in the plasma membrane open, allowing an influx of Ca^{2+} , which triggers the fusion of the membranes of neurotransmitter-containing secretory vesicles with the overlying plasma membrane. The neurotransmitter diffuses across the synaptic cleft and binds to receptors on the postsynaptic membrane, inducing either the depolarization or hyperpolarization of the target cell. (p. 167)

Analytic Questions

1. What types of integral proteins would you expect to reside in the plasma membrane of an epithelial cell that might be absent from that of an erythrocyte? How do such differences relate to the activities of these cells?
2. Many different types of cells possess receptors that bind steroid hormones, which are lipid-soluble molecules. Where in the cell do you think such receptors might reside? Where in the cell would you expect the insulin receptor to reside? Why?
3. When the trilaminar appearance of the plasma membrane was first reported, the images (e.g., Figure 4.1a) were taken as evidence to support the Davson-Danielli model of plasma membrane structure. Why do you think these micrographs might have been interpreted in this way?
4. Suppose you were planning to use liposomes in an attempt to deliver drugs to a particular type of cell in the body, for example, a fat or muscle cell. Is there any way you might be able to construct the liposome to increase its target specificity?
5. How is it that, unlike polysaccharides such as starch and glycogen, the oligosaccharides on the surface of the plasma membrane can be involved in specific interactions? How is this feature illustrated by determining a person's blood type prior to receiving a transfusion?
6. Trypsin is an enzyme that can digest the hydrophilic portions of membrane proteins, but it is unable to penetrate the lipid bilayer and enter a cell. Because of these properties, trypsin has been used in conjunction with SDS-PAGE to determine which proteins have an extracellular domain. Describe an experiment using trypsin to determine the sidedness of proteins of the erythrocyte membrane.
7. Look at the scanning electron micrograph of erythrocytes in Figure 4.32a. These cells, which are flattened and have circular depressions on each side, are said to have a biconcave shape. What is the physiologic advantage of a biconcave erythrocyte over a spherical cell with respect to O_2 uptake?
8. Suppose you were culturing a population of bacteria at $15^\circ C$ and then raised the temperature of the culture to $37^\circ C$. What effect do you think this might have on the fatty acid composition of the membrane? on the transition temperature of the lipid bilayer? on the activity of membrane desaturases?
9. Looking at Figure 4.6, which lipids would you expect to have the greatest rate of flip-flop? which the least? Why? If you determined experimentally that phosphatidylcholine actually exhibited the greatest rate of flip-flop, how might you explain this finding? How would you expect the rate of phospholipid flip-flop to compare with that of an integral protein? Why?

10. What is the difference between a two-dimensional and a three-dimensional representation of a membrane protein? How are the different types of profiles obtained, and which is more useful? Why do you think there are so many more proteins whose two-dimensional structure is known?
11. If you were to inject a squid giant axon with a tiny volume of solution containing 0.1 M NaCl and 0.1 M KCl in which both the Na^+ and K^+ ions were radioactively labeled, which of the radioactively labeled ions would you expect to appear most rapidly within the seawater medium while the neuron remained at rest? after the neuron had been stimulated to conduct a number of action potentials?
12. It has been difficult to isolate proteins containing water channels (i.e., aquaporins) due to the high rate of diffusion of water through the lipid bilayer. Why would this make aquaporin isolation difficult? Is there any way you might be able to distinguish diffusion of water through the lipid bilayer versus that through aquaporins? The best approach to studying aquaporin behavior has been to express the aquaporin genes in frog oocytes. Is there any reason why the oocytes of a pond-dwelling amphibian might be particularly well suited for such studies?
13. How is it that diffusion coefficients measured for lipids within membranes tend to be closer to that expected for free diffusion than those measured for integral proteins in the same membranes?
14. Assume that the plasma membrane of a cell was suddenly permeable to the same degree to both Na^+ and K^+ and that both ions were present at a concentration gradient of the same magnitude. Would you expect these two ions to move across the membrane at the same rates? Why or why not?
15. Most marine invertebrates show no loss or gain of water by osmosis, whereas most marine vertebrates experience continual water loss in their high-salt environment. Speculate on the basis for this difference and how it might reflect different pathways of evolution of the two groups.
16. How would you expect the concentrations of solute inside a plant cell to compare to that of its extracellular fluids? Would you expect the same to be true of the cells of an animal?
17. What would be the consequence for impulse conduction if the Na^+ channels were able to reopen immediately after they had closed during an action potential?
18. What would be the value of the potassium equilibrium potential if the external K^+ concentration was 200 mM and the internal concentration was 10 mM at 25°C? at 37°C?
19. As discussed on page 160, the Na^+ /glucose cotransporter transports two Na^+ ions for each glucose molecule. What if this ratio were 1:1 rather than 2:1; how would this affect the glucose concentration that the transporter could work against?
20. A transmembrane protein usually has the following features: (1) the portion that transits the membrane bilayer is at least 20 amino acids in length, which are largely or exclusively non-

polar residues; (2) the portion that anchors the protein on the external face has two or more consecutive acidic residues; and (3) the portion that anchors the protein on the cytoplasmic face has two or more consecutive basic residues. Consider the transmembrane protein with the following sequence:

NH_2 -MLSTGVKRKGA VLLILLFPWMVAGGPLFWLA
ADESTYKGS-COOH

Draw this protein as it would reside in the plasma membrane. Make sure you label the N- and C-termini and the external and cytoplasmic faces of the membrane. (Single-letter code for amino acids is given in Figure 2.26.)

21. Many marine invertebrates, such as squid, have extracellular fluids that resemble seawater and therefore have much higher intracellular ion concentrations than mammals. For a squid neuron, the ionic concentrations are roughly

<i>ion</i>	<i>intracellular concentration</i>	<i>extracellular concentration</i>
K^+	350 mM	10 mM
Na^+	40 mM	440 mM
Cl^-	100 mM	560 mM
Ca^{2+}	2×10^{-4} mM	10 mM
pH	7.6	8.0

If the resting potential of the plasma membrane, V_m , is -70 mV, are any of the ions at equilibrium? How far out of equilibrium, in mV, is each ion? What is the direction of net movement of each ion through an open channel permeable to that ion?

22. The membrane potential of a cell is determined by the relative permeability of the membrane to various ions. When acetylcholine binds to its receptors on the postsynaptic muscle membrane, it causes a massive opening of channels that are equally permeable to sodium and potassium ions. Under these conditions,

$$V_m = (V_{\text{K}^+} + V_{\text{Na}^+})/2$$

If $[\text{K}^+]_{\text{in}} = 140$ mM and $[\text{Na}^+]_{\text{in}} = 10$ mM for the muscle cell, and $[\text{Na}^+]_{\text{out}} = 150$ mM and $[\text{K}^+]_{\text{out}} = 5$ mM, what is the membrane potential of the neuromuscular junction of an acetylcholine-stimulated muscle?

23. Transmembrane domains consist of individual α helices or a β sheet formed into a barrel. Looking at Figures 2.30 and 2.31, why is a single α helix more suited to spanning the bilayer than a single β strand?
24. Knowing how the K^+ channel selects for K^+ ions, suggest a mechanism by which the Na^+ channel is able to select for its ion.
25. How would you compare the rate of movement of ions passing through a channel versus those transported actively by a P-type pump? Why?

THE HUMAN PERSPECTIVE: The Role of Anaerobic and Aerobic Metabolism in Exercise
Diseases that Result from Abnormal Mitochondrial or Peroxisomal Function

During the first two billion years or so that life existed on Earth, the atmosphere consisted largely of reduced molecules, such as molecular hydrogen (H_2), ammonia (NH_3), and H_2O . The Earth of this period was populated by **anaerobes**—organisms that captured and utilized energy by means of oxygen-independent (anaerobic) metabolism, such as glycolysis and fermentation (Figures 3.24 and 3.29). Then, between 2.4 and 2.7 billion years ago, the cyanobacteria appeared—a new kind of organism that carried out a new type of photosynthetic process, one in which water molecules were split apart and molecular oxygen (O_2) was released. At some point following the appearance of the cyanobacteria, the Earth's atmosphere began to accumulate significant levels of oxygen, which set the stage for a dramatic change in the types of organisms that would come to inhabit the planet.

As discussed on page 35, molecular oxygen can be a very toxic substance, taking on extra electrons and reacting with a variety of biological molecules. The presence of oxygen in the atmosphere must have been a powerful agent for natural selection. Over time, species evolved that were not only protected from the damaging effects of molecular oxygen, but possessed

Micrograph of a mammalian fibroblast that has been fixed and stained with fluorescent antibodies that reveal the distribution of the mitochondria (green) and the microtubules of the cytoskeleton (red). The mitochondria are seen as an extensive network or reticulum that extends through much of the cell. (IMAGE COURTESY M.P. YAFFE, FROM SCIENCE 283: 1493, 1999, FIG. 1; © 1999, REPRINTED WITH PERMISSION FROM AAAS.)

metabolic pathways that utilized the molecule to great advantage. Without the ability to use oxygen, organisms could only extract a limited amount of energy from their foodstuffs, excreting energy-rich products such as lactic acid and ethanol, which they were unable to metabolize further. In contrast, organisms that incorporated O_2 into their metabolism could completely oxidize such compounds to CO_2 and H_2O and, in the process, extract a much larger percentage of their energy content. These organisms that

became dependent on oxygen were the Earth's first **aerobes**, and they eventually gave rise to all of the oxygen-dependent prokaryotes and eukaryotes living today. In eukaryotes, the utilization of oxygen as a means of energy extraction takes place in a specialized organelle, the **mitochondrion**. As discussed in Chapter 1, a massive body of data indicates that mitochondria have evolved from an ancient aerobic bacterium that took up residence inside the cytoplasm of an anaerobic host cell.

5.1 | Mitochondrial Structure and Function

Mitochondria are large enough to be seen in the light microscope (Figure 5.1*a*), and their presence within cells has been known for over a hundred years. Depending on the cell type, mitochondria can have a very different overall structure. At one end of the spectrum, mitochondria can appear as individual, bean-shaped organelles (Figure 5.1*b*), ranging from 1 to 4 μm in length. At the other end of the spectrum, mitochondria can appear as a highly branched, interconnected tubular network. This type of mitochondrial structure can be seen in the chapter-opening micrograph. Observations of fluorescently labeled mitochondria within living cells have shown them to be dynamic organelles capable of dramatic changes in shape. Most importantly, mitochondria can fuse with one another, or split in two (Figure 5.2*a*).

It has been known for many years that mitochondria and the endoplasmic reticulum (ER) engage in extensive interactions, but it was a surprise to discover that mitochondrial fission is apparently induced by contact with thin tubules from the ER. As shown in Figure 5.2*b*, ER tubules can encircle the

mitochondrion like a noose. These ER tubules appear to initiate constriction, which is then completed through the action of soluble proteins that are recruited to the outer surface of the mitochondrion from the cytosol (Figure 5.2*c*). The balance between fusion and fission is likely a major determinant of mitochondrial number, length, and degree of interconnection. When fusion becomes more frequent than fission, the mitochondria tend to become more elongated and interconnected, whereas a predominance of fission leads to the formation of more numerous and distinct mitochondria. A number of inherited neurologic diseases are caused by mutations in genes that encode components of the mitochondrial fusion machinery.

Mitochondria occupy 15 to 20 percent of the volume of an average mammalian liver cell and contain more than a thousand different proteins. These organelles are best known for their role in generating the ATP that is used to run most of the cell's energy-requiring activities. To accomplish this function, mitochondria are often associated with fatty acid-containing oil droplets from which they derive raw materials to be oxidized. A particularly striking arrangement of mitochondria occurs in sperm cells, where they are often located in the midpiece, just behind the nucleus (Figure 5.1*c*). The movements of a sperm are powered by ATP produced in these

Figure 5.1 Mitochondria. (a) A living fibroblast viewed with a phase-contrast microscope. Mitochondria are seen as elongated, dark bodies. (a)

Figure 5.2 Mitochondrial fusion and fission. (a) The dynamic nature of these organelles is captured in the frames of this movie, which shows a portion of a mouse fibroblast whose mitochondria have been labeled with a fluorescent protein. In the first three frames, two pairs of mitochondria (which have been artificially colored) contact end-to-end and immediately fuse. In the last three frames, the lower fusion product undergoes fission, and the daughter mitochondria move apart. (b) Three-dimensional model of contacts between the ER (green) and mitochondria (purple) in a yeast cell based on EM tomography (Section 18.2). ER tubules are seen to encircle portions of the yeast mitochondrial network, marking sites of future fission. Similar events occur in mammalian cells. Bar equals 200 nm. (c) In the model depicted here, contact with ER tubules initiates the process of mitochondrial constriction (step 1). Fission is subsequently accomplished by proteins (e.g., Drp1 in mammals) that assemble into helices around the outer surface of the mitochondrion (step 2). Drp1 is a member of the dynamin family of GTP-binding proteins that are

(b)

involved in severing membranous structures (see Figure 8.41). GTP binding and hydrolysis causes a conformational change in the Drp1 helices that fully constricts the mitochondrion, splitting it into two smaller organelles (step 3). (A: FROM DAVID C. CHAN, *CELL* 125:1242, 2006; © 2006, WITH PERMISSION OF ELSEVIER; B: IMAGE BY M. WEST, FROM JONATHAN R. FRIEDMAN, ET AL., *SCIENCE* 334:359, 2011, REPRINTED WITH PERMISSION FROM AAAS.)

mitochondria. Mitochondria are also prominent in many plant cells where they are the primary suppliers of ATP in nonphotosynthetic tissues, as well as being a source of ATP in photosynthetic leaf cells during periods of dark.

While energy metabolism has been the focus of interest in the study of mitochondria, these organelles are also involved in other activities. For example, mitochondria are the sites of synthesis of numerous substances, including certain amino acids and the heme groups shown in Figures 2.34 and 5.12. Mitochondria also play a vital role in the uptake and release of calcium ions. Calcium ions are essential triggers for cellular activities (Section 15.5), and mitochondria (along with the endoplasmic reticulum) play an important role in regulating the Ca^{2+} concentration of the cytosol. For example, when Ca^{2+} concentrations rise to abnormally high levels in the cytosol, a Ca^{2+} transporter in the inner mitochondrial membrane takes up some of the excess Ca^{2+} ions. The process of cell death, which plays an enormous role in the life of all multicellular animals, is also regulated to a large extent by events that occur within mitochondria (Section 15.8).

Mitochondrial Membranes

If you take a close look at the electron micrograph of Figure 5.1b, it can be seen that the outer boundary of a mitochondrion contains two membranes: the *outer mitochondrial membrane* and the *inner mitochondrial membrane*. The outer

mitochondrial membrane completely encloses the mitochondrion, serving as its outer boundary. The inner mitochondrial membrane is subdivided into two major domains that have different protein residents and carry out distinct functions. One of these domains, called the *inner boundary membrane*, lies just inside the outer mitochondrial membrane, forming a double-membrane outer envelope. The inner boundary membrane is particularly rich in the proteins responsible for the import of mitochondrial proteins (see Figure 8.47). The other domain of the inner mitochondrial membrane is present within the interior of the organelle as a series of invaginated membranous sheets, called **cris**tae. The role of mitochondria as energy transducers is intimately tied to the membranes of the cristae that are so prominent in electron micrographs of these organelles. The cristae contain a large amount of membrane surface, which houses the machinery needed for aerobic respiration and ATP formation (see Figure 5.22). The organization of the cristae is shown in a clearer profile in the scanning electron micrograph of Figure 5.3a and the three-dimensional reconstruction of Figure 5.3b. The inner boundary membrane and internal cristal membranes are joined to one another by narrow tubular connections, or *cristae junctions*, as shown in the schematic illustrations of Figure 5.3c.

The membranes of the mitochondrion divide the organelle into two aqueous compartments, one within the interior of the mitochondrion, called the **matrix**, and a second between the outer and inner membrane, called the

FIGURE IN FOCUS

Figure 5.3 The structure of a mitochondrion.

(b) Three-dimensional reconstruction of a mitochondrion based on a series of micrographs taken with a high-voltage electron microscope of a single thick section of brown fat tissue that had been tilted at various angles. High-voltage instruments accelerate electrons at velocities that allow them to penetrate thicker tissue sections (up to 1.5 μm). This technique suggests that the cristae are present as flattened sheets (lamellae) that

communicate with the intermembrane space by way of narrow tubular openings, rather than “wide-open” channels as is typically depicted. In this reconstruction, the inner mitochondrial membrane is shown in blue at the peripheral regions and in yellow when it penetrates into the matrix to form the cristae. (c) Schematic diagrams showing the three-dimensional internal structure (top) and a thin section (bottom) of a mitochondrion from bovine heart tissue. (A: FROM K. TANAKA AND T. NAGURO, INT. REV. intermembrane space. The matrix has a gel-like consistency owing to the presence of a high concentration (up to 500 mg/ml) of water-soluble proteins. The proteins of the intermembrane space are best known for their role in initiating cell suicide, a subject discussed in Section 15.8.

The outer and inner membranes have very different properties. The outer membrane is composed of approximately 50 percent lipid by weight and contains a curious mixture of enzymes involved in such diverse activities as the oxidation of epinephrine, the degradation of tryptophan, and the elongation of fatty acids. In contrast, the inner membrane contains more than 100 different polypeptides and has a very high protein/lipid ratio (more than 3:1 by weight, which corresponds to about one protein molecule for every 15 phospholipids). The inner membrane is virtually devoid of cholesterol and rich in an unusual phospholipid, cardiolipin (diphosphatidylglycerol; see Figure 4.6 for the structure), which are characteristics of bacterial plasma membranes, from which the inner mitochondrial membrane has presumably evolved. Cardiolipin plays an important role in facilitating the activity of several of the large protein complexes involved in electron transport and ATP synthesis. The outer mitochondrial membrane is thought to be homologous to an outer membrane present as part of the cell wall of certain bacterial cells. The outer mitochondrial membrane and outer bacterial membrane both contain *porins*, integral proteins that have a relatively large internal channel (e.g., 2–3 nm) surrounded by a barrel of β strands (Figure 5.4). The porins of the outer mitochondrial membrane are not static structures as was once thought but can undergo reversible closure in response to conditions within the cell. When the porin channels are wide open, the outer membrane is freely permeable to molecules such as ATP, NAD, and coenzyme A, which have key roles to play in energy metabolism within the mitochondrion. In contrast, the inner mitochondrial membrane is highly impermeable; virtually all molecules and ions require special membrane transporters to gain entrance to the matrix.

As will be discussed in following sections, the composition and organization of the inner mitochondrial membrane are the keys to the bioenergetic activities of the organelle. The architecture of the inner membrane and the apparent fluidity of its bilayer facilitate the interactions of components that are required for ATP formation.

The Mitochondrial Matrix

In addition to an array of enzymes, the mitochondrial matrix also contains ribosomes (of considerably smaller size than those found in the cytosol) and several molecules of DNA, which is circular in higher plants and animals (Figure 5.3c). Thus, mitochondria possess their own genetic material and the machinery to manufacture their own RNAs and proteins. This nonchromosomal DNA is important because it encodes a small number of mitochondrial polypeptides (13 in humans) that are tightly integrated into the inner mitochondrial membrane along with polypeptides encoded by genes residing within the nucleus. Human mitochondrial DNA also encodes 2 ribosomal RNAs and 22 tRNAs that are used in protein

Figure 5.4 Porins. Gram-negative bacteria have a lipid-containing outer membrane outside of their plasma membrane as part of their cell wall. This outer membrane contains proteins, called porins, that consist of a barrel of β sheet and form an opening through which moderate-sized molecules can penetrate. This image shows the protein OmpW embedded in the outer membrane of *E. coli*. The porin contains a small hydrophobic compound within its central channel. A variety of porins having different sized channels and selectivities are also found in the outer mitochondrial membrane in eukaryotic cells. (FROM HEEDEOK HONG ET AL., J. BIOL. CHEM. 281, COVER OF #11, 2006; © 2006, THE AMERICAN SOCIETY FOR BIOCHEMISTRY AND MOLECULAR BIOLOGY; IMAGE COURTESY OF BERT VAN DEN BERG.)

synthesis within the organelle. Mitochondrial DNA (mtDNA) is a relic of ancient history. It is thought to be the legacy from a single aerobic bacterium that took up residence in the cytoplasm of a primitive cell that ultimately became an ancestor of all eukaryotic cells (page 26). Most of the genes of this ancient symbiont were either lost or transferred over the course of evolution to the nucleus of the host cell, leaving only a handful of genes to encode some of the most hydrophobic proteins of the inner mitochondrial membrane. It is interesting to note that the RNA polymerase that synthesizes the various mitochondrial RNAs is not related to the multisubunit enzyme found in prokaryotic and eukaryotic cells. Instead, the mitochondrial RNA polymerase is a single subunit enzyme similar in many respects to certain bacterial viruses (bacteriophage) from which it appears to have evolved. For a number of reasons, mtDNA is well suited for use in the study of human migration and evolution. A number of companies, for example, employ mtDNA sequences to trace the ancestry of clients who are searching for their ethnic or geographic roots.

We will return later in the chapter to discuss the molecular architecture of mitochondrial membranes, but first let us consider the role of these organelles in the basic oxidative pathways of eukaryotic cells, which is summarized in Figure 5.5. It might help to examine this overview figure and read the accompanying legend before moving on to the following detailed descriptions of these pathways.

Figure 5.5 An overview of carbohydrate metabolism in eukaryotic cells. The reactions of glycolysis generate pyruvate and NADH in the cytosol. In the absence of O_2 , the pyruvate is reduced by NADH to lactate (or another product of fermentation, such as ethanol in yeast; see Figure 3.29 for details). The NAD^+ formed in the reaction is reutilized in the continuation of glycolysis. In the presence of O_2 , the pyruvate moves into the matrix (facilitated by a membrane transporter), where it is decarboxylated and linked to coenzyme A (CoA), a reaction that generates NADH. The NADH produced during glycolysis donates its high-energy electrons to a compound that crosses the inner

mitochondrial membrane (as shown in Figure 5.9). The acetyl CoA passes through the TCA cycle (as shown in Figure 5.7), which generates NADH and $FADH_2$. The electrons in these various NADH and $FADH_2$ molecules are passed along the electron-transport chain, which is made up of carriers that are embedded in the inner mitochondrial membrane, to molecular oxygen (O_2). The energy released during electron transport is used in the formation of ATP by a process discussed at length later in the chapter. If all of the energy from electron transport were to be utilized in ATP formation, approximately 36 ATPs could be generated from a single molecule of glucose.

REVIEW

1. Describe the metabolic changes in oxidative metabolism that must have accompanied the evolution and success of the cyanobacteria.
2. Compare the properties and evolutionary history of the inner and outer mitochondrial membranes; the inter-membrane space and the matrix.

5.2 | Oxidative Metabolism in the Mitochondrion

In Chapter 3 we described the initial stages in the oxidation of carbohydrates. Beginning with glucose, the first steps of the oxidation process are carried out by the enzymes of glycolysis, which are located in the cytosol (Figure 5.5). The 10 reactions that constitute the glycolytic pathway were illustrated in Figure 3.23; the major steps of the pathway are summarized in Figure 5.6. Only a small fraction of the free energy available in glucose is made available to the cell during glycolysis—enough for the net synthesis of only two molecules of ATP per molecule of glucose oxidized (Figure 5.6). Most of the energy

remains stored in pyruvate. Each molecule of NADH produced during the oxidation of glyceraldehyde 3-phosphate (reaction 6, Figure 5.6) also carries a pair of high-energy electrons.¹ The two products of glycolysis—pyruvate and NADH—can be metabolized in two very different ways, depending on the type of cell in which they are formed and the presence or absence of oxygen.

In the presence of O_2 , aerobic organisms are able to extract large amounts of additional energy from the pyruvate and NADH produced during glycolysis—enough to synthesize more than 30 additional ATP molecules. This energy is extracted in mitochondria (Figure 5.5). We will begin with pyruvate and return to consider the fate of the NADH later in the discussion. Each pyruvate molecule produced by glycolysis is transported across the inner mitochondrial membrane and into the matrix, where it is decarboxylated to form a two-carbon acetyl group ($-CH_2COO^-$). The acetyl group is transferred to *coenzyme A* (a complex organic compound

¹The terms *high-energy electrons* and *low-energy electrons* are not always well received by biochemists, but they convey a useful image. As discussed on page 189, high-energy electrons are ones that are held with lower affinity and are more readily transferred from a donor to an acceptor than are low-energy electrons.

Figure 5.6 An overview of glycolysis showing some of the key steps. These include the two reactions in which phosphate groups are transferred from ATP to the six-carbon sugar to produce fructose 1,6-bisphosphate (steps 1, 3); the oxidation and phosphorylation of glyceraldehyde 3-phosphate to produce 1,3-bisphosphoglycerate and NADH (step 6); and the transfer of phosphate groups from three-carbon phosphorylated substrates to ADP to produce ATP by substrate phosphorylation (steps 7 and 10). Keep in mind that two molecules of glyceraldehyde 3-phosphate are formed from each molecule of glucose, so reactions 6 through 10 shown here occur twice per glucose molecule oxidized.

Glucose is phosphorylated at the expense of one ATP, rearranged structurally to form fructose phosphate, and then phosphorylated again at the expense of a second ATP. The two phosphate groups are situated at the two ends (C1, C6) of the fructose chain.

The six-carbon bisphosphate is split into two three-carbon monophosphates.

The three-carbon aldehyde is oxidized to an acid as the electrons removed from the substrate are used to reduce the coenzyme NAD^+ to NADH. In addition, the C1 acid is phosphorylated to form an acyl phosphate, which has a high phosphate group-transfer potential (denoted by the yellow shading).

The phosphate group from C1 is transferred to ADP forming ATP by substrate-level phosphorylation. Two ATPs are formed per glucose oxidized.

These reactions result in the rearrangement and dehydration of the substrate to form an enol phosphate at the C2 position that has a high phosphate group-transfer potential.

The phosphate group is transferred to ADP forming ATP by substrate-level phosphorylation, generating a ketone at the C2 position. Two ATPs are formed per glucose oxidized.

Net reaction:

derived from the vitamin pantothenic acid) to produce acetyl CoA.

The decarboxylation of pyruvate and transfer of the acetyl group to CoA (Figures 5.5 and 5.7) along with the reduction of NAD^+ is catalyzed by the giant multienzyme complex pyruvate dehydrogenase, whose structure was shown in Figure 2.39.

The Tricarboxylic Acid (TCA) Cycle

Once formed, acetyl CoA is fed into a cyclic pathway, called the **tricarboxylic acid (TCA) cycle**, where the substrate is oxidized and its energy conserved. Other than succinate dehydrogenase, which is bound to the inner membrane, all the enzymes of the TCA cycle reside in the soluble phase of the matrix (Figure 5.5). The TCA cycle is also referred to as the Krebs cycle after the British biochemist Hans Krebs, who worked out the pathway in the 1930s. When Krebs first obtained sufficient evidence to support the idea of a metabolic cycle, he submitted the results to the British journal *Nature*. The paper was returned several days later accompanied by a letter of rejection. Krebs quickly published the paper in another journal.

The first step in the TCA cycle is the condensation of the two-carbon acetyl group with a four-carbon oxaloacetate to form a six-carbon citrate molecule (Figure 5.7, step 12). During the cycle, the citrate molecule is decreased in chain length, one carbon at a time, regenerating the four-carbon oxaloacetate molecule, which can condense with another acetyl CoA. It is the two carbons that are removed during the TCA cycle (which are not the same ones that were brought in with the acetyl group) that are completely oxidized to carbon dioxide.

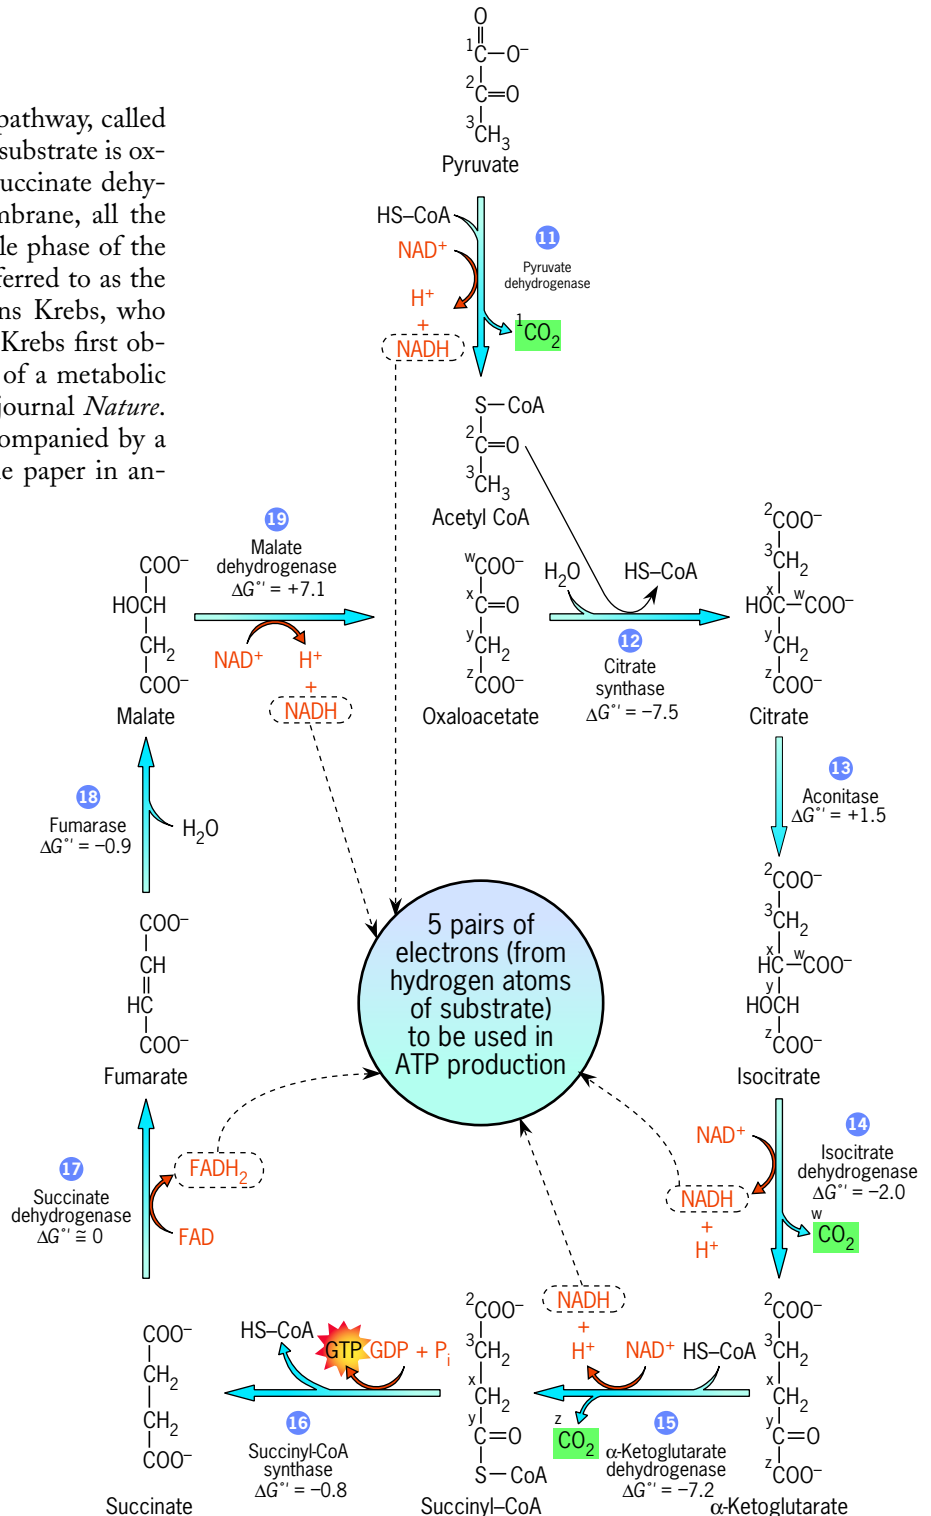

Figure 5.7 The tricarboxylic acid (TCA) cycle, also called the Krebs cycle after the person who formulated it, or the citric acid cycle after the first compound formed in it. The cycle begins with the condensation of oxaloacetate (OAA) and acetyl CoA (reaction 12). The carbons of these two compounds are marked with numbers or letters. The two carbons lost during passage through the cycle are derived from oxaloacetate. The standard free energies (in kcal/mol) and names of enzymes are also provided. Five pairs of electrons are removed from substrate molecules by pyruvate dehydrogenase and the enzymes of the TCA cycle. These high-energy electrons are transferred to NAD^+ or FAD and then passed down the electron-transport chain for use in ATP production. The reactions shown here begin with number 11 because the pathway continues where the last reaction of glycolysis (number 10 of Figure 5.6) leaves off.

During the TCA cycle, four reactions occur in which a pair of electrons are transferred from a substrate to an electron-accepting coenzyme. Three of the reactions reduce NAD^+ to NADH , and one reaction reduces FAD to FADH_2 (Figure 5.7). The net equation for the reactions of the TCA cycle can be written as

The TCA cycle is a critically important metabolic pathway. If the position of the TCA cycle in the overall metabolism of the cell is considered (Figure 5.8; see also Figure 3.22), the metabolites of this cycle are found to be the same compounds generated by most of the cell's catabolic pathways. Acetyl CoA, for example, is an important end product of a number of catabolic paths, including the disassembly of fatty acids, which are degraded within the matrix of the mitochondrion into two-carbon units (Figure 5.8*a*). These two-carbon compounds enter the TCA cycle as acetyl CoA. The catabolism of amino acids also generates metabolites of the TCA cycle (Figure 5.8*b*), which enter the matrix by means of special transport systems in the inner mitochondrial membrane. It is

apparent that all of a cell's energy-providing macromolecules (polysaccharides, fats, and proteins) are broken down into metabolites of the TCA cycle. Thus, the mitochondrion becomes the focus for the final energy-conserving steps in metabolism regardless of the nature of the starting material.

The Importance of Reduced Coenzymes in the Formation of ATP

It is evident from the net equation of the TCA cycle that the primary products of the pathway are the reduced coenzymes FADH_2 and NADH , which contain the high-energy electrons removed from various substrates as they are oxidized. NADH was also one of the products of glycolysis (along with pyruvate). Mitochondria are not able to import the NADH formed in the cytosol during glycolysis. Instead, the electrons of cytosolic NADH are used to reduce a low-molecular-weight metabolite that can either (1) enter the mitochondrion (by a pathway called the malate–aspartate shuttle) and reduce NAD^+ to NADH , or (2) transfer its electrons to FAD (by a pathway called the glycerol phosphate shuttle, which is shown in Figure 5.9) to produce FADH_2 . Both mechanisms allow the electrons from cytosolic NADH to be fed into the mitochondrial electron-transport chain and used for ATP formation.

Now that we have accounted for the formation of NADH and FADH_2 by both glycolysis and the TCA cycle, we can

Figure 5.8 Catabolic pathways generate compounds that are fed into the TCA cycle. (a) Oxidation of fatty acids. The first step in the oxidation of a fatty acid is its activation by linkage to the thiol ($-\text{SH}$) group of coenzyme A, which occurs after the fatty acyl group is transported across the inner mitochondrial membrane in association with a carrier protein (not shown). In the mitochondrion, the fatty acyl CoA molecule undergoes stepwise disassembly in which an acetyl CoA (shown in blue) is removed from the fatty acid chain with each round of the cycle. In addition to the molecule of acetyl CoA that is fed into the TCA cycle, each round of the fatty acid cycle produces one NADH and one FADH_2 . It is apparent from examination of this series of reactions why fats are such a rich storehouse of chemical energy. (b) Input of amino acids into the TCA cycle.

Figure 5.9 The glycerol phosphate shuttle. In the glycerol phosphate shuttle, electrons are transferred from NADH to dihydroxyacetone phosphate (DHAP) to form glycerol 3-phosphate, which shuttles them into the mitochondrion. These electrons then reduce FAD at the inner mitochondrial membrane, forming FADH₂, which can transfer the electrons to a carrier of the electron-transport chain.

turn to the steps that utilize these reduced coenzymes to produce ATP. The overall process can be divided into two steps, which can be summarized as follows:

Step 1 (Figure 5.10). *High-energy electrons are passed from FADH₂ or NADH* to the first of a series of electron carriers that make up the electron-transport chain, which is located in the inner mitochondrial membrane. Electrons pass along the electron-transport chain in energy-releasing reactions. These reactions are coupled to energy-requiring conformational changes in electron carriers that move protons outward across the inner mitochondrial membrane. As a result, the energy released during electron transport is stored in the form of an electrochemical gradient of protons across the membrane. Eventually, the low-energy electrons are transferred to the terminal electron acceptor, namely, molecular oxygen (O₂), which becomes reduced to water.

Step 2 (Figure 5.10). *The controlled movement of protons back across the membrane* through an ATP-synthesizing enzyme provides the energy required to phosphorylate ADP to ATP.

The importance of proton movements during electron transport and the formation of ATP was first proposed in 1961 by Peter Mitchell of the University of Edinburgh. The experiments that led to the acceptance of the **chemiosmotic mechanism**, as Mitchell called it, are discussed in the Experimental Pathways, which can be found at www.wiley.com/college/karp on the Web. Further analysis of the two steps summarized above will occupy us for much of the remainder of the chapter.

Each pair of electrons transferred from NADH to oxygen by means of the electron-transport chain releases sufficient

Figure 5.10 A summary of the process of oxidative phosphorylation. In the first step of the process, substrates such as isocitrate and succinate are oxidized (Figure 5.7) and the electrons are transferred to the coenzymes NAD⁺ or FAD to form NADH or FADH₂. These high-energy electrons are then transferred through a series of electron carriers of the electron transport chain. The energy released is used to translocate protons from the matrix to the intermembrane space, establishing a proton electrochemical gradient across the inner mitochondrial membrane. In step 2, the protons move down the electrochemical gradient, through an ATP-synthesizing complex. The energy stored in the gradient is used to synthesize ATP. These two essential steps of oxidative phosphorylation form the basis of the chemiosmotic mechanism proposed by Peter Mitchell in 1961.

energy to drive the formation of approximately three molecules of ATP. Each pair donated by FADH₂ releases sufficient energy for the formation of approximately two molecules of ATP. If one adds up all of the ATPs formed from one molecule of glucose completely catabolized by means of glycolysis and the TCA cycle, the net gain is about 36 ATPs (which includes the GTP formed by each round of the TCA cycle, step 16, Figure 5.7). The actual number of ATPs formed per molecule of glucose oxidized depends on the particular activities in which the cell is engaged. The relative importance of glycolysis versus the TCA cycle, that is, of anaerobic versus aerobic oxidative metabolism, in human skeletal muscle function is discussed in the accompanying Human Perspective.

REVIEW

1. How are the two products of glycolysis connected to the reactions of the TCA cycle?
2. Why is the TCA cycle considered to be the central pathway in the energy metabolism of a cell?
3. Describe the mechanism by which NADH produced in the cytosol by glycolysis is able to feed electrons into the TCA cycle.

THE HUMAN PERSPECTIVE

The Role of Anaerobic and Aerobic Metabolism in Exercise

Muscle contraction requires large amounts of energy. Most of the energy is utilized in causing actin- and myosin-containing filaments to slide over one another, as discussed in Chapter 9. The energy that drives muscle contraction is derived from ATP. The rate of ATP hydrolysis increases more than 100-fold in a skeletal muscle undergoing maximal contraction compared to the same muscle at rest. It is estimated that the average human skeletal muscle has enough ATP available to fuel a 2- to 5-second burst of vigorous contraction. Even as ATP is hydrolyzed, it is important that additional ATP be produced; otherwise the ATP/ADP ratio would fall and with it the free energy available to fuel contraction. Muscle cells contain a store of creatine phosphate (CrP), one of the compounds with a phosphate transfer potential greater than that of ATP (see Figure 3.28) and thus can be utilized to generate ATP in the following reaction:

Skeletal muscles typically have enough stored creatine phosphate to maintain elevated ATP levels for approximately 15 seconds. Because muscle cells have a limited supply of both ATP and creatine phosphate, it follows that intense or sustained muscular activity requires the formation of additional quantities of ATP, which must be obtained by oxidative metabolism.

Human skeletal muscles consist of two general types of fibers (Figure 1): fast-twitch fibers, which can contract very rapidly (e.g., 15–40 msec), and slow-twitch fibers, which contract more slowly (e.g., 40–100 msec). Fast-twitch fibers are seen under the electron microscope to be nearly devoid of mitochondria, which indicates that these cells are unable to produce much ATP by aerobic respiration. Slow-twitch fibers, on the other hand, contain large numbers of mitochondria. These two types of skeletal muscle fibers are suited for different types of activities. For example, lifting weights or running sprints depends primarily on fast-twitch fibers, which are able to generate more force than their slow-twitch counterparts. Fast-twitch fibers produce nearly all of their ATP anaerobically as a result of glycolysis. Even though glycolysis only produces about 5 percent as much ATP per molecule of glucose oxidized compared with aerobic respiration, the reactions of glycolysis occur much more rapidly

Figure 1 Skeletal muscles contain a mix of fast-twitch (or type II) fibers (darkly stained) and slow-twitch (or type I) fibers (lightly stained). (COURTESY OF DUNCAN MACDOUGALL.)

than those of the TCA cycle and electron transport; thus, the rate of anaerobic ATP production is actually higher than that achieved by aerobic respiration. The problems with producing ATP by glycolysis are the rapid use of the fiber's available glucose (stored as glycogen) and the production of an undesirable end product, lactic acid. Let's consider this latter aspect further.

Recall that the continuation of glycolysis requires the regeneration of NAD^+ , which occurs by fermentation (page 114). Muscle cells regenerate NAD^+ by reducing pyruvate—the end product of glycolysis—to lactic acid. Most of the lactic acid diffuses out of the active muscle cells into the blood, where it is carried to the liver and converted back to glucose. Glucose produced in the liver is released into the blood, where it can be returned to the active muscles to continue to fuel the high levels of glycolysis. However, the formation of lactic acid is associated with a drop in pH within the muscle tissue (from about pH 7.00 to 6.35), which may produce the pain and cramps that accompany vigorous exercise. Increased acidity, together with the depletion of glycogen stores, probably accounts for the sensation of muscle fatigue that accompanies anaerobic exercises.¹

If, instead of trying to use your muscles to lift weights or run sprints, you were to engage in an aerobic exercise, such as bicycling or fast walking, you would be able to continue to perform the activity for much longer periods of time without feeling muscle pain or fatigue. Aerobic exercises, as their name implies, are designed to allow your muscles to continue to perform aerobically, that is, to continue to produce the necessary ATP by electron transfer and oxidative phosphorylation. Aerobic exercises depend largely on the contraction of the slow-twitch fibers of the skeletal muscles. Although these fibers generate less force, they can continue to function for long periods of time due to the continuing aerobic production of ATP without production of lactic acid.

Aerobic exercise is initially fueled by the glucose molecules stored as glycogen in the muscles themselves, but after a few minutes, the muscles depend more and more on free fatty acids released into the blood from adipose (fat) tissue. The longer the period of exercise, the greater the dependency on fatty acids. After 20 minutes of vigorous aerobic exercise, it is estimated that about 50 percent of the calories being consumed by the muscles are derived from fat. Aerobic exercise, such as jogging, fast walking, swimming, or bicycling, is one of the best ways of reducing the body's fat content.

The ratio of fast-twitch to slow-twitch fibers varies from one particular muscle to another. For example, postural muscles in the back that are needed to allow a person to stand consist of a higher proportion of slow-twitch fibers than arm muscles used to throw or lift an object. The precise ratio of fast-twitch to slow-twitch fibers in a particular muscle is genetically determined and quite variable from person to person, allowing a particular individual to excel in certain types of physical activities. For example, world-class sprinters and weight lifters tend to have a higher proportion of fast-twitch fibers in their muscles than long-distance runners. In addition, training for sports such as weight lifting leads to a disproportionate enlargement of the fast-twitch fibers.

The muscle tissue of the heart must also increase its level of activity during vigorous exercise, but unlike skeletal muscle tissue, the heart can only produce ATP by aerobic metabolism. In fact, approximately 40 percent of the cytoplasmic space of a human heart muscle cell is occupied by mitochondria.

¹An alternate view can be found in *Science* 305:1112, 2004.

5.3 | The Role of Mitochondria in the Formation of ATP

Mitochondria are often described as miniature power plants. Like power plants, mitochondria extract energy from organic materials and store it, temporarily, in the form of electrical energy. More specifically, the energy extracted from substrates is utilized to generate an ionic gradient across the inner mitochondrial membrane. An ionic gradient across a membrane represents a form of energy that can be tapped to perform work. We saw in Chapter 4 how intestinal cells utilize an ionic gradient across their plasma membrane to transport sugars and amino acids out of the intestinal lumen, just as nerve cells use a similar gradient to conduct neural impulses. The use of ionic gradients as a form of energy currency requires several components, including a system to generate the gradient, a membrane capable of maintaining the gradient, and the machinery to utilize the gradient to perform work.

Mitochondria utilize an ionic gradient across their inner membrane to drive numerous energy-requiring activities, most notably the synthesis of ATP. When ATP formation is driven by energy that is released from electrons removed during substrate oxidation, the process is called **oxidative phosphorylation** and is summarized in Figure 5.10. Oxidative phosphorylation can be contrasted with substrate-level phosphorylation, as discussed on page 113, in which ATP is formed directly by transfer of a phosphate group from a substrate molecule to ADP. According to one estimate, oxidative phosphorylation accounts for the production of more than 2×10^{26} molecules (>160 kg) of ATP in our bodies per day. Unraveling the basic mechanism of oxidative phosphorylation has been one of the crowning achievements in the field of cell and molecular biology; filling in the remaining gaps continues to be an active area of research. To understand the mechanism of oxidative phosphorylation, it is first necessary to consider how substrate oxidation is able to release free energy.

Oxidation–Reduction Potentials

If one compares a variety of oxidizing agents, they can be ranked in a series according to their affinity for electrons: the greater the affinity, the stronger the oxidizing agent. Reducing agents can also be ranked according to their affinity for electrons: the lower the affinity (the more easily electrons are released), the stronger the reducing agent. To put this into quantifiable terms, reducing agents are ranked according to **electron-transfer potential**; those substances having a high electron-transfer potential, such as NADH, are strong reducing agents, whereas those with a low electron-transfer potential, such as H_2O , are weak reducing agents. Oxidizing and reducing agents occur as *couples*, such as NAD^+ and NADH, which differ in their number of electrons. Strong reducing agents are coupled to weak oxidizing agents, and vice versa. For example, NAD^+ (of the NAD^+ -NADH couple) is a weak oxidizing agent, whereas O_2 (of the O_2 - H_2O couple) is a strong oxidizing agent.

Because the movement of electrons generates a separation of charge, the affinity of substances for electrons can be meas-

Figure 5.11 Measuring the standard oxidation–reduction (redox) potential. The sample half-cell contains the oxidized and reduced members of the couple, both present at 1 M. The reference half-cell contains a 1 M solution of H^+ that is in equilibrium with hydrogen gas at 1 atm pressure. An electric circuit is formed by connecting the half-cells through a voltmeter and a salt bridge. If electrons flow preferentially from the sample half-cell to the reference half-cell, then the standard redox potential (E_0) of the sample couple is negative; if the electron flow is in the opposite direction, the standard redox potential of the sample couple is positive. The salt bridge, which consists of a saturated KCl solution, provides a path for counter-ions to move between the half-cells and maintain electrical neutrality in the two compartments.

ured by instruments that detect voltage (Figure 5.11). What is measured for a given couple is an **oxidation–reduction potential** (or **redox potential**) relative to the potential for some standard couple. The standard couple has arbitrarily been chosen as hydrogen (H^+ - H_2). As with free-energy changes, where the standard free-energy change, ΔG° , was used, a similar assignment is employed for redox couples. The standard redox potential, E_0 , for a given couple is designated as the voltage produced by a half-cell (with only members of one couple present) in which each member of the couple is present under standard conditions (as in Figure 5.11). Standard conditions are 1.0 M for solutes and ions and 1 atm pressure for gases (e.g., H_2) at 25°C . The standard redox potential for the oxidation–reduction reaction involving hydrogen ($2 \text{H}^+ + 2 \text{ electrons} \rightarrow \text{H}_2$) is 0.00 V. Table 5.1 gives the redox potentials of some biologically important couples. The value for the hydrogen couple in the table is not 0.00, but -0.42 V. This number represents the value when the concentration of H^+ is 10^{-7} M (pH of 7.0) rather than 1.0 M (pH of 0.0), which would be of little physiologic use. When calculated at pH 7, the standard redox potential is indicated by the symbol E'_0 rather than E_0 . The assignment of sign (positive or negative) to couples is arbitrary and varies among different disciplines. We will consider the assignment in the following way. Those couples whose reducing agents are better donors of electrons are assigned more negative redox potentials. For example, the standard redox potential for the NAD^+ -NADH couple is -0.32 V (Table 5.1). Acetaldehyde is a stronger reducing agent than NADH, and the acetate-acetaldehyde couple has a standard redox potential of -0.58 V. Those couples whose oxidizing agents are better electron acceptors

Table 5.1 Standard Redox Potentials of Selected Half-Reactions

Electrode equation	E'_0 (V)
Succinate + CO ₂ + 2 H ⁺ + 2 e ⁻ ⇌ α-ketoglutarate + H ₂ O	-0.670
Acetate + 2 H ⁺ + 2 e ⁻ ⇌ acetaldehyde	-0.580
2 H ⁺ + 2 e ⁻ ⇌ H ₂	-0.421
α-Ketoglutarate + CO ₂ + 2 H ⁺ + 2 e ⁻ ⇌ isocitrate	-0.380
Cystine + 2 H ⁺ + 2 e ⁻ ⇌ 2 cysteine	-0.340
NAD ⁺ + 2 H ⁺ + 2 e ⁻ ⇌ NADH + H ⁺	-0.320
NADP ⁺ + 2 H ⁺ + 2 e ⁻ ⇌ NADPH + H ⁺	-0.324
Acetaldehyde + 2 H ⁺ + 2 e ⁻ ⇌ ethanol	-0.197
Pyruvate + 2 H ⁺ + 2 e ⁻ ⇌ lactate	-0.185
Oxaloacetate + 2 H ⁺ + 2 e ⁻ ⇌ malate	-0.166
FAD + 2 H ⁺ + 2 e ⁻ ⇌ FADH ₂ (in flavoproteins)	+0.031
Fumarate + 2 H ⁺ + 2 e ⁻ ⇌ succinate	+0.031
Ubiquinone + 2 H ⁺ + 2 e ⁻ ⇌ ubiquinol	+0.045
2 cytochrome <i>b</i> _(ox) + 2 e ⁻ ⇌ 2 cytochrome <i>b</i> _(red)	+0.070
2 cytochrome <i>c</i> _(ox) + 2 e ⁻ ⇌ 2 cytochrome <i>c</i> _(red)	+0.254
2 cytochrome <i>a</i> _{3(ox)} + 2 e ⁻ ⇌ 2 cytochrome <i>a</i> _{3(red)}	+0.385
$\frac{1}{2}$ O ₂ + 2 H ⁺ + 2 e ⁻ ⇌ H ₂ O	+0.816

than NAD⁺, that is, have greater affinity for electrons than NAD⁺, have more positive redox potentials.

Just as any other spontaneous reaction is accompanied by a loss in free energy, so too are oxidation–reduction reactions. The standard free-energy change during a reaction of the type

can be calculated from the standard redox potentials of the two couples involved in the reaction according to the equation

$$\Delta G^{\circ'} = -nF \Delta E'_0$$

where n is the number of electrons transferred in the reaction, F is the Faraday constant (23.063 kcal/V · mol), and $\Delta E'_0$ is the difference in volts between the standard redox potentials of the two couples. The greater the difference in standard redox potential between two couples, the farther the reaction proceeds under standard conditions to the formation of products before an equilibrium state is reached. Let's consider the reaction in which NADH, a strong reducing agent, is oxidized by molecular oxygen, a strong oxidizing agent.

The standard redox potentials of the two couples can be written as

The voltage change for the total reaction is equal to the difference between the two E'_0 values ($\Delta E'_0$):

$$\Delta E'_0 = +0.82 \text{ V} - (-0.32 \text{ V}) = 1.14 \text{ V}$$

which is a measure of the free energy released when NADH is oxidized by molecular oxygen under standard conditions. Substituting this value into the above equation,

$$\begin{aligned} \Delta G^{\circ'} &= (-2)(23.063 \text{ kcal/V} \cdot \text{mol})(1.14 \text{ V}) \\ &= -52.6 \text{ kcal/mol of NADH oxidized} \end{aligned}$$

the standard free-energy difference ($\Delta G^{\circ'}$) is -52.6 kcal/mol. As with other reactions, the actual ΔG values depend on the relative concentrations of reactants and products (oxidized and reduced versions of the compounds) present in the cell at a given instant. Regardless, it would appear that the drop in free energy of a pair of electrons as they pass from NADH to molecular oxygen ($\Delta G^{\circ'} = -52.6$ kcal/mol) should be sufficient to drive the formation of several molecules of ATP ($\Delta G^{\circ'} = +7.3$ kcal/mol) even under conditions in the cell, where ATP/ADP ratios are much higher than those at standard conditions. The transfer of this energy from NADH to ATP within the mitochondrion occurs in a series of small, energy-releasing steps, which will be the primary topic of discussion in the remainder of the chapter.

Electrons are transferred to NAD⁺ (or FAD) within the mitochondrion from several substrates of the TCA cycle, namely, isocitrate, α-ketoglutarate, malate, and succinate (reactions 14, 15–16, 19, and 17 of Figure 5.7, respectively). The first three of these intermediates have redox potentials of relatively high negative values (Table 5.1)—sufficiently high to transfer electrons to NAD⁺ *under conditions that prevail in the cell*.² In contrast, the oxidation of succinate to fumarate, which has a more positive redox potential, proceeds by the reduction of FAD, a coenzyme of greater electron affinity than NAD⁺.

Electron Transport

Five of the nine reactions illustrated in Figure 5.7 are catalyzed by dehydrogenases, enzymes that transfer pairs of electrons from substrates to coenzymes. Four of these reactions generate NADH and one produces FADH₂. The NADH molecules, which are formed in the mitochondrial matrix, dissociate from their respective dehydrogenases and bind to NADH dehydrogenase, an integral protein of the inner mitochondrial membrane (see Figure 5.17). Unlike the other enzymes of the TCA cycle, succinate dehydrogenase, the enzyme that catalyzes the formation of FADH₂ (Figure 5.7, reaction 17), is a component of the inner mitochondrial membrane. In either case, the high-energy electrons associated with NADH or FADH₂ are transferred through a series of specific electron carriers that constitute the **electron-transport chain** (or **respiratory chain**) of the inner mitochondrial membrane.

²As indicated in Table 5.1, the standard redox potential (E'_0) of the oxaloacetate-malate couple is more positive than that of the NAD⁺-NADH couple. Thus, the oxidation of malate to oxaloacetate has a positive $\Delta G^{\circ'}$ (reaction 19, Figure 5.7) and can proceed to the formation of oxaloacetate only when the ratio of products to reactants is kept below that of standard conditions. The ΔG of this reaction is kept negative by maintenance of very low oxaloacetate concentrations, which is possible because the next reaction in the cycle (reaction 12, Figure 5.7) is highly exergonic and is catalyzed by one of the major rate-controlling enzymes of the TCA cycle.

Types of Electron Carriers

The electron-transport chain contains five types of membrane-bound electron carriers: flavoproteins, cytochromes, copper atoms, ubiquinone, and iron-sulfur proteins. With the exception of ubiquinone, all of the redox centers within the respiratory chain that accept and donate electrons are *prosthetic groups*, that is, non-amino acid components that are tightly associated with proteins.

■ **Flavoproteins** consist of a polypeptide bound tightly to one of two related prosthetic groups, either flavin adenine dinucleotide (FAD) or flavin mononucleotide (FMN) (Figure 5.12*a*). The prosthetic groups of flavoproteins are derived from riboflavin (vitamin B₂), and each is capable of accepting and donating two protons and two electrons. The major flavoproteins of the mitochondria are NADH dehydrogenase of the electron-transport chain and succinate dehydrogenase of the TCA cycle.

■ **Cytochromes** are proteins that contain *heme* prosthetic groups (such as that described for myoglobin on page 58). The iron atom of a heme undergoes reversible transition between the Fe³⁺ and Fe²⁺ oxidation states as a result of the acceptance and loss of a single electron (Figure 5.12*b*). There are three distinct cytochrome types—*a*, *b*, and *c*—present in the electron-transport chain, which differ from one another by substitutions within the heme group (indicated by the blue shaded portions of Figure 5.12*b*).

■ **Three copper atoms**, all located within a single protein complex of the inner mitochondrial membrane (see Figure 5.20), accept and donate a single electron as they alternate between the Cu²⁺ and Cu¹⁺ states.

■ **Ubiquinone (UQ_n or coenzyme Q)** is a lipid-soluble molecule containing a long hydrophobic chain composed of five-carbon isoprenoid units (Figure 5.12*c*). Like the flavoproteins, each ubiquinone is able to accept and donate two

Figure 5.12 Structures of the oxidized and reduced forms of three types of electron carriers. (a) FMN of NADH dehydrogenase, (b) the heme group of cytochrome *c*, and (c) ubiquinone (coenzyme Q). The heme groups of the various cytochromes of the electron-transport chain differ in the substitutions on the porphyrin rings (indicated by

the blue shading) and type of linkage to the protein. Cytochromes can accept only one electron, whereas FMN and quinones can accept two electrons and two protons in successive reactions, as shown. FAD differs from FMN in having an adenosine group bonded to the phosphate.

electrons and two protons. The partially reduced molecule is the free radical ubiquinone, and the fully reduced molecule is ubiquinol (UQH_2). UQ/UQH_2 remains within the lipid bilayer of the membrane, where it is capable of rapid lateral diffusion.

- **Iron-sulfur proteins** are iron-containing proteins in which the iron atoms are not located within a heme group but instead are linked to inorganic sulfide ions as part of an *iron-sulfur center*. The most common centers contain either two or four atoms of iron and sulfur—designated $[2\text{Fe}-2\text{S}]$ and $[4\text{Fe}-4\text{S}]$ —linked to the protein at cysteine residues (Figure 5.13). Even though a single center may have several iron atoms, the entire complex is capable of accepting and donating only a single electron. The redox potential of an iron-sulfur center depends on the hydrophobicity and charge of the amino acid residues that make up its local environment. As a group, iron-sulfur proteins have potentials ranging from about -700 mV to about $+300$ mV, corresponding to a major portion of the span over which electron transport occurs. More than a dozen distinct iron-sulfur centers have been identified within mitochondria.

The carriers of the electron-transport chain are arranged in order of increasingly positive redox potential (Figure 5.14). Each carrier is reduced by the gain of electrons from the preceding carrier in the chain and is subsequently oxidized by the loss of electrons to the carrier following it. Thus, electrons are passed from one carrier to the next, losing energy as they move “downhill” along the chain. The final acceptor of this electron “bucket brigade” is O_2 , which accepts the energy-depleted electrons and is reduced to water. The specific sequence of carriers that constitute the electron-transport chain was worked

Figure 5.13 Iron-sulfur centers. Structure of a $[2\text{Fe}-2\text{S}]$ (a) and a $[4\text{Fe}-4\text{S}]$ (b) iron-sulfur center. Both types of iron-sulfur centers are joined to the protein by linkage to a sulfur atom (shown in orange) of a cysteine residue. Inorganic sulfide ions (S^{2-}) are shown in yellow. Both types of iron-sulfur centers accept only a single electron, whose charge is distributed among the various iron atoms.

out by Britton Chance and co-workers at the University of Pennsylvania using a variety of inhibitors that blocked electron transport at specific sites along the route. The concept of these experiments is depicted by analogy in Figure 5.15. In each case, an inhibitor was added to cells, and the oxidation state of the various electron carriers in the inhibited cells was determined. This determination can be made using a spectrophotometer that measures the absorption of light of a sample at various wavelengths. This measurement reveals whether a particular carrier is in the oxidized or reduced state. In the case depicted in Figure 5.15, addition of rotenone blocked electron transport at a site that left NADH and FMNH_2 in the reduced state, and left cytochromes *b*, *c* and *a* in the oxidized state. This result indicates that NAD and FMN are situated “upstream” of the block. In contrast, an inhibitor (e.g., antimycin A) that acts between cytochromes *b* and *c* would leave NADH, FMNH_2 , QH_2 , and cytochrome *b* in the reduced state. Thus, by identifying reduced and oxidized components in the presence of different inhibitors, the sequences of the carriers could be determined.

The tendency for electrons to be transferred from one carrier to the next depends on the potential difference between the two redox centers, but the rate of transfer depends on the catalytic activities of the proteins involved. This distinction between thermodynamics and kinetics is similar to that discussed on page 95 regarding the activity of enzymes. Studies indicate that electrons may travel considerable distances ($10\text{--}20$ Å) between adjacent redox centers and that electrons probably flow through special “tunneling pathways” consisting of a series of covalent and hydrogen bonds that stretch across

Figure 5.14 The arrangement of several carriers in the electron-transport chain. The diagram illustrates the approximate redox potential of the carriers and the decline in free energy as electron pairs move along the respiratory chain to molecular oxygen. The numerous iron-sulfur centers are not indicated in this figure for the sake of simplicity. As discussed in the following section, each of the three electron transfers that are denoted by red arrows yields sufficient energy to move protons across the inner mitochondrial membrane, which in turn provides the energy required to generate ATP from ADP. (BASED ON A DRAWING FROM A. L. LEHNINGER, *BIOCHEMISTRY*, 2E, 1975.)

Figure 5.15 Experimental use of inhibitors to determine the sequence of carriers in the electron-transport chain. In this hydraulic analogy, treatment of mitochondria with the inhibitor rotenone leaves those carriers on the upstream (NADH) side of the point of inhibition in the fully reduced state and those carriers on the downstream (O_2) side of inhibition in the fully oxidized state. Comparison of the effects of several inhibitors revealed the order of the carriers within the chain. (BASED ON A DRAWING FROM A. L. LEHNINGER, *BIOCHEMISTRY*, 2E, 1975.)

parts of several amino acid residues. An example of such a pathway involving cytochrome *c* is shown in Figure 5.16.

Electron-Transport Complexes When the inner mitochondrial membrane is disrupted by detergent, the various electron carriers can be isolated as part of four distinct, asymmetric, membrane-spanning complexes, identified as complexes I, II, III, and IV (Figure 5.17). Each of these four complexes can be assigned a distinct function in the overall oxidation pathway. Two components of the electron-transport chain, cytochrome *c* and ubiquinone, are not part of any of the four complexes. Ubiquinone occurs as a pool of molecules dissolved in the lipid bilayer, and cytochrome *c* is a soluble protein in the intermembrane space. Ubiquinone and cytochrome *c* are thought to move within or along the membrane, shuttling electrons between the large, relatively immobile protein complexes. Once within one of the large, multiprotein complexes, electrons travel along defined pathways (of the type illustrated in Figure 5.16) between adjacent redox centers whose relative positions are fixed in place.

When NADH is the electron donor, electrons enter the respiratory chain by means of complex I, which transfers electrons to ubiquinone, generating ubiquinol (Figures 5.12 and 5.17). Unlike NADH, which can diffuse away from its soluble dehydrogenases, $FADH_2$ remains covalently bound to succi-

Figure 5.16 Electron-tunneling pathways for the yeast cytochrome *c*-cytochrome *c* peroxidase complex. The heme group of cytochrome *c* is blue, and that of cytochrome *c* peroxidase (which is not a carrier of the mitochondrial electron-transport chain but provides an analogous electron acceptor for which high-resolution crystal structures are available) is red. Several defined pathways (yellow) exist for the movement of electrons from one heme to the other. Each of the pathways carries the electrons through several amino acid residues situated between the heme groups. (It can be noted that other mechanisms of electron transfer have been proposed.) (BY JEFFREY J. REGAN AND J. N. ONUCHIC, FROM DAVID N. BERATAN ET AL., *SCIENCE* 258:1741, © 1992. REPRINTED WITH PERMISSION FROM AAAS.)

nate dehydrogenase, a component of complex II. When $FADH_2$ is the donor, electrons are passed directly to ubiquinone, bypassing the upstream end of the chain, which has too negative a redox potential to accept the less energetic electrons of the flavin nucleotide (Figure 5.14).

If one examines the redox potentials of successive carriers in Figure 5.14, it is apparent that there are three places in which the transfer of electrons is accompanied by a major release of free energy. Each of these *coupling sites*, as they are called, occurs between carriers that are part of one of the three complexes, I, III, and IV. The free energy, which is released as electrons are passed across these three sites, is conserved by translocation of protons from the matrix across the inner membrane into the intermembrane space. These three protein complexes are often described as *proton pumps*. Unlike other ions (e.g. Na^+ or Cl^-) that have to diffuse by themselves across the entire distance being traversed, H^+ ions can “hop” through a channel by exchanging themselves with other protons present along the pathway (as illustrated in Figure 5.19*b*). Such proton-conduction pathways (or “proton wires”) can be identified because they consist of strings of acidic residues, hydrogen-bonded residues, and/or trapped water molecules. The translocation of protons by these three electron-transporting complexes establishes the proton gradient that drives ATP synthesis. The ability of these remarkable molecular machines to act as independent proton-translocating units can be demonstrated by purifying each of them and incorporating them individually into artificial lipid vesicles. When given an appropriate electron donor, these protein-containing vesicles are capable of

(a)

(b)

Figure 5.17 The electron-transport chain of the inner mitochondrial membrane. (a) The respiratory chain consists of four complexes of electron carriers and two other carriers (ubiquinone and cytochrome c) that are independently disposed. Electrons enter the chain from either NADH (via complex I) or $FADH_2$ (a part of complex II). Electrons are passed from either complex I or II to ubiquinone (UQ), which exists as a pool within the lipid bilayer. Electrons are subsequently passed from reduced ubiquinone (ubiquinol) to complex III and then to the peripheral protein cytochrome c , which is thought to be mobile. Electrons are transferred from cytochrome c to complex IV (cytochrome oxidase) and then to O_2 to form H_2O . The sites of proton translocation from the matrix to the cytosol are indicated. The precise number of protons translocated at each site remains controversial; the number indicated is a general consensus. Keep in mind that the proton

numbers shown are those generated by each pair of electrons transported, which is sufficient to reduce only one-half of an O_2 molecule. (The translocation of protons by complex III occurs by way of a Q cycle, whose details are shown in Figure 4 of the Experimental Pathway on the Web. The Q cycle can be divided into two steps, each of which leads to the release of two protons into the cytosol.) (b) Structures of the protein components of the electron-transport chain (either mitochondrial or bacterial versions). The structure of a bacterial version of complex I is shown in Figure 5.19a. The membrane-embedded portion of complex I from *E. coli* includes 55 transmembrane helices. (B: FROM BRIAN E. SCHULTZ AND SUNNEY I. CHAN, FROM THE ANNUAL REVIEW OF BIOPHYSICS BIOMOLECULAR STRUCTURE, VOLUME 30, 2001. REPRINTED WITH PERMISSION FROM ANNUAL REVIEWS, INC.)

accepting electrons and using the released energy to pump protons across the vesicle membrane (see Figure 5.18).

Great strides have been made in the past few years in elucidating the molecular architecture of all the protein com-

plexes of the inner membrane (Figure 5.17b). Researchers are no longer asking what these proteins look like but are using the wealth of new structural information to understand how they work. We will briefly examine the mammalian versions of

Figure 5.18 Experimental demonstration that cytochrome oxidase is a proton pump. When purified cytochrome oxidase is incorporated into the artificial bilayer of a liposome, the medium becomes acidified following the addition of reduced cytochrome *c*. This indicates that as electrons are transferred from cytochrome *c* to cytochrome oxidase, and O_2 is being reduced to water, protons are being translocated from the compartment within the vesicle to the external medium. This experiment was originally carried out in the late 1960s by Märten Wikström and colleagues at the University of Helsinki in Finland. (REPRINTED WITH PERMISSION FROM MACMILLAN PUBLISHERS LTD: M. I. VERKHOVSKY ET AL. NATURE 400:481, 1999, COPYRIGHT 1999.)

Figure 5.19 Structure and a proposed mechanism of action of complex I of the respiratory chain. (a) Crystal structure of a bacterial form of complex I. The peripheral hydrophilic domain and the membrane-embedded hydrophobic domain are evident. The electron carriers within the peripheral arm—namely, FMN (magenta sphere), the seven Fe-S centers (red spheres), and the quinone binding site (Q)—are indicated. Helix HL of the membrane domain, which is proposed to act as a connecting rod or piston, is seen running roughly parallel to the plane of the membrane. (b) Proposed mechanism by which electron transfer in the peripheral hydrophilic arm is coupled by conformational changes to proton translocation across the membrane domain. Reduction of ubiquinone at the Q site leads to a rightward movement of helix HL

each of the four electron-transport complexes, which together contain about 70 different polypeptides. The bacterial versions are considerably simpler than their mammalian counterparts and contain far fewer subunits. However, the additional subunits of the mammalian complexes do not contain redox centers and are thought to function in either the regulation or assembly of the complex rather than electron transport. In other words, the basic process of electron transport during respiration has remained virtually unchanged since its evolution billions of years ago in our prokaryotic ancestors.

Complex I (or NADH dehydrogenase) Complex I is the gateway to the electron-transport chain, catalyzing the transfer of a pair of electrons from NADH to ubiquinone (UQ) to form ubiquinol (UQH_2). The mammalian version of complex I is a huge L-shaped conglomerate, containing 45 different subunits that constitute a molecular mass of nearly one million daltons. As indicated in Figures 5.17b and 5.19a, roughly half of the complex consists of a hydrophilic domain that projects into the matrix, with the remaining hydrophobic portion of

(indicated by the upper black arrow in the reduced version), which causes conformational changes in the transmembrane helices, leading to the movement of protons across the membrane. Crucial charged residues in subunits of the membrane domain are indicated by circles. Red circles represent unprotonated glutamic acid residues, and blue circles represent protonated lysine residues. The protonated and unprotonated forms of these residues are seen as empty circles, respectively. The movement of protons between these residues, which is driven by conformational changes in the transmembrane helices, forms the basis for proton translocation. (FROM ROUSLAN G. EFREMOV AND LEONID A. SAZANOV, NATURE 476:414, 2011; REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LIMITED.)

the complex embedded in the membrane. Seven of the subunits—all hydrophobic, membrane-spanning polypeptides—are encoded by mitochondrial genes and are homologues of bacterial polypeptides. Together, the hydrophilic and membrane-embedded portions of the complex carry out the two different activities that are required of the electron-transport chain: electron transfer and proton translocation.

All of the components required for electron transfer reside within the hydrophilic portion of the complex (Figure 5.19*b*). The chain of electron carriers begins with an FMN-containing flavoprotein that oxidizes NADH at the tip of the giant complex. Electrons are subsequently transferred through seven distinct iron-sulfur centers within the body of the hydrophilic domain, ending with the transfer of electrons to a protein-bound ubiquinone molecule situated near the membrane boundary. (An eighth Fe-S cluster and possibly a second quinone molecule are also present but not apparently in the direct path of electron transfer.) The passage of a pair of electrons from NADH to ubiquinone is thought to be accompanied by the movement of four protons from the matrix into the intermembrane space. The determination of the structure of complex I (Figure 5.19*a*) has led to a proposal that explains how electron transport through the peripheral arm of the complex can drive proton translocation through the distant membrane-embedded portion. It can be seen in Figure 5.19*b*, that the membrane-embedded domain of the complex contains a very long α helix, denoted HL (shown in purple), that is oriented roughly parallel to the membrane's surface. This helix, which runs nearly the entire length of the membrane domain, is in direct contact with three discontinuous transmembrane helices (shown in purple, blue, and olive green). Each of the discontinuous helices is part of a half channel. Each pair of half channels is connected by a network of polar amino acid side chains to provide a potential whole channel for the translocation of protons across the membrane. A fourth proton-conducting channel is probably located near the interface with the soluble domain as shown in Figure 5.19*b*. It is proposed that the movement of electrons to ubiquinone induces a conformational change in the complex that causes the lateral movement of helix HL (toward the right in Figure 5.19*b*). This in turn leads to the tilting movement of the transmembrane helices, which changes the ionic environment of certain proton-transferring residues, leading to the movement of protons across the membrane (black downward arrows). The authors of this proposal compare the mechanism of action of complex I to that of a steam engine, with helix HL acting as the piston that drives the movement of the downstream elements of the machinery.

It can be noted that complex I dysfunction has been linked to certain neurodegenerative disorders, as discussed in the Human Perspective on page 208.

Complex II (or succinate dehydrogenase) Complex II consists of four polypeptides: two hydrophobic subunits that anchor the protein in the membrane and two hydrophilic subunits that comprise the TCA cycle enzyme, succinate dehydrogenase. Complex II provides a pathway for feeding lower-energy electrons (ones close to 0 mV) from succinate to FAD to ubiquinone (Figures 5.14 and 5.17). The path from FADH₂

at the enzyme catalytic site to ubiquinone takes the electrons over a distance of 40 Å through three iron-sulfur clusters. Complex II also contains a heme group, which is thought to attract escaped electrons, thereby preventing the formation of destructive superoxide radicals (page 35). Electron transfer through complex II is not accompanied by proton translocation.

Complex III (or cytochrome bc₁) Complex III catalyzes the transfer of electrons from ubiquinol to cytochrome *c*. Experimental determinations suggest that four protons are translocated across the membrane for every pair of electrons transferred through complex III. The protons are released into the intermembrane space in two separate steps powered by the energy released as a pair of electrons are separated from one another and passed along different pathways through the complex. Two protons are derived from the molecule of ubiquinol that entered the complex. Two additional protons are removed from the matrix and translocated across the membrane as part of a second molecule of ubiquinol. These steps are described in further detail in Figure 4 of the Experimental Pathways, which can be seen on the Web at www.wiley.com/college/karp. Three of the subunits of complex III contain redox groups: cytochrome *b* contains two heme *b* molecules with different redox potentials, cytochrome *c*₁, and an iron-sulfur protein. Cytochrome *b* is the only polypeptide of the complex encoded by a mitochondrial gene.

*Complex IV (or cytochrome *c* oxidase)* The final step of electron transport in a mitochondrion is the successive transfer of electrons from reduced cytochrome *c* to oxygen according to the reaction

To reduce a whole molecule of O₂,

The reduction of O₂ is catalyzed by complex IV, a huge assembly of polypeptides referred to as **cytochrome oxidase**. Cytochrome oxidase was the first component of the electron-transport chain shown to act as a redox-driven proton pump. This was demonstrated in the experiment depicted in Figure 5.18 in which the purified enzyme was incorporated into vesicles containing an artificial lipid bilayer (liposomes). Addition of reduced cytochrome *c* to the medium was accompanied by the expulsion of H⁺ ions from the vesicles, which was measured as a drop in the surrounding pH. Whether inside a liposome or the inner mitochondrial membrane, translocation of protons is coupled to conformational changes generated by the release of energy that accompanies the transfer of electrons. For every molecule of O₂ reduced by cytochrome oxidase, eight protons are thought to be taken up from the matrix. Four of these protons are consumed in the formation of two molecules of water as indicated above, and the other four protons are translocated across the membrane and released into the intermembrane space (Figure 5.17). Consequently, the overall reaction can be written:

Humans produce about 300 ml of “metabolic water” from this reaction per day. It can be noted that a number of potent respiratory poisons, including carbon monoxide (CO), azide (N_3^-), and cyanide (CN^-), have their toxic effect by binding to the heme a_3 site of cytochrome oxidase. (Carbon monoxide also binds to the heme group of hemoglobin.)

A Closer Look at Cytochrome Oxidase Cytochrome oxidase consists of 13 subunits, three of which are encoded by the mitochondrial genome and contain all four of the protein’s redox centers. A major challenge for investigators is to explain how carriers that are only able to transfer single electrons can reduce a molecule of O_2 to two molecules of H_2O , a process that requires four electrons (together with four protons). Most importantly, the process must occur very efficiently because the cell is dealing with very dangerous substances; the “accidental” release of partially reduced oxygen species has the potential to damage virtually every macromolecule in the cell (page 35).

The movement of electrons between redox centers of cytochrome oxidase is shown in Figure 5.20. Electrons are transferred one at a time from cytochrome c through a bimetallic copper center (Cu_A) of subunit II to a heme (a) of subunit I. From there, electrons are passed to a

Figure 5.20 A summary of cytochrome oxidase activity. A model showing the flow of electrons through the four redox centers of cytochrome oxidase. Iron atoms are shown as red spheres, copper atoms as yellow spheres. Electrons are thought to be passed one at a time from cytochrome c to the dimeric copper center (Cu_A), then on to the iron of the heme group of cytochrome a , then on to the binuclear redox center consisting of a second iron (of the heme group of cytochrome a_3) and copper ion (Cu_B). The structures and suggested orientations of the redox centers are indicated. (REPRINTED FROM M. WIKSTROM ET AL., *BIOCHIM BIOPHYSICS. ACTA* 1459:515, 2000, WITH PERMISSION FROM ELSEVIER.)

redox center located in subunit I that contains a second heme (heme a_3) and another copper atom (Cu_B) situated less than 5 Å apart. Acceptance of the first two electrons reduces the a_3 - Cu_B binuclear center according to the reaction

Once the binuclear center accepts its second electron, an O_2 molecule binds to the center. The $\text{O}=\text{O}$ double bond is then broken as the O atoms accept a pair of electrons from the reduced a_3 - Cu_B binuclear center, likely forming a reactive peroxy anion O_2^{2-} .

In subsequent steps, the binuclear center accepts two more electrons from cytochrome c and four protons from the matrix, which leads to the formation of two molecules of water. For each proton removed from the matrix, an excess negative charge (in the form of an OH^-) is left behind, thus contributing directly to the electrochemical gradient across the inner mitochondrial membrane.

As noted above, protons taken up from the matrix are utilized in two very different ways. For every molecule of O_2 reduced to 2 H_2O by cytochrome oxidase: (1) four H^+ ions are consumed in this chemical reaction and (2) four additional H^+ ions are translocated across the inner mitochondrial membrane. The first four protons can be referred to as “substrate” protons and the latter four as “pumped” protons. Movement of both groups of protons contributes to the electrochemical gradient across the membrane.

With the publication of the three-dimensional crystal structure of cytochrome oxidase, it became possible to search for pathways through which substrate and pumped protons might move through the huge protein. Researchers have identified potential proton conduits within the molecule, but their role has not been experimentally established. Unfortunately, static structural models, by themselves, cannot reveal the dynamic movements that take place within the protein as it functions. The energy released by O_2 reduction is presumably used to drive conformational changes that alter the ionization states and precise locations of amino acid side chains within these channels. These changes would, in turn, promote the movement of H^+ ions through the protein, as occurs during electron transport in complex I (Figure 5.19*b*).

5.4 | Translocation of Protons and the Establishment of a Proton-Motive Force

We have seen that the free energy released during electron transport is utilized to move protons from the matrix to the intermembrane space and cytosol. Translocation of protons across the inner membrane is electrogenic (i.e., voltage producing) because it results in a greater number of positive charges in the intermembrane space and cytosol and a greater number of negative charges within the matrix. Thus, there are two components of the proton gradient to consider. One of the components is the concentration difference between hydrogen ions on one side of the membrane versus the other side; this is a pH gradient (ΔpH). The other component is the voltage (ψ) that results from the separation of charge across the membrane. A gradient that has both a concentration (chemical) and an electrical (voltage) component is an *electrochemical gradient* (page 148). The energy present in both components of the proton electrochemical gradient can be combined and expressed as the **proton-motive force (Δp)**, which is measured in millivolts. Thus,

$$\Delta p = \psi - 2.3 (RT/F) \Delta\text{pH}$$

Because $2.3 RT/F$ is equal to 59 mV at 25°C , the equation³ can be rewritten as

$$\Delta p = \psi - 59 \Delta\text{pH}$$

The contribution to the proton-motive force made by the electric potential versus the pH gradient depends on the permeability properties of the inner membrane. For example, if the outward movement of protons during electron transport is accompanied by negatively charged chloride ions, then the electric potential (ψ) is reduced without affecting the proton gradient (ΔpH). Measurements made in various laboratories suggest that actively respiring mitochondria generate a proton-motive force of approximately 220 mV across their inner

³In other words, a difference of one pH unit, which represents a tenfold difference in H^+ concentration across the membrane, is equivalent to a potential difference of 59 millivolts, which is equivalent to a free-energy difference of 1.37 kcal/mol.

membrane. In mammalian mitochondria, approximately 80 percent of the free energy of Δp is represented by the voltage component and the other 20 percent by the proton concentration difference (approximately 0.5 to 1 pH unit difference). If the proton concentration difference were much greater than this it would likely affect the activity of cytoplasmic enzymes. The transmembrane voltage across the inner mitochondrial membrane can be visualized by the use of positively charged, lipid-soluble dyes that distribute themselves across membranes in proportion to the electric potential (Figure 5.21).

When cells are treated with certain lipid-soluble agents, most notably 2,4-dinitrophenol (DNP), they continue to oxidize substrates without being able to generate ATP. In other words, DNP *uncouples* glucose oxidation and ADP phosphorylation. Because of this property, DNP has become widely used in the laboratory to inhibit ATP formation. During the 1920s, a few physicians even prescribed DNP as a diet pill. When exposed to the drug, the cells of obese patients continued to oxidize their stores of fat in a vain attempt to maintain normal ATP levels. The practice ceased with the deaths of a number of patients taking the drug. With the formulation of the chemiosmotic theory and the determination that mitochondria generate a proton gradient, the mechanism of DNP action became understood. This drug can uncouple oxidation and phosphorylation because it combines with protons and, because of its lipid solubility, carries the protons across the inner mitochondrial membrane down their electrochemical gradient.

Figure 5.21 Visualizing the proton-motive force. Fluorescence micrograph of a cultured cell stained with the fluorescent, cationic dye rhodamine. When the cell is active, the voltage generated across the inner mitochondrial membrane (inside negative) leads to the accumulation of the cationic dye within the mitochondria, causing the organelles to fluoresce. (FROM L. V. JOHNSON ET AL., J. CELL BIOL. 88:528, 1981, FIG. 7; © 1981, ROCKEFELLER UNIVERSITY PRESS; IMAGE COURTESY OF LAN BO CHEN.)

The maintenance of a proton-motive force requires that the inner mitochondrial membrane remain highly impermeable to protons. If not, the gradient established by electron transport is quickly dissipated by the movement of protons back into the matrix, leading to the release of energy as heat. It came as a surprise to discover that the inner mitochondrial membrane of certain cells contains proton-transporting proteins, called *uncoupling proteins* (or *UCPs*), that act as natural (endogenous) uncouplers. One of these proteins, UCP1, is especially abundant in brown adipose tissue of mammals, which functions as a source of heat production during exposure to cold temperatures. Human infants also rely on “burning” brown fat deposits to maintain body temperature. It was thought until recently that adult humans were largely devoid of brown adipose tissue, but several recent studies have shown the presence of brown fat cells in the neck and upper chest. As in infants, these cells become activated when we are exposed to cold temperatures. UCP1 is the focus of a number of drug companies that are hoping to develop products that stimulate this protein as part of a weight-loss regimen. Other UCP isoforms (UCP2-UCP5) are present in a variety of tissues, especially in cells of the nervous system, but their roles are debated. For example, UCPs in the inner mitochondrial membrane are thought to prevent the build-up of an excessively large proton-motive force. If such a high-energy state were to form, it could block the passage of electrons through the respiratory complexes, leading to the leakage of electrons and the production of reactive oxygen radicals.

The experiments that led to the acceptance of the proton-motive force as an intermediate in the formation of ATP are discussed in the Experimental Pathways, which can be found at www.wiley.com/college/karp on the Web.

5.5 | The Machinery for ATP Formation

Now that we have seen how the transport of electrons generates a proton electrochemical gradient across the inner mitochondrial membrane, we can turn to the molecular machinery that utilizes the energy stored in this gradient to drive the phosphorylation of ADP.

During the early 1960s, Humberto Fernandez-Moran of Massachusetts General Hospital was examining isolated mitochondria by the recently developed technique of negative staining. Fernandez-Moran discovered a layer of spheres attached to the inner (matrix) side of the inner membrane, projecting from the membrane and attached to it by stalks (Figure 5.22). A few years later, Efraim Racker of Cornell

Figure 5.22 The machinery for ATP synthesis. Electron micrograph of a small portion of a beef heart mitochondrion that has been air-dried and negatively stained. At magnifications of approximately one-half million, spherical particles are seen (arrow) attached by a thin stalk to the inner surface of the cristae membranes. (FROM HUMBERTO FERNANDEZ-MORAN ET AL., *J. CELL BIOL.* 22:73, 1964 FIG. 7; © 1964 ROCKEFELLER UNIVERSITY PRESS.)

University isolated the inner membrane spheres, which he called *coupling factor 1*, or simply F_1 . Racker discovered that the F_1 spheres behaved like an enzyme that hydrolyzed ATP, that is, an ATPase. At first glance this seems to be a peculiar finding. Why should mitochondria possess a predominant enzyme that hydrolyzes the substance it is supposed to produce?

If one considers that the hydrolysis of ATP is the reverse reaction from its formation, the function of the F_1 sphere becomes more evident; it contains the catalytic site at which ATP formation normally occurs. Recall that

1. Enzymes do not affect the equilibrium constant of the reaction they catalyze.
2. Enzymes are capable of catalyzing both the forward and reverse reactions.

Consequently, the direction of an enzyme-catalyzed reaction at any given time depends on the prevailing conditions. This is nicely shown in experiments with other ATPases, such as the Na^+/K^+ -ATPase of the plasma membrane (page 158). When this enzyme was discussed in Chapter 4, it was described as an enzyme that used the energy obtained from ATP hydrolysis to export Na^+ and import K^+ against their respective gradients. In the cell this is the only function of the enzyme. However, under experimental conditions, this enzyme can catalyze the formation of ATP rather than its hydrolysis (Figure 5.23). To obtain such conditions, red blood cell ghosts (page 145) are prepared with a *very* high internal K^+ concentration and a *very* high external Na^+ concentration, higher than normally exists in the body. Under these conditions, K^+ moves out of the “cell” and Na^+ moves into the “cell.” Both ions are moving down their respective gradients, rather than against them as would normally occur in a living cell. If ADP and P_i are present within the ghost, the movement of the ions causes ATP to be synthesized rather than hydrolyzed.

Figure 5.23 An experiment to drive ATP formation in membrane vesicles reconstituted with the Na^+/K^+ -ATPase. By causing these vesicles to have very high internal K^+ concentration and very high external Na^+ concentration, the reaction is made to run in the opposite direction from that of its normal course in the plasma membrane. In the process, ATP is formed from ADP and P_i . The size of the letters indicates the direction of the concentration gradients.

Experiments such as this illustrate the reality of what would be expected on the basis of the theoretical reversibility of enzyme-catalyzed reactions. They also illustrate how an ionic

gradient can be used to drive a reaction in which ADP is phosphorylated to ATP, which is precisely what occurs in the mitochondrion. The driving force is the proton-motive force established by electron transport.

The Structure of ATP Synthase

Although the F_1 sphere is the catalytic portion of the enzyme that manufactures ATP in the mitochondrion, it is not the whole story. The ATP-synthesizing enzyme, which is called **ATP synthase**, is a mushroom-shaped protein complex (Figure 5.24a) composed of two principal components: a spherical F_1 head (about 90 Å diameter) and a basal section, called F_0 , embedded in the inner membrane. High-resolution electron micrographs indicate that the two portions are connected by both a central and a peripheral stalk as shown in Figure 5.24b. A typical mammalian liver mitochondrion has roughly 15,000 copies of the ATP synthase. Homologous versions of the ATP synthase are found in the plasma membrane of bacteria, the thylakoid membrane of plant chloroplasts, and the inner membrane of mitochondria.

The F_1 portions of the bacterial and mitochondrial ATP synthases are highly conserved; both contain five different polypeptides with a composition of $\alpha_3\beta_3\delta\gamma\epsilon$. The α and β subunits are arranged alternately within the F_1 head in a man-

(a)

Figure 5.24 The structure of the bacterial ATP synthase.

(a) Schematic diagram of the ATP synthase from *E. coli*. The enzyme consists of two major portions, called F_1 and F_0 . The F_1 head consists of five different subunits in the ratio $3\alpha:3\beta:1\delta:1\gamma:1\epsilon$. The α and β subunits are organized in a circular array to form the spherical head of the particle; the γ subunit runs through the core of the ATP synthase from the tip of F_1 down to F_0 to form a central stalk; the ϵ subunit helps attach the γ subunit to the F_0 base. The F_0 base, which is embedded in the bacterial plasma membrane, consists of three different subunits in the ratio $1a:2b:10c$. As discussed later, the c subunits form a rotating ring within the membrane; the paired b subunits of the F_0 base

(b)

and the δ subunit of the F_1 head form a peripheral stalk that holds the α/β subunits in a fixed position; and the a subunit contains the proton channel that allows protons to traverse the membrane. The mammalian enzyme contains seven to nine small additional subunits whose functions are not well established. (b) Three-dimensional structure of the bacterial ATP synthase. This image is composed of several partial structures of the enzyme from various organisms. ner resembling the segments of an orange (Figure 5.24a; see also 5.26b). Two aspects can be noted for later discussion: (1) each F_1 contains three catalytic sites for ATP synthesis, one on each β subunit, and (2) the γ subunit runs from the outer tip of the F_1 head through the central stalk and makes contact with the F_0 basepiece. In the mitochondrial enzyme, all five polypeptides of F_1 are encoded by the nuclear DNA, synthesized in the cytosol, and then imported (see Figure 8.47).

The F_0 portion of the ATP synthase resides within the membrane and consists of three different polypeptides with a stoichiometry of ab_2c_{10} in *E. coli* (Figure 5.24b). The number of subunits in the *c* ring can vary depending on the source of the enzyme. Both the yeast mitochondrial and *E. coli* ATP synthase, for example, have 10 *c* subunits, whereas a chloroplast enzyme has 14 *c* subunits (Figure 5.25) and, surprisingly, the mammalian enzyme has only 8 *c* subunits. The F_0 base contains a channel through which protons are conducted from the intermembrane space to the matrix.

The Basis of ATP Formation According to the Binding Change Mechanism

How does a proton electrochemical gradient provide the energy required to drive the synthesis of ATP? To answer this question, Paul Boyer of UCLA published an innovative hypothesis in 1979, called the *binding change mechanism*, which has since gained wide acceptance. Overall, the binding

change hypothesis has several distinct components, which we will discuss in sequence.

1. **The energy released by the movement of protons is not used to drive ADP phosphorylation directly but principally to change the binding affinity of the active site for the ATP product.** We are used to thinking of cellular reactions occurring in an aqueous environment in which the concentration of water is 55 M and the reactants and products are simply dissolved in the medium. Under these conditions, energy is required to drive the formation of the covalent bond linking ADP with inorganic phosphate to form ATP. It has been demonstrated, however, that once ADP and P_i are bound within the catalytic site of the ATP synthase, the two reactants readily condense to form a tightly bound ATP molecule without the input of additional energy. In other words, even though the reaction

may require the input of considerable energy (7.3 kcal/mol under standard conditions), the reaction

can occur spontaneously without the input of energy (page 90). This does not mean that ATP can be formed from ADP without energy expenditure. Instead, the energy is required for the release of the tightly bound product from the catalytic site, rather than the phosphorylation event itself.

2. **Each active site progresses successively through three distinct conformations that have different affinities for substrates and product.** Recall that the F_1 complex has three catalytic sites, one on each of the three β subunits. When investigators examined the properties of the three catalytic sites in a *static* enzyme (one that was not engaged in enzymatic turnover), the different sites exhibited different chemical properties. Boyer proposed that, at any one time, the three catalytic sites are present in different conformations, which causes them to have different affinity for nucleotides. At any given instant, one site is in the “loose” or L conformation in which ADP and P_i are loosely bound; a second site is in the “tight” or T conformation in which nucleotides (ADP + P_i substrates, or ATP product) are tightly bound; and the third site is in the “open” or O conformation, which, because it has a very low affinity for nucleotides, allows release of ATP.

Although there were differences among the three catalytic sites in a static enzyme, Boyer obtained evidence that all of the ATP molecules produced by an active enzyme were synthesized by the same catalytic mechanism. It seemed, in other words, that all three of the catalytic sites of the enzyme were operating identically. To explain the apparent contradiction between the asymmetry of the enzyme’s structure and the uniformity of its

catalytic mechanism, Boyer proposed that each of the three catalytic sites passed sequentially through the same L, T, and O conformations (see Figure 5.27).

3. **ATP is synthesized by rotational catalysis in which one part of the ATP synthase rotates relative to another part.** To explain the sequential changes in the conformation of each of the catalytic sites, Boyer proposed that the α and β subunits, which form a hexagonal ring of subunits within the F_1 head (Figure 5.24), rotate *relative* to the central stalk. In this model, which is referred to as *rotational catalysis*, rotation is driven by the movement of protons through the membrane via the channel in the F_0 base. Thus, according to this model, electrical energy stored in the proton gradient is transduced into mechanical energy of a rotating stalk, which is transduced into chemical energy stored in ATP.

Evidence to Support the Binding Change Mechanism and Rotary Catalysis The publication in 1994 of a detailed atomic model of the F_1 head by John Walker and his colleagues of the Medical Research Council in England provided a remarkable body of structural evidence to support Boyer's binding change mechanism. First, it revealed the structure of each of the catalytic sites in a static enzyme, confirming that they differ in their conformation and their affinity for nucleotides. Structures corresponding to the L, T, and O conformations were identified in the catalytic sites of the three β subunits. Second, it revealed that the γ subunit of the enzyme is perfectly positioned within the ATP synthase to

transmit conformational changes from the F_0 membrane sector to the F_1 catalytic sites. The γ subunit could be seen to extend as a shaft from the F_0 sector through the stalk and into a central cavity within the F_1 sphere (Figure 5.26a), where it contacts each of the three β subunits differently (Figure 5.26b).

The apical end of the γ subunit is highly asymmetric, and at any given instant, different faces of the γ subunit interact with the different β subunits, causing them to adopt different (L, T, and O) conformations. As it rotates in steps of 120° , each binding site on the γ subunit interacts successively with the three β subunits of F_1 . During a single catalytic cycle, the γ subunit rotates a full 360° , causing each catalytic site to pass sequentially through the L, T, and O conformations. This mechanism is illustrated schematically in Figure 5.27 and discussed in detail in the accompanying legend. As indicated in Figure 5.27a, condensation of ADP and P_i to form ATP occurs while each subunit is in the T conformation. As indicated in Figure 5.24b, the ϵ subunit is associated with the "lower" portion of the γ subunit, and the two subunits rotate together as a unit.

Direct evidence for the rotation of the γ subunit relative to the $\alpha\beta$ subunits has been obtained in a variety of experiments. If "seeing is believing," then the most convincing demonstration came in 1997 from the work of Masasuke Yoshida and colleagues at the Tokyo Institute of Technology and Keio University in Japan. These researchers devised an ingenious system to watch individual enzyme molecules catalyze the reverse reaction from that normally operating in

(a)

Figure 5.26 The structural basis of catalytic site conformation. (a) A section through the F_1 head shows the spatial organization of three of its subunits. The γ subunit is constructed of two extended and intertwined α helices. This helical stalk projects into the central cavity of the F_1 , and between the α and β subunits on each side. The conformation of the catalytic site of the β subunit (shown on the left) is determined by its contact with the γ subunit. (b) A top view of the F_1 head showing the arrangement of the six α and β subunits (shown in

(b)

red and yellow) around the asymmetric γ subunit (shown in blue). The γ subunit is in position to rotate relative to the surrounding subunits. It is also evident that the γ subunit makes contact in a different way with each of the three β subunits, inducing each of them to adopt a different conformation. β_E corresponds to the O conformation, β_{TP} to the L conformation, and β_{DP} to the T conformation. (FROM J. P. ABRAHAMAS, ET AL, NATURE 370:624, 627, 1994, REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD. COURTESY OF JOHN E. WALKER.)

Figure 5.27 The binding change mechanism for ATP synthesis.

(a) Schematic drawing showing changes in a single catalytic site during a cycle of catalysis. At the beginning of the cycle, the site is in the open (O) conformation, and substrates ADP and P_i are entering the site. In step 1, the movement of protons through the membrane induces a shift to the loose (L) conformation in which the substrates are loosely bound. In step 2, the movement of additional protons induces a shift to the tight (T) conformation, in which the affinity for substrates increases, causing them to be tightly bound to the catalytic site. In step 3, the tightly bound ADP and P_i spontaneously condense to form a tightly bound ATP; no change in conformation is required for this step. In

step 4, the movement of additional protons induces a shift to the open (O) conformation, in which the affinity for ATP is greatly decreased, allowing the product to be released from the site. Once the ATP has dissociated, the catalytic site is available for substrate binding, and the cycle is repeated. (b) Schematic drawing showing changes at all three catalytic sites of the enzyme simultaneously. The movement of protons through the F_0 part of the enzyme causes the rotation of the asymmetric γ subunit, which displays three different faces to the catalytic subunits. As the γ subunit rotates, it induces changes in the conformation of the catalytic site of the β subunits, causing each catalytic site to pass successively through the T, O, and L conformations.

the cell. First, they prepared a genetically engineered version of the F_1 portion of the ATP synthase, consisting of three α subunits, three β subunits, and a γ subunit ($\alpha_3\beta_3\gamma$) (Figure 5.28a). This polypeptide complex was then fixed to a glass coverslip by its head, and a short, fluorescently labeled actin filament was attached to the end of the γ subunit that projected into the medium (Figure 5.28a). When the preparation was incubated with ATP and observed under the microscope, the fluorescently labeled actin filament was seen to rotate like a microscopic propeller (Figure 5.28b), powered by the energy released as ATP molecules were bound and hydrolyzed by the catalytic sites of the β subunits.

More recently, a similar type of F_1 complex was “forced” to perform the more challenging activity that it normally carries out within the cell—the synthesis of ATP. In this study, a microscope magnetic bead was attached to the γ subunit of a single F_1 molecule and then caused to rotate in a clockwise direction by subjecting the preparation to a revolving magnetic field. When one of these F_1 molecules was placed within a tiny transparent microchamber in the presence of ADP and P_i , the forced rotation of the γ subunit led to the synthesis of ATP, which built up to μM concentrations. As would be expected from the model, three molecules of ATP were synthesized with each 360° turn. When the magnetic field was switched off, the γ subunit rotated spontaneously in the reverse direction, driven by the hydrolysis of the recently synthesized ATP. Taken together, these innovative bioengineering experiments demonstrate unequivocally that ATP synthase operates as a rotary motor.

Rotary machines are common in our industrialized society; we use rotary turbines, rotary drills, rotary wheels and propeller-

Figure 5.28 Direct observation of rotational catalysis. (a) To carry out the experiment, a modified version of a portion of the ATP synthase consisting of $\alpha_3\beta_3\gamma$ was prepared. Each β subunit was modified to contain 10 histidine (His) residues at its N-terminus, a site located on the outer (matrix) face of the F_1 head. The side chains of histidine have a high affinity for a substance (Ni-NTA), which was used to coat the coverslip. The γ subunit was modified by replacing one of the serine residues near the end of the stalk with a cysteine residue, which provided a means to attach the fluorescently labeled actin filament. In the presence of ATP, the actin filament was observed to rotate counterclockwise (when viewed from the membrane side). At low ATP concentrations, the actin filaments could be seen to rotate in steps of 120° . (b) A sequence of four frames from a video of a rotating actin filament. (FROM H. NOJI, ET AL., NATURE 386: 299, 1997, REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD; COURTESY OF MASASUKE YOSHIDA.)

lors, to name just a few. But rotary devices are extremely rare in living organisms. There are, for example, no known rotary organelles in eukaryotic cells, rotary joints in animals, or rotary feeding structures in the biological world. In fact, only two types of biological structures are known that contain rotating parts: ATP synthases (and related proteins that act as ionic pumps) and bacterial flagella (which are pictured in Figure 1.14a, inset), both of which can be described as rotary “nanomachines” because their size is measured in nanometers. Engineers have begun to invent nanoscale devices made of inorganic materials that may one day carry out various types of submicroscopic mechanical activities. The construction of nanosized motors poses a particular challenge, and attempts have already been made to use the ATP synthase to power simple, inorganic devices. Someday humans may be using ATP instead of electricity to power some of their most delicate instruments.

Using the Proton Gradient to Drive the Catalytic Machinery: The Role of the F_0 Portion of ATP Synthase

By 1997, a detailed understanding of the working machinery of the F_1 complex was in hand, but major questions about the structure and function of the membrane-bound F_0 portion of the enzyme remained to be answered. Most important among them were: What is the path taken by protons as they move through the F_0 complex, and how does this movement lead to the synthesis of ATP? It had been postulated that:

1. The c subunits of the F_0 base were assembled into a ring that resides within the lipid bilayer (as in Figure 5.24b).
2. The c ring is physically bound to the γ subunit of the stalk.
3. The “downhill” movement of protons through the membrane drives the rotation of the ring of c subunits.
4. The rotation of the c ring of F_0 provides the twisting force (*torque*) that drives the rotation of the attached γ subunit, leading to the synthesis and release of ATP by catalytic subunits of the F_1 ring.

All of these presumptions have been confirmed. We will look at each of these aspects in more detail.

A body of evidence, including X-ray crystallography and atomic force microscopy, has shown that the c subunits are indeed organized into a circle to form a ring-shaped complex (Figure 5.25). High-resolution electron micrographs indicate that the two b subunits and the single a subunit of the F_0 complex reside outside the ring of c subunits, as shown in Figure 5.24. The b subunits are thought to be primarily structural components of the ATP synthase. The two elongated b subunits form a *peripheral stalk* that connects the F_0 and F_1 portions of the enzyme (Figure 5.24b) and, along with the δ subunit of F_1 , are thought to hold the $\alpha_3\beta_3$ subunits in a fixed position while the γ subunit rotates within the center of the complex.

The rotation of the c ring of F_0 during ATP synthesis has been demonstrated in numerous experiments, confirming that both the c ring and γ subunit act as rotors during enzyme activity. How are these two “moving parts” connected? Each c subunit is built like a hairpin: it contains two transmembrane helices connected by a hydrophilic loop that projects toward the F_1 head. The hydrophilic loops situated on the tops of the c subunits are thought to form a binding site for the bases of

the γ and ϵ subunits, which together act like a “foot” that is firmly attached to the c ring (Figures 5.24 and 5.29). As a result of this attachment, rotation of the c ring drives rotation of the attached γ subunit, which can occur at rates of more than 100 revolutions per second.

The mechanism by which H^+ movements drive the rotation of the c ring is more complex and less well understood. Figure 5.29 provides a model as to how H^+ ions might flow through the F_0 complex. Keep in mind in the following discussion of this model (1) that the subunits of the c ring move successively past a *stationary* a subunit and (2) that protons are picked up from the intermembrane space one at a time by each c subunit and carried *completely around a circle* before they are released into the matrix. In this model, each a subunit has two half-channels that are physically separated (offset) from one another. One half-channel leads from the intermembrane (cytosolic) space into the middle of the a subunit and the other leads from the middle of the a subunit into the matrix. It is proposed that each proton moves from the intermembrane space through the half-channel and binds to a negatively charged acidic residue situated at the surface of the adjoining c subunit.

Figure 5.29 A model in which proton diffusion is coupled to the rotation of the c ring of the F_0 complex. As discussed in the text, the number of subunits in the c ring is variable. For the sake of simplicity, this c ring consists of 12 subunits. It is proposed in this model that each proton from the intermembrane space enters a half-channel within the a subunit and then binds to an acidic residue (Asp 61 in *E. coli*) that is accessible on one of the c subunits. Proton binding induces a conformational change that causes the ring to move by approximately 30° . The bound proton is carried in a full circle by the rotation of the c ring and is then released into a second half-channel that opens into the matrix. A succession of protons that engage in this activity causes the c ring to rotate in a counterclockwise direction as shown.

This acidic residue is apparently an aspartic acid in *E. coli* (Figure 5.29), but is a glutamic acid residue in animal mitochondria. Binding of the proton to the carboxyl group of that residue causes that subunit to rotate approximately 30° in a counterclockwise direction. The movement of the recently protonated c subunit brings the adjoining subunit in the ring (which was protonated at an earlier step) into alignment with the second half-channel of the a subunit. Once there, the acidic residue releases its associated proton, which diffuses into the matrix. Following dissociation of the proton, the c subunit returns to its original conformation and is ready to accept another proton from the intermembrane space and repeat the cycle.

According to this model, the proton-binding residue of each c subunit acts like a revolving proton carrier. A proton hops onto the carrier at a selected pick-up site and is then carried around a circle before being released at a selected drop-off site. Movement of the ring is driven by the conformational changes associated with the sequential protonation and deprotonation of the acidic residue of each c subunit. Consequently, the number of protons translocated for each rotation of the c ring is generally considered to be equal to the number of subunits that make up the ring, although this is not always experimentally validated. The c ring has been shown to contain between 8 and 15 subunits, depending on the source. For the sake of simplicity, we will describe a c ring composed of 12 subunits, as illustrated in Figure 5.29. In this case, the association/dissociation of four protons in the manner described would move the ring 120° . Movement of the c ring 120° would

drive a corresponding rotation of the attached γ subunit 120° , which would lead to the release of one newly synthesized molecule of ATP by the F_1 complex. According to this stoichiometry, the translocation of 12 protons would lead to the full 360° rotation of the c ring and γ subunit, and the synthesis and release of three molecules of ATP. If the c ring were to contain greater or fewer than 12 subunits, the H^+/ATP ratio would change, but this can easily be accommodated within the basic model of proton-driven rotation shown in Figure 5.29.

Other Roles for the Proton-Motive Force in Addition to ATP Synthesis

Although the production of ATP may be the most important activity of mitochondria, these organelles are engaged in numerous other processes that require the input of energy. Unlike most organelles that rely primarily on ATP hydrolysis to power their activities, mitochondria rely on an alternate source of energy—the proton-motive force. For example, the proton-motive force drives the uptake of ADP and P_i into the mitochondria in exchange for ATP and H^+ , respectively. Exchange of ATP for ADP across the membrane is accomplished by the *adenine nucleotide translocase (ANT)*, which makes the ATP produced within the mitochondria available to meet the energy needs of the remainder of the cell. These and other activities that take place during aerobic respiration are summarized in Figure 5.30. In other examples, the proton-motive force may be used as the source of energy to “pull” calcium ions into the mitochondrion; to drive the events of mitochondrial fusion; and to cause specifically targeted polypeptides to enter the mitochondrion from the matrix (Figure 8.47).

Figure 5.30 Summary of the major activities during aerobic respiration in a mitochondrion.

REVIEW

1. Describe the basic structure of the ATP synthase.
2. Describe the steps in ATP synthesis according to the binding change mechanism.
3. Describe some of the evidence that supports the binding change mechanism.
4. Describe a proposed mechanism whereby proton diffusion from the intermembrane space into the matrix drives the phosphorylation of ADP.

5.6 | Peroxisomes

Peroxisomes are simple, membrane-bound vesicles (Figure 5.31a) with a diameter of 0.1 to 1.0 μm that may contain a dense, crystalline core of oxidative enzymes. Peroxisomes (or *microbodies*, as they are also called) are multifunctional organelles, containing more than 50 enzymes involved in such diverse activities as the oxidation of very-long-chain fatty acids (VLCFAs, ones whose chain typically contains 24 to 26 carbons) and the synthesis of plasmalogens, which are an unusual class of phospholipids in which one of the fatty acids is linked to glycerol by an ether linkage rather than an ester linkage. Plasmalogens are very abundant in the myelin sheaths that insulate axons in the brain (Figure 4.5). Abnormalities in the synthesis of plasmalogens can lead to severe neurological dysfunction. The enzyme luciferase, which generates the light emitted by fireflies, is also a peroxisomal enzyme. Peroxisomes are considered in the present chapter because they share several properties with mitochondria: both mitochondria and peroxisomes form by splitting from preexisting organelles, using some of the same proteins to accomplish the feat; both types of organelles import preformed

proteins from the cytosol (Section 8.9); and both engage in similar types of oxidative metabolism. In fact, at least one enzyme, alanine/glyoxylate aminotransferase, is found in the mitochondria of some mammals (e.g., cats and dogs) and in the peroxisomes of other mammals (e.g., rabbits and humans). The two types of organelles have become even more closely linked with recent reports that mitochondria form vesicles that carry cargo destined for peroxisomes.

These organelles were named “peroxisomes” because they are the site of synthesis and degradation of hydrogen peroxide (H_2O_2), a highly reactive and toxic oxidizing agent. Hydrogen peroxide is produced by a number of peroxisomal enzymes, including urate oxidase, glycolate oxidase, and amino acid oxidases, that utilize molecular oxygen to oxidize their respective substrates (Figure 5.31b). The H_2O_2 generated in these reactions is rapidly broken down by the enzyme catalase, which is present in high concentrations in these organelles. The importance of peroxisomes in human metabolism is evident from the discussion in the accompanying Human Perspective.

Peroxisomes are also present in plants. Plant seedlings contain a specialized type of peroxisome, called a **glyoxysome** (Figure 5.32). Plant seedlings rely on stored fatty acids to provide the energy and material to form a new plant. One of the primary metabolic activities in these germinating seedlings is the conversion of stored fatty acids to carbohydrate. Disassembly of stored fatty acids generates acetyl CoA, which condenses with oxaloacetate (OAA) to form citrate, which is then converted into glucose by a series of enzymes of the glyoxylate cycle localized in the glyoxysome. The role of peroxisomes in the metabolism of leaf cells is discussed in Section 6.6.

REVIEW

1. What are some of the major activities of peroxisomes? What is the role of catalase in these activities?
2. In what ways are peroxisomes similar to mitochondria? In what ways are they unique?

(a)

(b)

Figure 5.31 The structure and function of peroxisomes.

(a) Electron micrograph of a section of a rat liver cell, which had been stained for catalase, an enzyme localized in peroxisomes. Note the close association between the darkly stained peroxisomes and mitochondria. An electron micrograph of a peroxisome within a plant cell is shown in Figure 6.23. Bar equals 250 nm. (b) Peroxisomes contain enzymes that carry out the two-step reduction of molecular oxygen to water. In the first step, an oxidase removes electrons from a variety of substrates (RH_2), such as uric acid or amino acids. In the second step, the enzyme catalase converts the hydrogen peroxide formed in the first step to water. The glyoxysomes, which are seen as small dark structures (arrow), have been made visible by a cytochemical stain for the enzyme catalase. (FROM RICHARD N. TRELEASE AND KENT D. CHAPMAN, *J. CELL BIOL.* 115:998, 1991, FIG. 1. © 1991 ROCKEFELLER UNIVERSITY PRESS.)

THE HUMAN PERSPECTIVE

Diseases that Result from Abnormal Mitochondrial or Peroxisomal Function

Mitochondria

In 1962, Rolf Luft of the University of Stockholm in Sweden reported on a study of mitochondria isolated from a woman who had been suffering from long-standing fatigue and muscle weakness and who exhibited an elevated metabolic rate and body temperature. The mitochondria from this patient were somehow released from their normal respiratory control. Normally, when ADP levels are low, isolated mitochondria stop oxidizing substrate. In contrast, the mitochondria from this patient continued to oxidize substrate at a high rate, even in the absence of ADP to phosphorylate, producing heat rather than mechanical work. Since that initial report, a variety of disorders have been traced to mitochondrial dysfunction. Most of these disorders are characterized by degeneration of muscle or brain tissue, both of which utilize exceptionally large amounts of ATP. These conditions range in severity from diseases that lead to death during infancy; to disorders

that produce seizures, blindness, deafness, and/or stroke-like episodes; to mild conditions characterized by intolerance to exercise or non-motile sperm. Patients with serious conditions generally have abnormal skeletal muscle fibers, which contain large peripheral aggregates of mitochondria (Figure 1*a*). Closer examination of the mitochondria reveals large numbers of abnormal inclusions (Figure 1*b*).

More than 95 percent of the polypeptides of the respiratory chain are encoded by genes that reside in the nucleus. Yet the majority of mutations linked to mitochondrial-based diseases have been traced to mutations in mitochondrial DNA, or mtDNA. The most serious disorders usually stem from mutations (or deletions) that affect genes encoding mitochondrial transfer RNAs, which are re-

(a)

crystalline structures within the mitochondrial matrix from cells of a patient with abnormal mitochondria. (A: COURTESY OF DONALD R. JOHNS; B: FROM JOHN A. MORGAN-HUGHES AND D. N. LANDON, IN *MYOLOGY*, 2D ED., A. G. ENGEL AND C. FRANZINI-ARMSTRONG, EDS., REPRODUCED WITH PERMISSION OF MCGRAW-HILL, © 1994.)

quired for the synthesis of all 13 polypeptides produced in human mitochondria. Because all of the genes carried in mtDNA encode proteins required for oxidative phosphorylation, one would expect all types of mtDNA mutations to produce a similar clinical phenotype. Clearly, this is not the case.

The inheritance of mitochondrial disorders contrasts in several ways with the Mendelian inheritance of nuclear genes. The mitochondria present in the cells of a human embryo are derived exclusively from mitochondria that were present in the egg at the time of conception without any contribution from the fertilizing sperm. Consequently, mitochondrial disorders are inherited maternally. In addition, the mitochondria of a cell can contain a mixture of normal (i.e., wild-type) and mutant mtDNA, a condition known as *heteroplasmy*. The level of mutant mtDNA can vary from one organ to another within a single individual, and it is only when a preponderance of the mitochondria of a particular tissue contains defective genetic information that clinical symptoms usually appear. Because of this variability, members of a family carrying the same mtDNA mutation can exhibit strikingly different symptoms.

Flow of electrons along the mitochondrial electron transport chain has been shown to be a major source of mutagenic oxygen radicals—so-called *reactive oxygen species (ROS)* (page 35). Because of its proximity to the inner mitochondrial membrane where electron transport occurs, mtDNA is thought to come under a much greater level of attack than nuclear DNA. In addition, nuclear DNA is better protected from persistent damage by the presence of a greater variety of DNA repair systems (Section 13.2). For these reasons, mtDNA experiences more than 10 times the mutation rate of nuclear DNA. Mitochondrial mutations are particularly likely to accumulate in cells that remain in the body for long periods of time, such as those of nerve and muscle tissue. The degenerative changes in mitochondrial function are thought to contribute to a number of common neurologic diseases with adult onset, most notably Parkinson's disease (PD). This possibility originally came to light in the early 1980s when a number of young drug addicts reported to hospitals with the sudden onset of severe muscular tremors that are characteristic of advanced Parkinson's disease in elderly adults. It was discovered that these individuals had injected themselves intravenously with a synthetic heroin that was contaminated with a compound called MPTP. Subsequent studies revealed that MPTP caused damage to complex I of the mitochondrial respiratory chain, leading to the death of nerve cells in the same region of the brain (the substantia nigra) that is affected in patients with PD. When cells from the substantia nigra of PD patients were then studied, they too were found to have a marked and selective decrease in complex I activity. This complex I deficiency is probably due to a documented increase in the mutation rate in the DNA of these cells compared to other cells. Studies have also implicated exposure to certain pesticides, particularly rotenone, a known complex I inhibitor, as an environmental risk factor for development of PD. Administration of rotenone to rats causes the destruction of dopamine-producing neurons, which is characteristic of the human disease. The possible link between rotenone and Parkinson's disease is being investigated.

It has long been speculated that the gradual accumulation of mutations in mtDNA is a major causal factor in human aging. This hypothesis is fueled by the fact that cells taken from older persons have an increased number of mtDNA mutations compared to the same cells from younger individuals. But are these mutations a cause of aging or simply a consequence of a more basic underlying aging process that affects many physiological properties? The experiments that may be the most relevant to this question have been performed on mice that are homozygous for a mutant gene (called *Polg*) that encodes the enzyme that replicates mtDNA. The mtDNA of these mice accumulates a much higher level of mutations than that of their

Figure 2 A premature-aging phenotype caused by increased mutations in mtDNA. The photograph shows a 13-month-old normal mouse and its “aged” littermate whose mitochondrial DNA harbors an abnormally high number of mutations. This premature-aging phenotype was caused by a mutation in the nuclear gene that encodes the DNA polymerase responsible for replication of mtDNA. (COURTESY OF JEFF MILLER, UNIVERSITY OF WISCONSIN-MADISON, IMAGE PROVIDED BY G. C. KUJOTH.)

normal littermates. These “mutator” mice appear normal for the first 6 to 9 months of age, but then rapidly develop signs of premature aging, such as hearing loss, graying hair, and osteoporosis (Figure 2). Whereas the control mice have a life span of more than two years, members of the experimental group live, on average, only about one year. Interestingly, the genetically modified animals show no evidence of increased oxidative (free radical) damage, so it is not clear how the increased mtDNA mutation rate causes this phenotype. It is also noteworthy that mice that are heterozygous for the *Polg* mutation have an elevated mtDNA mutation rate (although far less than the homozygotes), yet they do not exhibit a shortened life span. If mtDNA mutations were a major contributor to the normal aging process, these heterozygotes should have a significantly shorter life. Taken together, these results suggest that mutations in mtDNA may be sufficient to cause an animal to age prematurely, but they are not necessarily required as part of the *normal* aging process. Whether these studies on mice bear directly on human aging remains unclear.

Peroxisomes

Zellweger syndrome (ZS) is a rare inherited disease characterized by a variety of neurologic, visual, and liver abnormalities leading to death during early infancy. In 1973, Sidney Goldfischer and his colleagues at Albert Einstein College of Medicine reported that liver and renal cells from these patients were lacking peroxisomes. Subsequent investigations revealed that peroxisomes were not entirely absent from the cells of these individuals, but, rather, they were present as empty membranous “ghosts”—that is, organelles lacking the enzymes that were normally found in peroxisomes. It is not that these individuals are unable to synthesize peroxisomal enzymes, but rather that the enzymes fail to be imported into the peroxisomes and remain largely in the cytosol where they are unable to carry out their normal functions. Genetic studies of cells from ZS patients showed that the disorder can arise from mutations in at least 12 different genes, all encoding proteins involved in the uptake of peroxisomal enzymes from the cytosol.

Unlike Zellweger syndrome, which affects a wide variety of peroxisomal functions, a number of inherited diseases are characterized by the absence of a single peroxisomal enzyme. One of these single-enzyme deficiency diseases is X-linked adrenoleukodystrophy (X-ALD), which was the subject of the 1993 movie *Lorenzo's Oil*. Boys with the disease are typically unaffected until mid-childhood, when symptoms of adrenal insufficiency and neurological dysfunction

begin. The disease results from a defect in a membrane protein (ABCD1) that transports very-long-chain fatty acids (VLCFAs) into the peroxisomes, where they are normally metabolized. In the absence of this protein, VLCFAs accumulate in the brain and destroy the myelin sheaths that insulate nerve cells. In *Lorenzo's Oil*, the parents of a boy stricken with X-ALD discover that a diet rich in certain fatty acids is able to retard the progress of the disease. Subsequent studies have generated contradictory results regarding the value of this diet. A number of X-ALD patients have been successfully treated by bone marrow transplantation, which provides normal cells capable of metabolizing VLCFAs, and by administration of

drugs (e.g., lovastatin) that may lower VLCFA levels. The most exciting prospects for the treatment of X-ALD came in 2009 with the report that two boys in France had been successfully treated by gene therapy. In this clinical trial, stem cells were isolated from blood, a normal copy of the *ABCD1* gene was introduced into the cells, which were then infused back into the patients from which they were derived. Some of these genetically engineered stem cells gave rise to differentiated cells that took up residence in the brain. These cells were able to produce the missing protein, leading to the arrest of further neurodegeneration. Two years after the treatment, the boys were reported to be living normal lives.

Synopsis

Mitochondria are large organelles comprised of an outer porous membrane and a highly impermeable inner membrane that consists primarily of folds (cristae) that contain much of the machinery required for aerobic respiration. The porosity of the outer membrane results from integral proteins called porins. The architecture of the inner membrane and the apparent fluidity of its bilayer facilitate the interactions of components that are required during electron transport and ATP formation. The inner membrane surrounds a gel-like matrix that contains, in addition to proteins, a genetic system that includes DNA, RNA, ribosomes, and all the machinery necessary to transcribe and translate genetic information. Many of the properties of mitochondria can be accounted for by their presumed evolution from ancient symbiotic bacteria. (p. 179)

The mitochondrion is the center of oxidative metabolism in the cell, converting the products from carbohydrate, fat, and protein catabolism into chemical energy stored in ATP. Pyruvate and NADH are the two products of glycolysis. Pyruvate is transported across the inner mitochondrial membrane where it is decarboxylated and combined with coenzyme A to form acetyl CoA, which is condensed with oxaloacetate to form citrate, which begins the TCA cycle. As it traverses the reactions of the TCA cycle, two of the carbons from the citrate are removed and released as CO₂, which represents the most highly oxidized state of the carbon atom. Electrons removed from substrates are transferred to FAD and NAD⁺ to form FADH₂ and NADH. Fatty acids are broken down into acetyl CoA, which is fed into the TCA cycle, and all 20 amino acids are broken down into either pyruvate, acetyl CoA, or TCA cycle intermediates. Thus, the TCA cycle is the pathway on which the cell's major catabolic pathways converge. (p. 183)

Electrons transferred from substrates to FADH₂ and NADH are passed along a chain of electron carriers to O₂, releasing energy that is used to generate an electrochemical gradient across the inner mitochondrial membrane. The controlled movement of protons back across the membrane through an ATP-synthesizing enzyme is used to drive the formation of ATP at the enzyme's catalytic site. Each pair of electrons from NADH releases sufficient energy to drive the formation of approximately three ATPs, whereas the energy released from a pair of electrons from FADH₂ accounts for the formation of approximately two ATPs. (p. 186)

The amount of energy released as an electron is transferred from a donor (reducing agent) to an acceptor (oxidizing agent) can be calculated from the difference in redox potential between the two couples. The standard redox potential of a couple is measured under standard conditions and compared to the H₂-H⁺ couple. The standard redox potential of the NADH-NAD⁺ couple is -0.32 V, reflecting the fact that NADH is a strong reducing agent, that is, one that readily transfers its electrons. The standard redox potential of the H₂O-O₂ couple is +0.82 V, reflecting the fact that O₂ is a strong

oxidizing agent, that is, one that has a strong affinity for electrons. The difference between these two couples, which is equivalent to 1.14 V, provides a measure of the free energy released (52.6 kcal/mol) when a pair of electrons is passed from NADH along the entire electron-transport chain to O₂. (p. 189)

The electron-transport chain contains five different types of carriers: heme-containing cytochromes, flavin nucleotide-containing flavoproteins, iron-sulfur proteins, copper atoms, and quinones. Flavoproteins and quinones are capable of accepting and donating hydrogen atoms, while cytochromes, copper atoms, and iron-sulfur proteins are capable of accepting and donating only electrons. The carriers of the electron-transport chain are arranged in order of increasingly positive redox potential. The various carriers are organized into four large, multiprotein complexes. Cytochrome *c* and ubiquinone are mobile carriers, shuttling electrons between the larger complexes. As pairs of electrons are passed through complexes I, III, and IV, protons are translocated from the matrix across the membrane into the intermembrane space. The translocation of protons by these electron-transporting complexes establishes the proton gradient in which energy is stored. The last of the complexes is cytochrome oxidase, which transfers electrons from cytochrome *c* to O₂, reducing it to form water, a step that also removes protons from the matrix, contributing to the proton gradient. (p. 191)

The translocation of protons creates a separation of charge across the membrane, in addition to a difference in proton concentration. Consequently, the proton gradient has two components—a voltage and a pH gradient—the magnitudes of which depend on the movement of other ions across the membrane. Together the two components constitute a proton-motive force (Δp). In mammals, approximately 80 percent of the free energy of Δp is represented by the voltage and 20 percent by the pH gradient. (p. 198)

The enzyme that catalyzes the formation of ATP is a large multi-protein complex called ATP synthase. ATP synthase contains two distinct parts: an F₁ head that projects into the matrix and includes the catalytic sites, and an F₀ base that is embedded in the lipid bilayer and forms a channel through which protons are conducted from the intermembrane space into the matrix. In the binding change hypothesis of ATP formation, which is now generally accepted, the controlled movement of protons through the F₀ portion of the enzyme induces the rotation of the γ subunit of the enzyme, which forms the stalk connecting the F₀ and F₁ portions of the enzyme. Rotation of the γ subunit is brought about by rotation of the *c* ring of the F₀ base, which is induced by the movement of protons through half-channels in the *a* subunit. The rotation of the γ subunit induces changes in the conformation of the F₁ catalytic sites, driving the formation of ATP. Evidence indicates that the energy-requiring step is not the actual phosphorylation of ADP, but the release of the ATP product from the active site, which occurs in response to the induced changes in

conformation. In addition to the formation of ATP, the proton-motive force also provides the energy required for a number of transport activities, including the uptake of ADP into the mitochondrion in exchange for the release of ATP to the cytosol, the uptake of phosphate and calcium ions, and the import of mitochondrial proteins. (p. 199)

Analytic Questions

1. Consider the reaction $A:H + B \rightleftharpoons B:H + A$. If, at equilibrium, the ratio of $[B:H]/[B]$ is equal to 2.0, one can conclude that (1) $B:H$ is the strongest reducing agent of the four compounds; (2) the $(A:H-A)$ couple has a more negative redox potential than the $(B:H-B)$ couple; (3) none of the four compounds are cytochromes; (4) the electrons associated with B are higher energy than those associated with A . Which of the previous statements are true? Draw one of the half-reactions for this redox reaction.
2. Mitochondrial DNA is replicated by the enzyme DNA polymerase γ . The “mutator” mice discussed on page 208 had this phenotype because they possessed a polymerase γ that tended to make mistakes as it copied its mtDNA template. A couple of limitations in interpreting these studies in terms of the normal aging process were pointed out. What do you think could be learned by generating mice that had a super-accurate polymerase γ , that is, one that made fewer mistakes than the normal (wild-type) version?
3. Protein A is a flavoprotein with a redox potential of -0.2 V. Protein B is a cytochrome with a redox potential of $+0.1$ V.
 - a. Draw the half-reactions for each of these two electron carriers.
 - b. Give the reaction that would occur if one were to mix reduced A molecules and oxidized B molecules.
 - c. Which two compounds in the reaction of part b would be present at the highest concentration when the reaction reached equilibrium?
4. Of the following substances—ubiquinone, cytochrome c , NAD^+ , $NADH$, O_2 , H_2O —which is the strongest reducing agent? Which is the strongest oxidizing agent? Which has the greatest affinity for electrons?
5. If it were determined that the inner mitochondrial membrane was freely permeable to chloride ions, what effect might this have on the proton-motive force across the inner mitochondrial membrane?
6. Look at the drop in energy during electron transport shown in Figure 5.14. How would this profile be different if the original electron donor was $FADH_2$ rather than $NADH$?
7. Would you expect the import of P_i to lead to a decrease in the proton-motive force? Why?
8. In the chart of standard redox potentials in Table 5.1, the oxaloacetate-malate couple is less negative than the NAD^+ - $NADH$ couple. How are these values compatible with the transfer of electrons from malate to NAD^+ in the TCA cycle?
9. How many high-energy triphosphates are formed by substrate-level phosphorylation during each turn of the TCA cycle (consider the TCA cycle reactions only)? How many are formed as the result of oxidative phosphorylation? How many molecules of CO_2 are released? How many molecules of FAD are reduced? How many pairs of electrons are stripped from substrate?
10. The assembly of Fe-S clusters, which takes place in the mitochondrial matrix, is highly vulnerable to the presence of O_2 .

Given the importance of mitochondria in aerobic metabolism, does this seem to be an unlikely place for this process to occur?
11. The drop in $\Delta G^{\circ'}$ of a pair of electrons as they pass from $NADH$ to O_2 is -52.6 kcal/mol, and the $\Delta G^{\circ'}$ of ATP formation is $+7.3$ kcal/mol. If three ATPs are formed for each pair of electrons removed from substrate, can you conclude that oxidative phosphorylation is only $21.9/52.6$ or 42 percent efficient? Why or why not?
12. Would you expect metabolically active, isolated mitochondria to acidify or alkalinize the medium in which they were suspended? Why?
13. Suppose the movement of three protons were required for the synthesis of one ATP molecule. Calculate the energy released by the passage of three moles of protons into the matrix when the proton-motive force is measured at 220 mV (see p. 198 for information).
14. Would you expect isolated mitochondria to be able to carry out the oxidation of glucose with the accompanying production of ATP? Why or why not? What might be a good compound to add to a preparation of isolated mitochondria to achieve ATP synthesis?
15. Calculate the free energy released when $FADH_2$ is oxidized by molecular O_2 under standard conditions.
16. Using your understanding of the organization of the mitochondrion and how it generates ATP, answer the following questions. Give a brief explanation of each answer.
 - a. What would be the effect on ATP production of adding a substance (protonophore) that makes the mitochondrial membrane leaky to protons?
 - b. What would be the effect on the pH of the mitochondrial matrix of reducing the oxygen supply?
 - c. Suppose that the glucose supply to the cell is greatly reduced. What would be the effect on CO_2 production by the mitochondria?
17. Suppose that you are able to manipulate the potential of the inner membrane of an isolated mitochondrion. You measure the pH of the mitochondrial matrix and find it to be 8.0. You measure the bathing solution and find its pH to be 7.0. You clamp the inner membrane potential at $+59$ mV—that is, you force the matrix to be 59 mV positive with respect to the bathing medium. Under these circumstances, can the mitochondrion use the proton gradient to drive the synthesis of ATP? Explain your answer.
18. Suppose you were able to synthesize an ATP synthase that was devoid of the γ subunit. How would the catalytic sites of the β subunits of such an enzyme compare to one another. Why?
19. In functional terms, the ATP synthase can be divided into two parts: a “stator” made up of subunits that do not move during catalysis, and a “rotor” made up of parts that do move. Which subunits of the enzyme make up each of these two parts. How are the immovable parts of the stator in F_0 related structurally to the immovable parts of the stator in F_1 ?

Peroxisomes are membrane-bound cytoplasmic vesicles that carry out a number of diverse reactions, including the oxidation of urate, glycolate, and amino acids, generating H_2O_2 . (p. 206)

The Earth's earliest life forms must have obtained their raw materials and energy from simple organic molecules dissolved in their aqueous environment. These organic molecules had to have formed *abiotically*, that is, as a result of nonbiological chemical reactions occurring in the primeval seas. Thus, just as we survive on nutrients taken in from our environment, so too must have the original life forms. Organisms that depend on an external source of organic compounds are called **heterotrophs**.

The number of heterotrophic organisms living on the primitive Earth must have been severely restricted because the spontaneous production of organic molecules occurs very slowly. The evolution of life on Earth received a tremendous boost with the appearance of organisms that employed a new metabolic strategy. Unlike their predecessors, these organisms could manufacture their own organic nutrients from the simplest types of inorganic molecules, such as carbon dioxide (CO₂) and hydrogen sulfide (H₂S). Organisms capable of surviving on CO₂ as their principal carbon source are called **autotrophs**.

Light micrograph of a living leaf cell from Arabidopsis thaliana. The cell contains a number of chloroplasts—the organelles that house the plant's photosynthetic machinery. Chloroplasts normally divide by binary fission in which a single constriction splits the organelle into two equal daughters. This cell is from a mutant plant that is characterized by asymmetric fission. The highly elongated chloroplast has initiated fission asymmetrically at several sites, as indicated by the multiple constrictions. Mutants have proven invaluable in the identification of genes involved in all types of cellular processes. It is only when a gene malfunctions that its effects usually become visible, providing researchers with an idea of the gene's normal function—in this case a role in chloroplast fission. (COURTESY OF KEVIN D. STOKES AND STANISLAV VITHAR.)

The manufacture of complex organic molecules from CO_2 requires the input of large amounts of energy. Over the course of evolution, two main types of autotrophs have evolved that can be distinguished by their source of energy. **Chemoautotrophs** utilize the chemical energy stored in inorganic molecules (such as ammonia, hydrogen sulfide, or nitrites) to convert CO_2 into organic compounds, while **photoautotrophs** utilize the radiant energy of the sun to achieve this result. Because all chemoautotrophs are prokaryotes, and their relative contribution to the formation of biomass on Earth is small, we will not consider their metabolic activities further. Photoautotrophs, on the other hand, are responsible for capturing the energy that fuels the activities of most organisms on Earth. Photoautotrophs include plants and eukaryotic algae, various flagellated protists, and members of several groups of prokaryotes. All of these organisms carry out **photosynthesis**, a process in which energy from sunlight is transformed into chemical energy that is stored in carbohydrates and other organic molecules.

During photosynthesis, relatively low-energy electrons are removed from a donor compound and converted into high-energy electrons using the energy absorbed from light.¹ These high-energy electrons are then employed in the synthesis of reduced biological molecules, such as starch and oils. It is likely that the first groups of photoautotrophs, which may have dominated Earth for two billion years, utilized hydrogen sulfide as their source of electrons for photosynthesis, carrying out the overall reaction

where (CH_2O) represents a unit of carbohydrate. There are numerous bacteria living today that carry out this type of photosynthesis; an example is shown in Figure 6.1. But, today, hydrogen sulfide is neither abundant nor widespread; consequently, organisms that depend on this compound as an electron source are restricted to habitats such as sulfur springs and deep-sea vents.

Approximately 2.7 to 2.4 billion years ago, a new type of photosynthetic prokaryote appeared on Earth that was able to utilize a much more abundant source of electrons, namely, water. Not only did the use of water allow these organisms—the cyanobacteria—to exploit a much more diverse array of habitats on Earth (see Figure 1.15), it produced a waste product of enormous consequence for all forms of life. The waste product was molecular oxygen (O_2), which is formed in the overall reaction

The switch from H_2S to H_2O as the substrate for photosynthesis is more difficult than switching one letter in the alphabet for another. The redox potential of the S- H_2S couple is -0.25 V as compared to $+0.816 \text{ V}$ for the O_2 - H_2O couple (page 190). In other words, the sulfur atom in a molecule of H_2S has much less affinity for its electrons (and so is easier to oxidize) than does the oxygen atom in a molecule of H_2O . Thus, if an organism is going

¹See the footnote on page 183 regarding use of the term *high-energy electrons*.

Figure 6.1 Photosynthetic green sulfur bacteria are present as a ring of peripheral cells that are living in a symbiotic relationship with a single anaerobic, heterotrophic bacterium in the center of the “colony.” The heterotrophic bacterium receives organic matter produced by the photosynthetic symbionts. Photosynthetic vesicles containing the light-capturing machinery are visible in the green sulfur bacteria. (FROM TOM FENCHEL, SCIENCE 296:1070, 2002, ELECTRON MICROGRAPH BY KEN CLARKE, CEH-WINDERMERE, U.K. © 2002, REPRINTED WITH PERMISSION FROM AAAS.)

to carry out *oxygenic* (oxygen-releasing) photosynthesis, it has to generate a very strong oxidizing agent as part of its photosynthetic metabolism in order to pull tightly held electrons from water. The switch from H_2S (or other reduced substrates) to H_2O as the electron source for photosynthesis required an overhaul of the photosynthetic machinery.

At some point in time, one of these ancient, O_2 -producing cyanobacteria took up residence inside a mitochondria-containing, nonphotosynthetic, primitive eukaryotic cell (page 27). Over a long period of evolution, the symbiotic cyanobacterium was transformed from a separate organism living within a host cell into a cytoplasmic organelle, the **chloroplast**. As the chloroplast evolved, most of the genes that were originally present in the symbiotic cyanobacterium were either lost or transferred to the plant cell nucleus. As a result, the polypeptides found within modern-day chloroplasts are encoded by both the nuclear and chloroplast genomes. Extensive genetic analyses of chloroplast genomes suggest that all modern chloroplasts have arisen from a single, ancient symbiotic relationship. As a result of their common ancestry, chloroplasts and cyanobacteria share many basic characteristics, including a similar photosynthetic machinery, which will be discussed in detail in the following pages.

6.1 | Chloroplast Structure and Function

Chloroplasts are located predominantly in the mesophyll cells of leaves. The structure of a leaf and the arrangement of chloroplasts around the central vacuole of a mesophyll cell are shown in Figure 6.2. Chloroplasts of higher plants are generally lens-shaped (Figure 6.3), approximately 2 to 4 μm wide and 5 to 10 μm long, and typically numbering 20 to 40 per cell. Their dimensions make chloroplasts giants among organelles—as large as an entire mammalian red blood cell. As illustrated in the chapter-opening micrograph, chloroplasts arise by fission from preexisting chloroplasts (or their nonpigmented precursors, which are called **proplastids**).

Chloroplasts were identified as the site of photosynthesis in 1881 in an ingenious experiment by the German biologist T. Engelmann. Engelmann illuminated cells of the green alga *Spirogyra* and found that actively moving bacteria would collect outside the cell near the site of the large ribbon-like chloroplast (see Figure 1.5). The bacteria were utilizing the minute quantities of oxygen released during photosynthesis in the chloroplast for their aerobic respiration.

The outer covering of a chloroplast consists of an envelope composed of two membranes separated by a narrow space (Figure 6.3). Like the outer membrane of a mitochondrion, the outer membrane of a chloroplast envelope contains several different porins (page 182). Although these proteins have relatively large channels, they exhibit some selectivity toward various solutes and thus may not be as freely permeable to key metabolites as is often described. The inner membrane of the envelope is highly impermeable; substances moving through this membrane do so only with the aid of a variety of transporters.

Much of the photosynthetic machinery of the chloroplast—including light-absorbing pigments, a complex chain of electron

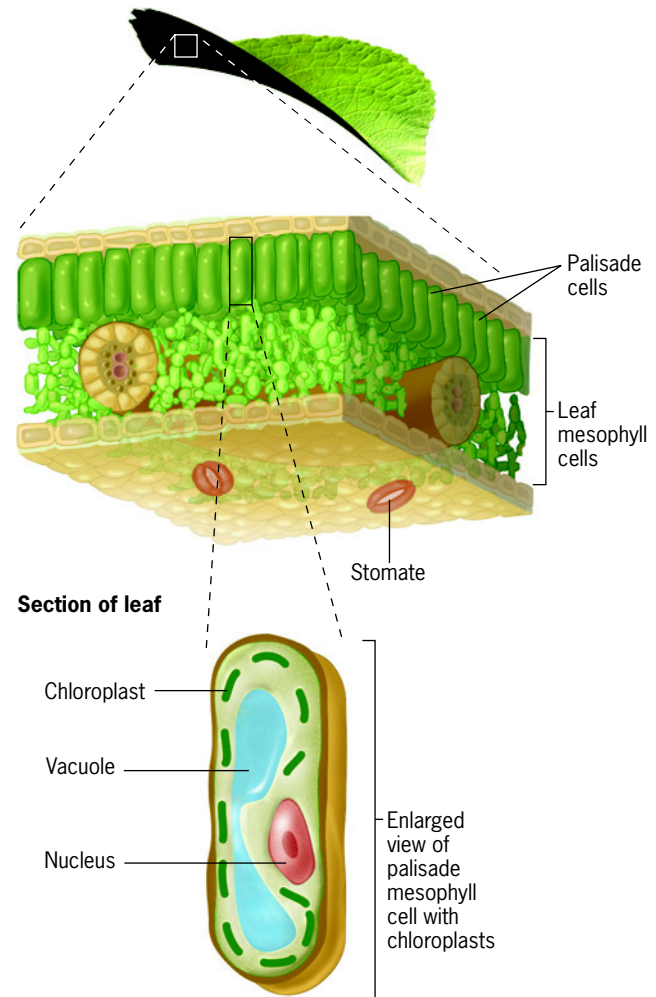

Figure 6.2 The functional organization of a leaf. The section of the leaf shows several layers of cells that contain chloroplasts distributed within their cytoplasm. These chloroplasts carry out photosynthesis, providing raw materials and chemical energy for the entire plant.

Figure 6.3 The internal structure of a chloroplast. (a) Transmission electron micrograph through a single chloroplast. The internal membrane is arranged in stacks (grana) of disk-like thylakoids that are physically separate from the outer double membrane that forms the

envelope. (b) Schematic diagram of a chloroplast showing the outer double membrane and the thylakoid membranes. (A: BIOLOGY PICS/PHOTO RESEARCHERS, INC.)

carriers, and an ATP-synthesizing apparatus—is part of an internal membrane system that is physically separate from the double-layered envelope. The internal membrane of the chloroplast is organized into flattened membranous sacs, called **thylakoids**. Thylakoids are arranged in orderly stacks called **grana** (Figures 6.3 and 6.4). The space inside a thylakoid sac is the *lumen*, and the space outside the thylakoid and within the chloroplast envelope is the **stroma**, which contains the enzymes responsible for carbohydrate synthesis. The thylakoid membrane contains the chlorophyll molecules and protein complexes that comprise the energy-transducing machinery of the chloroplast.

Like the matrix of a mitochondrion, the stroma of a chloroplast contains small, double-stranded, circular DNA molecules and prokaryotic-like ribosomes. As discussed above, the DNA of the chloroplast is a relic of the genome of an ancient bacterial endosymbiont. Depending on the organism, chloroplast DNA contains between about 60 and 200 genes involved in either gene expression (e.g., tRNAs, rRNAs, ribosomal proteins) or photosynthesis. The vast majority of the estimated 2000–3500 polypeptides of a plant chloroplast are encoded by the DNA of the nucleus and synthesized in the cytosol. These proteins must be imported into the chloroplast by a specialized transport machinery (Section 8.9).

Thylakoid membranes have a high protein content and are unusual in having relatively little phospholipid. Instead, these membranes have a high percentage of galactose-containing glycolipids such as the following:

Monogalactosyl diacylglycerol

Both fatty acids of these lipids contain several double bonds, which makes the lipid bilayer of thylakoid membranes highly fluid. The fluidity of the lipid bilayer facilitates lateral diffusion of protein complexes through the membrane during photosynthesis.

REVIEW

1. Describe the effect that the evolution of cyanobacteria is thought to have had on the metabolism of organisms.
2. Describe the organization of the membranes of a chloroplast. How does this organization differ from that of mitochondria?
3. Distinguish between stroma and lumen, envelope membrane and thylakoid membrane, autotrophs and heterotrophs.

Electron micrograph of a section through a portion of a chloroplast showing the stacked grana thylakoids, which are connected to one another by unstacked stroma thylakoids (or stroma lamellae). The dark spheres are osmium-stained lipid granules. (DR. KENNETH R. MILLER/PHOTO RESEARCHERS, INC.)

6.2 | An Overview of Photosynthetic Metabolism

A major advance in our understanding of the chemical reactions of photosynthesis came in the early 1930s with a proposal by C. B. van Niel, who was then a graduate student at Stanford University. Consider the overall equation of photosynthesis as given earlier:

The prevailing belief in 1930 was that the energy of light was used to split CO_2 , releasing molecular oxygen (O_2) and transferring the carbon atom to a molecule of water to form a unit of carbohydrate (CH_2O). In 1931, van Niel proposed an alternate mechanism based on his work with sulfur bacteria. It had been demonstrated that these organisms were able to reduce CO_2 to carbohydrate using the energy of light without the simultaneous production of molecular O_2 . The proposed reaction for sulfur bacteria was

Postulating a basic similarity in the photosynthetic processes of all organisms, van Niel proposed a general reaction to include all these activities:

For the production of a hexose, such as glucose, the reaction would be

Van Niel recognized that photosynthesis was essentially a process of oxidation–reduction. In the preceding reaction, H_2A is an electron donor (reducing agent) and can be represented by H_2O , H_2S , or other reduced substrates utilized by various types of bacteria. Carbon dioxide, however, is an oxi-

dizing agent, which, in a plant cell, is reduced to form hexose in the following reaction:

In this scheme, each molecule of oxygen is derived not from CO_2 but from the breakdown of two molecules of H_2O , a process driven by the absorption of light. The role of water in the formation of molecular oxygen was clearly established in 1941 by Samuel Ruben and Martin Kamen of the University of California, Berkeley. These investigators carried out experiments on suspensions of green algae using a specially labeled isotope of oxygen, ^{18}O , as a replacement for the common isotope, ^{16}O . One sample of algae was exposed to labeled $\text{C}[^{18}\text{O}_2]$ and unlabeled water, while another sample was exposed to unlabeled carbon dioxide and labeled $\text{H}_2[^{18}\text{O}]$. The investigators asked a simple question: Which of these two samples of photosynthetic organisms released labeled $^{18}\text{O}_2$? The algae given labeled water produced labeled oxygen, demonstrating that O_2 produced during photosynthesis derived from H_2O . The algae given labeled carbon dioxide produced unlabeled oxygen, confirming that O_2 was not being produced by a chemical splitting of CO_2 . Contrary to popular belief, it wasn't carbon dioxide that was being split into its two atomic components, but water. Van Niel's hypothesis had been confirmed.

The van Niel proposal placed photosynthesis in a different perspective; it became, in essence, the reverse of mitochondrial respiration. Whereas respiration in mitochondria reduces oxygen to water, photosynthesis in chloroplasts oxidizes water to oxygen. The former process releases energy, so the latter process must require energy. An overview of the thermodynamics of photosynthesis and aerobic respiration is

indicated in Figure 6.5. Many similarities between these two metabolic activities will be apparent in the following pages.

The events of photosynthesis can be divided into two series of reactions. During the first stage, the **light-dependent reactions**, energy from sunlight is absorbed and stored as chemical energy in two key biological molecules: ATP and NADPH. As discussed in Chapter 3, ATP is the cell's primary source of chemical energy, and NADPH is its primary source of reducing power. During the second stage, the **light-independent reactions** (or "dark reactions" as they are often called), carbohydrates are synthesized from carbon dioxide using the energy stored in the ATP and NADPH molecules produced in the light-dependent reactions. In actual fact, these "dark reactions" take place much more rapidly when the light-dependent reactions are also occurring (see page 229). It is estimated that plant life on Earth converts approximately 500 trillion kg of CO_2 to carbohydrate each year, an amount roughly 10,000 times the world's yearly beef production.

We will begin with the light-dependent reactions, which are complex and remain incompletely understood.

REVIEW

1. In what ways is photosynthesis the reverse of respiration?
2. In what ways is nonoxygenic photosynthesis that uses H_2S as an electron source similar to oxygenic photosynthesis that uses H_2O as an electron source? In what ways are they different?
3. In general terms, how do the light-independent reactions differ from the light-dependent reactions? What are the primary products of the two types of reactions?

Figure 6.5 An overview of the energetics of photosynthesis and aerobic respiration.

6.3 | The Absorption of Light

Light travels in packets (or quanta) of energy called **photons**, which can be thought of as “particles” of light.² The energy content of a photon depends on the wavelength of the light according to the equation

$$E = hc/\lambda$$

where h is Planck’s constant (1.58×10^{-34} cal · sec), c is the speed of light in a vacuum, and λ is the wavelength of light. The shorter the wavelength, the higher the energy content. One mole (6.02×10^{23}) of photons of 680 nm wavelength, which is an important wavelength in photosynthesis, contains approximately 42 kcal of energy, which is equivalent to a change in redox potential of approximately 1.8 V (calculated by dividing 42 kcal by the Faraday constant of 23.06 kcal/V).

The absorption of light is the first step in any photochemical process. When a photon is absorbed by a molecule, an electron becomes sufficiently energetic to be pushed from an inner to an outer orbital. The molecule is said to have shifted from the **ground state** to an **excited state**. Because the number of orbitals in which an electron can exist is limited and each orbital has a specific energy level, it follows that any given atom or molecule can absorb only light of certain specific wavelengths.

The excited state of a molecule is unstable and can be expected to last only about 10^{-9} second. Several consequences can befall an excited electron, depending on the circumstances. Consider a molecule of **chlorophyll**, which is the most important light-absorbing photosynthetic pigment. If the electron of an excited chlorophyll molecule drops back to a lower orbital, the energy it had absorbed must be released. If the energy is released in the form of light (fluorescence or phosphorescence) or heat, the chlorophyll has returned to the original ground state and the energy of the absorbed photon has not been utilized. This is precisely what is observed when a preparation of *isolated chlorophyll* in solution is illuminated: the solution becomes strongly fluorescent because the absorbed energy is reemitted at a longer (i.e., lower energy) wavelength. However, if the same experiment is performed on a preparation of *isolated chloroplasts*, only a faint fluorescence is observed, indicating that very little of the absorbed energy is dissipated. Instead, the excited electrons of chlorophyll molecules are transferred to electron acceptors within the chloroplast membranes before they have a chance to drop back to lower energy orbitals. Thus, chloroplasts are able to harness the absorbed energy before it dissipates.

Photosynthetic Pigments

Pigments are compounds that appear colored because they only absorb light of particular wavelength(s) within the visible spectrum. Leaves are green because their chloroplasts contain large quantities of the pigment chlorophyll, which absorbs

²The idea that electromagnetic radiation (e.g., light) has both wave-like and particle-like properties emerged at the start of the twentieth century from the work of Max Planck and Albert Einstein and marked the beginning of the study of quantum mechanics.

most strongly in the blue and red, leaving the intermediate green wavelengths to be reflected to our eyes. The structure of chlorophyll is shown in Figure 6.6. Each molecule consists of

Figure 6.6 The structure of chlorophyll *a*. The molecule consists of a porphyrin ring (which in turn is constructed of four smaller pyrrole rings) with a magnesium ion at its center and a long hydrocarbon tail. The green shading around the edge of the porphyrin indicates the delocalization of electrons that form a cloud. The structure of the magnesium-containing porphyrin of chlorophyll can be compared to the iron-containing porphyrin of a heme shown in Figure 5.12. Chlorophyll *b* and bacteriochlorophyll *a* contain specific substitutions as indicated. For example, the —CH₃ group on ring II is replaced by a —CHO group in chlorophyll *b*. Chlorophyll *a* is present in all oxygen-producing photosynthetic organisms, but it is absent in the various sulfur bacteria. In addition to chlorophyll *a*, chlorophyll *b* is present in all higher plants and green algae. Others not shown are chlorophyll *c*, present in brown algae, diatoms, and certain protozoa, and chlorophyll *d*, found in red algae. Bacteriochlorophyll is found only in green and purple bacteria, organisms that do not produce O₂ during photosynthesis.

Figure 6.7 Absorption spectrum for several photosynthetic pigments of higher plants. The background shows the colors that we perceive for the wavelengths of the visible spectrum. Chlorophylls absorb most strongly in the violet, blue, and red regions of the spectrum, while carotenoids (e.g., β -carotene) also absorb into the green region. Red algae and cyanobacteria contain additional pigments (phycobilins) that absorb in the middle bands of the spectrum.

two parts: (1) a porphyrin ring that functions in light absorption and (2) a hydrophobic phytol chain that keeps the chlorophyll embedded in the photosynthetic membrane. Unlike the red, iron-containing porphyrins (heme groups) of hemoglobin and myoglobin, the porphyrin in a chlorophyll molecule contains a magnesium atom. The alternating single and double bonds along the edge of the porphyrin ring delocalize electrons, which form a cloud around the ring (Figure 6.6). Systems of this type are said to be *conjugated* and are strong absorbers of visible light. The absorbed energy causes a redistribution of the electron density of the molecule, which

Figure 6.8 Action spectrum for photosynthesis. The action spectrum (red-colored line) indicates the relative efficiency with which light of various wavelengths is able to promote photosynthesis in the leaves of a plant. An action spectrum can be generated by measuring the O_2 produced by the leaves following exposure to various wavelengths. The black lines indicate the absorption spectra of each of the major photosynthetic pigments. The green line shows the combined absorption spectrum of all pigments.

in turn favors loss of an electron to a suitable acceptor. The conjugated bond system also broadens the absorption peaks, enabling individual molecules to absorb energy of a range of wavelengths. These features are evident in an absorption spectrum of purified chlorophyll molecules (Figure 6.7). An **absorption spectrum** is a plot of the intensity of light absorbed relative to its wavelength. The range of wavelengths absorbed by photosynthetic pigments situated within the thylakoids is further increased because the pigments are noncovalently associated with a variety of different polypeptides.

Several classes of chlorophyll, differing from one another in the side groups attached to the porphyrin ring, occur among photosynthetic organisms. The structures of these pigments are indicated in Figure 6.6. Chlorophylls are the primary light-absorbing photosynthetic pigments, but terrestrial plants also contain orange and red accessory pigments called *carotenoids*, including β -carotene, which contain a linear system of conjugated double bonds:

Carotenoids absorb light primarily in the blue and green region of the spectrum (Figure 6.7), while reflecting those of the yellow, orange, and red regions. Carotenoids produce the characteristic colors of carrots and oranges, and the leaves of some plants during the fall. Carotenoids have multiple functions: they act as secondary light collectors during photosynthesis, and they draw excess energy away from excited chlorophyll molecules and dissipate it as heat. If this excess energy were not absorbed by carotenoids, it could be transferred to oxygen, producing an ultrareactive form of the molecule called singlet oxygen ($^1O^*$) that can destroy biological molecules and cause cell death.

Because the light falling on a leaf is composed of a variety of wavelengths, the presence of pigments with varying absorption properties ensures that a greater percentage of incoming photons will stimulate photosynthesis. This can be seen by examining an **action spectrum** (Figure 6.8), which is a plot of the relative rate (or efficiency) of photosynthesis produced by light of various wavelengths. Unlike an absorption spectrum, which simply measures the wavelengths of light that are absorbed by particular pigments, an action spectrum identifies the wavelengths that are effective in bringing about a given physiologic response. The action spectrum for photosynthesis follows the absorption spectrum of chlorophylls and carotenoids fairly closely, reflecting the participation of these pigments in the photosynthetic process.

REVIEW

1. What is the difference between an absorption spectrum and an action spectrum?
2. Compare the structure, absorption, and function of chlorophylls and carotenoids.

6.4 | Photosynthetic Units and Reaction Centers

In 1932, Robert Emerson and William Arnold of the California Institute of Technology carried out an experiment suggesting that not all of the chlorophyll molecules in a chloroplast were directly involved in conversion of light energy into chemical energy. Using suspensions of the green alga *Chlorella* and flashing lights of extremely short duration at saturating intensity, they determined the minimum amount of light needed to produce maximal O_2 production during photosynthesis. Based on the number of chlorophyll molecules present in the preparation, they calculated that one molecule of oxygen was being released during a brief flash of light for every 2500 molecules of chlorophyll present. Later, Emerson showed that a minimum of eight photons must be absorbed to produce one molecule of O_2 , which meant that chloroplasts contain approximately 300 times as many chlorophyll molecules as would appear to be necessary to oxidize water and generate O_2 .

One possible interpretation of this finding is that only a very small percentage of chlorophyll molecules is involved in photosynthesis. This is not the case, however. Rather, several hundred chlorophyll molecules act together as one **photosynthetic unit** in which only one member of the group—the **reaction-center chlorophyll**—actually transfers electrons to an electron acceptor. Even though the bulk of the pigment molecules do not participate *directly* in the conversion of light energy into chemical energy, they are responsible for light absorption. These pigment molecules form a light-harvesting **antenna** that absorbs photons of varying wavelength and

transfers that energy (called *excitation energy*) very rapidly to the pigment molecule at the reaction center.

The transfer of excitation energy from one pigment molecule to another is very sensitive to the distance between the molecules. The chlorophyll molecules of an antenna are kept in close proximity (less than 1.5 nm separation) and proper orientation by noncovalent linkage to integral membrane polypeptides. A “rule” that operates among antenna pigments is that energy can only be transferred to an equal or less energy-requiring molecule. In other words, energy can only be passed to a pigment molecule that absorbs light of equal or longer wavelength (lower energy) than that absorbed by the donor molecule. As the energy “wanders” through a photosynthetic unit (Figure 6.9), it is repeatedly transferred to a pigment molecule that absorbs at a longer wavelength. The energy is ultimately transferred to a chlorophyll of the reaction center, which absorbs light of longer wavelength than any of its neighbors. Once the energy is received by the reaction center, the electron excited by light absorption can be transferred to its acceptor.

Oxygen Formation: Coordinating the Action of Two Different Photosynthetic Systems

The evolution of organisms capable of using H_2O as an electron source was accompanied by major changes in the photosynthetic machinery. The reason for these changes is revealed by considering the energetics of oxygenic (O_2 -releasing) photosynthesis. The O_2 - H_2O couple has a standard redox potential of +0.82 V, whereas that of the $NADP^+$ - $NADPH$ couple is -0.32 V (Table 5.1, page 190). The difference between the redox potentials of these two couples (1.14 V) provides a measure of the minimal energy that must be absorbed by the system to remove an electron from H_2O and pass it to $NADP^+$ *under standard conditions*. However, cells don't operate under standard conditions, and the transfer of electrons from H_2O to $NADP^+$ requires more than the minimal input of energy. It is estimated that, during actual operations in the chloroplast, more than 2 V of energy are utilized to carry out this oxidation-reduction reaction. (This value of 2 V is estimated from the left-hand scale of Figure 6.10, which extends from below +1 V to above -1 V.) It was noted on page 216 that one mole of photons of 680 nm wavelength (red light) is equivalent to a change in redox potential of 1.8 V. Thus, while it is theoretically possible for one photon of red light to boost an electron to an energy level required to reduce $NADP^+$ under standard conditions (i.e., 1.14 V), the process is accomplished in the cell through the combined action of two different light-absorbing reactions.

The light-absorbing reactions of photosynthesis occur in large pigment-protein complexes called **photosystems**. Two types of photosystems are required to catalyze the two light-absorbing reactions utilized in oxygenic photosynthesis. One photosystem, **photosystem II (PSII)**, boosts electrons from an energy level below that of water to a midway point (Figure 6.10). The other photosystem, **photosystem I (PSI)**, raises electrons from a midway point to an energy level well above that of $NADP^+$. The two photosystems act in series, that is,

Figure 6.9 The transfer of excitation energy. Energy is transferred randomly through a network of pigment molecules that absorb light of increasingly longer wavelength until the energy reaches a reaction-center chlorophyll, which transfers an excited electron to a primary acceptor, as described later in the chapter.

Figure 6.10 An overview of the flow of electrons during the light-dependent reactions of photosynthesis. The events depicted in this schematic drawing are described in detail in the following pages. The energy content of electrons is given in volts. To convert these values to calories, multiply by the Faraday constant, 23.06 kcal/V. For example, a difference of 2.0 V corresponds to an energy difference of 46 kcal/mol of electrons. This can be compared to the energy of red light (680 nm), which contains about 42 kcal/mol of photons.

one after the other. Even though they mediate distinctly different photochemical reactions, the two types of photosystems in plants, as well as those of photosynthetic bacterial cells, exhibit marked similarities in protein composition and overall architecture. These shared properties suggest that all photosynthetic reaction centers have evolved from a common ancestral structure that has been conserved for more than three billion years.

The reaction center of photosystem II is a chlorophyll dimer referred to as **P680**, “P” standing for “pigment” and “680” standing for the wavelength of light that this particular pair of chlorophylls absorbs most strongly. The reaction center of photosystem I is also a chlorophyll dimer and is referred to as **P700** for comparable reasons. When sunlight strikes a thylakoid membrane, energy is absorbed by antenna pigments of both PSII and PSI and passed to the reaction centers of both photosystems. Electrons of both reaction-center pigments are boosted to an outer orbital, and each electron is transferred to a **primary electron acceptor**. After losing their electrons, the reaction-center chlorophylls of PSII and PSI become positively charged pigments referred to as $P680^+$ and $P700^+$, respectively. The electron acceptors, in turn, become negatively charged. In essence, this separation of charge within the photosystems is the light reaction—the conversion of light energy into chemical energy. Positively charged reaction centers act as

attractants for electrons, and negatively charged acceptors act as electron donors. Consequently, the separation of charge within each photosystem sets the stage for the flow of electrons along a chain of specific carriers.

In oxygenic photosynthesis, where the two photosystems act in series, electron flow occurs along three legs—from water to PSII, from PSII to PSI, and from PSI to $NADP^+$ —an arrangement described as the *Z scheme*, which was first proposed by Robert Hill and Fay Bendall of the University of Cambridge. The broad outline of the *Z scheme* is illustrated in Figure 6.10; we will fill in the names of some of the specific components as we examine each of the major parts of the pathway. Like the members of the respiratory chain of mitochondria (Chapter 5), most of the electron carriers of the *Z scheme* are found as part of large membrane protein complexes (see Figure 6.16). Over the years, researchers have generated increasingly detailed portraits of the structures of these complexes. These efforts have culminated in the past few years with the publication of X-ray crystallographic structures of both PSI and PSII by several laboratories at increasingly higher resolution. These studies form the basis for the structures of the photosystems shown in Figures 6.11, 6.15, and 6.16.

As in mitochondria, electron transfer releases energy, which is used to establish a proton gradient, which in turn drives the synthesis of ATP. As discussed on page 228,

ATP produced in the chloroplast is used primarily within the organelle in the synthesis of carbohydrates; ATP utilized outside the chloroplast is derived largely from that produced in plant cell mitochondria.

PSII Operations: Obtaining Electrons by Splitting Water Photosystem II uses absorbed light energy for two interrelated activities: removing electrons from water and generating a proton gradient. The PSII of plant cells is a complex of more than 20 different polypeptides, most of which are embedded in the thylakoid membrane. Two of these proteins, designated D1 and D2, are particularly important because together they bind the P680 reaction-center chlorophyll dimer and all of the cofactors involved in electron transport through the photosystem (Figure 6.11).

The first step in PSII activation is the absorption of light by an antenna pigment. Most of the antenna pigments that collect solar energy for PSII reside within a separate pigment-

protein complex, called **light-harvesting complex II** or, simply, **LHCII**. LHCII proteins bind both chlorophylls and carotenoids and are situated outside the core of the photosystem (Figure 6.11a). As discussed in the Experimental Pathways, which can be accessed on the Web at www.wiley.com/college/karp, LHCII is not always associated with PSII but, under appropriate conditions, can migrate along the thylakoid membrane and become associated with PSI, serving as a light-harvesting complex for the PSI reaction center as well.

The Flow of Electrons from PSII to Plastoquinone Excitation energy is passed from the outer-antenna pigments of LHCII to a small number of inner-antenna chlorophyll molecules situated within the core of PSII. From there, the energy is ultimately passed to the PSII reaction center. The excited reaction-center pigment (P680*) responds by transferring a single photoexcited electron to a closely associated chlorophyll-like pheophytin molecule (step 1, Figure 6.11a), which is the

Figure 6.11 The functional organization of photosystem II.

(a) A schematic model of the huge protein-pigment complex, which catalyzes the light-driven oxidation of water and reduction of plastoquinone. The path taken by electrons through PSII is indicated by the yellow arrows. Events begin with the absorption of light by an antenna pigment in the outer light-harvesting complex (LHCII). Energy is transferred from LHCII through an inner antenna pigment-protein complex to a P680 reaction-center chlorophyll *a*, which is one of four closely spaced chlorophyll *a* molecules (the P680 dimer and two accessory chlorophyll *a* molecules). Absorption of this energy by P680 excites an electron, which is transferred to pheophytin (Pheo) (step 1), the primary electron acceptor of PSII. (Pheophytin is a chlorophyll molecule that lacks the Mg^{2+} ion.) The electron subsequently passes to a plastoquinone PQ_A (step 2) and then through a nonheme Fe^{2+} to PQ_B (step 3) to form a negatively charged free radical $PQ_B^{\cdot -}$. Absorption of a second photon sends a second electron along the same pathway, converting the acceptor to PQ_B^{2-} (step 4). Two protons then enter from the stroma (step 5) generating PQH_2 , which is released into the lipid bilayer and replaced by a new oxidized PQ_B molecule (step 6).

As the above events are occurring, electrons are moving from H_2O by way of Tyr_z to the positively charged reaction-center pigment (steps B and A). Thus, overall, PSII catalyzes the transfer of electrons from water to plastoquinone. The oxidation of two molecules of H_2O to release one molecule of O_2 generates two molecules of PQH_2 . Because the oxidation of water releases protons into the thylakoid lumen and the reduction of PQ_B^{2-} removes protons from the stroma, the operation of PSII makes a major contribution to formation of a H^+ gradient. The figure shows one monomer of a dimeric PSII complex. (b) The oxygen-evolving complex contains a Mn_4CaO_5 cluster whose structure has been determined to a resolution of 1.9 Å by X-ray crystallography. Three Mn atoms (#1-3), a Ca atom, and four O atoms (#1, 2, 3, 5) are arranged as part of an asymmetric cube-like cluster with a bridge to a fourth Mn and fifth O atom at nearby sites. Two water molecules are bound to the Ca and two more are bound to Mn4. It is likely that reaction between the oxygen atoms of two of these bound water molecules leads to formation of an $O=O$ bond. (B: FROM YASUFUMI UMENA, ET AL., NATURE 473:57, 2011; COURTESY NOBUO KAMIYA. © 2011, REPRINTED WITH PERMISSION FROM MACMILLAN PUBLISHERS LIMITED).

primary electron acceptor. This electron transfer generates a separation of charge in PSII between a positively charged donor (P680⁺) and a negatively charged acceptor (Pheo⁻). The importance of the formation of two oppositely charged species, P680⁺ and Pheo⁻, becomes more apparent when we consider the oxidation–reduction capabilities of these two species. P680⁺ is electron-deficient and can accept electrons, making it an oxidizing agent. In contrast, Pheo⁻ has an extra electron that it will readily lose, making it a reducing agent. This event—the light-driven formation of an oxidizing agent and a reducing agent—takes less than one billionth of a second and is the essential first step in photosynthesis.

Because they are oppositely charged, P680⁺ and Pheo⁻ exhibit an obvious reactivity with one another. Interaction between the oppositely charged species is prevented by moving the separated charges farther apart, ultimately to opposite sides of the membrane, by passage through several different sites. Pheo⁻ first transfers its electron (step 2, Figure 6.11*a*) to a molecule of plastoquinone (designated PQ_A in Figure 6.11*a*) bound near the outer (stromal) side of the membrane. Plastoquinone (PQ) is a lipid-soluble molecule (Figure 6.12) similar in structure to ubiquinone (see Figure 5.12*c*). The electron from PQ_A is transferred (step 3, Figure 6.11*a*) to a second plastoquinone (designated PQ_B in Figure 6.11) to produce a semireduced form of the molecule (PQ_B⁻) that remains firmly bound to the D1 protein of the reaction center. With each of these transfers, the electron moves closer to the stromal side of the membrane.

The positively charged pigment (P680⁺) is reduced back to P680 (as described below), which primes the reaction center for the absorption of another photon. The absorption of a

second photon sends a second energized electron along the path from P680 to pheophytin to PQ_A to (PQ_B⁻), forming PQ_B²⁻ (step 4, Figure 6.11), which combines with two protons to form plastoquinol, PQH₂ (step 5, Figure 6.11*a*; Figure 6.12). The protons utilized in the formation of PQH₂ are derived from the stroma, causing a decrease in H⁺ concentration of the stroma, which contributes to formation of the proton gradient. The reduced PQH₂ molecule dissociates from the D1 protein and diffuses into the lipid bilayer. The displaced PQH₂ is replaced by a fully oxidized PQ molecule derived from a small “pool” of plastoquinone molecules in the bilayer (step 6, Figure 6.11*a*). We can summarize this portion of the PSII reaction with the equation

As we will see shortly, the oxidation of a molecule of water by PSII requires four photons, so we can better describe this portion of the PSII reaction with the equation

We will follow the fate of the electrons (and protons) carried by PQH₂ in a following section.

The Flow of Electrons from Water to PSII The least understood part of the flow of electrons from water to NADP⁺ is the first step between H₂O and PSII. Water is a very stable molecule made up of tightly held hydrogen and oxygen atoms. In fact, the splitting of water is the most thermodynamically challenging (endergonic) reaction known to occur in living organisms. Splitting water in a laboratory requires the use of a strong electric current or temperatures approaching 2000°C. Yet a plant cell can accomplish this feat on a snowy mountainside using only the energy of visible light.

We saw in the previous section how the absorption of light by PSII leads to the formation of two charged molecules, P680⁺ and Pheo⁻. We have followed the route taken by the excited electron associated with Pheo⁻; now we turn to the other species, P680⁺, which is the most powerful oxidizing agent yet to be discovered in a biological system. The redox potential of the oxidized form of P680 is sufficiently strong to pull tightly held (low-energy) electrons from water (redox potential of +0.82 V), thus splitting the molecule. The splitting of water during photosynthesis is called **photolysis**. The formation of one molecule of oxygen during photolysis is thought to require the *simultaneous* loss of four electrons from two molecules of water according to the reaction

Yet one PSII reaction center can only generate one positive charge (P680⁺), or oxidizing equivalent, at a time. A solution to this problem was proposed around 1970 by Pierre Joliot and Bessel Kok as the S-state hypothesis, which allows the photosystem to accumulate the four oxidizing equivalents needed to oxidize water. Closely associated with the D1 protein of PSII at its luminal surface is a cluster of five metal atoms—four manganese (Mn) atoms and one calcium (Ca) atom—that is stabilized and protected by a number of peripheral proteins that form the *oxygen-evolving complex* (Figure 6.11*a*). The geometric

Figure 6.12 Plastoquinone. The acceptance of two electrons and two protons reduces PQ (plastoquinone) to PQH₂ (plastoquinol). The intermediates are similar to those shown in Figure 5.12*c* for ubiquinone of the mitochondrion.

organization of the Mn-Ca cluster is shown in Figure 6.11*b* and discussed in the accompanying legend. The Mn-Ca cluster accumulates four oxidizing equivalents by transferring four electrons, one at a time, to the nearby P680⁺. The transfer of each electron from the Mn-Ca cluster to P680⁺ (steps B and A of Figure 6.11) is accomplished by passage through an intermediate electron carrier, a tyrosine residue on the D1 protein, termed Tyr_z. After each electron is transferred to P680⁺, regenerating P680, the pigment becomes reoxidized (back to P680⁺) following the absorption of another photon by the photosystem. Thus, the stepwise accumulation of four oxidizing equivalents by the Mn-Ca cluster is driven by the successive absorption of four photons of light by the PSII photosystem. Once this has occurred, the system can now catalyze the removal of 4 e⁻ from two closely bound H₂O molecules (Figure 6.11*b*), as indicated in the following manner:

where the subscript on the S indicates the number of oxidizing equivalents stored by the Mn-Ca cluster. Evidence for the accumulation of successive oxidizing equivalents was first obtained by exposure of algal cells to very brief (1 μsec) flashes of light (Figure 6.13). It can be seen in this plot that O₂ production peaks after every fourth flash of light, indicating that the effect of four individual photoreactions must accumulate before O₂ can be released.

The protons produced in the photolysis reaction are retained in the thylakoid lumen (Figure 6.11), where they contribute to the proton gradient. The four electrons produced in the photolysis reaction serve to regenerate the fully reduced Mn-Ca cluster (S₀ state), while the O₂ is released as a waste product into the environment.

Before leaving the subject of PSII, it can be noted that the activity and integrity of this photosystem can be negatively

Figure 6.13 Measuring the kinetics of O₂ release. The plot shows the response by isolated chloroplasts that have been kept in the dark to a succession of light flashes of very short duration. The amount of oxygen released peaks with every fourth flash of light. The first peak occurs after three flashes (rather than four) because most of the manganese cluster is present in the S₁ state (one oxidizing equivalent) when kept in the dark. The oscillations become damped as the number of flashes increases.

affected by high light intensity. This phenomenon is termed *photoinhibition*. The formation of a very strong oxidizing agent, and the ever-present danger of forming highly toxic oxygen species, gives PSII the potential for its own self-destruction as the result of overexcitation of the system. Most of the damage appears to be targeted to the polypeptide (D1) that binds the active redox centers and Mn-Ca cluster of the photosystem. Chloroplasts contain a mechanism for the selective proteolytic degradation of D1 and its replacement by a newly synthesized polypeptide molecule.

From PSII to PSI It was described earlier how the successive absorption of two photons by the reaction center of PSII leads to the formation of a fully reduced PQH₂ molecule. Consequently, the production of a single O₂ molecule, which requires the absorption of four photons by PSII, leads to the formation of two molecules of PQH₂. PQH₂ is a mobile electron carrier that diffuses through the lipid bilayer of the thylakoid membrane and binds to a large multiprotein complex called *cytochrome b₆f* (Figure 6.14). Each PQH₂ molecule donates its two electrons to cytochrome *b₆f*, while its two protons are released into the lumen. Cytochrome *b₆f* is related in structure and function to cytochrome *bc₁* of the electron transport chain of mitochondria (page 196). Both complexes have quinols as substrates and share similar redox groups, both can be poisoned by some of the same inhibitors, and both engage in a Q cycle that translocates 4 H⁺ for each pair of electrons. In this case, 2 H⁺ are donated by PQH₂, and 2 additional H⁺ are translocated through the complex from the stroma. Because all of these protons had originally been derived from the stroma, their release into the lumen constitutes a movement of protons across the thylakoid membrane (see Figure 6.16*b*). The electrons from cytochrome *b₆f* are passed to another mobile electron carrier, a water-soluble, copper-containing, peripheral membrane protein called *plastocyanin*, situated on the luminal side of the thylakoid membrane (Figure 6.14). Plastocyanin carries electrons to the luminal side of PSI, where they are transferred to P700⁺, the positively charged

Figure 6.14 Electron transport between PSII and PSI. The flow of a pair of electrons is indicated by the yellow arrow. Cytochrome *b₆f* operates in a manner very similar to that of cytochrome *bc₁* in the mitochondria and engages in a Q cycle (not discussed in the text) that translocates four protons for every pair of electrons that moves through the complex. PQH₂ and PC (plastocyanin) are mobile carriers that can transport electrons between distantly separated photosystems.

reaction-center pigment of PSI, thus completing the link between PSII and PSI.

Keep in mind that all of the electron transfers described in this discussion are exergonic and occur as electrons are passed to carriers with increasing affinity for electrons (more positive redox potentials, page 189). The need for mobile electron carriers, such as PQH₂ and plastocyanin, became evident when it was discovered that the two types of photosystems (PSII and PSI) are not situated in close proximity to one another in the membrane but rather are separated by distances on the order of 0.1 μm. The experiments that led to this discovery are described in detail in the Chapter 6 Experimental Pathways, which can be found on the Web at www.wiley.com/college/karp.

PSI Operations: The Production of NADPH PSI of higher plants consists of a reaction-center core made up of 12–14 polypeptide subunits and a peripheral complex of protein-bound pigments called LHCI. Light energy is absorbed by the antenna pigments of LHCI and passed to the PSI reaction-center pigment P700, which is a chlorophyll *a* dimer (Figure 6.15). Following energy absorption, an excited reaction-center pigment (P700*) transfers an electron to a separate monomeric chlorophyll *a* molecule (designated A₀), which acts as the primary electron acceptor (step 1, Figure 6.14). As in PSII, absorption of light leads to the production of two charged species, in this case P700⁻ and A₀⁻. A₀⁻ is a very strong reducing agent with a redox potential of approximately -1.0 V, which is well above that needed to reduce NADP⁺ (redox potential of -0.32 V). The positive charge of P700⁺ pigment is neutralized by an incoming electron donated by plastocyanin, as noted earlier.

The initial separation of charge in PSI is stabilized by passage of the electron from A₀⁻ through several cofactors beginning with a type of quinone called *phylloquinone* (designated A₁) and then three iron-sulfur clusters (designated F_X, F_B, and F_A) (steps 2–4, Figure 6.15). The oxidation of P700 to P700⁺ occurs at the luminal side of the membrane. As indicated in Figure 6.15, the electron that is lost to the primary acceptor passes through PSI to the iron-sulfur centers bound at the stromal side of the membrane. The electron is subsequently transferred out of PSI to a small, water-soluble, iron-sulfur protein called *ferredoxin* (step 5, Figure 6.15) associated with the stromal surface of the membrane. The reduction of NADP⁺ to form NADPH (step 6, Figure 6.15) is catalyzed by a large enzyme called ferredoxin-NADP⁺ reductase, which contains an FAD prosthetic group capable of accepting and transferring two electrons (page 191). An individual ferredoxin molecule can donate only one electron, so that two ferredoxins act together in the reduction:

The removal of a proton from the stroma also adds to the proton gradient across the thylakoid membrane. We can write the overall reaction for PSI, based on the absorption of four photons as was done for PSII, as

Figure 6.15 The functional organization of photosystem I. The path taken by electrons is indicated by the yellow arrow. Events begin with the absorption of light by an antenna pigment and transfer of the energy to a P700 chlorophyll at the PSI reaction center. Absorption of energy by P700 causes the excitation of an electron and its transfer (step 1) to A₀, which is the primary electron acceptor of PSI. The electron subsequently passes to A₁ (step 2) and then to an iron-sulfur center named F_X (step 3). From F_X the electron is transferred (step 4) through two more iron-sulfur centers (F_A and F_B), which are bound by a peripheral protein at the stromal side of the membrane. The electron is finally transferred to ferredoxin, a small iron-sulfur protein (step 5) that is external to the PSI complex. When two different ferredoxin molecules have accepted an electron, they act together to reduce a molecule of NADP⁺ to NADPH (step 6). The electron-deficient reaction-center pigment (P700⁺) is reduced by an electron donated by plastocyanin (step A).

Not all electrons passed to ferredoxin inevitably end up in NADPH; alternate routes can be taken depending on the particular organism and conditions. For example, electrons from PSI can be used to reduce various inorganic acceptors. These paths for electrons can lead to the eventual reduction of nitrate (NO₃⁻) to ammonia (NH₃), or of sulfate (SO₄²⁻) to sulfhydryl (-SH), which are key ingredients of biological molecules. Thus, the energy of sunlight is used not only to reduce the most oxidized carbon atoms (those in CO₂), but also to reduce highly oxidized forms of nitrogen and sulfur atoms.

An Overview of Photosynthetic Electron Transport

Figure 6.16a shows the molecular structure of the major components involved in the light-dependent reactions of the thylakoid membrane. Knowledge of these structures has proven invaluable in unlocking many of the mysteries of photosynthesis

FIGURE IN FOCUS

Figure 6.16 Summary of the light-dependent reactions. (a) Three-dimensional structures of the proteins of the thylakoid membrane that carry out the light-dependent reactions of photosynthesis. Of the four major protein complexes, PSII and cytochrome b_6f are present in the membrane as dimers, whereas PSI and the ATP synthase (shown in greater detail in Figure 5.24) are present as monomers. (b) Summary of the flow of electrons from H_2O to NADPH through the three transmembrane complexes. This figure

shows the estimated number of protons translocated through the membrane as the result of the oxidation of two molecules of water, yielding two pairs of electrons. The ATP synthase of the thylakoid membranes is also shown (see Section 5.5 for discussion of the ATP-synthesizing enzyme). Approximately four protons are required for the synthesis of each molecule of ATP (page 205). (A: FROM NATURE REVS. MOL. CELL BIOL. 5:973, 2004, FIG. 1B. (b)

at the molecular level. If we look back over the entire process of electron transport that takes place during oxygenic photosynthesis (summarized in Figure 6.16), we can see that electrons travel from water to NADP^+ by the action of two light-absorbing photosystems. Events occurring in PSII generate a strong oxidizing agent capable of producing O_2 from water, whereas events in PSI generate a strong reducing agent capable of producing NADPH from NADP^+ . These two events lie at the opposite ends of redox chemistry in living organisms. As noted on page 221, the production of one molecule of O_2 requires the removal of four electrons from two molecules of water. The removal of four electrons from water requires the absorption of four photons, one for each electron. At the same time, the reduction of one molecule of NADP^+ requires the transfer of two electrons. Thus, hypothetically, if only one photosystem were able to transfer electrons from H_2O to NADP^+ , four photons would be sufficient to produce two molecules of NADPH. Because two photosystems are utilized in the cell, that number is doubled to eight photons, four being utilized in PSII and four in PSI. In other words, a total of eight moles of photons must be absorbed by the cell to generate one mole of molecular oxygen and two moles of NADPH. Thus, if we add the reactions of PSII (page 221) and PSI (page 223), *ignoring the protons for a moment*, we arrive at an overall equation for the light reactions of

In addition, the light reactions of photosynthesis establish a proton gradient across the thylakoid membrane that leads to the formation of ATP. The proton gradient forms as the result of the removal of H^+ from the stroma and the addition of H^+ to the thylakoid lumen. Contributions to the proton gradient (see Figure 6.16) arise from (1) the splitting of water in the lumen, (2) oxidation of plastoquinol (PQH_2) by cytochrome b_6f , releasing protons into the lumen, and (3) reductions of NADP^+ and PQ , which remove protons from the stroma.

Killing Weeds by Inhibiting Electron Transport

The light reactions of photosynthesis employ a considerable number of electron carriers, which serve as targets for a variety of different plant-killing chemicals (herbicides). A number of common herbicides, including diuron, atrazine, and terbutryn, act by binding to a core protein of PSII. We saw on page 221 how absorption of light by PSII leads to production of a PQH_2 molecule that is subsequently released from the Q_B site of PSII and replaced by a PQ from the pool. The herbicides listed above act by binding to the open Q_B site after release of PQH_2 , blocking electron transport through PSII. The herbicide paraquat has received attention in the news media because it is used to kill marijuana plants and because its residues are highly toxic to humans. Paraquat interferes with PSI function by competing with ferredoxin for electrons from the PSI reaction center. Electrons that are diverted to paraquat are subsequently transferred to O_2 , generating highly reactive oxygen radicals (page 35) that damage the chloroplasts and kill the plant. Paraquat destroys human tissue by

generating oxygen radicals using electrons diverted from complex I of the respiratory chain (page 195).

REVIEW

1. What is the relationship between the energy content of a photon and the wavelength of light? How does the wavelength of light determine whether or not it will stimulate photosynthesis? How do the absorbance properties of photosynthetic pigments determine the direction in which energy is transferred within a photosynthetic unit?
2. What is the role in photosynthesis of the light-harvesting antenna pigments?

4. Describe the difference in the redox potentials of the reaction-center pigments of the two photosystems.
5. Describe the process by which water is split during photolysis. How many photons must be absorbed by PSII for this to occur?

6.5 | Photophosphorylation

The light-dependent reactions discussed in previous pages provide the energy required to reduce CO_2 to carbohydrate. The conversion of one mole of CO_2 to one mole of carbohydrate (CH_2O) requires the input of three moles of ATP and two moles of NADPH (see Figure 6.19). We have seen how plant cells produce the NADPH required for manufacture of carbohydrate; let us now examine how these same cells produce the required ATP.

The machinery for ATP synthesis in a chloroplast is virtually identical to that of a mitochondrion or a plasma membrane of an aerobic bacterium. As in those cases, the ATP synthase (Figure 6.16) consists of a head (called CF_1 in chloroplasts), which contains the catalytic site of the enzyme, and a base (CF_0), which spans the membrane and mediates proton movement. The two parts are connected by a rotary stalk. The CF_1 heads project outward into the stroma in keeping with the orientation of the proton gradient, which has its higher concentration within the thylakoid lumen (Figure 6.16). Thus, protons move from higher concentration in the lumen through the CF_0 base of the ATP synthase and into the stroma, thereby driving phosphorylation of ADP, as described in Chapter 5 for the mitochondrion.

Measurements made during periods of maximal ATP synthesis suggest that differences in H^+ concentrations of 1000- to 2000-fold exist across the thylakoid membranes, corresponding to a pH gradient (ΔpH) of more than three units. The movement of protons into the lumen during electron transport is neutralized by movement of other ions, so that a significant membrane potential is not built up. Thus, unlike in

mitochondria where the proton-motive force is expressed primarily as an electrochemical potential (page 198), the proton-motive force (Δp) acting in the chloroplasts is largely, if not exclusively, due to a gradient of pH.

Noncyclic Versus Cyclic Photophosphorylation

The formation of ATP during the process of oxygenic photosynthesis is called **noncyclic photophosphorylation** because electrons move in a linear (i.e., noncyclic) path from H_2O to $NADP^+$ (Figure 6.16). During the 1950s, Daniel Arnon of the University of California, Berkeley, discovered that isolated chloroplasts were not only capable of synthesizing ATP from ADP but could do so even in the absence of added CO_2 or $NADP^+$. These experiments indicated that chloroplasts had a means for ATP formation that did not require most of the photosynthetic reactions that would have led to oxygen production, CO_2 fixation, or $NADP^+$ reduction. All that was necessary was illumination, chloroplasts, ADP, and P_i . The process Arnon had discovered was later called **cyclic photophosphorylation** and is a process that is carried out by PSI independent of PSII. Despite the fact that it was discovered over 50 years ago, cyclic photophosphorylation is not well understood. Recent studies suggest that there are two overlapping pathways for cyclic electron transport, one of which is outlined in Figure 6.17. Cyclic electron transport begins with the absorption of a quantum of light by PSI and transfer of a high-energy electron to the primary acceptor. In the pathway depicted in Figure 6.17, the electron is passed along to ferredoxin, as is always the case, but rather than being transferred to $NADP^+$, the electron is routed back to the electron-deficient reaction center (as shown in Figure 6.17) to complete the cycle. During the flow of an electron around this course, sufficient free energy is released to translocate protons (estimated at two H^+/e^-) across the membrane by the cytochrome b_6f complex and to build a proton gradient capable of driving ATP synthesis. Cyclic photophosphorylation is thought to provide

additional ATP required for carbohydrate synthesis (see Figure 6.19) and also for other ATP-requiring activities in the chloroplast (e.g., molecular chaperone involvement in protein import). Inhibition of cyclic photophosphorylation leads to impaired development and growth of higher plants.

Now that we have seen how the light reactions of photosynthesis lead to the production of ATP and NADPH, which are the energy stores required for the synthesis of carbohydrates, we can turn to the reactions that lead to carbohydrate formation.

REVIEW

1. Which steps in the light-dependent reactions are responsible for generating an electrochemical proton gradient across the thylakoid membrane?
2. To what degree is this gradient reflected in a pH gradient versus a voltage gradient?
3. How does the proton gradient lead to the formation of ATP?

6.6 | Carbon Dioxide Fixation and the Synthesis of Carbohydrate

After World War II, Melvin Calvin of the University of California, Berkeley, along with colleagues Andrew Benson and James Bassham, began what was to be a decade-long study of the enzymatic reactions by which carbon dioxide was assimilated into the organic molecules of the cell. Armed with the newly available, long-lived radioactive isotope of carbon (^{14}C) and a new technique, two-dimensional paper chromatography, they began the task of identifying all the labeled molecules produced when cells took up $[^{14}C]O_2$. The studies began with plant leaves but soon shifted to a simpler system, the green alga *Chlorella*. Algal cultures were grown in closed chambers in the presence of unlabeled CO_2 , after which radioactive CO_2 was introduced by injection into the culture medium. After the desired period of incubation with the labeled CO_2 , the algal suspension was drained into a container of hot alcohol, which had the combined effects of killing the cells immediately, stopping enzyme activity, and extracting soluble molecules. Extracts of the cells were then placed as a spot on chromatographic paper and subjected to two-dimensional chromatography. To locate the radioactive compounds at the end of the procedure, a piece of X-ray film was pressed against the chromatogram, and the plates were kept in the dark to expose the film. After photographic development, identification of radiolabeled compounds on the autoradiogram was made by comparison to known standards and by chemical analysis of the original spots. Let us consider some of their findings.

Carbohydrate Synthesis in C_3 Plants

Labeled CO_2 was converted to reduced organic compounds very rapidly. If the incubation period was very short (up to a few seconds), one radioactive spot on the chromatogram predominated (Figure 6.18). The compound that formed the spot was determined to be 3-phosphoglycerate (PGA), one of the

Figure 6.17 Simplified scheme for cyclic photophosphorylation.

Absorption of light by PSI excites an electron, which is transferred to ferredoxin (step 1) and on to cytochrome b_6f (step 2), plastocyanin (step 3), and back to $P700^+$ (step 4). In the process, protons are translocated by cytochrome b_6f to form a gradient utilized for ATP synthesis (step 5). Another cyclic pathway for electron transport that involves movement of electrons from PSI through NADPH to cytochrome b_6f is not shown.

Figure 6.18 Chromatogram showing the results of an experiment in which algal cells were incubated for 5 seconds in $[^{14}\text{C}]\text{O}_2$ prior to immersion in alcohol. One spot, which corresponds to 3-phosphoglycerate (labeled PGA), contains most of the radioactivity. (COURTESY OF JAMES BASSHAM AND MELVIN CALVIN.)

intermediates of glycolysis. Calvin's group initially suspected that CO_2 was being covalently linked (or *fixed*) to a two-carbon compound to form the three-carbon PGA molecule. Because the first intermediate to be identified was a three-carbon molecule, plants that utilize this pathway to fix atmospheric CO_2 are referred to as **C_3 plants**.

After considerable investigation, it became apparent that the initial acceptor was not a two-carbon compound, but a five-carbon compound, ribulose 1,5-bisphosphate (RuBP), which condensed with CO_2 to produce a six-carbon molecule. This six-carbon compound rapidly fragmented into two molecules of PGA, one of which contained the recently added carbon atom. Both the condensation of RuBP and the splitting of the six-carbon product (Figure 6.19a) are carried out in the stroma by a large multisubunit enzyme, *ribulose biphosphate carboxylase oxygenase*, which is known familiarly as *Rubisco*. As the enzyme responsible for converting inorganic

Figure 6.19 Converting CO_2 into carbohydrate.

(a) The reaction catalyzed by ribulose biphosphate carboxylase oxygenase (Rubisco) in which CO_2 is fixed by linkage to RuBP. The product rapidly splits into two molecules of 3-phosphoglycerate (PGA). (b) An abbreviated version of the Calvin cycle showing the fate of 6 molecules of CO_2 that are fixed by combination with 6 molecules of RuBP. (Numerous reactions have been deleted). The fixation of CO_2 is indicated in step 1. In step 2, the 12 PGA molecules are phosphorylated via ATP hydrolysis to form 12 1,3-bisphosphoglycerate (BPG) molecules, which are reduced in step 3 by electrons provided by NADPH to form 12 molecules of glyceraldehyde 3-phosphate (GAP). Here, 2 of the GAPs are drained away (step 4) to be used in the synthesis of sucrose in the cytosol, which can be considered the product of the light-independent reactions. The other 10 molecules are converted into 6 molecules of RuBP (step 5), which can act as the acceptor for 6 more molecules of CO_2 . The regeneration of 6 RuBPs requires the hydrolysis of 6 molecules of ATP. The NADPH and ATP used in the Calvin cycle represent the two high-energy products of the light-dependent reactions.

carbon into useful biological molecules, Rubisco is one of the key proteins in the biosphere. As it happens, Rubisco is capable of fixing only about three molecules of CO_2 per second, which may be the worst turnover number of any known enzyme (see Table 3.3). To compensate for this inefficiency, as much as half of the protein of leaves is present as Rubisco. In fact, Rubisco constitutes the most abundant protein on Earth, accounting for 5–10 kg for every human.

As the structure of the various intermediates was determined, together with the positions of the labeled carbon atoms, it became apparent that the pathway for conversion of CO_2 into carbohydrate was cyclic and complex. This pathway has become known as the **Calvin cycle (or Calvin-Benson cycle)**, and it occurs in cyanobacteria and all eukaryotic photosynthetic cells. A simplified version of the Calvin cycle is shown in Figure 6.19*b*. The cycle comprises three main parts: (1) carboxylation of RuBP to form PGA; (2) reduction of PGA to the level of a sugar (CH_2O) by formation of glyceraldehyde 3-phosphate (GAP) using the NADPH and ATP produced in the light-dependent reactions; and (3) the regeneration of RuBP, which also requires ATP. If you look back at Figure 3.24, you will see that the formation of GAP from PGA in the Calvin cycle is the reverse of steps 5–7 of the glycolytic pathway. This simple comparison of a few reactions serves as another reminder that respiration and photosynthesis are biochemical pathways running in opposite directions. In this reaction series, respiration generates NADH and ATP, whereas the reverse reactions of photosynthesis expend NADPH and ATP.

It can be seen in Figure 6.19*b* that for every 6 molecules of CO_2 fixed, 12 molecules of GAP are produced. (GAP is the spot marked triose phosphate on the chromatogram of Figure 6.18.) The atoms in 10 of these three-carbon GAP molecules are rearranged to regenerate 6 molecules of the five-carbon CO_2 acceptor, RuBP (Figure 6.19*b*). The other 2 GAP molecules can be considered as product. These GAP molecules can be exported to the cytosol in exchange for phosphate ions (see Figure 6.20) and used to synthesize the disaccharide sucrose. Alternatively, GAP can remain in the chloroplast where it is converted to starch. An overview of the entire process of photosynthesis, including the light reactions (light absorption, oxidation of water, reduction of NADP^+ , translocation of protons), phosphorylation of ADP, the Calvin cycle, and the synthesis of starch or sucrose, is shown in Figure 6.20.

Sucrose molecules that are formed in the cytosol from the GAPs of the Calvin cycle are transported out of the leaf cells and into the phloem, where they are carried to the various nonphotosynthetic organs of the plant. Just as glucose serves as the source of energy and organic building blocks in most animals, sucrose serves an analogous role in most plants. Starch, on the other hand, is stored within chloroplasts as granules (see Figure 2.17*b*). Just as stored glycogen provides animals with readily available glucose in times of need, the starch stored in a plant's leaves provides it with sugars at night when the light reactions are not possible. It is evident from the reactions of Figure 6.19*b* that the synthesis of carbohydrate is an expensive activity. The conversion of 6 molecules of CO_2 to 1 six-carbon sugar molecule and the regeneration of RuBP

Figure 6.20 An overview of the various stages of photosynthesis.

requires 12 molecules of NADPH and 18 molecules of ATP. This large energy expenditure reflects the fact that CO_2 is the most highly oxidized form in which carbon can occur.

Redox Control Through the course of this book, we will discuss a diverse array of mechanisms used by cells to control the activity of proteins. One of these mechanisms, known as *redox control*, is turning up more and more often as a regulator of basic cellular processes, including protein folding, transcription, and translation. We will consider it here because it is best understood as a regulator of chloroplast metabolism. Several key enzymes of the Calvin cycle are only active in the light when ATP and NADPH are being produced by photosynthesis. This light-dependent control of chloroplast enzymes is exercised by a small protein called thioredoxin that can occur in either a reduced or oxidized form. As noted on page 223, not all of the electrons that pass through ferredoxin are used to reduce NADP^+ . In fact, some of these electrons are transferred to thioredoxin. Once it has accepted a pair of electrons,

Figure 6.21 Redox control of the Calvin cycle. In the light, ferredoxin is reduced, and a fraction of these electrons are transferred to the small protein thioredoxin, which reduces the disulfide groups of certain Calvin cycle enzymes, maintaining them in an active state. In the dark, electron flow to thioredoxin ceases, the sulfhydryl groups of the regulated enzymes become oxidized to the disulfide state, and the enzymes are inactivated.

thioredoxin reduces certain disulfide bridges ($-S-S-$) into sulfhydryl groups ($-SH$) in selected Calvin cycle enzymes (Figure 6.21). This covalent change in protein structure activates these enzymes, promoting the synthesis of carbohydrates

in the chloroplast. In the dark, when photosynthesis has ceased, thioredoxin is no longer reduced by ferredoxin, and the Calvin cycle enzymes revert to an oxidized ($-S-S-$) state in which they are inactive. It can also be noted that several Calvin cycle enzymes are much more active at alkaline pH than at acid pH. This pH rise only occurs in the stroma when it is light and protons are being translocated into the thylakoid lumen as the result of photosynthetic electron transport (Figure 6.16*b*). It follows from these findings that reference to the reactions of the Calvin cycle as “dark reactions” is a misnomer.

Photorespiration One of the spots that appeared on the chromatograms from Calvin’s early work on algal cells was identified as the compound glycolate, which was ignored (and correctly so) in formulating the Calvin cycle of Figure 6.19. While glycolate is not part of the Calvin cycle, it is a product of a reaction catalyzed by Rubisco. Approximately 20 years after it was found that Rubisco catalyzed the attachment of CO_2 to RuBP, it was discovered that Rubisco also catalyzed a second reaction in which O_2 is attached to RuBP to produce 2-phosphoglycolate (along with PGA) (Figure 6.22). Phosphoglycolate is subsequently converted to glycolate by an enzyme in the stroma. Glycolate produced in the chloroplast is transferred to the peroxisome and eventually leads to the release of CO_2 as described later (see Figure 6.23).

Because it involves the uptake of O_2 and the release of CO_2 , this series of reactions is called **photorespiration**. Because photorespiration leads to the release of previously fixed CO_2 molecules, it is a waste of the plant’s energy. In fact, photorespiration can account for the loss of up to 50 percent of

Figure 6.22 The reactions of photorespiration. Rubisco can catalyze two different reactions with RuBP as a substrate (shown in the enediol state within the plane; see Figure 6.19*a*). If the RuBP reacts with O_2 (step 1b), the reaction produces an oxygenase intermediate (step 2b) that breaks down into 3-PGA and 2-phosphoglycolate (step 3b). The subsequent reactions of phosphoglycolate are shown in Figure 6.23.

The eventual outcome of these reactions is the release of CO_2 , a molecule that the cell had previously expended energy to fix. In contrast, if the RuBP molecule reacts with CO_2 (step 1a), the reaction produces a carboxylase intermediate (step 2a) that breaks down into two molecules of PGA (step 3a), which continue through the Calvin cycle.

Figure 6.23 The cellular basis of photorespiration. Electron micrograph of a portion of a leaf mesophyll cell of a tobacco plant showing a peroxisome (identified by its crystalline core) pressed against a pair of chloroplasts and close to a mitochondrion. The reactions of photorespiration that occur in each of these organelles are described in the text and shown superimposed on the organelles in which they occur. This

series of reactions is referred to as the C_2 cycle. The last steps of the cycle—the conversion of serine to glycerate in the peroxisome and then to 3-PGA in the chloroplast—are not shown. (FROM SUE ELLEN FREDERICK AND ELDON H. NEWCOMB, *JOURNAL OF CELL BIOLOGY*, 43: 343–353, FIG. 6, 1969. © ROCKEFELLER UNIVERSITY PRESS.)

newly fixed carbon dioxide by crop plants growing under hot, dry conditions. To understand the reasons for this phenomenon, we need to consider an important aspect of plant physiology. The most serious problem faced by plants living in a hot, dry climate is loss of water through openings, called stomata, at the surfaces of their leaves (Figure 6.2). Although open stomata lead to loss of water, they also provide the channel through which CO_2 enters the leaves. When it is hot and dry, C_3 plants close their stomata, which prevents dehydration. But stomata closure also prevents gas exchange so that the CO_2 concentration inside the leaf declines as it is used in the Calvin cycle and the O_2 concentration increases, as water is split by photolysis. When the concentration of O_2 is relatively high compared to the CO_2 concentration, photorespiration becomes a serious problem. As you might expect, a concerted effort has been underway for decades to breed plants that are less likely to engage in photorespiration. So far, these efforts have met with virtually no success.

Studies of the enzymatic activity of purified Rubisco show that the enzyme exhibits only a modest preference for

CO_2 as a substrate over O_2 . The reason for this relative lack of specificity is that neither CO_2 nor O_2 binds to the active site of the enzyme (see Figure 3.11a). Rather, the enzyme binds RuBP, which adopts the enediol form shown in Figure 6.22. This form of RuBP can then be attacked by either CO_2 or O_2 . Viewed in this way, photorespiration appears to be an unavoidable consequence of the catalytic properties of Rubisco, an enzyme that is presumed to have evolved at a time when O_2 levels in the atmosphere were virtually nonexistent. Under today's atmospheric conditions, O_2 and CO_2 compete with one another, and the predominant direction of the Rubisco-catalyzed reaction is determined by the ratio of CO_2/O_2 that is available to the enzyme. When plants are grown in closed environments containing elevated levels of CO_2 , they are capable of much more rapid growth by virtue of their elevated rates of CO_2 fixation. It is suggested that the rise in atmospheric CO_2 levels over the past century (from about 270 parts per million in 1870 to 390 ppm in 2009) is responsible for as much as 10 percent of the increased crop yield that has occurred during this period. This rise in atmospheric CO_2

concentration is also thought to be responsible for global warming. Even a small rise in Earth's temperature could have major effects on global conditions, such as a rise in the level of the seas and a spread of the planet's deserts.

Peroxisomes and Photorespiration Peroxisomes are cytoplasmic organelles whose role in oxidative metabolism was discussed in Section 5.6 of the last chapter. Studies on the peroxisomes of leaf cells have revealed a striking example of interdependence among different organelles, a feature that is often lost in studies with isolated cellular structures. The electron micrograph in Figure 6.23 shows a peroxisome of a leaf cell closely apposed to the surfaces of two adjacent chloroplasts and in close proximity to a nearby mitochondrion. This arrangement is not coincidental but reflects an underlying biochemical relationship whereby the products of one organelle serve as substrates in another organelle. The reactions that take place in the different organelles are superimposed on the micrograph in Figure 6.23 and summarized below.

It was noted above that photorespiration begins when RuBP reacts with O_2 to form 3-PGA and a two-carbon compound, phosphoglycolate (Figure 6.22). Once formed, phosphoglycolate is converted to glycolate, which is shuttled out of the chloroplast into a peroxisome. In the peroxisome, the enzyme glycolate oxidase converts glycolate to glyoxylate, which may then be converted to glycine and transferred to a mito-

chondrion. In the mitochondrion, two molecules of glycine (a two-carbon molecule) are converted to one molecule of serine (a three-carbon molecule), with the accompanying release of one molecule of CO_2 . Thus, for every two molecules of phosphoglycolate produced by Rubisco, one carbon atom that had previously been fixed is lost back to the atmosphere. The serine produced in the mitochondrion may be shuttled back to the peroxisome and converted to glycerate, which can be transported to the chloroplast and utilized in carbohydrate synthesis by means of the formation of 3-PGA.

Two groups of plants, called C_4 and CAM plants, have overcome the negative effects of photorespiration by evolving metabolic mechanisms that increase the CO_2/O_2 ratio to which the Rubisco enzyme molecules are exposed.

Carbohydrate Synthesis in C_4 Plants

In 1965, Hugo Kortschak reported that when sugarcane was supplied with $[^{14}C]O_2$, radioactivity first appeared in organic compounds containing four-carbon skeletons rather than the three-carbon PGA molecule found in other types of plants. Further analysis revealed that these four-carbon compounds (predominantly oxaloacetate and malate) resulted from combination of CO_2 with phosphoenolpyruvate (PEP) and thus represented a second mechanism of fixation of atmospheric carbon dioxide (Figure 6.24). The enzyme responsible for

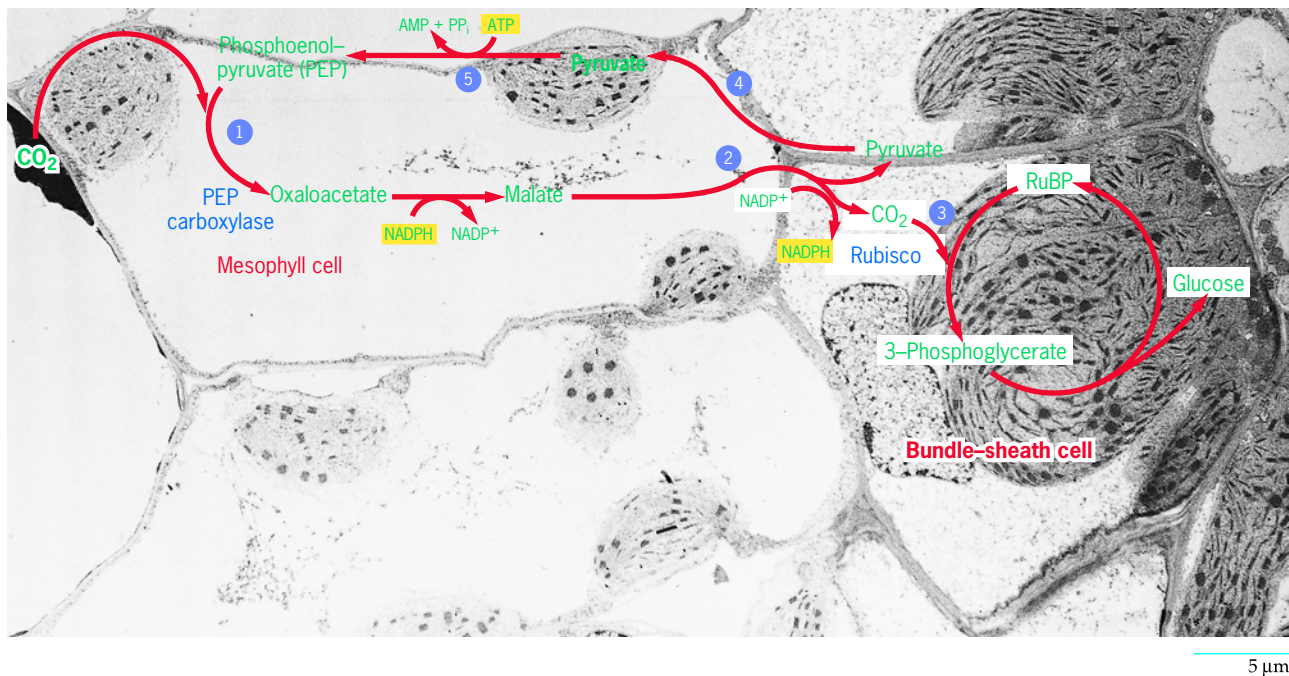

Figure 6.24 Structure and function in C_4 plants. Electron micrograph of a transverse section through the leaf of a C_4 plant showing the spatial relationship between the mesophyll and bundle-sheath cells. Superimposed on the micrograph are the reactions of CO_2 fixation that occur in each type of cell. In step 1, CO_2 is joined to PEP by the enzyme PEP carboxylase in a mesophyll cell that is located close to the leaf exterior. The four-carbon malate formed by the reaction is transported to the more centrally located bundle-sheath cell (step 2),

where the CO_2 is released. The CO_2 becomes highly concentrated in the bundle-sheath cell, favoring the fixation of CO_2 by Rubisco to form 3-PGA (step 3), which can be circulated through the Calvin cycle. The pyruvate formed when CO_2 is released is shipped back to the mesophyll cell (step 4), where it is converted to PEP. Although the process requires the hydrolysis of ATP (step 5), the high CO_2/O_2 in the bundle-sheath cell minimizes the rate of photorespiration. (COURTESY OF S. CRAIG, CSIRO PLANT INDUSTRY.)

linkage of CO₂ to PEP was named *phosphoenolpyruvate carboxylase*, and it catalyzes the first step of the **C₄ pathway**. Plants that utilize this pathway are referred to as **C₄ plants** and are represented primarily by tropical grasses. Before considering the fate of this newly fixed carbon atom, it is useful to examine the likely reasons an alternate pathway of CO₂ fixation has evolved.

When a C₃ plant is placed in a closed chamber and its photosynthetic activity monitored, it is found that, once the plant reduces CO₂ levels in the chamber to approximately 50 parts per million (ppm), the rate of CO₂ release by photorespiration equals the rate of CO₂ fixation by photosynthesis, so that net production of carbohydrate stops. In contrast, a plant that utilizes the C₄ pathway continues the net synthesis of carbohydrate until CO₂ levels have dropped to 1 to 2 ppm. C₄ plants have this ability because PEP carboxylase continues to operate at much lower CO₂ levels than does Rubisco and is not inhibited by O₂. But what is the value to a plant of being able to fix CO₂ at such low levels when the atmosphere invariably contains CO₂ at levels well above 300 ppm?

The value of the C₄ pathway becomes apparent when C₄ plants are placed in a dry, hot environment similar to that in which many of them live. C₄ plants are adapted to hot, arid environments because they are capable of closing their stomata to prevent water loss, yet they are still capable of maintaining sufficient CO₂ uptake to fuel their photosynthetic activity at a maximal rate. This is the reason that crabgrass, a C₄ plant, tends to take over a lawn, displacing the domestic C₃ grasses originally planted. Sugarcane, corn, and sorghum are the most important crop plants that utilize the C₄ pathway. There is a disadvantage to C₄ metabolism; it requires more ATP and NADPH to produce carbohydrates than does C₃ metabolism. Consequently, under cooler, well-watered conditions, C₃ plants can outcompete C₄ plants because C₃ photosynthesis is more efficient than C₄ photosynthesis when photorespiration is not a problem. As a result, most C₄ plants do not do nearly as well in cooler temperatures or higher latitudes.

When the fate of the CO₂ fixed by means of the C₄ pathway is followed, it is found that the CO₂ group is soon released, only to be recaptured by Rubisco and converted to metabolic intermediates of the C₃ pathway (Figure 6.24). The basis for this seemingly paradoxical metabolism becomes evident when the leaf anatomy of a C₄ plant is examined. Unlike those of C₃ plants, leaves of C₄ plants contain two concentric cylinders of cells. An outer cylinder is made of *mesophyll cells* and an inner cylinder of *bundle-sheath cells* (Figures 6.24). The fixation of CO₂ to PEP occurs in the outer mesophyll cells. PEP carboxylase activity can continue, even when the leaf stomata are almost entirely closed and the CO₂ level in the cells is very low. Once formed, the C₄ products are transported through plasmodesmata in the adjoining cell wall (see Figure 7.35) and into the thick-walled bundle-sheath cells, which are sealed off from atmospheric gases. Once in the bundle-sheath cells, the previously fixed CO₂ can be split from the C₄ carrier, producing a high CO₂ level in these interior cells—a level suitable for fixation by Rubisco. Carbon dioxide levels in the bundle-sheath cells may be 100 times that of the mesophyll. Thus, the C₄ pathway provides a mechanism to

drive CO₂ fixation by the less efficient C₃ pathway by “pumping” CO₂ into the bundle sheath. Once CO₂ is split from the four-carbon compound, the pyruvate formed returns to the mesophyll cells to be recharged as PEP (Figure 6.24). In addition to saving water, plants that utilize the C₄ pathway are able to generate high CO₂/O₂ ratios in the local Rubisco environment, thereby favoring the process of CO₂ fixation over that of photorespiration. In fact, attempts to demonstrate photorespiration in the intact leaves of C₄ plants usually fail.

Many major events in the course of biological evolution, such as the uptake of the bacterium that gave rise to mitochondria (page 27), are thought to have occurred on only one occasion. It is remarkable that C₄ plants have evolved independently from C₃ ancestors more than 45 times in 19 different families. Plant scientists are attempting to mimic this evolutionary process by introducing parts of the C₄ photosynthetic machinery into C₃ plants with the goal of boosting crop productivity. For example, the PEP carboxylase gene from maize (a C₄ plant) has been introduced into rice (a C₃ plant) in hopes of creating a CO₂-concentrating mechanism within the rice mesophyll cells where Rubisco is housed. Some of the field studies on these genetically engineered plants have been encouraging, but it is too soon to tell whether any observed increases in photosynthetic efficiency are due to increased levels of CO₂ assimilation, decreased levels of photorespiration, increased resistance to stress, or some other mechanism.

Carbohydrate Synthesis in CAM Plants

Many desert plants, such as cacti, have another biochemical adaptation that allows them to survive in very hot, dry habitats. These plants are called **CAM plants**, and they utilize PEP carboxylase in fixing atmospheric CO₂ just like C₄ plants.³ Unlike C₄ plants, however, CAM species carry out light-dependent reactions and CO₂ fixation at different times of the day, rather than in different cells of the leaf. In other words, evolution has followed two different pathways in overcoming the problem that photorespiration poses as it decreases photosynthetic efficiency. Whereas C₃ and C₄ plants open their leaf stomata and fix CO₂ during the daytime, CAM plants keep their stomata closed during the hot, dry daylight hours. Then, at night, when the rate of water vapor loss is greatly reduced, they open their stomata and fix CO₂ by means of PEP carboxylase. As more and more carbon dioxide is fixed in the mesophyll cells during the night, the malate that is generated is transported into the cell's central vacuole. The presence of malate (in the form of malic acid within the acidic vacuole) is evident by the sour “morning taste” of the plants. During the daylight hours, the stomata close, and the malic acid is moved into the cytoplasm. There it gives up its CO₂, which can be fixed by Rubisco under conditions of low O₂ concentration that exist when the stomata are closed. Carbohydrates are then synthesized using energy from ATP and NADPH generated by the light-dependent reactions.

³CAM is an acronym for *crassulacean acid metabolism*, named for plants of the family Crassulaceae in which it was first discovered.

REVIEW

1. Describe the basic plan of the Calvin cycle, indicating the reactions that require energy input. Why is it described as a cycle? Why does energy have to be expended in this type of pathway? What are the eventual products of the pathway?
2. Describe the major structural and biochemical differences between C_3 plants and C_4 plants. How do these differences affect the ability of these two types of plants to grow in hot, dry climates?

Synopsis

The earliest life forms are presumed to have been heterotrophs that depended on organic molecules formed abiotically; these forms were eventually succeeded by autotrophs—organisms that were capable of surviving on CO_2 as their principal carbon source. The first autotrophs are thought to have carried out nonoxygenic photosynthesis in which compounds such as H_2S were oxidized as a source of electrons. The evolution of oxygenic photosynthesis, in which water is oxidized and O_2 is released, allowed cyanobacteria to exploit a wide array of habitats and set the stage for aerobic respiration. (p. 211)

Chloroplasts are large membrane-bound organelles that have evolved from a photosynthetic prokaryote. Chloroplasts are bounded by a double membrane made porous by the inclusion of porins in the outer membrane. Thylakoids are flattened membranous sacs arranged in orderly stacks, or grana. The thylakoids are surrounded by a fluid stroma containing DNA, ribosomes, and the machinery required for gene expression. (p. 213)

The light-dependent reactions of photosynthesis begin with the absorption of photons of light by photosynthetic pigments, an event that pushes electrons to outer orbitals from which they can be transferred to an electron acceptor. The major light-absorbing pigments of plants are chlorophylls and carotenoids. Each chlorophyll molecule consists of a Mg^{2+} -containing porphyrin ring that acts in light absorption and a hydrocarbon tail (a phytol) that keeps the pigment embedded in the bilayer. Chlorophyll absorbs most strongly in the blue and red region of the visible spectrum and least strongly in the green. Carotenoids absorb most strongly in the blue and green region and least strongly in the red and orange. The action spectrum of photosynthesis, which shows the wavelengths of light that are able to stimulate photosynthesis, follows the absorption spectrum of the pigments quite closely. Photosynthetic pigments are organized into functional units in which only one molecule—the reaction-center chlorophyll—transfers electrons to an electron acceptor. The bulk of the pigment molecules form a light-harvesting antenna that traps photons of differing wavelengths and transfers the energy of excitation to the pigment molecule at the reaction center. (p. 216)

The transfer of a pair of electrons from H_2O to $NADP^+$ under conditions operating in the chloroplast utilizes the input of approximately 2 V of energy, which is delivered by the combined action of two separate photosystems. Photosystem II (PSII) boosts electrons from an energy level below that of water to a midway point, while photosystem I (PSI) raises electrons to the highest energy level, above $NADP^+$. As photons are absorbed by each photosystem, energy is passed to their respective reaction-center pigments (P680 for PSII and P700 for PSI). The energy absorbed by the reaction-center chlorophylls serves to boost an electron to an outer orbital where it is transferred to a primary acceptor, producing a positively charged pigment (P680⁺ and P700⁺). (p. 218)

The path of noncyclic electron flow from water to PSII and then to PSI and $NADP^+$ is denoted in the form of a Z. The first leg of the Z is from H_2O to PSII. Most of the antenna pigments that collect light for PSII reside within a separate complex, called LHCII.

Energy flows from LHCII to the PSII reaction center, where an electron is transferred from P680 to a primary acceptor, which is a chlorophyll-like pheophytin molecule. This transfer of electrons generates a strong oxidizing agent (P680⁺) and a weak reducing agent (Pheo⁻). The separation of charge in PSII is stabilized by moving the oppositely charged molecules farther apart; this is accomplished as the electron is transferred from pheophytin to the quinone PQ_A and then PQ_B . The successive absorption of two photons by PSII leads to the transfer of two electrons to PQ_B to form PQ_B^{2-} , which then picks up two protons from the stroma, forming PQH_2 (reduced plastoquinone). The reduced plastoquinone leaves the reaction center and is replaced by an oxidized plastoquinone that is capable of receiving additional electrons. As each electron is transferred from P680 to the primary acceptor and on to PQ_B , the positively charged reaction-center pigment (P680⁺) is neutralized by an electron from a cluster containing four manganese ions and a calcium ion. As each electron is transferred to P680, the Mn-Ca-containing protein accumulates an oxidizing equivalent. Once the cluster has accumulated four oxidizing equivalents, it is capable of removing four electrons from water, a reaction that generates O_2 and delivers four H^+ to the thylakoid lumen, which contributes to the proton gradient. (p. 219)

Electrons from reduced plastoquinone are transferred to the multiprotein complex cytochrome b_6f , while the protons are released into the thylakoid lumen, thus contributing to the proton gradient. Electrons from cytochrome b_6f are passed to plastocyanin located on the luminal side of the thylakoid membrane and on to P700⁺, the reaction-center pigment of PSI that had lost an electron following absorption of a photon. As each photon is absorbed by P700, the electron is transferred to a primary acceptor, A_0 , and then through several iron-sulfur centers of the PSI reaction center to ferredoxin. Electrons are transferred from ferredoxin to $NADP^+$ forming NADPH, which requires a proton from the stroma, contributing to the proton gradient. In summary, noncyclic electron flow results in the oxidation of H_2O to O_2 , with the transfer of electrons to $NADP^+$, forming NADPH, and the establishment of a H^+ gradient across the membrane. (p. 222)

The proton gradient established during the light-dependent reactions provides the energy required for the formation of ATP in the chloroplast, a process called photophosphorylation. The machinery for ATP synthesis in the chloroplast is virtually identical to that of the mitochondrion; the ATP synthase consists of a CF_1 headpiece that projects into the stroma and a CF_0 base that is embedded in the thylakoid membrane. Protons drive the formation of ATP as they move from higher concentration in the thylakoid lumen through the CF_0 base and into the stroma, thereby dissipating the H^+ gradient. ATP synthesis can occur in the absence of the oxidation of H_2O through a process of cyclic photophosphorylation that does not involve PSII. Light is absorbed by P700 of PSI, passed to ferredoxin, and returned to the electron-deficient PSI reaction center through cytochrome b_6f . As electrons pass around the cyclic pathway, protons are translocated into the thylakoid lumen and subsequently drive the formation of ATP. (p. 225)

During the light-independent reactions, the chemical energy stored in NADPH and ATP is used in the synthesis of carbohydrates from CO₂. CO₂ is converted to carbohydrate by the C₃ pathway (or Calvin cycle) in which CO₂ is fixed by RuBP carboxylase oxygenase (Rubisco) to a five-carbon compound, RuBP, forming an unstable six-carbon intermediate, which splits into two molecules of 3-phosphoglyceric acid. NADPH and ATP are used to convert PGA molecules to glyceraldehyde phosphate (GAP). For every 6 molecules of CO₂ fixed, 2 molecules of GAP can be directed toward the formation of sucrose or starch, while the remaining 10 molecules of GAP can be used to regenerate RuBP for additional rounds of CO₂ fixation. (p. 227)

Rubisco can also catalyze a reaction in which O₂, rather than CO₂, is covalently joined to RuBP. This process, which is called photorespiration, leads to the formation of compounds that are metabolized in reactions that lead to the loss of CO₂. Because photorespiration involves the uptake of O₂ and the release of CO₂, it represents a waste of the plant's energy. The rate of photorespiration versus CO₂ fixation depends on the CO₂/O₂ ratio faced by Rubisco. C₄ and CAM plants possess mechanisms that increase this ratio. (p. 229)

C₄ and CAM plants possess an additional CO₂-fixing enzyme, called PEP carboxylase, that is able to operate at very low CO₂ concentrations. C₄ plants possess a unique leaf structure containing an outer cylinder of mesophyll cells and an inner cylinder of bundle sheath cells that are sealed off from atmospheric gases. PEP carboxylase operates in the mesophyll, where CO₂ is fixed to the three-carbon compound phosphoenolpyruvate (PEP) to form a four-carbon acid, which is transported to the bundle sheath, where it is decarboxylated. The CO₂ released in the bundle sheath accumulates to high concentration, favoring CO₂ fixation to RuBP and the formation of PGA and GAP by means of the Calvin cycle. CAM plants carry out the light-dependent and light-independent reactions at different times of the day. CAM plants keep their stomata closed during hot, dry daylight hours, thereby avoiding water loss. Then, during the night, they open their stomata and fix CO₂ by means of PEP carboxylase. The malic acid produced is stored in the vacuole until daylight hours, when the compound is moved back into the chloroplast. There it gives up its CO₂, which can be fixed by Rubisco under conditions of low O₂ concentration and converted to carbohydrate using energy from the ATP and NADPH generated by the light-dependent reactions. (p. 231)

Analytic Questions

- Which of the two photosystems operates at the most negative redox potential? Which generates the strongest reducing agent? Which must absorb four photons during each round of non-cyclic photophosphorylation?
- Which type of plant (C₃, C₄, or CAM) might you expect to do best if exposed to continuous daylight under hot, dry conditions? Why?
- Of the following substances, PQH₂, reduced cytochrome *b*₆, reduced ferredoxin, NADP⁺, NADPH, O₂, H₂O, which is the strongest reducing agent? Which is the strongest oxidizing agent? Which has the greatest affinity for electrons? Which has the most energetic electrons?
- Suppose you were to add the uncoupler dinitrophenol (DNP, page 198) to a preparation of chloroplasts carrying out photosynthesis. Which of the following activities would you expect to be affected? (1) absorption of light, (2) cyclic photophosphorylation, (3) electron transport between PSII and PSI, (4) noncyclic photophosphorylation, (5) synthesis of PGA, (6) NADP⁺ reduction.
- Calculate the proton-motive force that would be formed across a thylakoid membrane that maintained a 10,000-fold difference in [H⁺] and no electric potential difference. (The equation for proton-motive force is on page 198.)
- Under what conditions would you expect a plant to be engaged most heavily in cyclic photophosphorylation?
- Contrast the change in pH of the medium that occurs when isolated chloroplasts carry out photosynthesis compared to isolated mitochondria carrying out aerobic respiration.
- It was noted in the previous chapter that the majority of the proton-motive force in mitochondria is expressed as a voltage. In contrast, the proton-motive force generated during photosynthesis is almost exclusively expressed as a pH gradient. How can you explain these differences?
- Contrast the roles of PSI and PSII in generating the electrochemical gradient across the thylakoid membrane.
- Would you agree that a C₃ plant has to expend more energy per molecule of CO₂ converted to carbohydrate than a C₄ plant? Why or why not?
- In photosynthesis, the capture of light energy results in the release and subsequent transfer of electrons. From what molecules are the electrons originally derived? In what molecules do these electrons eventually reside?
- How many ATP and NADPH molecules are required in the C₃ pathway to make one six-carbon sugar? If the synthesis of a molecule of ATP were to require four protons, would you expect that these relative requirements for ATP and NADPH could be met by noncyclic photophosphorylation in the absence of cyclic photophosphorylation?
- If pheophytin and A₀ (a chlorophyll *a* molecule) are the primary electron acceptors of PSII and PSI, respectively, what are the primary electron donors of each photosystem?
- Contrast the roles of three different metal atoms in the light-dependent reactions of photosynthesis.
- Would you expect the greenhouse effect (an increase in the CO₂ content of the atmosphere) to have a greater effect on C₄ plants or C₃ plants? Why?
- Would you expect the water content of the atmosphere to be an important factor in the success of a C₃ plant? Why?
- It has been suggested that low CO₂ levels play a key role in keeping O₂ levels stable at 21 percent. How is it possible that CO₂ levels could affect O₂ levels in the atmosphere?
- Suppose CO₂ levels were to rise to 600 ppm, which in fact they probably were about 300 million years ago. What effect would you suppose this might have regarding competition between C₃ and C₄ plants?
- Suppose you were to place a C₃ plant under hot, dry conditions and provide it with radioactively labeled ¹⁸O₂. In what compounds would you find this label incorporated?

Although the plasma membrane constitutes the boundary between a living cell and its nonliving environment, materials present outside the plasma membrane play an important role in the life of a cell. Most cells in a multicellular plant or animal are organized into clearly defined tissues in which the component cells maintain a defined relationship with one another and with the extracellular materials that lie between the cells. Even those cells that have no fixed relationship within a solid tissue, such as white blood cells that patrol the body, must interact in highly specific ways with other cells and with extracellular materials with which they come in contact. These interactions regulate such diverse activities as cell migration, cell growth, and cell differentiation, and they determine the three-dimensional organization of tissues and organs that emerges during embryonic development.

We will focus in this chapter on the extracellular environment of cells and the types of interactions in which cells engage. Figure 7.1 shows a diagrammatic section of human skin and provides an overview of several of the subjects to be discussed in

Fluorescence micrograph of an endothelial cell—a type of cell that lines the inner surface of blood vessels. The cell is square because it has spread itself over a tiny square-shaped patch of an adhesive protein called fibronectin that was applied to a culture dish. The cell appears to be mounted in a green frame because it was treated with a green fluorescent antibody that binds to the cytoplasmic protein actin, a component of the cytoskeleton. (FROM CHRISTOPHER S. CHEN, CLIFFORD BRANGWYNNE, AND DONALD E. INGBER, TRENDS CELL BIOL. 9:283, 1999; © 1999, WITH PERMISSION OF ELSEVIER.)

Figure 7.1 An overview of how cells are organized into tissues and how they interact with one another and with their extracellular environment. In this schematic diagram of a section through human skin, the cells of the epidermis are seen to adhere to one another by specialized contacts. The basal layer of epidermal cells also adheres to an

derlying, noncellular layer (the basement membrane). The dermis consists largely of extracellular elements that interact with each other and with the surfaces of scattered cells (primarily fibroblasts). The cells contain receptors that interact with extracellular materials and transmit signals to the cell interior.

the chapter. The outer layer of skin (the epidermis) is a type of **epithelial tissue**. Like other epithelia, which line the spaces and free surfaces of the body, the epidermis consists largely of closely packed cells attached to one another and to an underlying noncellular layer by specialized contacts (depicted in the top inset of Figure 7.1). These contacts provide a mechanism for cells to adhere to and communicate with one another. In contrast, the deeper layer of the skin (the dermis) is a type of **connective tissue**. Like other connective tissues, such as those that form a tendon or cartilage, the dermis consists largely of extracellular

material, including a variety of distinct fibers that interact with each other in specific ways. A closer look at one of the scattered cells (fibroblasts) of the dermis shows that the outer surface of the plasma membrane contains receptors that mediate interactions between the cell and the components of its environment (depicted in the lower inset of Figure 7.1). These cell-surface receptors interact not only with the external surroundings, but are connected at their internal end to various cytoplasmic proteins. Receptors with this type of dual attachment are well suited to transmit messages between a cell and its environment.

7.1 | The Extracellular Space

If we begin at the plasma membrane and move outward, we can examine the types of extracellular elements that surround various types of cells. It was noted in Chapter 4 that virtually all integral membrane proteins, as well as certain membrane lipids, bear chains of sugars (oligosaccharides) of variable length that project outward from the plasma membrane (see Figure 4.4c). These carbohydrate projections form part of a layer closely applied to the outer surface of the plasma membrane called the **glycocalyx** (or *cell coat*) (Figure 7.2a). This extracellular material is very prominent in some types of cells, such as the epithelial cells that line the mammalian digestive tract (Figure 7.2b). The glycocalyx is thought to mediate cell–cell and cell–substratum interactions, provide mechanical protection to cells, serve as a

barrier to particles moving toward the plasma membrane, and bind important regulatory factors that act on the cell surface.

The Extracellular Matrix

Many types of animal cells are surrounded by an **extracellular matrix (ECM)**—an organized network of extracellular materials that is present beyond the immediate vicinity of the plasma membrane (Figure 7.3). The ECM is more than an inert packing material or a nonspecific glue that holds cells together; it provides both physical and biochemical signals that can play key regulatory roles in determining the shape and activities of the cell. For example, enzymatic digestion of the ECM that surrounds cultured cartilage cells or mammary gland epithelial cells causes a marked decrease in the synthetic and secretory activities of the cells. Addition of extracellular

Figure 7.2 The glycocalyx. (a) The basal surface of an ectodermal cell of an early chick embryo. Two distinct structures closely applied to the outer cell surface can be distinguished: an inner glycocalyx (GC) and an outer basement membrane (BM). (b) Electron micrograph of the apical surface of an epithelial cell from the lining of the intestine,

showing the extensive glycocalyx, which has been stained with the iron-containing protein ferritin. (A: FROM A. MARTINEZ-PALOMO, INT. REV. CYTOL. 29:64, 1970. © 1970, WITH PERMISSION FROM ELSEVIER.; B: DON FAWCETT/S. ITO/PHOTO RESEARCHERS, INC.)

matrix materials back to the culture dish can restore the differentiated state of the cells and their ability to manufacture their usual cell products (see Figure 7.29).

One of the best defined extracellular matrices is the **basement membrane** (or basal lamina), a continuous sheet 50 to 200 nm thick that (1) surrounds nerve fibers, muscles, and fat cells, (2) underlies the basal surface of epithelial tissues, such as the epidermis of the skin (Figures 7.1 and 7.4a), or the lining of the digestive and respiratory tracts, and (3) underlies the inner endothelial lining of blood vessels. Basement membranes provide mechanical support for the attached cells, gen-

erate signals that maintain cell survival, serve as a substratum for cell migration, separate adjacent tissues within an organ, and act as a barrier to the passage of macromolecules. In this latter capacity, basement membranes of the capillaries play an important role in preventing the passage of proteins out of the blood and into the tissues. This is particularly important in the kidney, where the blood is filtered under high pressure through a double-layered basement membrane that separates the capillaries of the glomerulus from the wall of the kidney tubules (Figure 7.4b). Kidney failure in long-term diabetics may result from an abnormal thickening of the basement

Figure 7.3 The extracellular matrix (ECM) of cartilage cells. (a) Scanning electron micrograph of a portion of a colony of cartilage cells (chondrocytes) showing the extracellular materials secreted by the cells. (b) The ECM of a single chondrocyte has been made visible by adding a suspension of red blood cells (RBCs). The thickness of the

ECM is evident by the clear space (arrowhead) that is not penetrated by the RBCs. The bar represents 10 μm . (A: COURTESY MICHAEL SOLURSH AND GERALD KARP; B: COURTESY OF GRETA M. LEE, BRIAN JOHNSTON, KEN JACOBSON, AND BRUCE CATERSON.)

(a) 10 μm

Figure 7.4 The basement membrane (basal lamina). (a) Scanning electron micrograph of human skin. The epidermis has pulled away from part of the basement membrane, which is visible beneath the epidermal cells. (b) An unusually thick basement membrane is formed between the blood vessels of the glomerulus and the proximal end of the renal tubules of the kidney. This extracellular layer plays an important role in filtering the fluid that is forced out of the capillaries into the renal tubules during urine formation. The black dots within the

(b)

glomerular basement membrane (GBM) are gold particles attached to antibodies that are bound to type IV collagen molecules in the basement membrane (CL, capillary lumen; P, podocyte of renal tubule). The bar represents 0.5 μm. (A: COURTESY OF KAREN HOLBROOK; B: FROM MICHAEL DESJARDINS AND M. BENDAYAN, *J. CELL BIOL.* 113:695, 1991, FIG. 5. REPRODUCED WITH PERMISSION OF ROCKEFELLER UNIVERSITY PRESS.)

membranes surrounding the glomeruli. Basement membranes also serve as a barrier to invasion of tissues by cancer cells. The molecular organization of basement membranes is discussed later (see Figure 7.12). Those cells that do not lie on a basement membrane sheet, such as the fibroblasts of a connective tissue, are typically surrounded by a less organized ECM consisting largely of threadlike fibrils.

Even though the extracellular matrix may take diverse forms in different tissues and organisms, it tends to be composed of similar macromolecules. Unlike most proteins present inside of cells, which are compact, globular molecules, those of the extracellular space are typically extended, *fibrous* species. These proteins are secreted into the extracellular space where they are capable of self-assembling into an interconnected three-dimensional network, which is depicted in Figure 7.5 and discussed in the following sections. Among their diverse functions, the proteins of the ECM serve as trail markers, scaffolds, girders, wire, and glue. As noted throughout the following discussion, alterations in the amino acid sequence of extracellular proteins can lead to serious disorders. We will begin with one of the most important, and ubiquitous, molecules of the ECM, the glycoprotein collagen.

Collagen Collagens comprise a family of fibrous glycoproteins that are present only in extracellular matrices. Collagens are found throughout the animal kingdom and are noted for their high tensile strength, that is, their resistance to pulling forces. It is estimated that a collagen fiber 1 mm in diameter is capable of suspending a weight of 10 kg (22 lb) without breaking. Collagen is the single most abundant protein in the human body—constituting more than 25 percent of all protein—a fact that reflects the widespread occurrence of extracellular materials.

Collagen is produced primarily by fibroblasts, the cells found in various types of connective tissues, but also by smooth muscle cells and epithelial cells. To date, 27 distinct types of human collagen have been identified. Each collagen type is restricted to particular locations within the body, but two or more different types are often present together in the same ECM. Additional functional complexity is provided by mixing several collagen types within the same fiber. These “heterotypic” fibers are the biological equivalent of a metal alloy. It is likely that different structural and mechanical properties result from different mixtures of collagens in fibers. Although there are many differences among the members of the collagen family, all share at least two important structural features. (1) All collagen molecules are trimers consisting of three polypeptide chains, called α chains. (2) Along at least part of their length, the three polypeptide chains of a collagen molecule are wound around each other to form a unique, rod-like triple helix (Figure 7.6a).

The α chains of collagen molecules contain large amounts of proline, and many of the proline (and lysine) residues are hydroxylated following synthesis of the polypeptide. The hydroxylated amino acids are important in maintaining the stability of the triple helix by forming hydrogen bonds between component chains. Failure to hydroxylate collagen chains has serious consequences for the structure and function of connective tissues. This is evident from the symptoms of scurvy, a disease that results from a deficiency of vitamin C (ascorbic acid) and is characterized by inflamed gums and tooth loss, poor wound healing, brittle bones, and the weakening of the lining of blood vessels, causing internal bleeding. Ascorbic acid is required as a coenzyme by the enzymes that add hydroxyl groups to the lysine and proline amino acids of collagen.

Figure 7.5 An overview of the macromolecular organization of the extracellular matrix. The proteins and polysaccharides shown in this illustration will be discussed in the following sections. The proteins depicted (fibronectin, collagen, and laminin) contain binding sites for

one another, as well as binding sites for receptors (integrins) that are located at the cell surface. The proteoglycans are huge protein–polysaccharide complexes that occupy much of the volume of the extracellular space.

A number of the collagens, including types I, II, and III, are described as *fibrillar collagens* because they assemble into rigid, cable-like fibrils, which in turn become packaged into thicker fibers that are typically large enough to be seen in the light microscope. The side-by-side packaging of the rows of collagen I molecules within a collagen fibril is depicted in Fig-

ure 7.6*b,c*. The fibrils are strengthened by covalent cross-links between lysine and hydroxylysine residues on adjacent collagen

Figure 7.6 The structure of collagen I. This figure depicts several levels of organization of a fibrillar collagen. (a) The collagen molecule (or monomer) is a triple helix composed of three helical α chains. Some types of collagen contain three identical α chains and thus are homotrimers, while others are heterotrimers containing two or three different chains. Each collagen I molecule is 295 nm in length. (b) Collagen I molecules become aligned in rows in which the molecules in one row are staggered relative to those in the neighboring row. A bundle of collagen I molecules, such as that shown here, forms a collagen fibril. The staggered arrangement of the molecules produces bands (horizontal black lines in the illustration) across the fibril that repeat

(c) 0.3 μm

(d) 250 nm

with a periodicity of 67 nm (which is equal to the length of the gap between molecules plus the overlap). (e) An electron micrograph of human collagen fibrils observed after metal shadowing (see Figure 18.15). The banding pattern of the fibrils is evident. (d) An atomic force micrograph showing the surface of a collagen fibril that suggests that its subcomponents are twisted spirally around the fibril axis like a rope. The banding pattern remains evident. The arrows point to places where the fibril is slightly unwound, as would occur if you were to twist a rope in the opposite direction it is wound. (C: COURTESY OF JEROME GROSS AND FRANCIS O. SCHMITT; D: FROM LAURENT BOZEC ET AL., *BIOPHYS. J.* 92:71, 2007. © 2007, WITH PERMISSION FROM ELSEVIER.)

molecules. This cross-linking process continues through life and may contribute to the decreased elasticity of skin and increased brittleness of bones among the elderly. Recent studies that probe the surface of collagen fibrils suggest that they are composed of strands that are twisted around the axis of the fibril to form a structure that is more like a nanosized rope than a cable (Figure 7.6*d*).

Among the various components of the ECM, collagen molecules provide the insoluble framework that determines many of the mechanical properties of the matrix. In fact, the properties of a particular tissue can often be correlated with the three-dimensional organization of its collagen molecules. For example, tendons, which connect muscles to bones, must resist tremendous pulling forces during times of muscular contraction. Tendons contain an ECM in which the collagen fibrils are aligned parallel to the long axis of the tendon and thus parallel to the direction of the pulling forces. The cornea is also a remarkable tissue; it must serve as a durable, protective layer at the surface of the eyeball but must also be transparent so that light can pass through the lens to the retina. The thick, middle layer of the cornea is the stroma, which contains relatively short collagen fibrils that are organized into distinct layers. The layered structure of the stroma is similar to that of plywood: the fibrils of each layer are parallel to other fibrils in the layer but nearly perpendicular to the fibrils in the layer on either side (Figure 7.7). This plywood-like structure provides strength to this delicate tissue, while the uniformity of size and ordered packing of the fibrils minimize the scattering of incoming light rays, thereby promoting the tissue's transparency.

Given their abundance and widespread distribution, it is not surprising that abnormalities in fibrillar collagen formation can lead to serious disorders. Burns or traumatic injuries

Figure 7.7 The corneal stroma consists largely of layers of collagen fibrils of uniform diameter and spacing. The molecules of alternate layers are arranged at right angles to one another, resembling the structure of plywood. (FROM NIGEL J. FULLWOOD, STRUCTURE 12:169, 2004, FIG. 1; © 2004, WITH PERMISSION FROM ELSEVIER.)

to internal organs can lead to an accumulation of scar tissue, which consists largely of fibrillar collagen. A common condition described as *fibrosis* results from excessive production of collagen-containing connective tissue. Fibrosis occurs most often in the lungs (pulmonary fibrosis) and liver (cirrhosis) where the collagen-containing scar tissue gradually replaces the normal tissue of the organ. Mutations in genes encoding type I collagen can produce *osteogenesis imperfecta*, a potentially lethal condition characterized by extremely fragile bones, thin skin, and weak tendons. Mutations in genes encoding type II collagen alter the properties of cartilage tissue, causing dwarfism and skeletal deformities. Mutations in a number of other collagen genes can lead to a variety of distinct but related defects in collagen matrix structure (called *Ehler-Danlos syndromes*). Persons with one of these syndromes have hyperflexible joints and highly extensible skin.

Not all collagens form fibrils. One of the nonfibrillar collagens is type IV, whose distribution is restricted to basement membranes. Basement membranes are thin, supportive sheets, and the type IV collagen molecules are organized into a network that provides mechanical support and serves as a lattice for the deposition of other extracellular materials (see Figure 7.12). Unlike type I collagen, which consists of a long, uninterrupted triple helix, the type IV collagen trimer contains nonhelical segments interspersed along the molecule and globular domains at each end. The nonhelical segments make the molecule flexible, while the globular ends serve as sites of interaction between molecules that give the complex its lattice-like character (Figure 7.8). Mutations in type IV collagen genes have been identified in patients with *Alport syndrome*, an inherited kidney disease in which the glomerular basement membrane (Figure 7.4*b*) is disrupted.

Proteoglycans In addition to collagen, basement membranes and other extracellular matrices typically contain large amounts of a distinctive type of protein-polysaccharide complex called a **proteoglycan**. A proteoglycan (Figure 7.9*a*) consists of a core protein molecule (shown in black in Figure 7.9*a*) to which chains of *glycosaminoglycans* (GAGs) are covalently attached (shown in red in the figure). Each glycosaminoglycan chain is composed of a repeating disaccharide; that is, it has the structure -A-B-A-B-A-, where A and B represent two different sugars. GAGs are highly acidic due to the presence of both sulfate and carboxyl groups attached to the sugar rings (Figure 7.9*b*). Proteoglycans of the extracellular matrix may be assembled into gigantic complexes by linkage of their core proteins to a molecule of *hyaluronic acid*, a nonsulfated GAG (Figure 7.9*c*). The microscopic appearance of one of these complexes, which can occupy a volume equivalent to that of a bacterial cell, is shown in Figure 7.9*d*.

Because of the negative charges borne on the sulfated GAGs, proteoglycans bind huge numbers of cations, which in turn bind large numbers of water molecules. As a result, proteoglycans form a porous, hydrated gel that fills the extracellular space like packing material (Figure 7.5) and resists crushing (compression) forces. This property complements that of the adjacent collagen molecules, which resist pulling forces and provide a scaffold for the proteoglycans. Together,

Figure 7.8 The type IV collagen network of the basement membrane. Electron micrograph of a basement membrane from human amniotic tissue that had been extracted with a series of salt solutions to remove noncollagenous materials. The treatment leaves behind an extensive, branching, polygonal network of strands that form an irregular lattice. Evidence indicates that this lattice consists of type IV collagen molecules covalently linked to one another in a complex three-dimensional array. A model of the basement membrane scaffold is shown in Figure 7.12. (B: FROM PETER D. YURCHENCO AND GEORGE C. RUBEN, *J. CELL BIOL.* 105:2561, 1987, FIG. 1D. © 1987, REPRODUCED WITH PERMISSION OF ROCKEFELLER UNIVERSITY PRESS. IMAGE COURTESY PETER D. YURCHENCO, ROBERT WOOD JOHNSON MEDICAL SCHOOL.)

collagens and proteoglycans give cartilage and other extracellular matrices strength and resistance to deformation. The extracellular matrix of bone is also composed of collagen and proteoglycans, but it becomes hardened by impregnation with calcium phosphate salts. Both sulfated and nonsulfated GAGs are taken widely as health supplements with the aim of improving the condition of skin and joints.

Fibronectin The term *matrix* implies a structure made up of a network of interacting components. The term has proven very apt for the extracellular matrix, which contains a number of proteins, in addition to collagen and proteoglycans, that interact with one another in highly specific ways (Figure 7.5). *Fibronectin*, like several other proteins to be discussed in this chapter, consists of a linear array of distinct “building blocks”

that gives each polypeptide a modular construction (Figure 7.10a). Each fibronectin polypeptide is constructed from a sequence of approximately 30 independently folding Fn modules, two of which are depicted in the top inset of Figure 7.10a. While Fn-type modules were first discovered in fibronectin, they are found as part of many other proteins,

Figure 7.9 The structure of a cartilage-type proteoglycan complex. (a) Schematic representation of a single proteoglycan consisting of a core protein to which a large number of glycosaminoglycan chains (GAGs, shown in red) are attached. A proteoglycan from cartilage matrix (e.g., aggrecan) may contain about 30 keratan sulfate and 100 chondroitin sulfate chains. Proteoglycans found in basement membranes (e.g., perlecan and agrin) have only a few GAG chains attached to the core protein. (b) The structures of the repeating disaccharides that make up each of the GAGs shown in this figure. All GAGs bear

large numbers of negative charges (indicated by the blue shading). (c) In the cartilage matrix, individual proteoglycans are linked to a non-sulfated GAG, called hyaluronic acid (or hyaluronan), to form a giant complex with a molecular mass of about 3 million daltons. The box indicates one of the proteoglycans of the type shown in part a. (d) Electron micrograph of a proteoglycan complex, comparable to that illustrated in part c, that was isolated from cartilage matrix. (D: COURTESY JOSEPH A. BUCKWALTER.)

Figure 7.10 Structure of fibronectin and its importance during embryonic development. (a) A human fibronectin molecule consists of two similar, but nonidentical, polypeptides joined by a pair of disulfide bonds located near the C-termini. Each polypeptide is composed of a linear series of distinct modules, which are organized into several larger functional units, illustrated by the colored cylinders in this figure. Each of these functional units contains one or more binding sites for either a specific component of the ECM or for the surface of cells. Some of these binding activities are indicated by the labels. The cell-binding site of the polypeptide that contains the sequence arg-gly-asp, or RGD, is indicated. As discussed later in the chapter, this sequence binds specifically to a particular class of integral plasma membrane proteins (integrins) that are involved in cell attachment and signal transduction. The inset shows two of the 30 or so repeating Fn modules that comprise the polypeptide; the RGD sequence forms a loop of the polypeptide, protruding from one module. (b) A section through a young chick embryo that has been treated with fluorescent antibodies against fibronectin. Fibronectin is present as fibrils in the basement membranes (dark red sites) that lie beneath the embryonic epithelia and provide a substratum over which cells migrate. (c) In this micrograph, neural crest cells are migrating out from a portion of the

developing chick nervous system (beyond the edge of the photo) onto a glass culture dish that contains strips of fibronectin-coated surface alternating with strips of bare glass. The boundary of a fibronectin-coated region is indicated by the white lines. It is evident that the cells remain exclusively on the fibronectin-coated surface. Cells that reach the glass substratum (arrowheads) tend to round up and lose their migratory capabilities. The arrow indicates the direction of migration. (d, e) The role of fibronectin in the formation of the embryonic salivary gland. The micrograph in d shows a mouse embryonic salivary gland that has been grown for 10 hours in culture. The gland is seen to be divided into separate buds by a series of clefts (open triangles). The gland shown in e has been grown for the same period of time in the presence of an anti-fibronectin antibody, which has completely inhibited cleft formation. Scale bar equals 100 μm . (B: COURTESY OF JAMES W. LASH; C: FROM GIOVANNI LEVI, JEAN-LOUP DUBAND, AND JEAN PAUL THIERY, INT. REV. CYTOL. 123:213, 1990. © 1990, WITH PERMISSION OF ELSEVIER; D, E: FROM TAKAYOSHI SAKAI, MELINDA LARSEN, & KENNETH M. YAMADA, NATURE 423:877, 2003, FIGS. 3A AND 3B © 2003, REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LTD.)

ranging from blood clotting factors to membrane receptors (see Figure 7.22). As discussed on page 59, the presence of shared segments among diverse proteins strongly suggests that many present-day genes have arisen during evolution by the fusion of parts of separate ancestral genes. In fibronectin, the 30 or so structural modules combine to form five or six larger functional domains, illustrated by the colored cylinders in Figure 7.10a. Each of the two polypeptide chains that make up a fibronectin molecule contains

1. Binding sites for numerous components of the ECM, such as collagens, proteoglycans, and other fibronectin molecules. These binding sites facilitate interactions that link these diverse molecules into a stable, interconnected network (Figure 7.5). Binding activities of fibronectin molecules are enhanced by mechanical forces that pull on these fibrous proteins and unfold its component modules. Unfolding of these modules exposes binding sites that would otherwise have remained buried.

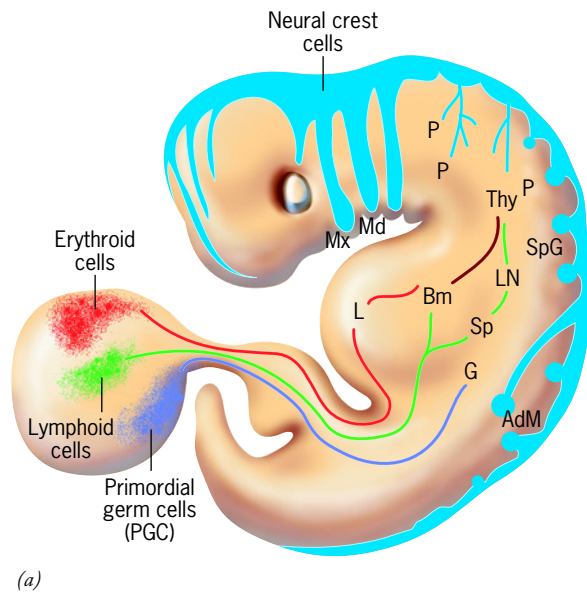

2. Binding sites for receptors on the cell surface. These binding sites hold the ECM in a stable attachment to the cell (Figure 7.5). The importance of a fibronectin-containing substratum for cell attachment is illustrated in the chapter-opening micrograph on page 235. The cultured endothelial cell shown in this photo has adopted a shape unlike any it would have in the body because it has spread itself over the available surface provided by a square coat of fibronectin.

The importance of fibronectin and other extracellular proteins is particularly evident during embryonic development. Development is characterized by waves of cell migration during which different cells follow different routes from one part of the embryo to another (Figure 7.11*a*). Migrating cells are guided by proteins, such as fibronectin, that are contained within the molecular landscape through which they pass. For example, the cells of the neural crest, which migrate out of the developing nervous system into virtually all parts of the embryo, traverse pathways rich in fibrils composed of interconnected fibronectin molecules (Figure 7.10*b*). The importance of fibronectin in neural crest cell migration is readily revealed on a culture dish as shown in Figure 7.10*c*. A number of organs of the body, including the salivary gland, kidney, and lung are formed by a process of branching in which the epithelial layer becomes divided by a series of clefts (Figure

7.10*d*). The importance of fibronectin in the formation of these clefts is illustrated in Figure 7.10*e*, which shows a salivary gland that has been incubated with antibodies that bind to fibronectin. Cleft formation and branching is entirely abolished as a result of the inactivation of fibronectin molecules.

Laminin *Laminins* are a family of extracellular glycoproteins that consist of three different polypeptide chains linked by disulfide bonds and organized into a molecule resembling a cross with three short arms and one long arm (Figure 7.5). At least 15 different laminins have been identified. Like fibronectin, extracellular laminins can greatly influence a cell's potential for migration, growth, and differentiation. For example, laminins play a critical role in the migration of primordial germ cells (Figure 7.11*a*). These cells arise in the yolk sac, which is located outside the embryo itself, and then migrate by way of the bloodstream and embryonic tissues to the developing gonad, where they eventually give rise to sperm or eggs. During their migration, the primordial germ cells traverse surfaces that are particularly rich in laminin (Figure 7.11*b*). Primordial germ cells possess a cell-surface protein that adheres strongly to one of the subunits of the laminin molecule. The influence of laminin on nerve outgrowth is shown in Figure 9.48*a*.

In addition to binding tightly to cell-surface receptors, laminins can bind to other laminin molecules, to proteoglycans,

(a)

Figure 7.11 The role of cell migration during embryonic development. (a) A summary of some of the cellular traffic occurring during mammalian development. The most extensive movements are conducted by the neural crest cells (shown in blue), which migrate out of the neural plate in the dorsal midline of the embryo and give rise to all the pigment cells of the skin (P), the sympathetic ganglia (SpG), adrenal medulla (AdM), and the cartilage of the embryonic skull (Mx, Md for maxillary and mandibular arches). The primordial germ cells (PGC) migrate from the yolk sac to the site of gonad (G) formation within the embryo. The progenitors of lymphoid cells are transported to the liver (L), bone marrow (Bm), thymus (Thy), lymph nodes (LN), and spleen (Sp). (Note: The “pathways” shown here connect the original sites of cells with their destinations; they do not accurately

(b)

20 μ m

depict the actual routes of the cells.) (b) Micrograph of a section of a portion of the hind gut of a 10-day mouse embryo. The primordial germ cells (green) are seen to be migrating along the dorsal mesentery on their way to the developing gonad. The tissue has been stained with antibodies against the protein laminin (red), which is seen to be concentrated in the surface over which the cells are migrating. (A: A. A. MOSCONA & R. E. HAUSMAN, CELL AND TISSUE INTERACTIONS, J. W. LASH & M. M. BURGER EDs. RAVEN PRESS, 1977 ISBN: 0890041806; B: FROM MARTIN I. GARCIA-CASTRO, ROBERT ANDERSON, JANET HEASMAN, AND CHRISTOPHER WYLIE, J. CELL BIOL. 138:475, 1997, FIG. 3. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

Figure 7.12 A model of the basement membrane scaffold. Basement membranes contain two network-forming molecules, collagen IV (pink), which was illustrated in Figure 7.8, and laminin (green), which is indicated by the thickened cross-shaped molecules. The collagen and laminin networks are connected by entactin molecules (purple). (COPYRIGHT 1992, ROCKEFELLER UNIVERSITY PRESS. ORIGINALLY PUBLISHED IN THE JOURNAL OF CELL BIOLOGY 117:1132.)

and to other components of basement membranes (Figure 7.5). The laminin and type IV collagen molecules of basement membranes are thought to form separate, but interconnected, networks, as depicted in Figure 7.12. These interwoven networks give basement membranes both strength and flexibility. In fact, basement membranes fail to form in mouse embryos that are unable to synthesize laminin, causing the death of the embryo around the time of implantation.

Dynamic Properties of the ECM The micrographs and diagrams presented in the first section of this chapter portray the ECM as a static structure. In actual fact, however, the ECM can exhibit dynamic properties, both in space and over time. Spatially, for example, ECM fibrils can be seen to stretch several times their normal length as they are pulled on by cells and contract when tension is relieved. Temporally, the components of an ECM are subject to continual degradation and reconstruction. These processes serve to renew the matrix and to allow it to be remodeled during embryonic development or following tissue injury. Even the calcified matrix of our bones, which we think of as a stable, inert structure, is subject to continual restoration.

The degradation of extracellular materials, along with cell-surface proteins, is accomplished largely by a family of zinc-containing enzymes called **matrix metalloproteinases (MMPs)** that are either secreted into the extracellular space or anchored to the plasma membrane. As a group, MMPs can digest nearly all of the diverse ECM components, although individual family members are limited as to the types of extracellular molecules they can attack. The physiological roles of MMPs are not well understood, but they are thought to be involved in tissue remodeling, embryonic cell migration, wound healing, and the formation of blood vessels. As might be expected from enzymes whose normal function is to destroy extracellular materials, the excessive or inappropriate activity of MMPs is likely to cause disease. In fact, MMPs have been implicated in a number of pathological conditions, including arthritis, tooth and gum disease, formation of blood clots and heart attack, and tumor progression

(page 256). At least three inherited skeletal disorders have been traced to mutations in MMP genes.

REVIEW

1. Distinguish between the glycocalyx, a basement membrane, and the extracellular matrix of cartilage tissue.
2. Contrast the roles of collagen and proteoglycans in the extracellular space. How do fibronectin and laminin contribute to embryonic development?
3. List a few of the functions of the extracellular matrix in animal tissues.

7.2 | Interactions of Cells with Extracellular Materials

It was noted in the previous discussion that components of the ECM, such as fibronectin, laminin, proteoglycans, and collagen, are capable of binding to receptors situated on the cell surface (as in Figure 7.5). The most important family of receptors that attach cells to their extracellular microenvironment is the integrins.

Integrins

Integrins are a family of membrane proteins found only in animals that play a key role in integrating the extracellular and intracellular environments. On the outer side of the plasma membrane, integrins bind to a remarkably diverse array of molecules (ligands) that are present in the extracellular environment. On the intracellular side of the membrane, integrins interact either directly or indirectly with dozens of different proteins to influence the course of events within the cell. Integrins are composed of two membrane-spanning polypeptide chains, an α chain and a β chain, that are noncovalently linked. Eighteen different α subunits and eight different β subunits have been identified. Although more than a hundred possible pairings of α and β subunits could theoretically occur, only about two dozen different integrins have been identified on the surfaces of cells, each with a specific distribution within the body. Whereas many subunits occur in only a single integrin heterodimer, the β_1 subunit is found in 12 different integrins and the α_v subunit in 5 of them (see Table 7.1). Most cells possess a variety of different integrins, and conversely, most integrins are present on a variety of different cell types.

Electron microscopic observations of integrin molecules beginning in the late 1980s suggested that the two subunits are oriented so as to form a globular extracellular head connected to the membrane by a pair of elongated “legs” (as depicted in Figure 7.5). The legs of each subunit extend through the lipid bilayer as a single transmembrane helix and end in a small cytoplasmic domain of about 20 to 70 amino acids.¹ The first

¹One exception to this molecular architecture is the β_4 chain, which has an extra thousand or so amino acids as part of its cytoplasmic domain. This huge addition makes β_4 integrins capable of extending much more deeply into the cytoplasm (see Figure 7.19)

Table 7.1 Classification of Integrin Receptors Based on Recognition of RGD Sequences

RGD Recognition		Non-RGD Recognition	
Integrin receptor	Key ligands	Integrin receptor	Key ligands

X-ray crystallographic structure of the extracellular portion of an integrin was published in 2001 and displayed a highly unexpected feature. Rather than “standing upright” as predicted, the integrin $\alpha_v\beta_3$ was bent dramatically at the “knees” so that the head faces the outer surface of the plasma membrane (Figure 7.13a). To understand the significance of this bent structure, we need to explore the properties of integrins.

Many integrins, including the one shown in Figure 7.13, can exist on the surface of a cell in an inactive conformation. These integrins can be activated rapidly by events within the cell that alter the conformation of the cytoplasmic domains of the integrin's subunits. Changes in conformation of the cytoplasmic domains are propagated through the molecule, increasing the integrin's affinity for an extracellular ligand. For example, the aggregation of platelets during blood clotting (see Figure 7.15) occurs only after the cytoplasmic activation of $\alpha_{IIb}\beta_3$ integrins, which increases their affinity for fibrinogen. This type of alteration in integrin affinity triggered by changes occurring inside the cell is referred to as “inside-out” signaling. In the absence of the inside-out signal, the integrin remains in the inactive state, which protects the body against the formation of an inappropriate blood clot.

A body of evidence strongly suggests that the bent conformation of an integrin shown in Figure 7.13a corresponds to the inactive state of the protein, one that is incapable of binding a ligand. In fact, when an $\alpha_v\beta_3$ integrin containing a bound ligand is analyzed, the integrin no longer exhibits the bent structure but is present instead in an upright conformation as illustrated in Figure 7.13b. The ligand is bound to the head of the integrin in a cleft where the α and β subunits come together (as in Figure 7.14). If the bent and upright structures represent the inactive and active states of an integrin, respectively, then it is important to consider what type of stimulus is capable of triggering such a remarkable transformation in protein conformation.

In the bent, inactive conformation, the transmembrane domains of the two subunits are in close proximity, apparently held together by noncovalent interactions between residues of the two helices. The cytoplasmic domains of integrins bind a wide array of proteins; one of these proteins, called talin, causes separation of the α and β subunits, as shown in the structure of the activated integrin in Figure 7.13b and the schematic model of Figure 7.14. Mutations in talin that block its interaction with β -integrin subunits also prevent activation of integrins and adhesion to the ECM. Separation of the cytoplasmic tails and transmembrane domains of an integrin that results when talin is bound is thought to send a change in

Figure 7.13 Integrin conformations. (a) Ribbon drawing of a complete integrin in the bent, inactive conformation, and a corresponding electron micrograph of the extracellular portion of a similar molecule. (b) Ribbon drawing and electron micrograph of the same integrin in the extended, active (i.e., ligand-binding) conformation. Conformations that are intermediate between those shown here may also exist and exhibit reduced ligand-binding. Figure 7.14 A model of integrin activation. Schematic representation of a heterodimeric integrin molecule in the bent, inactive conformation (left) and the upright, active conformation (right). The switch in conformation is triggered by the binding of a protein, in this case talin, to the small cytoplasmic domain of the β subunit. Binding of talin induces a separation of the two subunits and conversion to the active conformation. Activated integrins typically become clustered as the result of interactions of their cytoplasmic domains with the underlying cytoskeleton as indicated in Figure 7.17c. The domain structure of each subunit seen in the ribbon drawings of Figure 7.13 is shown here using globular-shaped segments. The extracellular ligand, in this case a collagen fiber, binds to both of the subunits in the head region of the activated integrin dimer.

conformation through the legs of the integrin, causing the molecule to assume an upright position in which the head of the protein is capable of interacting specifically with its appropriate ligand. An increase in affinity of individual integrins is often followed by clustering of the activated integrins, which greatly enhances the overall strength of the interaction between the cell surface and its extracellular ligands.

Integrins have been implicated in two major types of activities: adhesion of cells to their substratum (or to other cells) and transmission of signals between the external environment and the cell interior. We have already discussed the transmission of signals in an inside-out direction, which primarily affects the binding properties of the integrins. Signaling can also occur in the opposite direction, a phenomenon known as “outside-in” signaling. The binding of the extracellular domain of an integrin to a ligand, such as fibronectin or collagen, can induce a conformational change at the opposite, cytoplasmic end of the integrin, especially its β subunit. Changes at the cytoplasmic end can, in turn, alter the way the integrin interacts with a host of different cytoplasmic proteins, modifying their activity. For example, outside-in signals can induce a conformational change in talin on the inside of the membrane, initiating a cascade of events leading to the polymerization of actin filaments of the cytoskeleton. Similarly, binding of integrins to an extracellular ligand can trigger the activation of cytoplasmic protein kinases, such as FAK and Src (see Figure 7.17c). These kinases can then phosphorylate other proteins, initiating a chain reaction. In

some cases, the chain reaction leads all the way to the nucleus, where a specific group of genes may be activated.

Outside-in signals transmitted by integrins (and other cell-surface molecules) can influence many aspects of cell behavior, including differentiation, motility, growth, and even the survival of the cell. The influence of integrins on cell survival is best illustrated by comparing normal and malignant cells. Most malignant cells are capable of growing while suspended in a liquid culture medium. Normal cells, in contrast, can only grow and divide if they are cultured on a solid substratum; if they are placed in suspension cultures, they die. Normal cells are thought to die in suspension culture because their integrins are not able to interact with extracellular substrates and, as a result, are not able to transmit life-saving signals to the interior of the cell. When cells become malignant, their survival no longer depends on integrin binding. The role of integrins in transmitting signals is a very active area of research and will be explored further on page 259.

Table 7.1 lists a number of known integrins and the key extracellular ligands to which they bind. Linkage between integrins and these ligands mediates adhesion between cells and their environment. Because individual cells may express a variety of different integrins on their cell surface, such cells are capable of binding to a variety of different extracellular components (Figure 7.5). Despite the apparent overlap seen in Table 7.1, most integrins do appear to have unique functions, as knockout mice (Section 18.17) that lack different integrin subunits exhibit distinct phenotypes. For example, α_8 knockouts show kidney defects, α_4 knockouts exhibit heart defects, and α_5 knockouts display vascular defects.

Many of the extracellular proteins that bind to integrins do so because they contain the amino acid sequence arginine-glycine-aspartic acid (or, in abbreviated amino acid nomenclature, RGD). This tripeptide is present in the cell-binding sites of proteoglycans, fibronectin, laminin, and various other extracellular proteins. The cell-binding domain of fibronectin, with its extended RGD-containing loop, is shown in Figure 7.10a.

The discovery of the importance of the RGD sequence has opened the door to new avenues for treatment of medical conditions that involve receptor-ligand interactions. When the wall of a blood vessel is injured, the damaged region is sealed by the controlled aggregation of blood platelets, which are nonnucleated cell fragments that circulate in the blood. When it occurs at an inappropriate time or place, the aggregation of platelets can form a potentially dangerous blood clot (*thrombus*) that can block the flow of blood to major organs and is one of the leading causes of heart attack and stroke. The aggregation of platelets requires the interaction of a platelet-specific integrin ($\alpha_{IIb}\beta_3$) with soluble RGD-containing blood proteins, such as fibrinogen and von Willebrand factor, which act as linkers that hold the platelets together (Figure 7.15, top). Experiments with animals had indicated that RGD-containing peptides can inhibit blood clot formation by preventing the platelet integrin from binding to blood proteins (Figure 7.15, bottom). These findings led to the design of a new class of antithrombotic agents (Aggrastat and Integrelin) that resemble the RGD structure but bind selectively to the platelet integrin. Both of these drugs are based on the structures of compounds present in snake venom. A specific antibody (ReoPro) directed against the RGD binding site of $\alpha_{IIb}\beta_3$ integrins can also pre-

Figure 7.15 The role of integrins in platelet aggregation. (a) Blood clots form when platelets adhere to one another through fibrinogen bridges that bind to the platelet integrins. (b) The presence of synthetic RGD peptides can inhibit blood clot formation by competing with fibrinogen molecules for the RGD-binding sites on platelet $\alpha_{IIb}\beta_3$ integrins. Nonpeptide RGD analogues and anti-integrin antibodies can act in a similar way to prevent clot formation in high-risk patients.

vent blood clots in certain patients undergoing high-risk vascular surgeries. A different integrin-targeting antibody (Tysabri) is prescribed for treatment of multiple sclerosis (see The Human Perspective, Chapter 17).

The cytoplasmic domains of integrins contain binding sites for a variety of cytoplasmic proteins, including several that act as adaptors that link the integrin to actin filaments of the cytoskeleton (see Figure 7.17). The role of integrins in making the connection between the ECM and the cytoskeleton is best seen in two specialized structures: focal adhesions and hemidesmosomes.

Focal Adhesions and Hemidesmosomes: Anchoring Cells to Their Substratum

It is much easier to study the interaction of cells with the bottom of a culture dish than with an extracellular matrix inside an animal. Consequently, much of our knowledge of cell-matrix interactions has been obtained from the study of cells adhering to various substrates in vitro. The stages in the attachment of a cultured cell to its substratum are shown in Figure 7.16. At first, the cell has a rounded morphology, as is generally true of animal cells suspended in aqueous medium.

(b) 2.5 μ m

(c) 2.5 μ m

(d) 2.5 μ m

Figure 7.16 Steps in the process of cell spreading. Scanning electron micrographs showing the morphology of mouse fibroblasts at successive times during attachment and spreading on glass coverslips. Cells were fixed after (a) 30 minutes, (b) 60 minutes, (c) 2 hours, and (d) 24 hours of attachment. (FROM J. J. ROSEN AND L. A. CULP, EXP. CELL RES. 107:141, 1977 WITH PERMISSION FROM ELSVIER.)

Once the cell makes contact with the substratum, it sends out projections that form increasingly stable attachments. Over time, the cell flattens and spreads itself out on the substratum.

When fibroblasts or epithelial cells spread onto the bottom of a culture dish, the lower surface of the cell is not pressed uniformly against the substratum. Instead, the cell is anchored to the surface of the dish only at scattered, discrete sites, called **focal adhesions** (Figure 7.17*a*). Focal adhesions are dynamic structures that can be rapidly disassembled if the adherent cell is stimulated to move or enter mitosis. The plasma membrane of a focal adhesion contains large clusters of integrins. The cytoplasmic domains of the integrins are connected by various adaptor proteins (e.g., talin, α -actinin, and vinculin) to actin filaments of the cytoskeleton (Figure 7.17*b,c*). Focal adhesions may act as a type of sensory structure, collecting information about the physical and chemical

properties of the extracellular environment and transmitting that information to the cell interior, which may lead to changes in cell adhesion, proliferation, or survival. Focal adhesions also play a key role in cell locomotion, during which the integrins develop transient interactions with extracellular materials (see Figure 9.73*b*).

Focal adhesions are capable of creating mechanical forces or responding to such forces. These properties might be expected from a structure that contains actin and myosin, two of the cell's major contractile proteins. Figure 7.18*a* shows a cultured fibroblast attached to a gelled surface that can be deformed by local forces. The original surface contained a uniform grid pattern that has been distorted by traction

(a)

(b)

Figure 7.17 Focal adhesions are sites where cells adhere to their substratum and transmit signals in both directions across the plasma membrane. (a) This cultured cell has been stained with fluorescent antibodies to reveal the locations of actin filaments (gray-green) and integrins (red). The integrins are localized in small patches that correspond to the sites of focal adhesions. (b) The cytoplasmic surface of a focal adhesion of a cultured amphibian cell is shown here after the inner surface of the membrane was processed for quick-freeze, deep-etch analysis. Bundles of actin filaments are seen to associate with the inner surface of the membrane in the region of a focal adhesion. (c) Schematic drawing of a focal adhesion showing the interactions of integrin molecules with other proteins on both sides of the lipid bilayer. The binding of extracellular ligands, such as collagen and fibronectin, is thought to induce conformational changes in the cytoplasmic domains of the integrins that cause the integrins to become linked to actin filaments of the cytoskeleton. Linkages with the cytoskeleton lead, in turn, to the clustering of integrins at the cell surface. Linkages with the cytoskeleton are mediated by various actin-binding proteins, such as talin and α -actinin, that bind to the β subunit of the integrin. During the process of focal adhesion formation, talin undergoes a conformational change that exposes binding sites on talin's rod domain. The binding of vinculin to these exposed sites promotes the assembly of additional actin filaments. The cytoplasmic domains of integrins are also associated with protein kinases, such as FAK (focal adhesion kinase) and Src. The attachment of the integrin to an extracellular ligand can activate these protein kinases and start a chain reaction that transmits signals throughout the cell. The association of myosin molecules with the actin filaments can generate traction forces that are transmitted to sites of cell-substrate attachment. (A: FROM

(a)

Figure 7.18 Experimental demonstration of forces exerted by focal adhesions. (a) In this approach, fibroblasts are plated on a deformable surface that contains a visible, uniform grid pattern. Traction forces generated by focal adhesions can be monitored by observing deformations (arrowheads) in the grid pattern of the substratum to which the cells are adhering. The generation of force can be correlated with the locations of fluorescently labeled focal adhesions (see Figure 9.73). (b) Scanning-electron micrograph of a smooth muscle cell sitting atop a bed of flexible (elastomeric) micro-posts whose tips had been coated

(b)

with fibronectin. The attached cell is seen deflecting the position of multiple posts. The degree of movement of a particular post reflects the magnitude of the traction forces exerted by the cell on that post. (A: FROM N. Q. BALABAN ET AL., NATURE CELL BIOL. 3:468, 2001, COURTESY OF BENJAMIN GEIGER; © 2001, REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LTD. B: FROM JOHN L. TAN, ET AL., PNAS 100:1484, 2003, FIG. 2D, COURTESY OF CHRISTOPHER S. CHEN. © 2003 NATIONAL ACADEMY OF SCIENCES, U.S.A.)

(gripping/pulling) forces generated by focal adhesions at the undersurface of the cell. Figure 7.18b shows a fibroblast lying on a bed of fibronectin-coated posts. The posts are flexible and capable of being moved independently of one another. It can be seen in this micrograph that the tips of the posts are being deflected as a result of pulling forces exerted by the cell.

Acting in the opposite direction, mechanical forces applied to the surfaces of cells can be converted by focal adhesions into biochemical signals in the cytoplasm. This process of signal conversion is described as *mechanotransduction*, and the focal adhesion is acting as a *mechanosensor* by recognizing the physical properties of the environment. The ability of cells to respond to physical forces is important in many cellular behaviors and can be illustrated by a study in which cells were allowed to bind to beads that had been covered with a coating of fibronectin. When the membrane-bound beads were pulled by an optical tweezer (page 143), the mechanical stimulus was transmitted into the cell interior where it generated a wave of Src kinase activation. Mechanotransduction is thought to be mediated by conformational changes in some of the adaptor proteins, such as talin, that are induced by stretching. Such conformational changes can expose important binding sites in these proteins that were previously hidden, allowing additional protein molecules to be recruited to the adhesion complex.

Figure 7.17c illustrates how the pull of a fibronectin or collagen molecule is able to activate protein kinases, such as FAK or Src, which would then phosphorylate various substrates. Activation of these protein kinases can transmit signals throughout the cell, including the cell nucleus, where they can promote changes in gene expression. Activation of

either FAK or Src can dramatically alter cell behavior. The importance of the physical properties of a cell's environment in influencing cellular behavior is illustrated by a study in which mesenchymal stem cells (MSCs) derived from adult bone marrow were grown on substrates of varying elasticity (or stiffness). When these MSCs were grown on a soft, pliable substratum, such as might be encountered by a cell within the developing brain, the MSCs differentiated into nerve cells. When grown on a substratum of greater stiffness, these same cells differentiated into muscle cells. Finally, when grown on even stiffer substrates, such as those that might be home to cells growing in a skeletal tissue such as cartilage or bone, the MSCs differentiated into osteoblasts, which give rise to bone cells.

Focal adhesions are most commonly seen in cells grown in vitro, although similar types of adhesive contacts are found in certain tissues, such as muscle and tendon. Within the body, the tightest attachment between a cell and its extracellular matrix is seen at the basal surface of epithelial cells where the cells are anchored to the underlying basement membrane by a specialized adhesive structure called a **hemidesmosome** (Figures 7.1 and 7.19). Hemidesmosomes contain a dense plaque on the inner surface of the plasma membrane with filaments coursing outward into the cytoplasm. Unlike the filaments of focal adhesions, which consist of actin, the filaments of the hemidesmosome are thicker and consist of the protein keratin. Keratin-containing filaments are classified as intermediate filaments, which serve primarily in a supportive function (as discussed in detail in Section 9.4). The keratin filaments of the hemidesmosome are linked to the extracellular

(a)

0.3 μm

(b)

Figure 7.19 Hemidesmosomes are differentiated sites at the basal surfaces of epithelial cells where the cells are attached to the underlying basement membrane. (a) Electron micrograph of several hemidesmosomes showing the dense plaque on the inner surface of the plasma membrane and the intermediate filaments projecting into the cytoplasm. (b) Schematic diagram showing the major components of a hemidesmosome connecting the epidermis to the underlying dermis. The $\alpha_6\beta_4$ integrin molecules of the epidermal cells are linked to cytoplasmic intermediate filaments by a protein called plectin that is present in the dark-staining plaque and to the basement membrane by anchoring filaments of a particular type of laminin. A second transmembrane protein (BP180) is also present in hemidesmosomes. The collagen fibers are part of the underlying dermis. (A: FROM DOUGLAS E. KELLY, J. CELL BIOL. 28:51, 1966 (BOTTOM FIGURE), FIG. 11. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

matrix by membrane-spanning integrins, including $\alpha_6\beta_4$ (Figure 7.19b). Like their counterparts in focal adhesions, these integrins also transmit signals from the ECM that affect the shape and activities of the attached epithelial cells.

The importance of hemidesmosomes is revealed by a rare disease, *bullous pemphigoid*, in which individuals produce antibodies that bind to proteins (the *bullous pemphigoid antigens*) present in these adhesive structures. Diseases caused by production of antibodies directed against one's own tissues (i.e., autoantibodies) are called autoimmune disorders and are responsible for a wide variety of conditions. In this case, the presence of autoantibodies causes the lower layer of the epidermis to lose attachment to the underlying basement membrane (and thus to the underlying connective tissue layer of the dermis). The leakage of fluid into the space beneath the epidermis results in severe blistering of the skin. A similar inherited blistering disease, *epidermolysis bullosa*, can occur in patients with genetic alterations in any one of a number of hemidesmosomal proteins, including the α_6 or β_4 integrin subunit, collagen VII, or laminin-5.

REVIEW

1. How are integrins able to link the cell surface with materials that make up the ECM? How do the inactive and active structures of integrins differ from one another structurally and functionally? What is the significance of the presence of an RGD motif in an integrin ligand?
2. How can a cell-surface protein be involved in both cell adhesion and transmembrane signal transduction?
3. What is the difference between inside-out and outside-in signaling? What is the importance of each to cell activities?
4. List two characteristics that distinguish hemidesmosomes from focal adhesions.

7.3 | Interactions of Cells with Other Cells

Examination of a thin section through a major organ of an animal reveals a complex architecture involving a variety of different types of cells. Little is known about the mechanisms responsible for generating the complex three-dimensional cellular arrangements found within developing organs. It is presumed that this process depends heavily on *selective* interactions between cells of the same type, as well as between cells of a different type. It is evident that cells can recognize the surfaces of other cells, interacting with some and ignoring others.

It is very difficult to study cellular interactions that occur within the inaccessible organs of a developing embryo as tissue formation takes place. Early attempts to learn about cell-cell recognition and adhesion were carried out by removing a developing organ from a chick or amphibian embryo, dissociating the organ's tissues to form a suspension of single cells, and determining the ability of the cells to reaggregate in culture. In experiments in which cells from two different developing organs were dissociated and mixed together, the cells would initially aggregate to form a mixed clump. Over time,

however, the cells would move around within the aggregate and eventually “sort themselves out” so that each cell adhered only to cells of the same type (Figure 7.20). Once separated into a homogeneous cluster, these embryonic cells would

often differentiate into many of the structures they would have formed within an intact embryo.

Little was known about the nature of the molecules that mediated cell–cell adhesion until the development of techniques for purifying integral membrane proteins and, more recently, for the isolation and cloning of genes that encode these proteins. Dozens of different proteins involved in cell adhesion have now been identified. Different arrays of these molecules on the surfaces of different types of cells are thought to be responsible for the specific interactions between cells within complex tissues. Four distinct families of integral membrane proteins play a major role in mediating cell–cell adhesion: (1) selectins, (2) certain members of the immunoglobulin superfamily (IgSF), (3) certain members of the integrin family, and (4) cadherins.

Selectins

During the 1960s, it was discovered that lymphocytes that had been removed from peripheral lymph nodes, radioactively labeled, and injected back into the body would return to the sites from which they were originally derived—a phenomenon called *lymphocyte homing*. It was subsequently found that homing could be studied in vitro by allowing lymphocytes to adhere to frozen sections of lymphoid organs. Under these experimental conditions, the lymphocytes would selectively adhere to the endothelial lining of the venules (the smallest veins) of peripheral lymph nodes. Binding of lymphocytes to venules could be blocked by antibodies directed against a specific glycoprotein, called L-selectin, on the lymphocyte surface.

Selectins comprise a family of integral membrane glycoproteins that recognize and bind to a particular arrangement of sugars in the oligosaccharides that project from the surfaces

Figure 7.20 Experimental demonstration of cell–cell recognition.

When cells from different parts of an embryo are dissociated and then intermixed, the cells initially aggregate and then sort out by associating with other cells of the same type. The results of two such classic experiments are shown here. (a) In this experiment, two regions of an early amphibian embryo (the ectoderm and mesoderm) were dissociated into single cells and combined. At first the cells form a mixed aggregate, but eventually they sort out. The ectodermal cells (shown in red) move to the outer surface of the aggregate, which is where they would be located in the embryo, and the mesodermal cells (shown in purple) move to the interior, the position they would occupy in the embryo. Both types of cells then differentiate into the types of structures they would normally give rise to. (b) Light micrograph showing the results of an experiment in which precartilage cells from a chick limb are mixed with chick heart ventricle cells. The two types of cells have sorted themselves out of the mixed aggregate with the heart cells forming a layer on the outside of the precartilage cells. It is proposed that the precartilage cells collect in the center of the aggregate because the cells adhere to one another more strongly than do the cells from the heart. (This and other models are discussed in *Nat. Cell Biol.* 10:375, 2008.) (A: P. L. TOWNES, J. HOLTFRETER, *JOURNAL OF EXPERIMENTAL ZOOLOGY* 128:53, 1955; B: M. S. STEINBERG, *JOURNAL EXPERIMENTAL ZOOLOGY* 173-411, 1970. THIS MATERIAL IS USED BY PERMISSION OF JOHN WILEY & SONS INC.)

Figure 7.21 Selectins. Schematic drawing showing the three types of known selectins (a). All of them recognize and bind to a similar carbohydrate ligand at the ends of oligosaccharide chains on glycoproteins, such as the one shown in (b). (c) The detailed structure of the carbohydrate ligand. The terminal fucose and sialic acid moieties are particularly important in selectin recognition, and the *N*-acetylglucosamine moiety is often sulfated.

of other cells (page 129). The name of this class of cell-surface receptors is derived from the word “lectin,” a general term for a compound that binds to specific carbohydrate groups. Selectins possess a small cytoplasmic domain, a single membrane-spanning domain, and a large extracellular segment that consists of a number of separate modules, including an outermost domain that acts as the lectin (Figure 7.21). There are three known selectins: E-selectin, present on endothelial cells; P-selectin, present on platelets and endothelial cells; and L-selectin, present on leukocytes (white blood cells). All three selectins recognize a particular grouping of sugars (Figure 7.21c) that is found at the ends of the carbohydrate chains of certain complex glycoproteins. Binding of selectins to their carbohydrate ligands requires calcium. As a group, selectins mediate transient interactions between circulating leukocytes and vessel walls at sites of inflammation and clotting. Capturing a leukocyte is a challenging task because these cells are flowing through the bloodstream at a considerable rate of speed. Selectins are well-suited for this function because the bonds that they form with their ligands become stronger when the interaction is placed under mechanical stress, as occurs when the leukocyte is being pulled away from a given site

on the vessel wall. The role of selectins in inflammation is discussed further in the Human Perspective on page 255.

The Immunoglobulin Superfamily

Elucidation of the structure of blood-borne antibody molecules in the 1960s was one of the milestones in our understanding of the immune response. Antibodies, which are a type of protein called an immunoglobulin (or Ig), were found to consist of polypeptide chains composed of a number of similar domains. Each of these Ig domains, as they are called, is composed of 70 to 110 amino acids organized into a tightly folded structure, as shown in the inset of Figure 7.22. The human genome encodes 765 distinct Ig domains, making it the most abundant domain in human proteins. Taken as a group, these proteins are members of the **immunoglobulin superfamily**, or **IgSF**. Most members of the IgSF are involved in various aspects of immune function, but some of these proteins mediate calcium-independent cell–cell adhesion. In fact,

Figure 7.22 L1 is a cell-adhesion molecule of the immunoglobulin (Ig) superfamily. A model of cell–cell adhesion resulting from the specific interactions of the immunoglobulin (Ig) domains of two L1 molecules projecting from the surfaces of neighboring cells. Each L1 molecule contains a small cytoplasmic domain, a transmembrane segment, several segments that resemble one type of module found in fibronectin, and six Ig domains situated at the N-terminal portion of the molecule. The inset shows the structure of the two N-terminal Ig domains of VCAM, an IgSF molecule on the surface of endothelial cells. The Ig domains of VCAM and L1 have a similar three-dimensional structure consisting of two β sheets packed face-to-face. (INSET FROM E. YVONNE JONES ET AL., NATURE 373:540, 1995; © 1995, REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD.)

the discovery of Ig-like domains in cell-adhesion receptors in invertebrates—animals that lack a classic immune system—suggests that Ig-like proteins originally evolved as cell-adhesion mediators and only secondarily took on their functions as effectors of the vertebrate immune system.

Most IgSF cell-adhesion molecules mediate the specific interactions of lymphocytes with cells required for an immune response (e.g., macrophages, other lymphocytes, and target cells). However, some IgSF members, such as VCAM (vascular cell-adhesion molecule), NCAM (neural cell-adhesion molecule), and L1, mediate adhesion between nonimmune cells. NCAM and L1, for example, play important roles in nerve outgrowth, synapse formation, and other events during the development of the nervous system. Like fibronectin and many other proteins involved in cell adhesion, the IgSF cell-adhesion molecules have a modular construction (Figure 7.22) and are composed of individual domains of similar structure to the domains in other proteins.

The importance of L1 in neural development has been revealed in several ways. In humans, mutations in the *L1* gene can have devastating consequences. In extreme cases, babies are born with a fatal condition of hydrocephalus (“water on the brain”). Children with less severe mutations typically exhibit mental retardation and difficulty in controlling limb movements (spasticity). Autopsies on patients that have died of an L1-deficiency disease reveal a remarkable condition: they are often missing two large nerve tracts, one that runs between the two halves of the brain and the other that runs between the brain and the spinal cord. The absence of such nerve tracts suggests that L1 is involved in the directed growth of axons within the embryonic nervous system.

Various types of proteins serve as ligands for IgSF cell-surface molecules. As described earlier, most integrins facilitate adhesion of cells to their substratum, but a few integrins mediate cell–cell adhesion by binding to proteins on other cells. For example, the integrin $\alpha_4\beta_1$ on the surface of leukocytes binds to VCAM, an IgSF protein on the endothelial lining of certain blood vessels (page 255).

Cadherins

The **cadherins** are a large family of glycoproteins that mediate Ca^{2+} -dependent cell–cell adhesion and transmit signals from the ECM to the cytoplasm. Cadherins typically join cells of similar type to one another and do so predominantly by binding to the same cadherin present on the surface of the neighboring cell. This property of cadherins was first demonstrated by genetically engineering cells that were normally nonadhesive to express one of a variety of different cadherins. The cells were then mixed in various combinations and their interactions monitored. It was found that cells expressing one species of cadherin preferentially adhered to other cells expressing the same cadherin.

Like selectins and IgSF molecules, cadherins have a modular construction. The best studied cadherins are E-cadherin (epithelial), N-cadherin (neural), and P-cadherin (placental). These “classical” cadherins, as they are called, contain a relatively large extracellular segment consisting of five tandem domains of similar size and structure, a single transmembrane

segment, and a small cytoplasmic domain (Figure 7.23). The cytoplasmic domain is often associated with members of the *catenin* family of cytosolic proteins, which have a dual role: they tether the cadherins to the cytoskeleton (see Figure 7.26), and they transmit signals to the cytoplasm and nucleus.

A number of models of cadherin adhesion are depicted in Figure 7.23. Structural studies indicate that cadherins from the same cell-surface associate laterally to form parallel dimers. These studies also shed light on the role of calcium, which has been known for decades to be essential for cell–cell adhesion. As indicated in Figure 7.23, calcium ions form bridges between successive domains of a given molecule. These calcium ions maintain the extracellular portion of each cadherin in a rigid conformation required for cell adhesion. Adhesion between cells results from the interaction between the extracellular domains of cadherins from opposing cells to form a “cell-adhesion zipper.” Considerable controversy has arisen over the degree to which cadherins from opposing cells overlap with one another, which is the reason that several alternate configurations are shown in Figure 7.23. Different types of cells bearing different cadherins likely engage in different types of interactions, so that more than one (or all) of the configurations depicted in Figure 7.23 may occur within an organism. Just as cadherin interdigitation can be compared to a zipper, cadherin clusters can be compared to Velcro; the greater the number of interacting cadherins in a cluster, the greater the strength of adhesion between apposing cells.

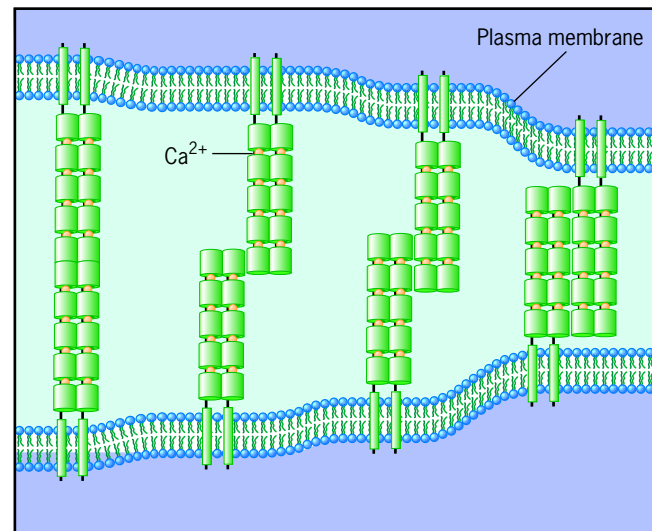

Figure 7.23 Cadherins and cell adhesion. Schematic representation of two cells adhering to one another as the result of interactions between similar types of cadherins projecting from the plasma membrane of each cell. Calcium ions (shown as small yellow spheres) are situated between the successive domains of the cadherin molecule where they play a critical role in maintaining the rigidity of the extracellular portion of the protein. This illustration shows several alternate models by which cadherins from opposing cells might interact. Different types of studies have suggested different degrees of overlap (interdigitation) between the extracellular domains of molecules from opposing cells. For consistency, subsequent figures will depict cadherins with a single domain overlap, which is likely the predominant configuration.

Cadherin-mediated adhesion is thought to be responsible for the ability of like cells to “sort out” of mixed aggregates, as was illustrated in Figure 7.20. In fact, cadherins may be the single most important factor in molding cells into cohesive tissues in the embryo and holding them together in the adult. As discussed in the Human Perspective, the loss of cadherin function may play a key role in the spread of malignant tumors.

Embryonic development is characterized by change: change in gene expression, change in cell shape, change in cell motility, change in cell adhesion, and so forth. Cadherins are thought to mediate many of the dynamic changes in adhesive contacts that are required to construct the tissues and organs of an embryo, which is known as the process of *morphogenesis*. For example, a number of morphogenetic events during embryonic development involve a group of cells changing from an epithelium (tightly adherent, apical-basal polarized, stationary cell layer) to a mesenchyme (solitary, nonadhesive, nonpolarized, migratory cells), or vice versa. The **epithelial-mesenchymal transition** (or **EMT**) is illustrated by the formation of the mesoderm during gastrulation in a chick or mammalian embryo. Typically, these cells break away from a cohesive epithelial layer (called the epiblast) at the dorsal surface of the early embryo and wander into the interior regions as mesenchymal cells

(a)

(b)

Figure 7.24 Cadherins and morphogenesis. (a) During gastrulation, cells in the upper layer of the embryo (the epiblast) move toward a groove in the center of the embryo, sink into the groove, and then migrate laterally as mesenchymal cells in the space beneath the epiblast. This epithelial-mesenchymal transition is marked by a loss of expression of E-cadherin that is characteristic of epithelial cells. Cells expressing E-cadherin are depicted in orange. (b) Scanning electron micrograph of a chick embryo during gastrulation that has been

(Figure 7.24a,b). These mesenchymal cells will eventually give rise to mesodermal tissues such as blood, muscle, and bone. The cells of the epiblast display E-cadherins on their surface, which is presumed to promote their close association with one another. Prior to their separation from the epiblast, the future mesodermal cells stop expressing E-cadherin, which is thought to promote their release from the epithelium and transformation into mesenchymal cells (Figure 7.24a). At a later stage of development, another major event, the formation of the primitive nervous system, is also characterized by changes in cadherin expression. Following gastrulation, the dorsal surface of the embryo is covered by a single-celled epithelial layer, which will become the ectodermal tissues of the animal (including the skin and nervous system). At this stage, the cells in the central region of this layer stop expressing E-cadherin and begin expressing N-cadherin (Figure 7.24c). In subsequent stages, the epithelial cells expressing N-cadherin separate from their neighbors on either side and roll into the neural tube, which will go on to become the animal’s brain and spinal cord. It is thought that cadherins (and other cell-adhesion molecules) play a key role in these events by changing the adhesive properties of cells.

Whereas cadherins are typically distributed diffusely all along the surfaces of two adherent cells, they also participate in the formation of specialized intercellular junctions, which are the subjects of the following section.

(c)

fractured to reveal the cells undergoing the epithelial-mesenchymal transition (arrow) depicted in part a. (c) This sequence of drawings depicts the development of the neural tube, which is an epithelial layer that forms by separation from the overlying layer of dorsal ectoderm. In the top drawing, the epithelial cells are expressing E-cadherin. In the lower drawings, the cells of the neural tube stop expressing E-cadherin (orange) and instead express N-cadherin (blue). THE HUMAN PERSPECTIVE

The Role of Cell Adhesion in Inflammation and Metastasis

Inflammation is one of the primary responses to infection. If a part of the body becomes contaminated by bacteria, as might occur following a puncture wound to the skin, the site of injury becomes a magnet for a variety of white blood cells. White blood cells (leukocytes) that would normally remain in the bloodstream are stimulated to traverse the endothelial layer that lines the smallest veins (venules) in the region and enter the tissue. Once in the tissue, the leukocytes move in response to chemical signals toward the invading microorganisms, which they ingest.* Although inflammation is a protective response, it also produces adverse side effects, such as fever, swelling due to fluid accumulation, redness, and pain.

Inflammation can also be triggered inappropriately. For example, damage to the tissues of the heart or brain can occur when blood flow to these organs is blocked during a heart attack or stroke. When blood flow to the organ is restored, circulating leukocytes may attack the damaged tissue, causing a condition known as *reperfusion damage*. An overzealous inflammatory response can also lead to asthma, toxic shock syndrome, and respiratory distress syndrome. A great deal of research has focused on questions related to these conditions: How are leukocytes recruited to sites of inflammation? How are they able to stop flowing through the bloodstream and adhere to vessel walls? How do they penetrate the walls of the vessels? How can some of the negative side effects of inflammation be blocked without interfering with the beneficial aspects of the response? Answers to questions about inflammation have focused on three types of cell-adhesion molecules: selectins, integrins, and IgSF proteins.

A chain of events that has been proposed to occur during acute inflammation is shown in Figure 1. The first step begins as the walls of the venules become activated in response to chemical signals from nearby damaged tissue. The endothelial cells that line these venules become more adhesive to circulating neutrophils, a type of phagocytic leukocyte that carries out a rapid, nonspecific attack on invading pathogens. This change in adhesion is mediated by a temporary display of P- and E-selectins on the surfaces of the activated en-

dothelial cells in the damaged area (step 2, Figure 1). When neutrophils encounter the selectins, they form transient adhesions that dramatically slow their movement through the vessel. At this stage, the neutrophils can be seen to “roll” slowly along the wall of the vessel. A number of biotechnology companies are attempting to develop anti-inflammatory drugs that act by interfering with binding of ligands to E- and P-selectins. Anti-selectin antibodies block neutrophil rolling on selectin-coated surfaces in vitro and suppress inflammation and reperfusion damage in animals. A similar type of blocking effect has been attained using synthetic carbohydrates (e.g., efomycines) that bind to E- and P-selectin, thereby competing with carbohydrate ligands on the surfaces of the neutrophils.

As the neutrophils interact with the inflamed venule endothelium, interactions take place between other molecules on the surfaces of the two types of cells. One of the molecules displayed on the surface of the endothelial cells is a phospholipid called *platelet activating factor (PAF)*. PAF binds to a receptor on the surface of the neutrophil sending a signal into the neutrophil that leads to an increase in the binding activity of certain integrins (e.g., $\alpha_1\beta_2$ and $\alpha_4\beta_1$) already situated on the neutrophil surface (step 3, Figure 1). This is an example of the type of inside-out signal that is illustrated in Figure 7.14. The activated integrins then bind with high affinity to IgSF molecules (e.g., ICAM-1 and VCAM-1) on the surface of the endothelial cells, causing the neutrophils to stop their rolling and adhere firmly to the wall of the vessel (step 4). The bound neutrophils then change their shape and squeeze between adjacent endothelial cells into the damaged tissue (step 5). Invading neutrophils appear capable of disassembling the adherens junctions (page 257) that form the major barrier between cells of the vessel wall. This cascade of events, which involves several different types of cell-adhesion molecules, ensures that attachment of blood cells to the walls of blood vessels and subsequent penetration will occur only at sites where leukocyte invasion is required.

The importance of integrins in the inflammatory response is demonstrated by a rare disease called *leukocyte adhesion deficiency (LAD)*. Persons with the type I form of LAD are unable to produce the β_2 subunit as part of a number of leukocyte integrins. As a result,

*A remarkable film of a leukocyte “chasing” a bacterium can be found on the Web by searching the keywords “neutrophil crawling.”

Figure 1 Steps in the movement of neutrophils from the bloodstream during inflammation. The steps are described in the text.

the leukocytes of these individuals lack the ability to adhere to the endothelial layer of venules, a step required for their exit from the bloodstream. These patients suffer from repeated life-threatening bacterial infections. The disease is best treated by bone marrow transplantation, which provides the patient with stem cells capable of forming normal leukocytes. Administration of antibodies against the β_2 subunit can mimic the effects of LAD, blocking the movement of neutrophils and other leukocytes out of blood vessels. Such antibodies might prove useful in preventing inflammatory responses associated with diseases such as asthma and rheumatoid arthritis or with reperfusion.

Cancer is a disease in which cells escape from the body's normal growth control mechanisms and proliferate in an unregulated manner. Were the malignant cells to remain in a single mass, as often occurs in some types of skin cancer or thyroid cancer, most cancers would be readily cured by surgical removal of the diseased tissue. Most malignant tumors, however, spawn cells that are capable of leaving the primary tumor mass and entering the bloodstream or lymphatic channels, thereby initiating the growth of secondary tumors in other parts of the body (Figure 2a). The spread of a tumor within the body is called **metastasis** and is the reason cancer is such a devastating disease. Metastatic cells (cancer cells that are able to initiate the formation of secondary tumors) are thought to have special cell-surface properties that are not shared by most other cells in the tumor. For example:

1. Metastatic cells must be less adhesive than other cells to break free of the tumor mass.

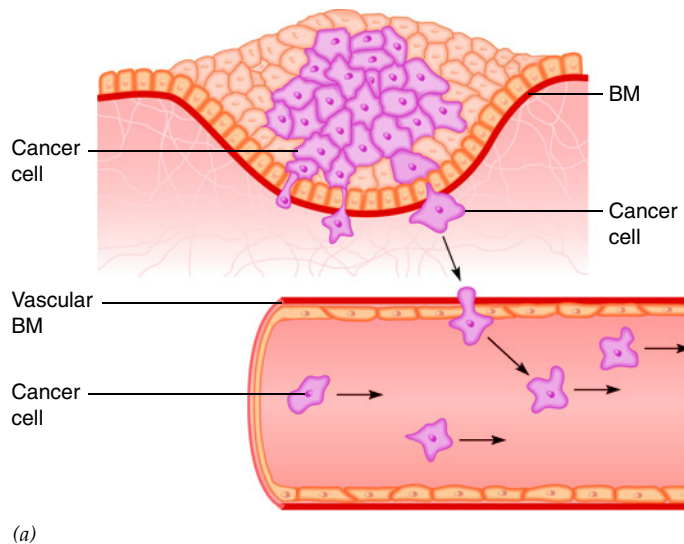

Figure 2 Steps leading to the metastatic spread of an epithelial cancer (a carcinoma). (a) A fraction of the cells of the primary tumor lose their adhesiveness to other tumor cells and gain the capability to penetrate the basement membrane (BM) barrier that underlies the epithelial tissue. These cells, which have assumed a mesenchymal-like appearance, migrate through the surrounding stromal tissue and cross the BM of a blood or lymph vessel, thereby entering the general circulation. The cells are carried to other tissues, where they migrate back across the BM of the vessel and enter a tissue in which they possess the potential to form secondary tumors. Only a very small percentage of tumor cells that are released from a primary tumor manage to overcome these numerous hurdles, but those that do pose a threat to the life of the host. (b) These circulating tumor cells (CTCs) have been isolated from a blood sample of a patient with prostate cancer. Even though the

2. Metastatic cells must be able to penetrate numerous barriers, such as the extracellular matrices of surrounding connective tissue and the basement membranes that underlie the epithelium and line the blood vessels that carry them to distant sites (Figure 2a). Although the presence of cancer cells in the bloodstream is a potentially lethal circumstance, it does provide an opportunity for nonsurgical access to a patient's cancer. A number of devices have recently been developed to trap rare circulating tumor cells (CTCs) present in blood samples taken from cancer patients (Figure 2b). Once they have been captured, CTCs from a patient can be studied to determine the molecular characteristics of the tumor, how aggressive the tumor is likely to be, how it might be best treated, and how well a particular therapy is progressing as reflected in the decreasing number of CTCs over time. One day CTCs might be used as the basis for early detection of disease.
3. Metastatic cells must be able to invade normal tissues and survive to form secondary colonies. For some reason, this third step appears to pose the greatest obstacle in the process of metastasis for most types of tumors. Consequently, only a very small fraction of cancer cells that exit the bloodstream typically produce viable secondary tumors.

The mechanisms used by cancer cells to penetrate extracellular matrices are poorly understood because such events have been virtually impossible to study within the tissues of a living animal. It is thought that movement through basement membranes is accomplished largely by ECM-digesting enzymes, most notably the matrix metalloproteinases (MMPs) discussed on page 244. These enzymes

blood of a cancer patient may contain less than one cancer cell for every billion normal cells, these rare cancer cells can be selectively trapped on a chip that has been coated with antibody molecules directed against a cell-surface protein (in this case, EpCAM) that is present on the cancer cells and absent from normal blood cells. are presumed to degrade the proteins and proteoglycans that stand in the way of cancer cell migration. In some types of cancer cells, MMPs are directly associated with long cell projections, called *invadopodia*, that push their way through the ECM. Among other tumor-promoting functions of MMPs, cleavage of certain proteins of the ECM or cell surface produces active protein fragments that act back on the cancer cells to stimulate their growth and invasive character. Because of their apparent roles in the development of malignant tumors, MMPs became a prominent target of the pharmaceutical industry. Once it was demonstrated that synthetic MMP inhibitors were able to reduce metastasis in mice, a number of clinical trials of these drugs were conducted on patients with a variety of advanced, inoperable cancers. Unfortunately, these inhibitors have shown little promise in stopping late-stage tumor progression and, in some cases, have led to joint damage. To date, the only FDA-approved MMP inhibitor (Periostat) is used to treat periodontal disease.

Changes in the numbers and types of various cell-adhesion molecules—and thus the ability of cells to adhere to other cells or to extracellular matrices—have also been implicated in promoting metastasis. The greatest focus in this area has centered on E-cadherin, which is the predominant cell-adhesion molecule of the adherens junctions that hold epithelial cells in a cohesive sheet. Page 254

describes how the loss of E-cadherin from epithelial cells during certain events of embryonic development is associated with conversion of the cells into a less adhesive, more motile, mesenchymal phenotype. A remarkably similar epithelial-mesenchymal transition occurs at the peripheral edges of a tumor as malignant cells separate from the primary tumor mass and invade the adjacent normal tissue (Figure 2a). This is an important step in the process of metastasis. Surveys of a variety of epithelial cell tumors (e.g., breast, prostate, and colon cancers) confirm that these malignant cells have greatly reduced levels of E-cadherin; the lower the level of expression of E-cadherin, the greater the cell's metastatic potential. Conversely, when malignant cells are forced to express extra copies of the E-cadherin gene, the cells become much less capable of causing tumors when injected into host animals. The presence of E-cadherin is thought to favor the adhesion of cells to one another and suppress the dispersal of tumor cells to distant sites. E-cadherin may also inhibit the signaling pathways within the cell that lead to tissue invasion and metastasis. The importance of E-cadherin is evident from a study of a family of native New Zealanders that had lost 25 members to stomach cancer over a 30-year period. Analysis of the DNA of family members has revealed that susceptible individuals carry mutations in the gene encoding E-cadherin.

Adherens Junctions and Desmosomes: Anchoring Cells to Other Cells

The cells of certain tissues, particularly epithelia and cardiac muscle, are notoriously difficult to separate from one another because they are held together tightly by specialized calcium-dependent adhesive junctions. There are two main types of cell-cell adhesive junctions: adherens junctions and desmosomes. In addition to adhesive junctions, epithelial cells often contain other types of cell junctions that are also located along their lateral surfaces near the apical lumen (Figure 7.25). When these junctions are arranged in a specific array, this assortment of surface specializations is called a *junctional complex*. The structures and functions of the two adhesive junctions of the complex are described in the following paragraphs, whereas discussion of the other types of epithelial junctions (tight junctions and gap junctions) is taken up later in the chapter.

Adherens junctions are found in a variety of sites within the body. They are particularly common in epithelia, such as the lining of the intestine, where they occur as “belts” (or *zonulae adherens*) that encircle each of the cells near its apical surface, binding that cell to its surrounding neighbors (Figure 7.25a). In an adherens junction, cells are held together by calcium-dependent linkages formed between the extracellular domains of cadherin molecules that bridge the 30-nm gap between neighboring cells (Figure 7.26). As Figure 7.26 illustrates, the cytoplasmic domain of these cadherins is linked by α - and β -catenins to a variety of cytoplasmic proteins, including actin filaments of the cytoskeleton. Thus, like the integrins of a focal adhesion, the cadherin clusters of an adherens junction (1) connect the external environment to the actin cytoskeleton and (2) provide a pathway for signals to be transmitted from the cell exterior to the cytoplasm. To

give one example, the adherens junctions situated between endothelial cells that line the walls of blood vessels transmit signals that ensure the survival of the cells. Mice that are lacking an endothelial cell cadherin are unable to transmit these survival signals, and these animals die during embryonic development as a result of the death of the cells lining the vessel walls.

Desmosomes (or *maculae adherens*) are disk-shaped adhesive junctions approximately 1 μm in diameter (Figure 7.27a) that are found in a variety of tissues. Desmosomes are particularly numerous in tissues that are subjected to mechanical stress, such as cardiac muscle and the epithelial layers of the skin and uterine cervix. Like adherens junctions, desmosomes contain cadherins that link the two cells across a narrow extracellular gap. The cadherins of desmosomes have a different domain structure from the classical cadherins found in adherens junctions and are referred to as *desmogleins* and *desmocollins* (Figure 7.27b). Dense cytoplasmic plaques on the inner surface of the plasma membranes serve as sites of anchorage for looping intermediate filaments similar to those of hemidesmosomes (Figure 7.19). The three-dimensional network of ropelike intermediate filaments provides structural continuity and tensile strength to the entire sheet of cells. Intermediate filaments are linked to the cytoplasmic domains of the desmosomal cadherins by additional proteins, as depicted in Figure 7.27b. The importance of cadherins in maintaining the structural integrity of an epithelium is illustrated by an autoimmune disease (*pemphigus vulgaris*) in which antibodies are produced against one of the desmogleins. The disease is characterized by a loss of epidermal cell-cell adhesion and severe blistering of the skin.

Figure 7.26 Schematic model of the molecular architecture of an adherens junction.

The cytoplasmic domain of each cadherin molecule is connected to the actin filaments of the cytoskeleton by linking proteins, including β -catenin, α -catenin, and various actin-binding proteins. One of these actin-binding proteins is formin, which participates in the polymerization of the actin filaments. Actin filament assembly at the junction may be regulated by α -catenin. β -catenin is also a key element in the Wnt signaling pathway, which transmits signals from the cell surface to the cell nucleus. Disassembly of adherens junctions may release β -catenin to participate in this pathway, leading to the activation of gene expression. Another member of the catenin family, p120 catenin, binds to a site near the membrane on the cytoplasmic domain of the cadherin. p120 catenin is thought to prevent internalization of cadherins from the membrane, promote lateral interactions between cadherins, and serve as a component of intracellular signaling pathways. Numerous other proteins found in these junctions are not indicated.

The Role of Cell-Adhesion Receptors in Transmembrane Signaling

Figure 7.28 provides a summary of some of the points that have been made in this chapter. The drawing depicts each of the four types of cell-adhesion molecules discussed and their interactions with both extracellular and cytoplasmic materials. One of the roles of integral membrane proteins is to transfer

information across the plasma membrane, a process known as **transmembrane signaling**. While the subject will be explored in detail in Chapter 15, it can be noted that all four types of cell-adhesion molecules illustrated in Figure 7.28 have the potential to carry out this function. For example, integrins and

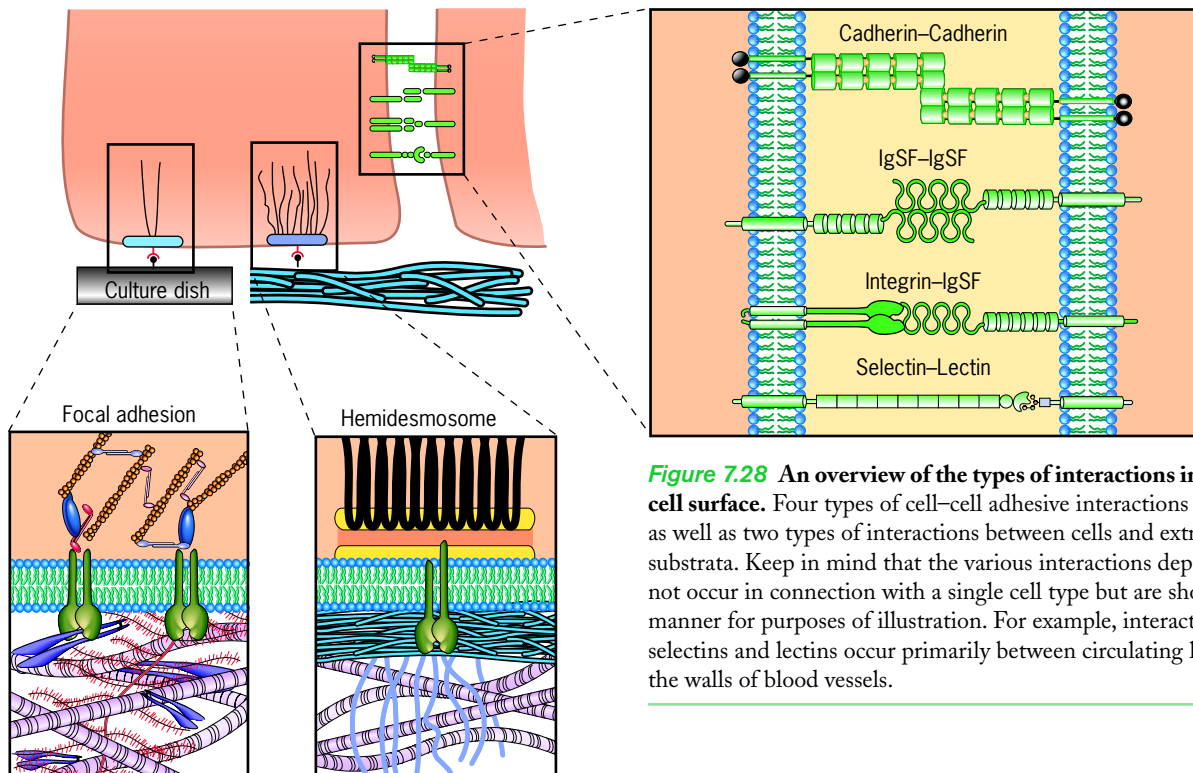

Figure 7.28 An overview of the types of interactions involving the cell surface. Four types of cell-cell adhesive interactions are shown, as well as two types of interactions between cells and extracellular substrata. Keep in mind that the various interactions depicted here do not occur in connection with a single cell type but are shown in this manner for purposes of illustration. For example, interactions between selectins and lectins occur primarily between circulating leukocytes and the walls of blood vessels.

cadherins can transmit signals from the extracellular environment to the cytoplasm by means of linkages with the cytoskeleton and with cytosolic regulatory molecules, such as protein kinases and G proteins. Protein kinases activate (or inhibit) their target proteins through phosphorylation, whereas G proteins activate (or inhibit) their protein targets through physical interaction (see Figure 15.21*b*). The engagement of an integrin with its ligand can induce a variety of responses within a cell, including changes in cytoplasmic pH or Ca^{2+} concentration, protein phosphorylation, and gene expression. These changes, in turn, can alter a cell's growth potential, migratory activity, state of differentiation, or survival. This type of phenomenon is illustrated by the mammary gland epithelial cells shown in Figure 7.29. When these cells are removed from a mammary gland and grown on a bare culture dish, they lose their ability to synthesize milk proteins and appear as flattened, undifferentiated cells (Figure 7.29*a*). When these same undifferentiated cells are cultured in the presence of certain extracellular molecules (e.g., laminin), they regain their differentiated appearance and become organized into milk-producing, gland-like structures (Figure 7.29*b*). Laminin is thought to stimulate mammary cells by binding to cell-surface integrins and activating kinases at the inner surface of the membrane (as in Figure 7.17*c*).

REVIEW

1. Distinguish between a hemidesmosome and a desmosome; a desmosome and an adherens junction.
2. Which type(s) of cell junctions contain actin filaments? Which contain(s) intermediate filaments? Which contain(s) integrins? Which contain(s) cadherins?
3. How do cadherins, IgSF members, and selectins differ at the molecular level in the way they mediate cell–cell adhesion?

7.4 | Tight Junctions: Sealing The Extracellular Space

A simple epithelium, like the lining of the intestine or lungs, is composed of a layer of cells that adhere tightly to one another to form a cellular sheet. Biologists have known for decades that when certain types of epithelia, such as frog skin or the wall of the urinary bladder, are mounted between two compartments containing different solute concentrations, very little diffusion of ions or solutes is observed across the wall of the epithelium from one compartment to the other. Given the impermeability of plasma membranes, it is not surprising that solutes cannot diffuse freely through the cells of an epithelial layer. But why aren't they able to pass between cells by way of the *paracellular pathway* (as in Figure 7.30*a*)? The reason became apparent during the 1960s with the discovery of specialized contacts, called **tight junctions** (or *zonulae occludens*), between neighboring epithelial cells.

Tight junctions (TJs) are located at the very apical end of the junctional complex between adjacent epithelial cells (see Figure 7.25). An electron micrograph of a section through a TJ that has been cut to include the plasma membranes of the adjacent cells is shown in Figure 7.30*a*. A higher magnification view showing the interaction between the membranes of a TJ is shown in the inset of Figure 7.30*a*. It is evident that the adjoining membranes make contact at intermittent points, rather than being fused over a large surface area. As indicated in Figure 7.30*b*, the points of cell–cell contact are sites where integral proteins of two adjacent membranes meet within the extracellular space.

Freeze fracture, which allows observation of the internal faces of a membrane (Figure 4.15), shows that the plasma membranes of a TJ contain interconnected strands (Figure 7.30*c*) that run mostly parallel to one another and to the apical surface of the epithelium. The strands (or grooves in the

(b)

are flattened and are not engaged in the synthesis of milk proteins. (b) When extracellular matrix molecules are added back to the culture, the cells regain their differentiated appearance and synthesize milk proteins. (COURTESY OF JOANNE EMERMAN.)

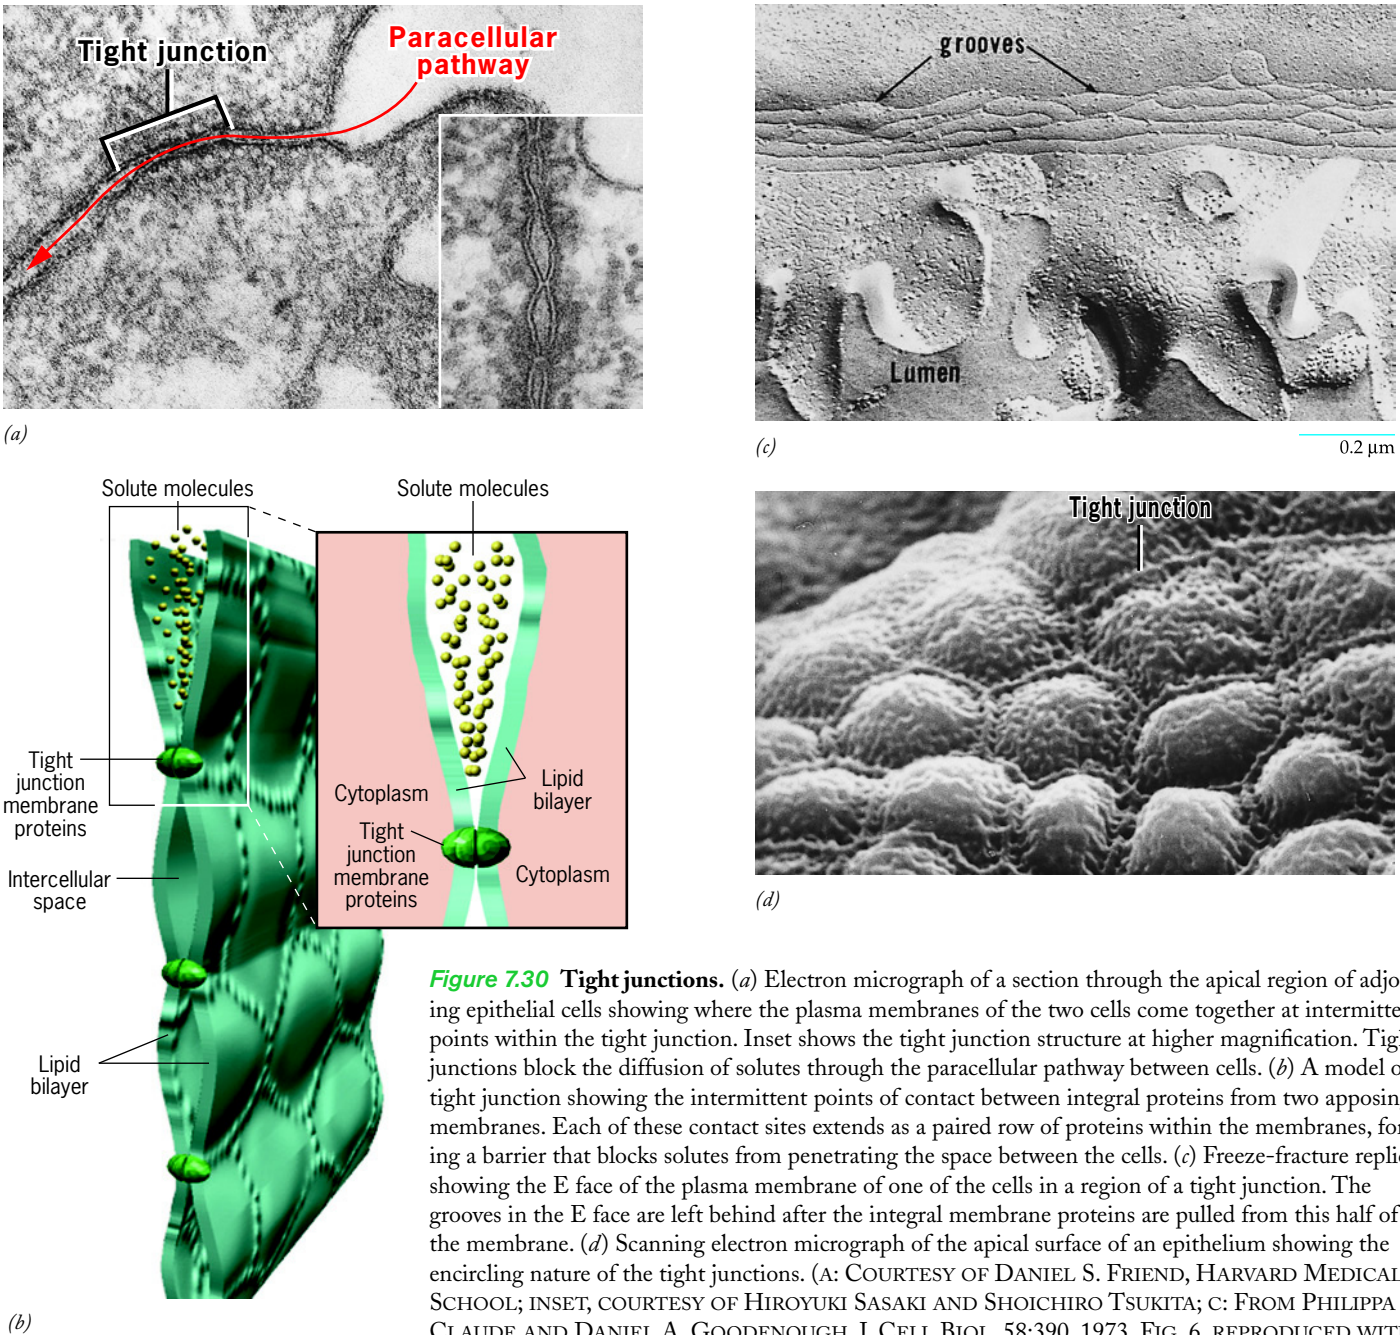

Figure 7.30 Tight junctions. (a) Electron micrograph of a section through the apical region of adjoining epithelial cells showing where the plasma membranes of the two cells come together at intermittent points within the tight junction. Inset shows the tight junction structure at higher magnification. Tight junctions block the diffusion of solutes through the paracellular pathway between cells. (b) A model of a tight junction showing the intermittent points of contact between integral proteins from two apposing membranes. Each of these contact sites extends as a paired row of proteins within the membranes, forming a barrier that blocks solutes from penetrating the space between the cells. (c) Freeze-fracture replica showing the E face of the plasma membrane of one of the cells in a region of a tight junction. The grooves in the E face are left behind after the integral membrane proteins are pulled from this half of the membrane. (d) Scanning electron micrograph of the apical surface of an epithelium showing the encircling nature of the tight junctions. (A: COURTESY OF DANIEL S. FRIEND, HARVARD MEDICAL SCHOOL; INSET, COURTESY OF HIROYUKI SASAKI AND SHOICHIRO TSUKITA; C: FROM PHILIPPA CLAUDE AND DANIEL A. GOODENOUGH, *J. CELL BIOL.* 58:390, 1973, FIG. 6. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS; D: COURTESY OF D. TARIN.)

opposite face of a fractured membrane) correspond to paired rows of aligned integral membrane proteins that are illustrated in the inset of Figure 7.30b. The integral proteins of TJs form continuous fibrils that completely encircle the cell like a gasket and make contact with neighboring cells on all sides (Figure 7.30d). As a result, TJs serve as a barrier to the free diffusion of water and solutes from the extracellular compartment on one side of an epithelial sheet to that on the other side. Tight junctions also serve as “fences” that help maintain the polarized character of epithelial cells (see Figure 4.30). They accomplish this by blocking the diffusion of integral proteins between the apical domain of the plasma membrane

and its lateral and basal domains. Like other sites of cell adhesion, tight junctions are also involved in signaling pathways that regulate numerous cellular processes.

Not all TJs exhibit the same permeability properties. Part of the explanation can be seen under the electron microscope: TJs with several parallel strands (such as that in Figure 7.30c) tend to form better seals than junctions with only one or a couple of strands. But there is more to the story than numbers of strands. Some TJs are permeable to *specific* ions or solutes to which other TJs are impermeable. Studies over the past decade have shed considerable light on the molecular basis of TJ permeability.

Up until 1998 it was thought that TJ strands were composed of a single protein, *occludin*. Then, it was found that cultured cells that lacked a gene for occludin, and thus could not produce the protein, were still able to form TJ strands of normal structure and function. Subsequent studies by Shoichiro Tsukita and his colleagues at the University of Kyoto led to the discovery of a family of proteins called *claudins* that form the major structural component of TJ strands. The electron micrograph of Figure 7.31 shows that occludin and claudin are present together within the linear fibrils of a TJ. At least 24 different claudins have been identified, and differences in the distribution of these proteins may explain selective differences in TJ permeability. For example, one small region of a human kidney tubule—a region known as the thick ascending limb (or TAL)—has TJs that are permeable to magnesium (Mg^{2+}) ions. It is thought that the loops of the claudin molecules that extend into the extracellular space form pores in the TAL that are selectively permeable to Mg^{2+} ions. Support for this concept has come from the finding that one specific member of the claudin family, claudin-16, is expressed primarily in the TAL. The importance of claudin-16 in kidney function was revealed in studies of patients suffering from a rare disease characterized by abnormally low Mg^{2+} levels in their blood. These patients were found to have mutations in both copies of their *claudin-16* gene. The Mg^{2+} level in their blood is low because tight junctions containing the abnormal claudin are impermeable to Mg^{2+} . As a result, this important ion fails to be reabsorbed from the tubule and is simply excreted in the urine.

Another important function of tight junctions came to light in 2002. It was thought for decades that the impermeability of mammalian skin to water was solely a property of

Figure 7.31 The molecular composition of tight junction strands. Electron micrograph of a freeze-fracture replica of cells that had been joined to one another by tight junctions. The fracture faces were incubated with two types of gold-labeled antibodies. The smaller gold particles (arrowheads) reveal the presence of claudin molecules, whereas the larger gold particles (arrows) indicate the presence of occludin. These experiments demonstrate that both proteins are present in the same tight junction strands. Bar equals 0.15 μm . The inset shows a possible arrangement of the two integral membrane proteins as they make contact in the intercellular space. Both the claudins (red) and occludin (brown) span the membrane four times. (MICROGRAPH FROM MIKIO FURUSE, HIROYUKI SASAKI, KAZUSHI FUJIMOTO, AND SHOICHIRO TSUKITA, *J. CELL BIOLOGY* 143:398, 1998, FIG. 6; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

the outer, cornified layer of the skin (see Figure 7.1), which contains tightly packed protein filaments and associated lipids. It was discovered, however, that mice lacking a gene for claudin-1 died shortly after birth as a result of dehydration. Further investigation revealed that the cells in one of the outer layers of *normal* epidermis are connected to one another by tight junctions. Animals lacking the gene for claudin-1 were unable to assemble watertight epidermal tight junctions and, as a result, suffered from uncontrolled water loss.

Tight junctions are also present between the endothelial cells that line the walls of capillaries. These junctions are particularly evident in the brain where they help form the *blood–brain barrier*, which prevents substances from passing from the bloodstream into the brain. Although small ions and even water molecules may not be able to penetrate the blood–brain barrier, cells of the immune system are able to pass across the endothelium through these junctions. These cells are thought to send a signal that opens the junction, allowing the cells to pass. While protecting the brain from unwanted solutes, the blood–brain barrier also prevents access of many drugs to the central nervous system. Consequently, a major goal of the pharmaceutical industry is to develop drugs that temporarily open the tight junctions of the brain to allow passage of therapeutic compounds.

REVIEW

1. What does freeze-fracture analysis tell you about the structure of a junction that can't be learned from examination of stained tissue sections?
2. How does the structure of a tight junction contribute to its function?

7.5 | Gap Junctions and Plasmodesmata: Mediating Intercellular Communication

Gap junctions are sites between animal cells that are specialized for intercellular communication. Electron micrographs reveal gap junctions to be sites where the plasma membranes of adjacent cells come very close to one another (within about 3 nm) but do not make direct contact. Instead, the cleft between the cells is spanned by very fine strands (Figure 7.32a) that are actually molecular “pipelines” that pass through the adjoining plasma membranes and open into the cytoplasm of the adjoining cells (Figure 7.32b).

Gap junctions have a simple molecular composition; they are composed entirely of an integral membrane protein called *connexin*. Connexins are organized into multisubunit complexes, called **connexons**, that completely span the membrane (Figure 7.32b). Each connexon is composed of six connexin subunits arranged in a ring around a central opening, or *annulus*, that is approximately 1.5 nm in diameter at its extracellular surface (Figure 7.32c, left).

During the formation of gap junctions, the connexons in the plasma membranes of apposing cells become tightly linked to one another through extensive noncovalent interac-

tions of the extracellular domains of the connexin subunits. Once aligned, connexons in apposing plasma membranes form complete intercellular channels connecting the cytoplasm of one cell with the cytoplasm of its neighbor (Figure 7.32*b*). Large numbers of connexons become clustered in specific regions of the membrane, forming gap-junction plaques that can be visualized when the membrane is split down the middle by freeze fracture (Figure 7.32*d*).

As discussed in the Experimental Pathways (see www.wiley.com/college/karp), gap junctions are sites of communication between the cytoplasms of adjacent cells. The existence of gap-junction intercellular communication (GJIC) is revealed through the passage of either ionic currents or low-molecular-weight dyes, such as fluorescein, from one cell to its neighbors (Figure 7.33). Mammalian gap junctions allow the diffusion

of molecules having a molecular mass below approximately 1000 daltons. In contrast to the highly selective ion channels that connect a cell to the external medium (page 153), gap-junction channels are relatively nonselective. Just as ion channels can be open or closed, gap-junction channels are also gated. Channel closure is probably triggered primarily by phosphorylation of connexin subunits. Closure can also be triggered by changes in voltage across the junction or abnormally high cytosolic Ca^{2+} concentrations (Figure 7.32*c*, right).

We saw in Chapter 4 how skeletal muscle cells are stimulated by chemicals released from the tips of nearby nerve cells. Stimulation of a cardiac or smooth muscle cell occurs by a very different process, one involving gap junctions. The contraction of the mammalian heart is stimulated by an electrical impulse generated in a small region of specialized heart muscle called the *sinoatrial node*, which acts as the heart's pacemaker. The impulse spreads rapidly as a current of ions flows through gap junctions from one cardiac muscle cell to its neighbors, causing the cells to contract in synchrony. Similarly, the flow of ions through gap

junctions that interconnect smooth muscle cells in the wall of the esophagus or intestine leads to the generation of coordinated peristaltic waves that move down the length of the wall.²

Gap junctions can put a large number of cells of a tissue into intimate cytoplasmic contact. This has important physiologic consequences because a number of highly active regulatory substances, such as cyclic AMP and inositol phosphates (Chapter 15), are small enough to fit through gap-junction channels. As a result, gap junctions have the potential to integrate the activities of individual cells of a tissue into a functional unit. If, for example, only a few cells near a particular blood vessel happen to be stimulated by a hormone, the stimulus can be rapidly transmitted to all cells of the tissue. Gap junctions also allow cells to cooperate metabolically by sharing key metabolites, such as ATP, sugar phosphates, amino acids, and many coenzymes, which are small enough to pass through these intercellular channels. This is particularly important in tissues such as the lens, which are avascular (i.e., lack blood vessels).

Connexins (Cx), the proteins of which gap junctions are constructed, are members of a multigene family. Approximately 20 different connexins with distinct tissue-specific distributions have been identified. Connexons composed of different connexins exhibit marked differences in conductance, permeability, and regulation. In some cases, connexons in neighboring cells that are composed of different connexins

²As discussed in the Experimental Pathways on the Web, gap junctions also occur between the presynaptic and postsynaptic membranes of adjacent nerve cells in certain parts of the brain, allowing nerve impulses to be transmitted directly from one neuron to another without requiring the release of chemical transmitters.

are able to dock and form functional channels, whereas in other cases, they are not. These compatibility differences may play important roles in either promoting or preventing communication between different types of cells in an organ. For example, connexons joining cardiac muscle cells are composed of the connexin Cx43, whereas connexons joining the cells that make up the heart's electrical conduction system are composed of Cx40. Because these two connexins form incompatible connexons, the two types of cells are electrically insulated from one another even though they are in physical contact. A number of inherited disorders have been associated with mutations in genes encoding connexins. Consequences of these disorders include deafness, blindness, cardiac arrhythmias, skin abnormalities, or nerve degeneration.

Over the past few years a new type of communication system has been discovered that consists of thin, highly elongated tubules capable of conducting cell-surface proteins, cytoplasmic vesicles, and calcium signals from one cell to another over long distances. They can also transmit infectious viral particles and prions between cells. To date, these *tunneling nanotubes*, as they are called, have been studied primarily in cultured cells (as in Figure 7.34), so it remains to be seen whether they have a significant physiological role within the body.

Figure 7.34 Tunneling nanotubes. Scanning electron micrograph showing two cultured neuroendocrine cells connected to one another by a thin tubular process capable of carrying materials between the cytoplasm of the neighboring cells. These processes, which are only about 100 nm in diameter, are supported by an internal actin "skeleton." The inset shows a number of fluorescently labeled vesicles caught in the act of movement between two cells. Plasmodesmata

Unlike animals, whose cells make intimate contact with one another, plant cells are separated from one another by a substantial barrier—the cell wall. It is not surprising, therefore, that plants lack the cell-adhesion molecules we have been discussing in this chapter. Although plants lack the specialized junctions found in animal tissues, most plant cells are connected to one another by plasmodesmata. **Plasmodesmata** (singular, **plasmodesma**) are cytoplasmic channels that pass through the cell walls of adjacent cells. A simple (i.e., unbranched) plasmodesma is shown in Figure 7.35a,b. Plasmodesmata are lined by plasma membrane and usually contain a dense central structure, the *desmotubule*, derived from the smooth endoplasmic reticulum of the two cells. Like gap junctions between animal cells, plasmodesmata serve as sites of cell-to-cell communication, as substances pass through the annulus surrounding the desmotubule.

It was thought for many years that plasmodesmata were impermeable to molecules greater than about 1000 daltons (1 kDa). This conclusion was based on studies in which different-sized fluorescent dyes were injected into cells. More recent studies suggest that plasmodesmata allow much larger molecules (up to 50 kDa) to pass between cells, owing to the fact that the plasmodesmatal pore is capable of dilation. The first insight

into this dynamic property was gained from studies in the 1980s on plant viruses that spread from one cell to another through plasmodesmata. It was found that the viruses encoded a *movement protein* that interacted with the wall of the plasmodesmata and increased the diameter of the pore. Subsequent studies revealed that plant cells produce their own movement proteins that regulate the flow of proteins and RNAs from cell to cell. Some of these macromolecules find their way into the vascular system of the plant, where they integrate plant-wide activities, such as the growth of new leaves and flowers or defense against pathogens. Figure 7.35c documents the movement of a protein (labeled with green fluorescence) from one type of plant tissue (the stele), where it was synthesized, to an

adjoining tissue (the endodermis). The protein is seen to be concentrated in the spherical nuclei of the single layer of endodermal cells where it acts to stimulate gene transcription.

REVIEW

1. Compare the arrangement of integral membrane proteins in a tight junction versus a gap junction.
2. How are plasmodesmata and gap junctions similar? How are they dissimilar? Would you expect a moderately sized protein to pass through a plasmodesma?

7.6 | Cell Walls

Because a lipid–protein plasma membrane of less than 10-nm thickness can be expected to offer only minimal protection for a cell’s contents, it is not surprising that “naked” cells are extremely fragile structures. The cells of nearly all organisms

other than animals are enclosed in a protective outer envelope. Protozoa have a thickened outer coat, whereas bacteria, fungi, and plants have distinct **cell walls**. We will restrict our discussion to the cell walls of plants, which were the first cellular structures to be observed with a light microscope (page 2).

Plant cell walls perform numerous vital functions. As discussed on page 150, plant cells develop turgor pressure that pushes against their surrounding wall. As a result, the wall gives the enclosed cell its characteristic polyhedral shape (Figure 7.36*a*). In addition to providing support for individual cells, cell walls serve collectively as a type of “skeleton” for the entire plant. In fact, a tree without cell walls might resemble, in many respects, a human without bones. Cell walls also protect the cell against damage from mechanical abrasion and pathogens, and they mediate cell–cell interactions. Like the ECM at the surface of an animal cell, a plant cell wall is a source of signals that alter the activities of the cells that it contacts.

Plant cell walls are often likened to fabricated materials such as reinforced concrete or fiberglass because they contain a fibrous element embedded in a nonfibrous, gel-like matrix. Cellulose, whose structure was described on page 47, provides the fibrous component of the cell wall, and proteins and pectin (described below) provide the matrix. Cellulose molecules are organized into rod-like **microfibrils** (Figure 7.36*b,c*) that confer rigidity on the cell wall and provide resistance to tensile (pulling) forces. Each microfibril is about 5 nm in diameter and is typically composed of bundles of 36 cellulose molecules oriented parallel to one another and held together by hydrogen

CELL SCI. 96:329, 1990; REPRODUCED BY PERMISSION OF THE COMPANY OF BIOLOGISTS, LTD. <http://jcs.biologists.org/content/96/2/323.full.pdf+html?sid=f1c1d0cf-55bf-4050-b9bb-af46eae08b0f>)

(c)

bonds. The walls of many plant cells are composed of layers in which the microfibrils of one layer are oriented at approximately 90° to those of adjacent layers (Figure 7.36*b*).

Cellulose molecules are polymerized at the cell surface. Glucose subunits are added to the end of a growing cellulose

molecule by a multisubunit enzyme called *cellulose synthase*. The subunits of the enzyme are organized into a six-membered ring, or rosette, which is embedded within the plasma membrane (Figure 7.37*a,b*). In contrast, materials of the matrix are synthesized within the cytoplasm (Figure 7.37*c*) and

FIGURE IN FOCUS

(c)

carried to the cell surface in secretory vesicles. The matrix is highly complex, requiring hundreds of enzymes for its synthesis and degradation. The matrix of the cell wall is composed of three types of macromolecules (Figure 7.36c):

1. **Hemicelluloses** are branched polysaccharides whose backbone consists of one sugar, such as glucose, and side chains of other sugars, such as xylose. Hemicellulose molecules bind to the surfaces of cellulose microfibrils, cross-linking them into a resilient structural network.
2. **Pectins** are a heterogeneous class of negatively charged polysaccharides containing galacturonic acid. Like the glycosaminoglycans of animal cell matrices, pectins hold water and thus form an extensive hydrated gel that fills in the spaces between the fibrous elements. When a plant is attacked by pathogens, fragments of pectins released from the wall trigger a defensive response by the plant cell. Purified pectin is used commercially to provide the gel-like consistency of jams and jellies.
3. **Proteins**, whose functions are not well understood, mediate dynamic activities. One class, the *expansins*, facilitate cell growth. These proteins cause localized relaxation of the cell wall, which allows the cell to elongate at that site in response to the turgor pressure generated within the cell. Cell wall-associated protein kinases span the plasma membrane and are thought to transmit signals from the cell wall to the cytoplasm.

The percentages of these various materials in cell walls are highly variable, depending on the type of plant, the type of cell, and the

Synopsis

The extracellular space extends outward from the outer surface of the plasma membrane and contains a variety of secreted materials that influence cell behavior. Epithelial tissues rest on a basement membrane, which consists of a thin, interwoven network of extracellular materials. Various types of connective tissue, including tendons, cartilage, and the corneal stroma, contain an expansive extracellular matrix that gives the tissue its characteristic properties. (p. 235)

The major components of extracellular matrices include collagens, proteoglycans, and a variety of proteins, such as fibronectin, and laminin. Each of the proteins of the ECM contains binding sites for one another and for receptors on the cell surface. As a result, these various extracellular materials interact to form an interconnected network that is bound to the cell surface. Collagens are highly abundant, fibrous proteins that give the extracellular matrix the capability to resist pulling forces. Proteoglycans consist of protein and glycosaminoglycans and serve as an amorphous packing material that fills the extracellular space. (p. 236)

Integrins are cell-surface receptors that mediate interactions between cells and their substratum. Integrins are heterodimeric integral membrane proteins whose cytoplasmic domains interact with cytoskeletal components, and whose extracellular domains contain binding sites for various extracellular materials. Internal changes within a cell can send “inside-out” signals that activate the ligand-binding activity of integrins. This activation is associated with a dramatic change in structure of the integrin from a bent to an upright conformation. Con-

versely, binding of an extracellular ligand to an integrin may send “outside-in” signals that initiate changes in cellular activities. (p. 244)

Cells attach to their substratum by means of cell-surface specializations such as focal adhesions and hemidesmosomes. Focal adhesions are sites of attachment where the plasma membrane contains clusters of integrins linked to actin-containing microfilaments of the cytoskeleton. Hemidesmosomes are sites of attachment where the plasma membrane contains clusters of integrins that are connected to the basement membrane on their outer surface and indirectly to keratin-containing intermediate filaments on their inner surface. Both types of adhesions are also sites of potential cell signaling. (p. 247)

The adhesion of cells to other cells is mediated by several distinct families of integral membrane proteins, including selectins, integrins, cadherins, and members of the immunoglobulin superfamily (IgSF). Selectins bind to specific arrangements of carbohydrate groups projecting from the surfaces of other cells and mediate calcium-dependent, transient interactions between circulating leukocytes and the walls of blood vessels at sites of inflammation and clotting. Cell-adhesion molecules of the Ig superfamily mediate calcium-independent cell-cell adhesion. An IgSF protein on one cell may interact with an integrin or with the same or a different IgSF protein projecting from another cell. Cadherins mediate calcium-dependent cell-cell adhesion by binding to the same cadherin species on the opposing cell, thereby facilitating the formation of tissues composed of similar types of cells. (p. 250)

REVIEW

1. Describe the components that make up a plant cell wall and the role of each in the wall's structure and function.
2. Distinguish between cellulose and hemicellulose, a cellulose molecule and a microfibril, a primary cell wall and a secondary cell wall.

Strong adhesions between cells are facilitated by the formation of specialized adherens junctions and desmosomes. Adherens junctions encircle a cell near its apical surface, allowing contact between the cell and all of its immediate neighbors. The plasma membranes of adherens junctions contain clusters of cadherins that are linked by means of intermediary proteins to the actin filaments of the cytoskeleton. Desmosomes occur as patches between cells and are characterized by dense cytoplasmic plaques on the inner surfaces of the membranes. Desmosomes are sites of concentration of cadherins, which are connected by means of intermediary proteins with intermediate filaments that loop through the cytoplasmic plaques. (p. 257)

Tight junctions are specialized sites of contact that block solutes from diffusing between the cells in an epithelium. A cross section through a tight junction shows the outer surfaces of adjacent cells come into direct contact at intermittent sites. Examination of the membranes by freeze fracture shows the sites to contain rows of aligned particles that form strands within the plasma membranes of the adjacent cells. (p. 260)

Gap junctions and plasmodesmata are specialized sites of communication between adjoining cells in animals and plants, respectively. The plasma membranes of a gap junction contain channels formed by a hexagonal array of connexin subunits forming a con-

nexon. These channels connect the cytoplasm of one cell with the cytoplasm of the adjoining cell. The central channel of a connexon allows the direct diffusion of substances up to about 1000 daltons between cells. The passage of ionic currents through gap junctions plays a pivotal role in numerous physiologic processes, including the spread of excitation through the cardiac muscle tissue of the heart. Plasmodesmata are cylindrical cytoplasmic channels that extend between adjacent plant cells directly through the intervening cell wall. These channels normally allow the free passage of solute molecules of approximately 1000 daltons, but they can be dilated by specific proteins to allow passage of macromolecules. (p. 262)

Plant cells are surrounded by a complex cell wall composed of cellulose and a variety of secreted materials that provide mechanical support and protect the cell from potentially damaging influences. Cellulose microfibrils, which are composed of bundles of cellulose molecules that are constructed by enzymes residing within the plasma membrane, provide rigidity and tensile strength. Hemicellulose molecules cross-link the cellulose fibers, whereas pectins form an extensively cross-linked gel that fills the spaces between the fibrous elements of the cell wall. Like the extracellular matrices of animal cells, plant cell walls are dynamic structures that can be modified in response to changing environmental conditions. (p. 266)

Analytic Questions

- Cell adhesion can often be blocked *in vitro* by treating cells with specific agents. Which of the following substances would be expected to interfere with cell adhesion mediated by selectins? with cell adhesion mediated by L1 molecules? The substances are trypsin, which digests proteins; a peptide containing RGD; neuraminidase, which removes sialic acid from an oligosaccharide; collagenase, which digests collagen; hyaluronidase, which digests hyaluronic acid; EGTA, which binds Ca^{2+} ions in the medium.
- What substance might you add to a culture dish to block the migration of neural crest cells? to block the adhesion of fibroblasts to the substratum?
- Mice lacking a gene for fibronectin do not survive early embryonic development. Name two processes that might be disrupted in such embryos.
- Suppose you found that molecule A, which had a molecular mass of 1500 daltons, was able to penetrate the channels of a gap junction, but molecule B, whose molecular mass was only 1200 daltons, was unable to diffuse between the same cells. How might these molecules be different so as to explain these results?
- In what ways are the extracellular matrices of animals and the cell walls of plants similar in construction?
- It was noted that two different autoimmune diseases, one producing antibodies against a component of hemidesmosomes and the other producing antibodies against a component of desmosomes, both cause severe blistering of the skin. Why do you think these two conditions have such similar symptoms?
- Which of the various types of molecules that mediate cell adhesion is most likely to be responsible for the type of sorting out demonstrated by the cells of Figure 7.20? Why? How could you test your conclusion?
- Follicle-stimulating hormone (FSH) is a pituitary hormone that acts on the follicle cells of the ovary to trigger the synthesis of cyclic AMP, which stimulates various metabolic changes. FSH normally has no effect on cardiac muscle cells. However, when ovarian follicle cells and cardiac muscle cells are grown together in a mixed culture, a number of the cardiac muscle cells are seen to contract following addition of FSH to the medium. How might this observation be explained?
- Why do you think animal cells are able to survive without the types of cell walls that are found in nearly every other group of organisms?
- Why would lowering the temperature of the medium in which cells were growing be expected to affect the ability of the cells to form gap junctions with one another?
- Certain of the cell junctions occur as encircling belts, while others occur as discrete patches. How do these two types of structural arrangements correlate with the functions of the respective junctions?
- Propose some mechanism that might explain how tobacco mosaic virus was able to alter the permeability of a plasmodesma. How might you be able to test your proposal?
- One type of vertebrate cell that is thought to lack integrins is the erythrocyte (red blood cell). Does this surprise you? Why or why not?

Under the light microscope, the cytoplasm of living cells appears relatively devoid of structure. Yet, even before the beginning of the twentieth century, examination of stained sections of animal tissues hinted at the existence of an extensive membrane network within the cytoplasm. It wasn't until the development of the electron microscope in the 1940s, however, that biologists began to appreciate the diverse array of membrane-bound structures present in the cytoplasm of most eukaryotic cells. These early electron microscopists saw membrane-bound vesicles of varying diameter containing material of different electron density; long channels bounded by membranes that radiate through the cytoplasm to form an interconnected network of canals; and stacks of flattened membrane-bound sacs, called *cisternae*.

It became evident from these early electron microscopic studies and the biochemical investigations that followed that the cytoplasm of eukaryotic cells was subdivided into a variety of distinct compartments bounded by membrane barriers. As more types of cells were examined, it became apparent that these membranous compartments in the cytoplasm formed different organelles that could be identified in diverse cells from yeast to multicellular plants and animals. The extent to which the

Colorized scanning electron micrograph of a human neutrophil, a type of white blood cell, ingesting a number of bacteria by the process of phagocytosis. Neutrophils are essential components of our innate immune response against pathogens. (FROM SCOTT D. KOBAYASHI ET AL., COVER OF PNAS, VOL. 100, #19, 2003, © 2003, NATIONAL ACADEMY OF SCIENCES, U.S.A., COURTESY OF FRANK R. DELEO.)

cytoplasm of a eukaryotic cell is occupied by membranous structures is illustrated in the electron micrograph of a maize root cell shown in Figure 8.1. As we will see in the following pages, each of these organelles contains a particular complement of proteins and is specialized for particular types of activities. Thus, just as a house or restaurant is divided into specialized rooms where different activities can take place independent of one another, the cytoplasm of a cell is divided into specialized membranous compartments for analogous reasons. Keep in mind, as you examine the micrographs in this chapter, that these cytoplasmic organelles may appear as stable structures, like the rooms of a house or restaurant, but in fact they are dynamic compartments that are in continual flux.

In the present chapter, we will examine the structure and functions of the endoplasmic reticulum, Golgi complex, endosomes, lysosomes, and vacuoles. Taken together, these organelles form an **endomembrane system** in which the individual components function as part of a coordinated unit. (Mitochondria and chloroplasts are not part of this interconnected system and were the subjects of Chapters 5 and 6. Current evidence suggests that peroxisomes, which were also discussed in Chapter 6, have a dual origin. The basic elements of the boundary membrane are thought to arise from the endoplasmic reticulum, but many of the membrane proteins and the soluble internal proteins are taken up from the cytosol, as described in Section 8.9.)

Figure 8.1 Membrane-bound compartments of the cytoplasm. The cytoplasm of this root cap cell of a maize plant contains an array of membrane-bound organelles whose structure and function will be examined in this chapter. As is evident in this micrograph, the combined surface area of the cytoplasmic membranes is many times greater than that of the surrounding plasma membrane. (COURTESY OF HILTON H. MOLLENHAUER.)

8.1 | An Overview of the Endomembrane System

The organelles of the endomembrane system are part of a dynamic, integrated network in which materials are shuttled back and forth from one part of the cell to another. For the most part, materials are shuttled between organelles—from the Golgi complex to the plasma membrane, for example—in small, membrane-bounded **transport vesicles** that bud from a donor membrane compartment (Figure 8.2a).¹ Transport vesicles move through the cytoplasm in a directed manner, often pulled by motor proteins that operate on tracks formed by microtubules and microfilaments of the cytoskeleton (see Figure 9.1a). When they reach their destination, the vesicles fuse with the membrane of the acceptor compartment, which receives the vesicle's soluble cargo as well as its membranous wrapper (Figure 8.2a). Repeated cycles of budding and fusion shuttle a diverse array of materials along numerous pathways that traverse the cell.

Several distinct pathways through the cytoplasm have been identified and are illustrated in the overview shown in Figure 8.2b. A **biosynthetic pathway** can be discerned in

which proteins are synthesized in the endoplasmic reticulum, modified during passage through the Golgi complex, and transported from the Golgi complex to various destinations, such as the plasma membrane, a lysosome, or the large vacuole of a plant cell. This route is also referred to as the **secretory pathway**, as many of the proteins synthesized in the endoplasmic reticulum (as well as complex polysaccharides synthesized in the Golgi complex, Figure 7.37c) are destined to be discharged (**secreted**) from the cell. Secretory activities of cells can be divided into two types: constitutive and regulated (Figure 8.2b). During **constitutive secretion**, materials are transported in secretory vesicles from their sites of synthesis and discharged into the extracellular space in a continual manner. Most cells engage in constitutive secretion, a process that contributes not only to the formation of the extracellular matrix (Section 7.1), but to the formation of the plasma membrane itself. During **regulated secretion**, materials are stored as membrane-bound packages and discharged only in response to an appropriate stimulus. Regulated secretion occurs, for example, in endocrine cells that release hormones, in pancreatic acinar cells that release digestive enzymes, and in nerve cells that release neurotransmitters. In some of these cells, materials to be secreted are stored in large, densely packed, membrane-bound **secretory granules** (see Figure 8.3).

Proteins, lipids, and complex polysaccharides are transported through the cell along the biosynthetic or secretory pathway. We will focus in the first part of the chapter on the

¹The term *vesicle* implies a spherical-shaped carrier. Cargo may also be transported in irregular or tubular-shaped membrane-bound carriers. For the sake of simplicity, we will generally refer to carriers as “vesicles,” while keeping in mind they are not always spherical.

(a)

Figure 8.2 An overview of the biosynthetic/secretory and endocytic pathways that unite endomembranes into a dynamic, interconnected network. (a) Schematic diagram illustrating the process of vesicle transport by which materials are transported from a donor compartment to a recipient compartment. Vesicles form by membrane budding, during which specific membrane proteins (green spheres) of the donor membrane are incorporated into the vesicle membrane and specific soluble proteins (purple spheres) in the donor compartment are bound to specific receptors. When the transport vesicle subsequently fuses to another membrane, the proteins of the vesicle membrane become part of the recipient membrane, and the soluble proteins become sequestered within the lumen of the recipient compartment. (b) Materials follow the biosynthetic (or secretory) pathway from the endoplasmic reticulum, through the Golgi complex, and out to various locations including lysosomes, endosomes, secretory vesicles, secretory granules, vacuoles, and the plasma membrane. Materials follow the endocytic pathway from the cell surface to the interior by way of endosomes and lysosomes, where they are generally degraded by lysosomal enzymes.

(b)

synthesis and transport of proteins, as summarized in Figure 8.2b. During the discussion, we will consider several distinct classes of proteins. These include soluble proteins that are discharged from the cell, integral proteins of the various membranes depicted in Figure 8.2b, and soluble proteins that reside within the various compartments enclosed by the endomembranes (e.g., lysosomal enzymes). Whereas materials move out of the cell by the secretory pathway, the endocytic pathway operates in the opposite direction. By following the **endocytic pathway**, materials move from the outer surface of the cell to compartments, such as endosomes and lysosomes, located within the cytoplasm (Figure 8.2b).

The movement of vesicles and their contents along the various pathways of a cell is analogous to the movement of trucks carrying different types of cargo along the various highways of a city. Both types of transport require defined *traffic patterns* to ensure that materials are accurately delivered to the appropriate sites. For example, protein trafficking within a salivary gland cell requires that the proteins of salivary mucus, which are synthesized in the endoplasmic reticulum, are specifically *targeted* to secretory granules, while

lysosomal enzymes, which are also manufactured in the endoplasmic reticulum, are specifically targeted to a lysosome. Different organelles also contain different integral membrane proteins. Consequently, membrane proteins must also be targeted to particular organelles, such as a lysosome or Golgi cisterna. These various types of cargo—secreted proteins, lysosomal enzymes, and membrane proteins—are routed to their appropriate cellular destinations by virtue of specific “addresses” or *sorting signals* that are encoded in the amino acid sequence of the proteins or in the attached oligosaccharides. The sorting signals are recognized by specific receptors that reside in the membranes or surface coats of budding vesicles, ensuring that the protein is transported to the appropriate destination. For the most part, the machinery responsible for driving this complex distribution system consists of soluble proteins that are *recruited* to specific membrane surfaces. During the course of this chapter we will try to understand why one protein is recruited, for example, to the endoplasmic

reticulum whereas another protein might be recruited to a particular region of the Golgi complex.

Great advances have been made over the past three decades in mapping the traffic patterns that exist in eukaryotic cells, identifying the specific addresses and receptors that govern the flow of traffic, and dissecting the machinery that ensures that materials are delivered to the appropriate sites in the cell. These subjects will be discussed in detail in the following pages. Motor proteins and cytoskeletal elements, which play key roles in the movements of transport vesicles and other endomembranes, will be described in the following chapter. We will begin the study of endomembranes by discussing a few of the most important experimental approaches that have led to our current understanding of the subject.

REVIEW

1. Compare and contrast the biosynthetic pathway with the endocytic pathway.
2. How are particular proteins targeted to particular sub-cellular compartments?

8.2 | A Few Approaches to the Study of Endomembranes

Early studies with the electron microscope provided biologists with a detailed portrait of the structure of cells but gave them little insight into the functions of the components they were observing. Determining the functions of cytoplasmic organelles required the development of new techniques and the execution of innovative experiments. The experimental approaches described in the following sections have proven particularly useful in providing the foundation of knowledge on which current research on cytoplasmic organelles is based.

Insights Gained from Autoradiography

Among the many cells in the body, the acinar cells of the pancreas have a particularly extensive endomembrane system. These cells function primarily in the synthesis and secretion of digestive enzymes. After secretion from the pancreas, these enzymes are shipped through ducts to the small intestine, where they degrade ingested food matter. Where within the pancreatic acinar cells are the secretory proteins synthesized, and how do they reach the surface of the cells where they are discharged? These questions are inherently difficult to answer because all of the steps in the process of secretion occur simultaneously within the cell. To follow the steps of a single cycle from start to finish, that is, from the synthesis of a secretory protein to its discharge from the cell, James Jamieson and George Palade of Rockefeller University utilized the technique of **autoradiography** (Section 18.4).

Autoradiography provides a means to visualize biochemical processes by allowing an investigator to determine the location of radioactively labeled materials within a cell. In this technique, tissue sections containing radioactive isotopes are

covered with a thin layer of photographic emulsion, which is exposed by radiation emanating from radioisotopes within the tissue. Sites in the cells containing radioactivity are revealed under the microscope by silver grains in the overlying emulsion (Figure 8.3).

To determine the sites where secretory proteins are synthesized, Palade and Jamieson incubated slices of pancreatic tissue in a solution containing radioactive amino acids for a brief period of time. During this period, labeled amino acids were taken up by the living cells and incorporated into the digestive enzymes as they were being synthesized on ribosomes. The tissues were quickly fixed, and the locations of proteins that had been synthesized during the brief incubation with labeled amino acids were determined autoradiographically. Using this approach, the endoplasmic reticulum was discovered to be the site of synthesis of secretory proteins (Figure 8.3a).

To determine the intracellular path followed by secretory proteins from their site of synthesis to their site of discharge, Palade and Jamieson carried out an additional experiment. After incubating the tissue for a brief period in radioactive amino acids, they washed the tissue free of excess isotope and transferred the tissue to a medium containing only unlabeled amino acids. An experiment of this type is called a “*pulse-chase*.” The *pulse* refers to the brief incubation with radioactivity during which labeled amino acids are incorporated into protein. The *chase* refers to the period when the tissue is exposed to the unlabeled medium, a period during which additional proteins are synthesized using nonradioactive amino acids. The longer the chase, the farther the radioactive proteins manufactured during the pulse will have traveled from their site of synthesis within the cell. Using this approach, one can ideally follow the movements of newly synthesized molecules by observing a wave of radioactive material moving through the cytoplasmic organelles of cells from one location to the next until the process is complete. The results of these experiments—which first defined the biosynthetic (or secretory) pathway and tied a number of seemingly separate membranous compartments into an integrated functional unit—are summarized in Figure 8.3b–d.

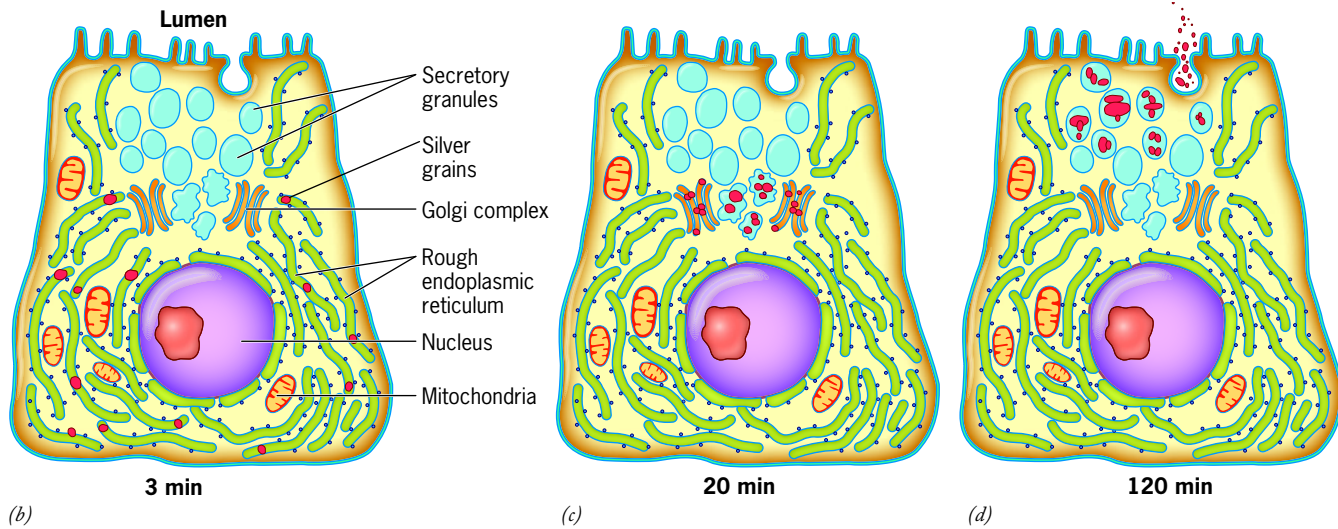

Insights Gained from the Use of the Green Fluorescent Protein

The autoradiographic experiments described in the previous section require investigators to examine thin sections of different cells that have been fixed at various times after introduction of a radioactive label. Techniques involving the use of radioactive isotopes have largely been abandoned by modern cell biologists. An alternative technology allows researchers to follow the dynamic movements of specific proteins with their own eyes as they occur within a single living cell. This technology utilizes a gene isolated from a jellyfish that encodes a small protein, called the **green fluorescent protein (GFP)**, which emits a green fluorescent light. In this approach, DNA encoding GFP is fused to DNA encoding the protein to be studied, and the resulting chimeric (i.e., composite) DNA is introduced into cells that can be observed under the microscope. Once inside a cell, the chimeric DNA expresses a

chimeric protein consisting of GFP fused to the end of the protein to be studied. In most cases, the presence of GFP joined to the end of a protein has little or no effect on the movement or function of that protein.

Figure 8.4 shows a pair of micrographs depicting cells that contain a GFP fusion protein. In this case, the cells were infected with a strain of the vesicular stomatitis virus (VSV) in which one of the viral genes (*VSVG*) is fused to the *GFP* gene. Viruses are useful in these types of studies because they turn infected cells into factories for the production of viral proteins, which are carried like any other protein cargo through the biosynthetic pathway. When a cell is infected

with VSV, massive amounts of the VSVG protein are produced in the endoplasmic reticulum (ER). The VSVG molecules then traffic through the Golgi complex and are transported to the plasma membrane of the infected cell where they are incorporated into viral envelopes. As in a radioactive pulse-chase experiment, the use of a virus allows investigators to follow a relatively synchronous wave of protein movement, in this case represented by a wave of green fluorescence that begins soon after infection. Synchrony can be enhanced, as was done in the experiment depicted in Figure 8.4, by use of a virus with a mutant VSVG protein that is unable to leave the ER of infected cells that are grown at an

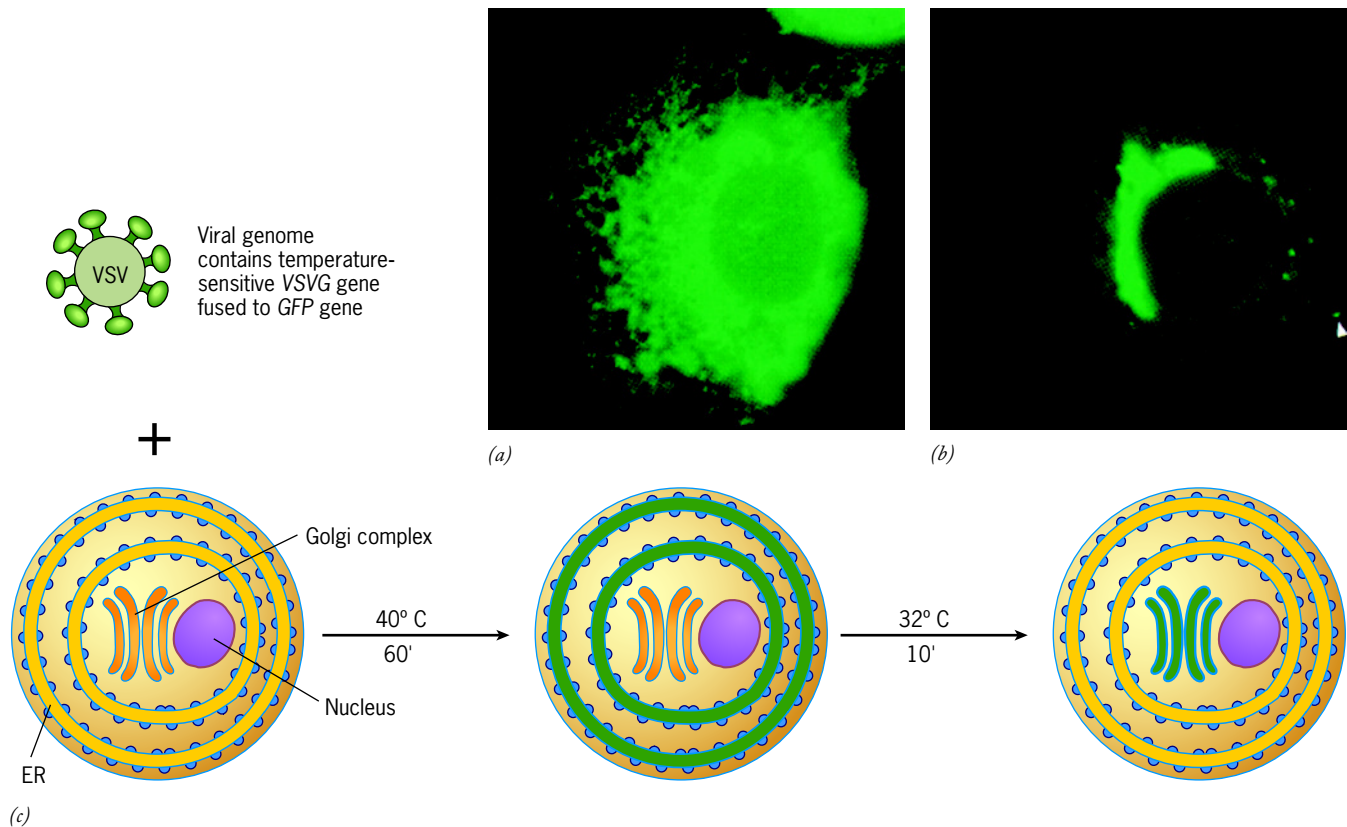

Figure 8.4 The use of green fluorescent protein (GFP) reveals the movement of proteins within a living cell.

(a) Fluorescence micrograph of a live cultured mammalian cell that had been infected with the VSV virus at 40°C. This particular strain of the VSV virus contained a *VSVG* gene that (1) was fused to a gene encoding the fluorescent protein GFP and (2) contained a temperature-sensitive mutation that prevented the newly synthesized VSVG protein from leaving the ER when kept at 40°C. The green fluorescence in this micrograph is restricted to the ER. (b) Fluorescence micrograph of a

live infected cell that was held at 40°C to allow the VSVG protein to accumulate in the ER and then incubated at 32°C for 10 minutes. The fluorescent VSVG protein has moved on to the Golgi complex. (c) Schematic drawing showing the retention of the mutant VSVG protein in the ER at 40°C and its synchronous movement to the Golgi complex within 10 minutes of incubation at the lower temperature. elevated temperature (e.g., 40°C). When the temperature is lowered to 32°C, the fluorescent GFP-VSVG protein that had accumulated in the ER (Figure 8.4a,c) moves synchronously to the Golgi complex (Figure 8.4b,c), where various processing events occur, and then on to the plasma membrane. Mutants of this type that function normally at a reduced (permissive) temperature, but not at an elevated (restrictive) temperature, are described as *temperature-sensitive mutants*. An experiment utilizing two different fluorescent probes is described on page 321.

Insights Gained from the Biochemical Analysis of Subcellular Fractions

Electron microscopy, autoradiography, and the use of GFP provide information on the structure and function of cellular organelles but fail to provide much insight into the molecular composition of these structures. Techniques to break up (**homogenize**) cells and isolate particular types of organelles were pioneered in the 1950s and 1960s by Albert Claude and Christian De Duve. When a cell is ruptured by homogenization, the

cytoplasmic membranes become fragmented and the fractured edges of the membrane fragments fuse to form spherical vesicles less than 100 nm in diameter. Vesicles derived from different organelles (nucleus, mitochondrion, plasma membrane, endoplasmic reticulum, and so forth) have different properties, which allow them to be separated from one another, an approach that is called **subcellular fractionation**.

Membranous vesicles derived from the endomembrane system (primarily the endoplasmic reticulum and Golgi complex) form a heterogeneous collection of similar sized vesicles referred to as **microsomes**. A rapid (and crude) preparation of the microsomal fraction of a cell is depicted in Figure 8.5a. The microsomal fraction can be further fractionated into smooth and rough membrane fractions (Figure 8.5b,c) by the gradient techniques discussed in Section 18.6. Once isolated, the biochemical composition of various fractions can be determined. In recent years, the identification of the proteins present in cell fractions has been carried out using sophisticated proteomic technology. Once a particular organelle has been isolated, the proteins can be extracted, separated, and identified by mass spectrometry as discussed on page 72. Hundreds of

Figure 8.5 Isolation of a microsomal fraction by differential centrifugation. (a) When a cell is broken by mechanical homogenization (step 1), the various membranous organelles become fragmented and form spherical membranous vesicles. Vesicles derived from different organelles can be separated by various techniques of centrifugation. In the procedure depicted here, the cell homogenate is first subjected to low-speed centrifugation to pellet the larger particles, such as nuclei and mitochondria, leaving the smaller vesicles (microsomes) in the supernatant (step 2). The microsomes can be removed from the supernatant by centrifugation at higher speeds for longer periods of time (step 3). A crude microsomal fraction of this type can be fractionated into different vesicle types in subsequent steps. (b) Electron micrograph of a smooth microsomal fraction in which the membranous vesicles lack ribosomes. (c) Electron micrograph of a rough microsomal fraction containing ribosome-studded membranes. (B,C: COURTESY OF J. A. HIGGINS AND R. J. BARNETT.)

proteins can be identified simultaneously, providing a comprehensive molecular portrait of any organelle that can be prepared in a relatively pure state. In one example of this technology, it was found that a simple phagosome (page 315) containing an ingested latex bead comprised more than 160 different proteins, many of which had never previously been identified or were not known to be involved in phagocytosis.

Insights Gained from the Use of Cell-Free Systems

Once techniques to fractionate membranous organelles were developed, researchers began to probe the capabilities of these crude subcellular preparations. They found that the isolated parts of a cell were capable of remarkable activities. These early **cell-free systems**—so called because they did not contain whole cells—provided a wealth of information about biological processes that were impossible to study within the complex environment of intact cells. During the 1960s, for example, George Palade, Philip Siekevitz, and their colleagues at Rockefeller University set out to learn more about the properties of the rough microsomal fraction (shown in Figure 8.5c), whose membrane vesicles are derived from the rough ER (page 280). They found that they could strip a rough microsomal preparation of its attached particles, and the isolated particles (i.e., ribosomes) were capable of synthesizing proteins when provided with required ingredients from the cytosol. Under these conditions, the newly synthesized proteins were simply released by the ribosomes into the aqueous fluid of the test tube. When the same experiment was carried out using intact rough microsomes, the newly synthesized proteins were no longer released into the incubation medium but were trapped within the lumen of the membranous vesicles. It was concluded from these studies that the microsomal membrane was not required for the incorporation of amino acids into proteins but for sequestering newly synthesized secretory proteins within the ER cisternal space.

Over the past few decades, researchers have used cell-free systems to identify the roles of many of the proteins involved in membrane trafficking. Figure 8.6 shows a liposome with vesicles budding from its surface (arrows). As discussed on page 128, liposomes are vesicles whose surface consists of an artificial bilayer that is created in the laboratory from purified phospholipids. The buds and vesicles seen in Figure 8.6 were produced after the preparation of liposomes was incubated

with purified proteins that normally comprise coats on the cytosolic surface of transport vesicles within the cell. Without the added coat proteins, vesicle budding could not occur. Using this strategy in which cellular processes are *reconstituted* in vitro from purified components, researchers have been able to study the proteins that bind to the membrane to initiate vesicle formation, the proteins responsible for cargo selection, and the proteins that sever the vesicle from the donor membrane.

Figure 8.6 Formation of coated vesicles in a cell-free system.

Electron micrograph of a liposome preparation that had been incubated with the components required to promote vesicle budding within the cell. The proteins in the medium have become attached to the surface of the liposomes and have induced the formation of protein-coated buds (arrows). (COURTESY OF LELIO ORCI AND RANDY SCHEKMAN.)

Insights Gained from the Study of Mutant Phenotypes

A mutant is an organism (or cultured cell) whose chromosomes contain one or more genes that encode abnormal proteins. When a protein encoded by a mutant gene is unable to carry out its normal function, the cell carrying the mutation exhibits a characteristic deficiency. Determining the precise nature of the deficiency provides information on the function of the normal protein. Study of the genetic basis of secretion has been carried out largely on yeast cells, most notably by Randy Schekman and colleagues at the University of California, Berkeley. Yeasts are particularly amenable to genetic studies because they have a small number of genes compared to other types of eukaryotes; they are small, single-celled organisms easily grown in culture; and they can be grown as haploids for the majority of their life cycle. A mutation in a single gene in a haploid cell produces an observable effect because the cells lack a second copy of the gene that would mask the presence of the abnormal one.

In yeast, as in all eukaryotic cells, vesicles bud from the ER and travel to the Golgi complex, where they fuse with the Golgi cisternae (Figure 8.7*a*). To identify genes whose encoded protein is involved in this portion of the secretory pathway (i.e., *SEC* genes), researchers screen for mutant cells that exhibit an abnormal distribution of cytoplasmic membranes. An electron micrograph of a wild-type yeast cell is shown in Figure 8.7*b*. The cell depicted in Figure 8.7*c* has a mutation in a gene that

Figure 8.7 The use of genetic mutants in the study of secretion.

(*a*) The first leg of the biosynthetic secretory pathway in budding yeast. The steps are described below. (*b*) Electron micrograph of a section through a wild-type yeast cell. (*c*) A yeast cell bearing a mutation in the *sec12* gene whose product is involved in the formation of vesicles at the ER membrane (step 1, part *a*). Because vesicles cannot form, expanded ER cisternae accumulate in the cell. (*d*) A yeast cell bearing a mutation in the *sec17* gene, whose product is involved in vesicle fusion (step 2, part *a*). Because they cannot fuse with Golgi membranes, the vesicles (indicated by the arrowheads) accumulate in the cell. [The mutants depicted in *c* and *d* are temperature-sensitive mutants. When kept at the lower (permissive) temperature, they are capable of normal growth and division.] (FROM CHRIS A. KAISER AND RANDY SCHEKMAN, *CELL* 61:724, 1990; © 1990, REPRINTED WITH PERMISSION FROM ELSEVIER.)

encodes a protein involved in the formation of vesicles at the ER membrane (step 1, Figure 8.7*a*). In the absence of vesicle formation, mutant cells accumulate an expanded endoplasmic reticulum. In contrast, the cell depicted in Figure 8.7*d* carries a mutation in a gene that encodes a protein involved in vesicle fusion (step 2, Figure 8.7*a*). When this gene product is defective, the mutant cells accumulate an excess number of unfused vesicles. Researchers have isolated dozens of different mutants which, taken as a group, exhibit disruptions in virtually every step of the secretory pathway. The genes responsible for these defects have been cloned and sequenced, and the proteins they encode have been isolated. Isolation of proteins from yeast has launched successful searches for homologous proteins (i.e., proteins with related sequence) in mammals.

One of the most important lessons learned from the use of all of these techniques is that the dynamic activities of the endomembrane system are highly conserved. Not only do yeast, plant, insect, and human cells carry out similar processes, but they do so with remarkably similar proteins. It is evident that the structural diversity of cells belies their underlying molecular similarities. In many cases, proteins from widely divergent species are interchangeable. For example, cell-free systems derived from mammalian cells can often utilize yeast proteins to facilitate vesicle transport. Conversely, yeast cells with genetic deficiencies that disrupt some phase of the biosynthetic pathway can often be “cured” by genetically engineering them to carry mammalian genes.

Over the past decade or so, researchers interested in searching for genes that affect a particular cellular process in plant or animal cells have taken advantage of a cellular phenomenon called *RNA interference (RNAi)*. RNAi is a process in which cells produce small RNAs (called *siRNAs*) that bind to specific mRNAs and inhibit the translation of these mRNAs into proteins. This phenomenon and its use are discussed in detail in Sections 11.5 and 18.17. For the present purpose we will simply note that researchers can synthesize a collection (library) of siRNAs that are capable of inhibiting the translation of virtually any mRNA that is produced by a genome. Each mRNA represents the expression of a specific gene; therefore, one can find which genes are involved in a particular process by determining which siRNAs interfere with that process. In the experiment depicted in Figure 8.8, researchers set out to identify genes that were involved in various steps of the secretory pathway, a goal similar to that of the investigators studying the yeast mutants shown in Figure 8.7. In this case, researchers used a strain of cultured *Drosophila* cells and attempted to identify genes that affected the localization of mannosidase II, an enzyme that is synthesized in the endoplasmic reticulum and moves via transport vesicles to the Golgi complex, where it takes up residence. Figure 8.8*a* shows a control cell that is synthesizing a GFP-labeled version of mannosidase II; the fluorescence becomes localized in the numerous Golgi complexes of the cell as would be expected. Figure 8.8*b* shows a cell that contains siRNA molecules that have caused a relocation of the GFP-mannosidase into the ER, which is seen to be fused with the Golgi complexes. This type of phenotype is typically caused by the absence of one of the proteins involved in the transport of the

Figure 8.8 Inhibition of gene expression with RNA interference. (a) A control *Drosophila* S2 cultured cell expressing GFP-labeled mannosidase II. The fluorescent enzyme becomes localized in the Golgi complex after its synthesis in the ER. (b) A cell that has been genetically engineered to express a specific siRNA, which binds to a complementary mRNA and inhibits translation of the encoded protein. In this case, the siRNA has caused the fluorescent enzyme to remain in the ER, which has fused with the Golgi membranes. This phenotype suggests that the mRNA being affected by the siRNA encodes a protein involved in an early step of the secretory pathway during which the enzyme is synthesized in the ER and traffics to the Golgi complex. Among the genes that exhibit this phenotype when targeted by siRNAs are those encoding proteins of the COPI coat, Sar1, and Sec23. The functions of these proteins are discussed later in the chapter. (FROM FREDERIC BARD ET AL., COURTESY OF VIVEK MALHOTRA, NATURE 439:604, 2006; © 2006, REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LTD.)

enzyme from the ER to the Golgi complex. Of the 130 different siRNAs that were found to interfere in some way with the secretory pathway in this study, 31 of them generated a phenotype similar to that shown in Figure 8.8*b*. Included among these 31 siRNAs were numerous species that inhibited the expression of genes that were already known to be involved in the secretory pathway. In addition, the study identified other genes whose function had been unknown and are now presumed to be involved in these processes as well. Because it is easier to synthesize a small RNA than to generate an organism with a mutant gene, RNAi has become a common strategy to investigate the effect of a missing protein.

REVIEW

1. Describe the differences between an autoradiograph of a pancreas cell that had been incubated in labeled amino acids for 3 minutes and immediately fixed and one of a cell that had been labeled for 3 minutes, chased for 40 minutes, and then fixed.
2. What techniques or approaches might you use to learn which proteins are normally present in the endoplasmic reticulum?
3. How does the isolation of a mutant yeast that accumulates vesicles provide information on the process of protein trafficking?
4. How can GFP be used to study membrane dynamics?

8.3 | The Endoplasmic Reticulum

The **endoplasmic reticulum (ER)** comprises a network of membranes that penetrates much of the cytoplasm. The ER probably evolved from invaginations of the plasma membrane as depicted in Figure 1, page 27. Enclosed within the ER is an extensive space, or lumen, that is separated from the surrounding cytosol by the ER membrane. As will be evident in the following discussion, the composition of the **luminal** (or **cisternal**) **space** inside the ER membranes is quite different from that of the surrounding **cytosolic space**. Like other subcellular organelles, the ER is a highly dynamic structure undergoing continual turnover and reorganization.

The endoplasmic reticulum is divided into two subcompartments, the **rough endoplasmic reticulum (RER)** and the **smooth endoplasmic reticulum (SER)**. The rough ER is defined by the presence of ribosomes bound to its cytosolic

surface, whereas the smooth ER lacks associated ribosomes. The RER is typically composed of a network of flattened sacs (**cisternae**), as shown in Figure 8.9*a*. The RER is continuous with the outer membrane of the nuclear envelope, which also bears ribosomes on its cytosolic surface (Figure 8.2*b*). In contrast, the membranes of the SER are highly curved and tubular, forming an interconnecting system of pipelines traversing the cytoplasm. When cells are homogenized, the SER tubules fragment into smooth-surfaced vesicles, whereas the RER sheets fragment into rough-surfaced vesicles (Figure 8.5*b,c*).

Fluorescently labeled proteins and lipids are capable of diffusing from one type of ER into the other, indicating that their membranes are continuous. In fact, the two types of ER share many of the same proteins and engage in certain common activities, such as the synthesis of certain lipids and cholesterol. At the same time, numerous proteins are found only in one or the other type of ER. For example, the high degree

Figure 8.9 The rough endoplasmic reticulum (RER). (a) Schematic diagram showing the stacks of flattened cisternae that make up the rough ER. The cytosolic surface of the ER membrane contains bound ribosomes, which gives the cisternae their rough appearance.

of curvature of the SER tubules is induced and maintained by the presence of membrane-bending proteins, called reticulons, which are largely absent from the flattened RER sheets. The RER, in contrast, contains proteins involved in the movement of nascent proteins into the ER lumen.

Different types of cells contain markedly different ratios of the two types of ER, depending on the activities of the cell. For example, cells that secrete large amounts of proteins, such as the cells of the pancreas or salivary glands, have extensive regions of RER (Figure 8.9*b–d*). We will return to the function of the RER shortly, but first we will describe the activities of the SER.

The Smooth Endoplasmic Reticulum

The SER is extensively developed in a number of cell types, including those of skeletal muscle, kidney tubules, and steroid-producing endocrine glands (Figure 8.10). SER functions include:

- Synthesis of steroid hormones in the endocrine cells of the gonad and adrenal cortex.
- Detoxification in the liver of a wide variety of organic compounds, including barbiturates and ethanol, whose chronic use can lead to proliferation of the SER in liver cells. Detoxification is carried out by a collection of oxygen-transferring enzymes (oxygenases), including the *cytochrome P450* family. These enzymes are noteworthy for their lack of substrate specificity, being able to oxidize thousands of different hydrophobic compounds and convert them into more hydrophilic, more readily excreted derivatives. The results are not always positive. For example, the relatively harmless compound benzo[*a*]pyrene formed when meat is charred on a grill is converted into a potent carcinogen by the “detoxifying” enzymes of the SER. Cytochrome P450s metabolize many prescribed medications, and genetic variation in these enzymes among humans may explain differences from one person to the next in the effectiveness and side effects of many drugs.

Figure 8.10 The smooth ER (SER). Electron micrograph of a Leydig cell from the testis showing the extensive smooth ER where steroid hormones are synthesized. DON FAWCETT/PHOTO RESEARCHERS, INC.

- Sequestering calcium ions within the cytoplasm of cells. The regulated release of Ca^{2+} from the SER of skeletal and cardiac muscle cells (known as the *sarcoplasmic reticulum* in muscle cells) triggers contraction.

Functions of the Rough Endoplasmic Reticulum

Early investigations into the functions of the RER were carried out on cells that secrete large quantities of proteins, such as the acinar cells of the pancreas (Figure 8.3) or the mucus-secreting cells of the lining of the digestive tract (Figure 8.11). It is evident from the drawing and micrograph of Figure 8.11 that the organelles of these epithelial secretory cells are positioned in the cell in such a way as to produce a distinct polarity from one end to the other. The nucleus and an extensive array of RER cisternae are located near the basal surface of the cell, which faces the blood supply. The Golgi complex is located in the central region of the cell. The apical surface of the cell faces a duct that carries the secreted proteins out of the organ. The cytoplasm at the apical end of the cell is filled with secretory granules whose contents are ready to be released into the duct upon arrival of the appropriate signal. The polarity of these glandular epithelial cells reflects the movement of secretory proteins through the cell from their site of synthesis to their site of discharge. The rough ER is the starting point of the biosynthetic pathway: it is the site of synthesis of the proteins, carbohydrate chains, and phospholipids that journey through the membranous compartments of the cell.

Synthesis of Proteins on Membrane-Bound versus Free Ribosomes

The discovery of the rough endoplasmic reticulum as the site of synthesis of secretory proteins in pancreatic acinar cells was described earlier (Figure 8.3). Similar results were found for other types of secretory cells, including intestinal goblet cells that secrete mucoproteins, endocrine cells that secrete polypeptide hormones, plasma cells that secrete antibodies, and liver cells that secrete blood serum proteins.

Further experiments revealed that polypeptides are synthesized at two distinct locales within the cell.

1. Approximately one-third of the proteins encoded by a mammalian genome are synthesized on ribosomes attached to the cytosolic surface of the RER membranes. These include (a) secreted proteins, (b) integral membrane proteins, and (c) soluble proteins that reside within compartments of the endomembrane system, including the ER, Golgi complex, lysosomes, endosomes, vesicles, and plant vacuoles.
2. Other polypeptides are synthesized on “free” ribosomes, that is, on ribosomes that are not attached to the RER, and are subsequently released into the cytosol. This class includes (a) proteins destined to remain in the cytosol (such as the enzymes of glycolysis and the proteins of the cytoskeleton), (b) peripheral proteins of the cytosolic surface of membranes (such as spectrins and ankyrins that are only weakly associated with the plasma membrane’s cytosolic surface), (c) proteins that are transported to the nucleus (Section 12.2), and (d) proteins to be incorporated

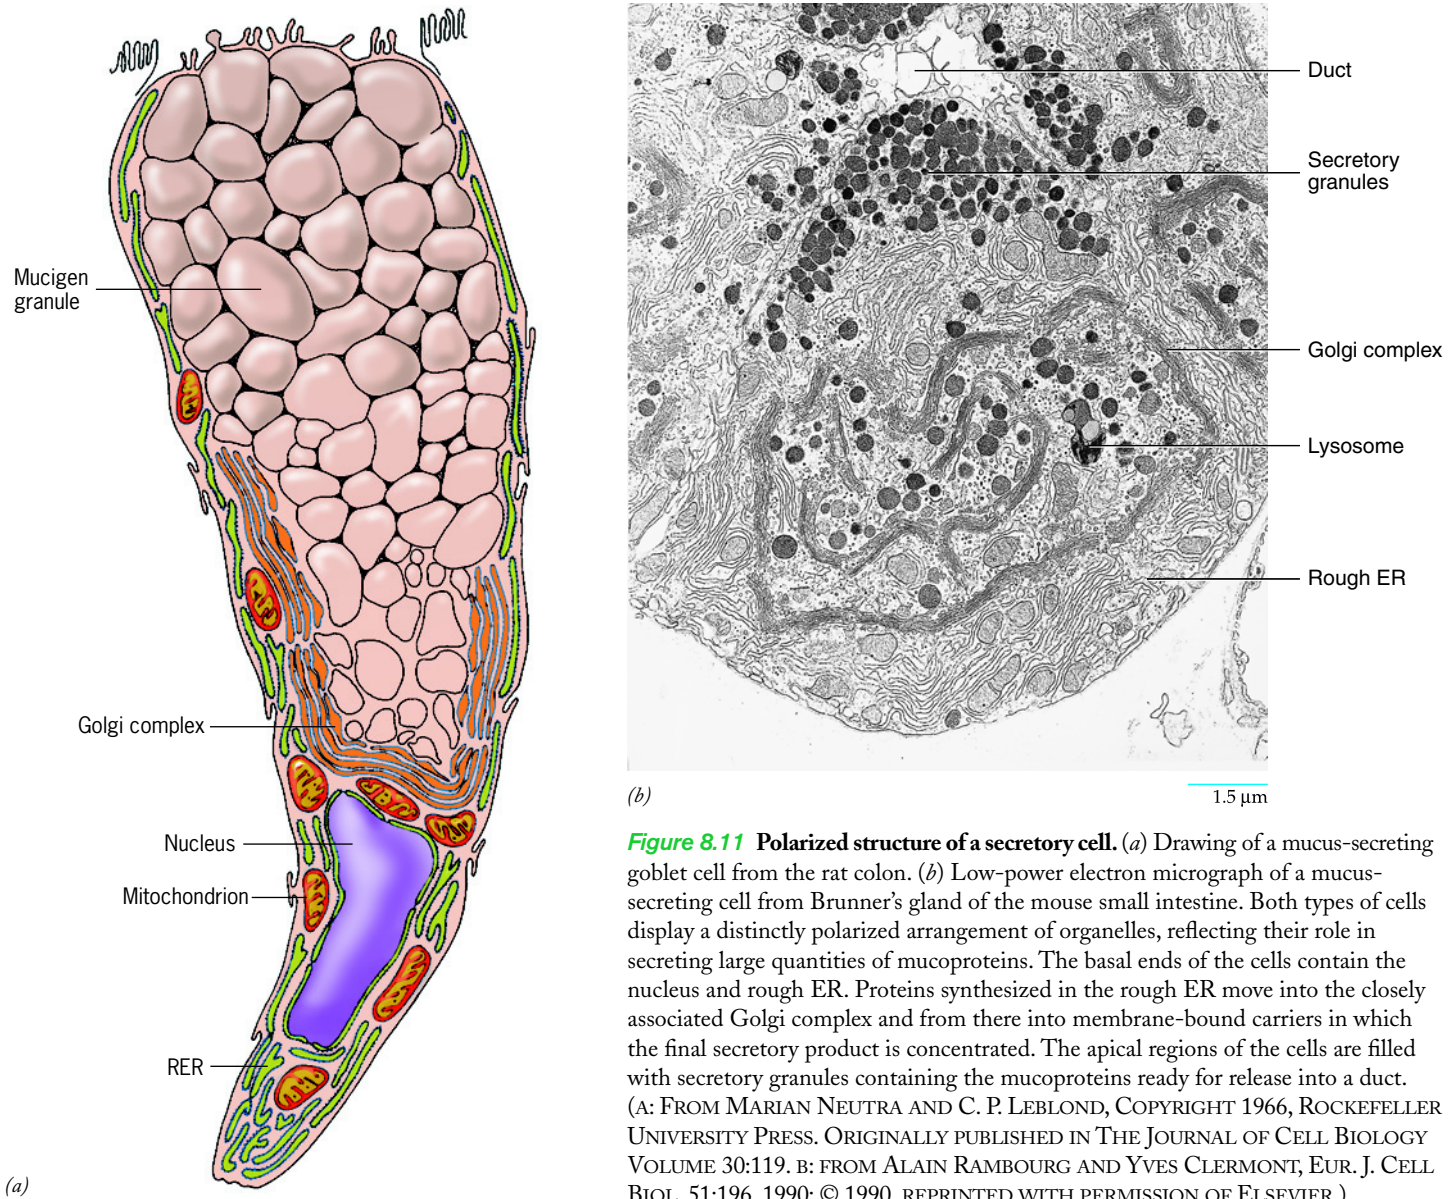

Figure 8.11 Polarized structure of a secretory cell. (a) Drawing of a mucus-secreting goblet cell from the rat colon. (b) Low-power electron micrograph of a mucus-secreting cell from Brunner's gland of the mouse small intestine. Both types of cells display a distinctly polarized arrangement of organelles, reflecting their role in secreting large quantities of mucoproteins. The basal ends of the cells contain the nucleus and rough ER. Proteins synthesized in the rough ER move into the closely associated Golgi complex and from there into membrane-bound carriers in which the final secretory product is concentrated. The apical regions of the cells are filled with secretory granules containing the mucoproteins ready for release into a duct. (A: FROM MARIAN NEUTRA AND C. P. LEBLOND, COPYRIGHT 1966, ROCKEFELLER UNIVERSITY PRESS. ORIGINALLY PUBLISHED IN THE JOURNAL OF CELL BIOLOGY VOLUME 30:119. B: FROM ALAIN RAMBOURG AND YVES CLERMONT, EUR. J. CELL BIOL. 51:196, 1990; © 1990, REPRINTED WITH PERMISSION OF ELSEVIER.)

into peroxisomes, chloroplasts, and mitochondria. Proteins in the latter two groups are synthesized to completion in the cytosol and then imported *posttranslationally* into the appropriate organelle across its boundary membrane(s) (page 316).

What determines the location in a cell where a protein is synthesized? In the early 1970s, Günter Blobel, in collaboration with David Sabatini and Bernhard Dobberstein of Rockefeller University, first proposed, and then demonstrated, that the site of synthesis of a protein was determined by the sequence of amino acids in the N-terminal portion of the polypeptide, which is the first part to emerge from the ribosome during protein synthesis. They suggested the following:

1. Secretory proteins contain a **signal sequence** at their N-terminus that directs the emerging polypeptide and ribosome to the ER membrane.

2. The polypeptide moves into the cisternal space of the ER through a protein-lined, aqueous channel in the ER membrane. It was proposed that the polypeptide moves through the membrane as it is being synthesized, that is, *cotranslationally*.²

²It should be noted that protein transport across the ER membrane can also occur *posttranslationally* (i.e., after synthesis). In this process, the polypeptide is synthesized totally in the cytosol and then imported into the ER lumen through the same protein-conducting channels used in the cotranslational pathway. The posttranslational pathway is utilized much more heavily in yeast than in mammalian cells for import into the ER. In fact, yeast cells that are unable to engage in cotranslational transport into the ER are still able to survive, even though they grow more slowly than normal cells. It can also be noted that a substantial number of integral membrane proteins (including the SNAREs discussed on page 302) have a single transmembrane domain located near the C-terminus of the polypeptide chain. Because of its position within the polypeptide, the transmembrane domain is the last segment to leave the ribosome and cannot be recognized by the SRP. These *tail-anchored proteins* must also be inserted into the membrane *posttranslationally* (see *Nature Revs. Mol. Cell Biol.* 12:787, 2011).

This proposal, known as the *signal hypothesis*, has been substantiated by a large body of experimental evidence. Even more importantly, Blobel's original concept that proteins contain built-in "address codes" has been shown to apply in principle to virtually all types of protein trafficking pathways throughout the cell.

Synthesis of Secretory, Lysosomal, or Plant Vacuolar Proteins on Membrane-Bound Ribosomes The steps that take place during the synthesis of a secretory, lysosomal, or plant vacuolar protein are shown in Figure 8.12a. The syn-

thesis of the polypeptide begins after a messenger RNA binds to a free ribosome, that is, one that is *not* attached to a cytoplasmic membrane. In fact, all ribosomes are thought to be identical; those employed in the synthesis of secretory, lysosomal, or plant vacuolar proteins are taken from the same population (*pool*) as those used for production of proteins that remain in the cytosol. Polypeptides synthesized on membrane-bound ribosomes contain a signal sequence—which typically includes a stretch of 6–15 hydrophobic amino acid residues—that targets the *nascent* polypeptide to the ER membrane and leads to the compartmentalization of the

FIGURE IN FOCUS

Figure 8.12 A schematic model of the synthesis of a secretory protein (or a lysosomal enzyme) on a membrane-bound ribosome of the RER. (a) Synthesis of the polypeptide begins on a free ribosome.

As the signal sequence (shown in red) emerges from the ribosome, it binds to the SRP (step 1), which stops further translation until the SRP-ribosome-nascent chain complex can make contact with the ER membrane. The SRP-ribosome complex then collides with and binds to an SRP receptor (SR) situated within the ER membrane (step 2). Attachment of this complex to the SRP receptor is followed by release of the SRP and the association of the ribosome with a translocon of the ER membrane (step 3). These latter events

are accompanied by the reciprocal hydrolysis of GTP molecules (not shown) bound to both the SRP and its receptor. In the model depicted here, the signal peptide then binds to the interior of the translocon, displacing the plug from the channel and allowing the remainder of the polypeptide to translocate through the membrane cotranslationally (step 4). After the nascent polypeptide passes into the lumen of the ER, the signal peptide is cleaved by a membrane protein (the signal peptidase, not shown), and the protein undergoes folding with the aid of ER chaperones, such as BiP. Studies suggest that translocons are organized into groups of two or four units rather than singly as shown here. (b) Cross-sectional view of the translocon channel from the side based on the X-ray crystal structure of an archaeobacterial translocon. The hour-glass shape of

polypeptide within the ER lumen. (A *nascent* polypeptide is one in the process of being synthesized.) Although the signal sequence is usually located at or near the N-terminus, it occupies an internal position in some polypeptides.

As it emerges from the ribosome, the hydrophobic signal sequence is recognized by a **signal recognition particle (SRP)**, which consists in mammalian cells of six distinct polypeptides and a small RNA molecule, called the 7SL RNA. The SRP binds to both the signal sequence on the nascent polypeptide and the ribosome (step 1, Figure 8.12*a*), temporarily arresting further synthesis of the polypeptide. The bound SRP serves as a tag that enables the entire complex (SRP-ribosome-nascent polypeptide) to bind specifically to the cytosolic surface of the ER membrane. Binding to the ER occurs through two sequential interactions: one between the SRP and the **SRP receptor** (step 2), and the other between the ribosome and the **translocon** (step 3). The translocon is a protein-lined channel embedded in the ER membrane through which the nascent polypeptide is able to move in its passage from the ribosome to the ER lumen.

One of the major feats in the field of membrane trafficking over the past few years has been the determination of the three-dimensional structure of a prokaryotic version of the translocon by X-ray crystallography (Figure 8.12*b*). This effort revealed the presence within the translocon of a pore in the shape of an hourglass with a ring of six hydrophobic amino acids situated at its narrowest diameter. In the inactive (i.e., nontranslocating) state, which was the state in which the translocon was crystallized, the opening in the pore ring is plugged by a short α helix. This plug was originally proposed to seal the channel, preventing the unwanted passage of calcium and other ions between the cytosol and the ER lumen, but this model is now debated.

Once the SRP-ribosome-nascent chain complex binds to the ER membrane (step 2, Figure 8.12*a*), the SRP is released from its ER receptor, the ribosome becomes attached to the cytosolic end of the translocon, and the signal sequence on the nascent polypeptide is inserted into the narrow aqueous channel of the translocon (step 3). It is proposed that contact of the signal sequence with the interior of the translocon leads to displacement of the plug and opening of the passageway. The growing polypeptide is then translocated through the hydrophobic pore ring and into the ER lumen (step 4 and Figure 8.12*c*). Because the pore ring observed in the crystal structure has a diameter (5–8Å) that is considerably smaller than that of a helical polypeptide chain, it is presumed that the pore expands as the nascent chain traverses the channel. (Expansion is possible because the residues that make up the ring are situated on different helices of the translocon protein.) Upon termination of translation and passage of the completed polypeptide through the translocon, the membrane-bound ribosome is released from the ER membrane and the helical plug is reinserted into the translocon channel.

Several of the steps involved in the synthesis and trafficking of secretory proteins are regulated by the binding or hy-

drolysis of GTP. As will be discussed at length in Chapter 15 and elsewhere in this chapter, **GTP-binding proteins** (or **G proteins**) play key regulatory roles in many different cellular processes.³ G proteins can be present in at least two alternate conformations, one containing a bound GTP molecule and the other a bound GDP molecule. GTP-bound and GDP-bound versions of a G protein have different conformations and thus have different abilities to bind other proteins. Because of this difference in binding properties, G proteins act like “molecular switches”; the GTP-bound protein typically turns the process on, and hydrolysis of the bound GTP turns it off. Among the components depicted in Figure 8.12, both the SRP and the SRP receptor are G proteins that interact with one another in their GTP-bound states. The hydrolysis of GTP bound to these two proteins occurs between steps 2 and 3 and triggers the release of the signal sequence by the SRP and its insertion into the translocon.

Processing of Newly Synthesized Proteins in the Endoplasmic Reticulum

As it enters the RER cisterna, a nascent polypeptide is acted on by a variety of enzymes located within either the membrane or the lumen of the RER. The N-terminal portion containing the signal peptide is removed from most nascent polypeptides by a proteolytic enzyme, the **signal peptidase**. Carbohydrates are added to the nascent protein by the enzyme *oligosaccharyltransferase* (discussed on page 286). Both the signal peptidase and oligosaccharyltransferase are integral membrane proteins associated with the translocon that act on nascent proteins as they enter the ER lumen.

The RER is a major protein processing plant. To meet its obligations, the RER lumen is packed with molecular chaperones that recognize and bind to unfolded or misfolded proteins and give them the opportunity to attain their correct (native) three-dimensional structure (page 288). The ER lumen also contains a number of protein-processing enzymes, such as *protein disulfide isomerase (PDI)*. Proteins enter the ER lumen with their cysteine residues in the reduced (—SH) state, but they leave the compartment with many of these residues joined to one another as oxidized disulfides (—SS—) (page 53). The formation (and rearrangement) of disulfide bonds is catalyzed by PDI. Disulfide bonds play an important role in maintaining the stability of proteins that are present at the extracellular surface of the plasma membrane or secreted into the extracellular space.

The endoplasmic reticulum is ideally constructed for its role as a port of entry for the biosynthetic pathway of the cell. Its membrane provides a large surface area to which many ribosomes can attach (an estimated 13 million per liver cell). The lumen of the ER cisternae provides a specialized local environment that favors the modification, folding, and assembly of a selected subset of the cell's proteins. The segregation of these newly synthesized proteins in the ER cisternae removes them from the cytosol and allows them to be modified and dispatched toward their ultimate destination, whether outside the cell or within one of the cytoplasm's membranous organelles.

Synthesis of Integral Membrane Proteins on Membrane-Bound Ribosomes Integral membrane proteins—other than those of mitochondria and chloroplasts—are also

³GTP proteins generally require accessory proteins to carry out their function. The roles of these proteins are discussed in Chapter 15 and illustrated in Figure 15.21. They will not be considered in the present chapter, even though they are involved in these activities.

synthesized on membrane-bound ribosomes of the ER. These membrane proteins are translocated into the ER membrane as they are synthesized (i.e., cotranslationally) using the same machinery described for the synthesis of secretory and lysosomal proteins (Figure 8.12). Unlike soluble secretory and lysosomal proteins, however, which pass entirely through the ER membrane during translocation, integral proteins contain one or more hydrophobic transmembrane segments (page 134) that are shunted directly from the channel of the translocon into the lipid bilayer. How can such a transfer take place?

The X-ray crystallographic studies of the translocon described above showed the translocon to have a clam-shaped conformation with a groove or seam along one side of the wall where the channel might open and close. As a polypeptide passes through the translocon, it is proposed that this lateral “gate” in the channel continually opens and closes, which gives each segment of the nascent polypeptide an opportunity to partition itself according to its solubility properties into either the aqueous compartment within the translocon channel or the surrounding hydrophobic core of the lipid bilayer. Those segments of the nascent polypeptide that are sufficiently hydrophobic will spontaneously “dissolve” into the lipid bilayer and ultimately become transmembrane segments of an integral membrane protein. This concept has received strong support from an *in vitro* study in which translocons were given the opportunity to translocate custom-designed nascent proteins that contained test segments of varying hydrophobicity. The more hydrophobic the test segment, the

greater the likelihood it would pass through the wall of the translocon and become integrated as a transmembrane segment of the bilayer.

Figure 8.13 shows the synthesis of a pair of integral membrane proteins containing a single transmembrane segment. Single-spanning membrane proteins can have an orientation with their N-terminus facing either the cytosol or the lumen of the ER (and eventually the extracellular space). As noted on page 135, the most common determinant of membrane protein alignment is the presence of positively charged amino acid residues flanking the cytosolic end of a transmembrane segment (see Figure 4.18). During the synthesis of membrane proteins, the inner lining of the translocon is thought to orient the nascent polypeptide, as indicated in Figure 8.13, so that the more positive end faces the cytosol. In multispanning proteins (as shown in Figure 4.32*d*), sequential transmembrane segments typically have opposite orientations. For these proteins, their arrangement within the membrane is determined by the direction in which the first transmembrane segment is inserted. Once that has been determined, every other transmembrane segment has to be rotated 180° before it can exit the translocon. Studies performed with purified components in cell-free systems suggest that a translocon, by itself, is capable of properly orienting transmembrane segments. It would appear that the translocon is more than a simple passageway through the ER membrane; it is a complex machine capable of recognizing various signal sequences and performing complex mechanical activities.

Figure 8.13 A schematic model for the synthesis of an integral membrane protein that contains a single transmembrane segment near the N-terminus of the nascent polypeptide. The SRP and the various components of the membrane that were shown in Figure 8.12 are also involved in the synthesis of integral proteins, but they have been omitted for simplicity. The nascent polypeptide enters the translocon just as if it were a secretory protein (step 1). However, the entry of the hydrophobic transmembrane sequence into the pore blocks further translocation of the nascent polypeptide through the channel. Steps 2–3 show the synthesis of a transmembrane protein whose N-terminus is in the lumen of the ER and C-terminus is in the cytosol. In step 2, the lateral gate of the translocon has opened and expelled the transmembrane segment into the bilayer. Step 3 shows the final disposition of the protein. Steps 2a–4a show the synthesis of a

transmembrane protein whose C-terminus is in the lumen and N-terminus is in the cytosol. In step 2a, the translocon has reoriented the transmembrane segment, in keeping with its reversed positively and negatively charged flanks. In step 3a, the translocon has opened laterally and expelled the transmembrane segment into the bilayer. Step 4a shows the final disposition of the protein. White-colored + and – signs indicate the proposed charge displayed by the inner lining of the translocon. The difference in charge between the phospholipids of the cytosolic and luminal leaflets of the bilayer (indicated by the yellow + and – signs) is also thought to play a role in determining membrane protein topology. The transmembrane segments are shown as helices based on studies indicating that these regions adopt a helical secondary structure within the ribosomal exit tunnel before they enter the translocon.

Membrane Biosynthesis in the ER Membranes do not arise *de novo*, that is, as new entities from pools of protein and lipid that mix together. Instead, membranes arise from preexisting membranes. Membranes grow as newly synthesized proteins and lipids are inserted into existing membranes in the ER. As will be apparent in the following discussion, membrane components move from the ER to virtually every other compartment in the cell. As the membrane moves from one compartment to the next, its proteins and lipids are modified by enzymes that reside in the cell's various organelles. These modifications contribute to giving each membrane compartment a unique composition and distinct identity.

Keep in mind that cellular membranes are asymmetric: the two phospholipid layers (leaflets) of a membrane have different compositions (page 128). This asymmetry is established initially in the endoplasmic reticulum. Asymmetry is maintained as membrane carriers bud from one compartment and fuse to the next. As a result, domains situated at the cytosolic surface of the ER membrane can be identified on the cytosolic surface of transport vesicles, the cytosolic surface of Golgi cisternae, and the internal (cytoplasmic) surface of the plasma membrane (Figure 8.14). Similarly, domains situated at the

Figure 8.14 Maintenance of membrane asymmetry. As each protein is synthesized in the rough ER, it becomes inserted into the lipid bilayer in a predictable orientation determined by its amino acid sequence. This orientation is maintained throughout its travels in the endomembrane system, as illustrated in this figure. The carbohydrate chains, which are first added in the ER, provide a convenient way to assess membrane sidedness because they are always present on the cisternal side of the cytoplasmic membranes, which becomes the exoplasmic side of the plasma membrane following the fusion of vesicles with the plasma membrane.

luminal surface of the ER membrane maintain their orientation and are found at the external (exoplasmic) surface of the plasma membrane. In fact, in many ways, including its high calcium concentration and abundance of proteins with disulfide bonds and carbohydrate chains, the lumen of the ER (as well as other compartments of the secretory pathway) is a lot like the extracellular space.

Synthesis of Membrane Lipids Most membrane lipids are synthesized entirely within the endoplasmic reticulum. The major exceptions are (1) sphingomyelin and glycolipids, whose synthesis begins in the ER and is completed in the Golgi complex, and (2) some of the unique lipids of the mitochondrial and chloroplast membranes, which are synthesized by enzymes that reside in those membranes. The enzymes involved in the synthesis of phospholipids are themselves integral proteins of the ER membrane with their active sites facing the cytosol. Newly synthesized phospholipids are inserted into the half of the bilayer facing the cytosol. Some of these lipid molecules are later flipped into the opposite leaflet through the action of enzymes called *flippases*. Lipids are carried from the ER to the Golgi complex and plasma membrane as part of the bilayer that makes up the walls of transport vesicles.

The membranes of different organelles have markedly different lipid composition (Figure 8.15a), which indicates that changes take place as membrane flows through the cell. Several factors may contribute to such changes (Figure 8.15b):

1. Most membranous organelles contain enzymes that modify lipids already present within a membrane, converting one type of phospholipid (e.g., phosphatidylserine) to another (e.g., phosphatidylcholine) (step 1, Figure 8.15b).
2. When vesicles bud from a compartment (as in Figure 8.2a), some types of phospholipids may be preferentially included within the membrane of the forming vesicle, while other types may be left behind (step 2, Figure 8.15b).
3. Cells contain **lipid-transfer proteins** that can bind and transport lipids *through the aqueous cytosol* from one membrane compartment to another (step 3, Figure 8.15b). These proteins facilitate the movement of specific lipids from the ER to other organelles without the involvement of transport vesicles. Lipid transfer is thought to occur at sites where the ER comes into very close proximity to the outer membrane of other organelles.

Glycosylation in the Rough Endoplasmic Reticulum

Nearly all of the proteins produced on membrane-bound ribosomes—whether integral components of a membrane, soluble lysosomal or vacuolar enzymes, or parts of the extracellular matrix—become glycoproteins. Carbohydrate groups have key roles in the function of many glycoproteins, particularly as binding sites in their interactions with other macromolecules, as occurs during many cellular processes. They also aid in the proper folding and stabilization of the protein to which they are attached. The sequences of sugars that comprise the oligosaccharides of glycoproteins are highly specific; if the oligosaccharides are isolated from a purified protein of a

Figure 8.15 Modifying the lipid composition of membranes.

(a) Histogram indicating percentage of each of three phospholipids (phosphatidylcholine, phosphatidylserine, and sphingomyelin) in three different cellular membranes (ER, Golgi complex, and plasma membrane). The percentage of each lipid changes gradually as membrane flows from the ER to the Golgi to the plasma membrane. (b) Schematic diagram showing three distinct mechanisms that might explain how the phospholipid composition of one membrane in the endomembrane system can be different from another membrane in the system, even though the membranous compartments are spatially and temporally continuous. (1) The head groups of phospholipids of the bilayer are modified enzymatically; (2) the membrane of a forming vesicle contains a different phospholipid composition from the membrane it buds from; (3) lipids can be removed from one membrane and inserted into another membrane by lipid-transfer proteins.

given type of cell, their sequence is consistent and predictable. How is the order of sugars in oligosaccharides achieved?

The addition of sugars to an oligosaccharide chain is catalyzed by a large family of membrane-bound enzymes called **glycosyltransferases**. Each of these enzymes transfers a specific monosaccharide from a nucleotide sugar, such as GDP-mannose or UDP-*N*-acetylglucosamine (Figure 8.16), to the growing end of the carbohydrate chain. The sequence in which sugars are transferred during assembly of an oligosaccharide depends on the sequence of action of glycosyltransferases that participate in the process. This in turn depends on the location of specific enzymes within the various membranes of the secretory pathway. Thus the arrangement of sugars in the oligosaccharide chains of a glycoprotein depends on the spatial localization of particular enzymes in the assembly line.

The initial steps in the assembly of *N*-linked oligosaccharides (as opposed to *O*-linked oligosaccharides; see Figure 4.11) of both soluble proteins and integral membrane proteins are shown in Figure 8.16. The basal, or core, segment of each carbohydrate chain is not assembled on the protein itself but put together independently on a lipid carrier and then transferred, as a block, to specific asparagine residues of the polypeptide. This lipid carrier, which is named **dolichol phosphate**, is embedded in the ER membrane. Sugars are added to the dolichol phosphate molecule one at a time by membrane-bound glycosyltransferases, beginning with step 1 of Figure 8.16. This part of the glycosylation process is essentially invariant; in mammalian cells, it begins with the transfer of *N*-acetylglucosamine 1-phosphate, followed by the transfer of another *N*-acetylglucosamine, then nine mannose and three glucose units in the precise pattern indicated in Figure 8.16. This preassembled block of 14 sugars is then transferred by the ER enzyme oligosaccharyltransferase from dolichol phosphate to certain asparagines in the nascent polypeptide (step 10, Figure 8.16) as the polypeptide is being translocated into the ER lumen.

Mutations that lead to the total absence of *N*-glycosylation cause the death of embryos prior to implantation. However, mutations that lead to partial disruption of the glycosylation pathway in the ER are responsible for serious inherited disorders affecting nearly every organ system. These diseases are called Congenital Diseases of Glycosylation, or CDGs and they are usually identified through blood tests that detect abnormal glycosylation of serum proteins. One of these diseases, CDG1b, can be managed through a remarkably simple

Figure 8.16 Steps in the synthesis of the core portion of an N-linked oligosaccharide in the rough ER. The first seven sugars (five mannose and two NAG residues) are transferred one at a time to the dolichol-PP on the cytosolic side of the ER membrane (steps 1 and 2). At this stage, the dolichol with its attached oligosaccharide is then flipped across the membrane (step 3), and the remaining sugars (four mannose and three glucose residues) are attached on the luminal side of the membrane. These latter sugars are attached one at a time on the cytosolic side of the membrane to the end of a dolichol phosphate molecule (as in steps 4 and 7), which then flips across the membrane

(steps 5 and 8) and donates its sugar to the growing end of the oligosaccharide chain (steps 6 and 9). Once the oligosaccharide is completely assembled, it is transferred enzymatically to an asparagine residue (within the sequence N-X-S/T) of the nascent polypeptide (step 10). The dolichol-PP is flipped back across the membrane (step 11) and is ready to begin accepting sugars again (steps 12 and 13). (FROM D. VOET AND J. G. VOET, *BIOCHEMISTRY*, 2E, COPYRIGHT 1995; JOHN WILEY & SONS, INC. REPRINTED BY PERMISSION OF JOHN WILEY & SONS, INC.)

treatment. CDG1b results from the deficiency of the enzyme phosphomannose isomerase, which catalyzes the conversion of fructose 6-phosphate to mannose 6-phosphate, a crucial reaction in the pathway that makes mannose available for incorporation into oligosaccharides. The disease can be managed by providing patients with oral supplements of mannose. The treatment was first tested in a boy who was dying from uncontrolled gastrointestinal bleeding, one of the usual complications of the disease. Within months of taking mannose supplements the child was living a normal life.

Shortly after it is transferred to the nascent polypeptide, the oligosaccharide chain undergoes a process of gradual modification. This modification begins in the ER with the enzymatic removal of two of the three terminal glucose residues (step 1, Figure 8.17). This sets the stage for an important

event in the life of a newly synthesized glycoprotein in which it is screened by a system of **quality control** that determines whether or not it is fit to move on to the next compartment of the biosynthetic pathway. To begin this screening process, each glycoprotein, which at this stage contains a single remaining glucose, binds to an ER chaperone (calnexin or calreticulin) (step 2). Removal of the remaining glucose by glucosidase II leads to release of the glycoprotein from the chaperone (step 3). If a glycoprotein at this stage has not completed its folding or has misfolded, it is recognized by a conformation-sensing enzyme (called UGGT) that adds a single glucose residue back to one of the mannose residues at the exposed end of the recently trimmed oligosaccharide (step 4). UGGT recognizes incompletely folded or misfolded proteins because they display exposed hydrophobic residues

Figure 8.17 Quality control: ensuring that misfolded proteins do not proceed forward. Based on this proposed mechanism, misfolded proteins are recognized by a glucosyltransferase (UGGT) which adds a glucose to the end of the oligosaccharide chains. Glycoproteins containing monoglucosylated oligosaccharides are recognized by the membrane-bound chaperone calnexin and given an opportunity to achieve their correctly folded (native) state. If that does not occur after repeated attempts, the protein is dislocated to the cytosol and destroyed. The steps are described in the text. A soluble chaperone (calreticulin) participates in this same quality-control pathway. (L. ELLGAARD ET AL., SCIENCE 286:984, 1999; COPYRIGHT 1999, REPRINTED WITH PERMISSION FROM AAAS.)

that are absent from properly folded proteins. Once the glucose residue has been added, the “tagged” glycoprotein is recognized by the same ER chaperones, which give the protein another chance to fold properly (step 5). After a period of time with the chaperone, the added glucose residue is removed and the conformation-sensing enzyme checks it again to see if it has achieved its proper three-dimensional structure. If it is still partially unfolded or misfolded, another glucose residue is added and the process is repeated until, eventually, the glycoprotein has either folded correctly and continues on its way (step 6), or remains misfolded and is destroyed. Studies suggest that the “decision” to destroy the defective protein begins with the activity of a slow-acting enzyme in the ER that trims a mannose residue from an exposed end of the oligosaccharide of a protein that has been in the ER for an extended period. Once one or more of these mannose residues have been removed (step 7), the protein can no longer be recycled and, instead, is sentenced to degradation (step 8).

We will pick up the story of protein glycosylation again on page 292, where the oligosaccharide that is assembled in

the ER is enlarged as it passes through the Golgi complex on its journey through the biosynthetic pathway.

Mechanisms that Ensure the Destruction of Misfolded Proteins

We have just seen how proteins that fail to fold properly are detected by ER enzymes. It was a surprise to discover that misfolded proteins are not destroyed in the ER, but instead are transported into the cytosol by a process of *dislocation*. The precise mechanism of dislocation remains a matter of debate. Once in the cytosol, the oligosaccharide chains are removed, and the misfolded proteins are destroyed in proteasomes, which are protein-degrading machines whose structure and function are discussed in Section 12.7. This process, known as *ER-associated degradation (ERAD)*, ensures that aberrant proteins are not transported to other parts of the cell, but it can have negative consequences. In most patients with cystic fibrosis, the plasma membrane of epithelial cells is lacking the abnormal protein encoded by the cystic fibrosis gene (page 162). In these cases, the mutant protein is destroyed by the quality-control process of the ER and thus fails to reach the cell surface.

Under certain circumstances, misfolded proteins can be generated in the ER at a rate faster than they can be exported to the cytoplasm. The accumulation of misfolded proteins, which is potentially lethal to cells, triggers a comprehensive “plan of action” within the cell known as the **unfolded protein response (UPR)**. The ER contains protein sensors that monitor the concentration of unfolded or misfolded proteins in the ER lumen. According to the prevailing model outlined in Figure 8.18, the sensors are normally kept in an inactive state by molecular chaperones, particularly BiP. If circumstances should lead to an accumulation of misfolded proteins, the BiP molecules in the ER lumen are called into service as chaperones for the misfolded proteins, rendering them incapable of inhibiting the sensors. Activation of the sensors leads to a multitude of signals that are transmitted into both the nucleus and cytosol and result in

- the expression of hundreds of different genes whose encoded proteins have the potential to alleviate stressful conditions within the ER. These include genes that encode (1) ER-based molecular chaperones that can help misfolded proteins reach the native state, (2) proteins involved in the transport of the proteins out of the ER, and (3) proteins involved in the selective destruction of abnormal proteins as discussed above.
- phosphorylation of a key protein (eIF α) required for protein synthesis. This modification inhibits protein synthesis and decreases the flow of newly synthesized proteins into the ER. This gives the cell an opportunity to remove those proteins that are already present in the ER lumen.

Interestingly, the UPR is more than a cell-survival mechanism; it also includes the activation of a pathway that leads to the death of the cell. It is presumed that the UPR provides a mechanism to relieve itself of the stressful conditions. If these corrective measures are not successful, the cell-death pathway is triggered and the cell is destroyed.

Figure 8.18 A model of the mammalian unfolded protein response (UPR). The ER contains transmembrane proteins that function as sensors of stressful events that occur within the ER lumen. Under normal conditions, these sensors are present in an inactive state as the result of their association with chaperones, particularly BiP (step 1). If the number of unfolded or misfolded proteins should increase to a high level, the chaperones are recruited to aid in protein folding, which leaves the sensors in their unbound, activated state and capable of initiating a UPR. At least three distinct UPR pathways have been identified in mammalian cells, each activated by a different protein sensor. Two of these pathways are depicted in this illustration. In one of these pathways, the release of the inhibitory BiP protein leads to the dimerization of a sensor (called PERK) (step 2). In its dimeric state, PERK becomes an activated protein kinase that phosphorylates a protein (eIF2 α) that is required for the initiation of protein synthesis (step 3). This translation factor is inactive in the phosphorylated state, which stops the cell from synthesizing additional proteins in the ER (step 4), giving the cell more time to process those proteins already present in the ER lumen. In the second pathway depicted here, release of the inhibitory BiP protein allows the sensor (called ATF6) to move on to the Golgi complex where the cytosolic domain of the protein is cleaved away from its transmembrane domain (step 2a). The cytosolic portion of the sensor diffuses through the cytosol (step 3a) and into the nucleus (step 4a), where it stimulates the expression of genes whose encoded proteins can alleviate the stress in the ER (step 5a). These include chaperones, coat proteins that form on transport vesicles, and proteins of the quality-control machinery. (Discussion of the third protein sensor (IRE1) can be found in *Science* 334:1081, 2011.)

From the ER to the Golgi Complex: The First Step in Vesicular Transport

The RER cisternae contain specialized exit sites that are devoid of ribosomes and serve as places where the first transport vesicles in the biosynthetic pathway are formed. The trip from the ER toward the Golgi complex can be followed visually in living cells by tagging secretory proteins with the green fluorescent protein (GFP) as described on page 273. Using this technique it is found that soon after they bud from the ER membrane, transport vesicles fuse with one another to form larger vesicles and interconnected tubules in the region between the ER and Golgi complex. This region has been named the *ERGIC* (endoplasmic reticulum Golgi intermediate compartment), and the vesicular-tubular carriers that form there are called *VTCs* (see Figure 8.25a). Once formed, the VTCs move farther away from the ER toward the Golgi com-

plex. The movement of two of these vesicular-tubular membranous carriers from the ERGIC to the Golgi complex is shown in Figure 8.19. Movement of VTCs occurs along tracks composed of microtubules.

Figure 8.19 Visualizing membrane traffic with the use of a fluorescent tag. This series of photographs shows a small portion of a living mammalian cell that has been infected with the vesicular stomatitis virus (VSV) containing a *VSVG-GFP* chimeric gene (page 274). Once it is synthesized in the RER, the fusion protein emits a green fluorescence, which can be followed as the protein moves through the cell. In the series of photographs shown here, two

vesicular-tubular carriers (VTCs) (arrows) containing the fluorescent protein have budded from the ER and are moving toward the Golgi complex (GC). The series of events depicted here took place over a period of 13 seconds. Bar represents 6 μm . (FROM JOHN F. PRESLEY ET AL., *NATURE* 389:82, 1997; © 1997, REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LTD.)

6. Describe the mechanisms by which the cell ensures that misfolded proteins (1) will not go unrecognized within the ER and (2) will not accumulate to excessive levels within the ER lumen.

8.4 | The Golgi Complex

In the latter years of the nineteenth century, an Italian biologist, Camillo Golgi, was inventing new types of staining procedures that might reveal the organization of nerve cells within the central nervous system. In 1898, Golgi applied a metallic stain to nerve cells from the cerebellum and discovered a darkly stained reticular network located near the cell nucleus. This network, which was later identified in other cell types and named the **Golgi complex**, helped earn its discoverer the Nobel Prize in 1906. The Golgi complex remained a center of controversy for decades between those who believed that the organelle existed in living cells and those who believed it was an *artifact*, that is, an artificial structure formed during preparation for microscopy. It wasn't until the Golgi complex was clearly identified in unfixed, freeze-fractured cells (see Figure 18.17) that its existence was verified beyond reasonable doubt.

The Golgi complex has a characteristic morphology consisting primarily of flattened, disklike, membranous cisternae with dilated rims and associated vesicles and tubules (Figure 8.20*a*). The cisternae, whose diameters are typically 0.5 to 1.0 μm , are arranged in an orderly stack, much like a stack of pancakes, and are curved so as to resemble a shallow bowl (Figure 8.20*b*).⁴ Typically, a Golgi stack contains fewer than eight cisternae. An individual cell may contain from a few to several thousand distinct stacks, depending on the cell type. The Golgi stacks in mammalian cells are interconnected to form a single, large ribbon-like complex (Figure 8.20*c*) situated adjacent to the cell's nucleus (Figure 8.20*d*). A closer look at an individual cisterna suggests that vesicles bud from a peripheral tubular domain of each cisterna (Figure 8.20*e*). As

⁴A single Golgi stack in plant cells is sometimes called a *dictyosome*.

discussed later, many of these vesicles contain a distinct protein coat that is visible in Figure 8.20*e*.

The Golgi complex is divided into several functionally distinct compartments arranged along an axis from the *cis* or entry face closest to the ER to the *trans* or exit face at the opposite end of the stack (Figures 8.20*a,b*). The *cis*-most face of the organelle is composed of an interconnected network of tubules referred to as the ***cis* Golgi network (CGN)**. The CGN is thought to function primarily as a sorting station that distinguishes between proteins to be shipped back to the ER (page 298) and those that are allowed to proceed to the next Golgi station. The bulk of the Golgi complex consists of a series of large, flattened cisternae, which are divided into ***cis*, *medial*, and *trans* cisternae** (Figure 8.20*a*). The *trans*-most face of the organelle contains a distinct network of tubules and vesicles called the ***trans* Golgi network (TGN)**. The TGN is a sorting station where proteins are segregated into different types of vesicles heading either to the plasma membrane or to various intracellular destinations. The membranous elements of the Golgi complex are thought to be supported mechanically by a peripheral membrane skeleton or scaffold composed of a variety of proteins, including members of the spectrin, ankyrin, and actin families—proteins that are also present as part of the plasma membrane skeleton (page 147). The Golgi scaffold may be physically linked with motor proteins that direct the movement of vesicles and tubules entering and exiting the Golgi complex. A separate group of fibrous proteins are thought to form a Golgi “matrix,” that plays a key role in the disassembly and reassembly of the Golgi complex during mitosis.

Figure 8.20 The Golgi complex. (*opposite*) (a) Schematic model of a portion of a Golgi complex from an epithelial cell of the male rat reproductive tract. The elements of the *cis* and *trans* compartments are often discontinuous and appear as tubular networks. (b) Electron micrograph of a portion of a tobacco root cap cell showing the *cis* to *trans* polarity of the Golgi stack. (c) Electron tomographic image of a slice from a mouse pancreatic beta cell that synthesizes and secretes the protein insulin. The individual Golgi stacks are seen to be interconnected to form a continuous ribbon. The *trans* face (or TGN) of each Golgi stack has been colored red and the *cis* face has been colored light blue. Cellular tomography is discussed in Section 18.2. (d) Fluorescence micrograph of a cultured mammalian cell. The position of the Golgi complex is revealed by the red fluorescence, which marks the localization of antibodies to a COPI coat protein. Figure 8.21 provides visual evidence that the Golgi complex is not uniform in composition from one end to the other. Differences in composition of the membrane compartments from the *cis* to the *trans* face reflect the fact that the Golgi complex is primarily a “processing plant.” Newly synthesized membrane proteins, as well as secretory and lysosomal proteins, leave the ER and enter the Golgi complex at its *cis* face and then pass across the stack to the *trans* face. As they progress along the stack, proteins that were originally synthesized in the rough ER are sequentially modified in specific ways. In the best-studied Golgi activity, a protein’s carbohydrates are modified by a series of step-wise enzymatic reactions, as discussed in the following section.

Glycosylation in the Golgi Complex

The Golgi complex plays a key role in the assembly of the carbohydrate component of glycoproteins and glycolipids. When we left the topic of synthesis of *N*-linked carbohydrate chains on page 288, the glucose residues had just been removed from the ends of the core oligosaccharide. As newly synthesized soluble and membrane glycoproteins pass through the *cis* and *medial* cisternae of the Golgi stack, most of the mannose residues are also removed from the core oligosaccharides, and other sugars are added sequentially by various glycosyltransferases.

In the Golgi complex, as in the RER, the sequence in which sugars are incorporated into oligosaccharides is determined by the spatial arrangement of the specific glycosyltransferases that come into contact with the newly synthesized protein as it

moves through the Golgi stack. The enzyme sialyltransferase, for example, which places a sialic acid at the terminal position of the chain in animal cells, is localized in the *trans* face of the Golgi stack, as would be expected if newly synthesized glycoproteins were continually moving toward this part of the organelle. In contrast to the glycosylation events that occur in the ER, which assemble a single core oligosaccharide, the glycosylation steps in the Golgi complex can be quite varied, producing carbohydrate domains of remarkable sequence diversity. One of many possible glycosylation pathways is shown in Figure 8.22. Unlike the *N*-linked oligosaccharides, whose synthesis begins in the ER, those attached to proteins by *O*-linkages (Figure 4.11) are assembled entirely within the Golgi complex.

The Golgi complex is also the site of synthesis of most of a cell’s complex polysaccharides, including the glycosaminoglycan chains of the proteoglycan shown in Figure 7.9a and the pectins and hemicellulose found in the cell walls of plants (see Figure 7.36c).

The Movement of Materials through the Golgi Complex

That materials move through the various compartments of the Golgi complex has long been established; however, two contrasting views of the way this occurs have dominated the field for years. Up until the mid-1980s, it was generally accepted that Golgi cisternae were transient structures. It was supposed that Golgi cisternae formed at the *cis* face of the

Figure 8.22 Steps in the glycosylation of a typical mammalian *N*-linked oligosaccharide in the Golgi complex. Following the removal of the three glucose residues, various mannose residues are subsequently removed, while a variety of sugars (*N*-acetylglucosamine, galactose, fucose, and sialic acid) are added to the oligosaccharide by specific glycosyltransferases. These enzymes are integral membrane proteins whose active sites face the lumen of the Golgi cisternae. This is only one of numerous glycosylation pathways.

stack by fusion of membranous carriers from the ER and ERGIC and that each cisterna physically moved from the *cis* to the *trans* end of the stack, changing in composition as it progressed. This is known as the *cisternal maturation model* because, according to the model, each cisterna “matures” into the next cisterna along the stack.

From the mid-1980s to the mid-1990s, the maturation model of Golgi movement was largely abandoned and replaced by an alternate model, which proposed that the cisternae of a Golgi stack remain in place as stable compartments. In this latter model, which is known as the *vesicular transport model*, cargo (i.e., secretory, lysosomal, and membrane proteins) is shuttled through the Golgi stack, from the CGN to the TGN, in vesicles that bud from one membrane compartment and fuse with a neighboring compartment farther along the stack. The vesicular transport model is illustrated in Figure 8.23*a*, and its acceptance was based largely on the following observations:

1. Each of the various Golgi cisternae of a stack has a distinct population of resident enzymes (Figure 8.21). How could the various cisternae have such different properties if each cisterna was giving rise to the next one in line, as suggested by the cisternal maturation model?
2. Large numbers of vesicles can be seen in electron micrographs to bud from the rims of Golgi cisternae. In 1983, James Rothman and his colleagues at Stanford University demonstrated, using cell-free preparations of Golgi membranes (page 276), that transport vesicles were capable of budding from one Golgi cisterna and fusing with another Golgi cisterna *in vitro*. This landmark experiment formed the basis for a hypothesis suggesting that inside the cell, cargo-bearing vesicles budded from *cis* cisternae and fused with cisternae situated at a more *trans* position in the stack.

Although both models of Golgi function continue to have their proponents, the consensus of opinion has shifted back to the cisternal maturation model. Several of the major reasons for this shift can be noted:

- The cisternal maturation model envisions a highly dynamic Golgi complex in which the major elements of the organelle, the cisternae, are continually being formed at the *cis* face and dispersed at the *trans* face. According to this view, the very existence of the Golgi complex itself depends on the continual influx of transport carriers from the ER and ERGIC. As predicted by the cisternal maturation model, when the formation of transport carriers from the ER is blocked either by treatment of cells with specific drugs or the use of temperature-sensitive mutants (page 275), the Golgi complex simply disappears. When the drugs are removed or the mutant cells are returned to the permissive temperature, the Golgi complex rapidly reassembles as ER-to-Golgi transport is renewed.
- Certain materials that are produced in the endoplasmic reticulum and travel through the Golgi complex can be shown to remain within the Golgi cisternae and never appear within Golgi-associated transport vesicles. For example, studies on fibroblasts indicate that large complexes of procollagen molecules (the precursors of extracellular collagen) (illustrated by the red objects in Figure 8.23*b*) move from the *cis* cisternae to the *trans* cisternae without ever leaving the cisternal lumen.
- It was assumed until the mid-1990s that transport vesicles always moved in a “forward” (*anterograde*) direction, that is, from a *cis* origin to a more *trans* destination. But a large body of evidence has indicated that vesicles can move in a “backward” (*retrograde*) direction, that is, from a *trans* donor membrane to a *cis* acceptor membrane.
- Studies on live budding yeast cells containing fluorescently labeled Golgi proteins have shown directly that the composition of an individual Golgi cisterna can change over time—from one that contains early (*cis*) Golgi resident proteins to one that contains late (*trans*) Golgi resident proteins. The results of this experiment are shown in the opening micrograph of Chapter 18, and they are not

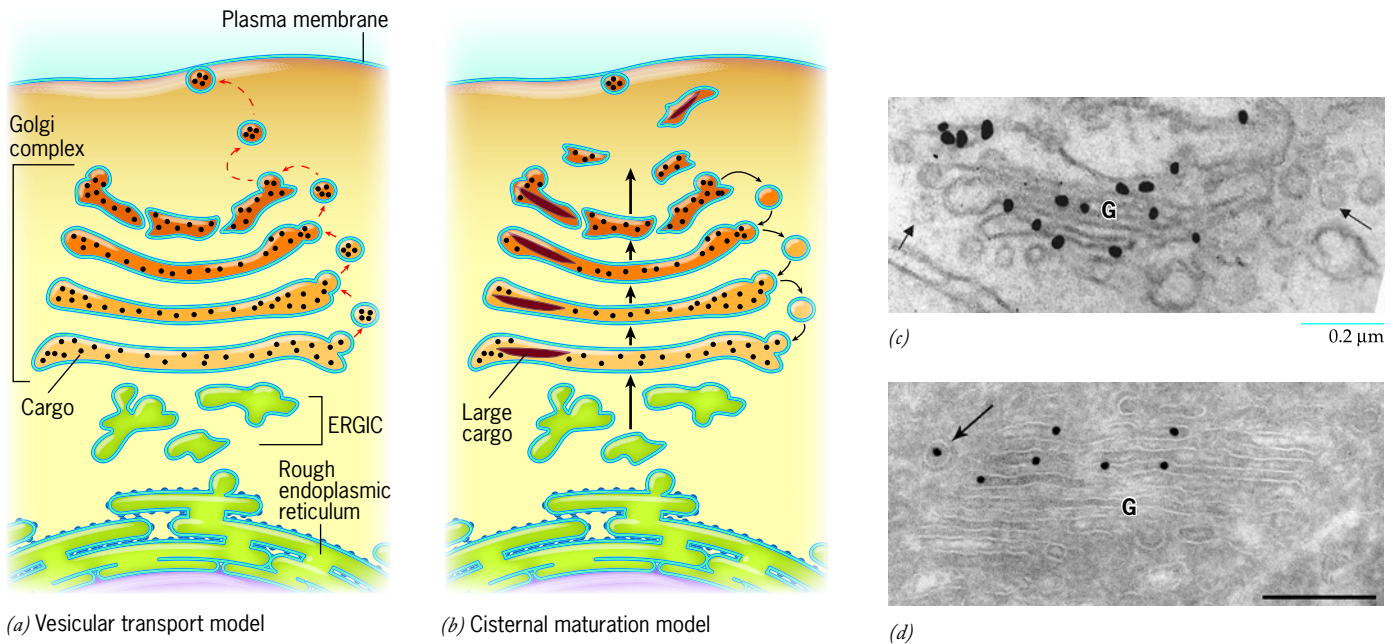

Figure 8.23 The dynamics of transport through the Golgi complex. (a) In the vesicular transport model, cargo (black dots) is carried in an anterograde direction by transport vesicles, while the cisternae themselves remain as stable elements. (b) In the cisternal maturation model, the cisternae progress gradually from a *cis* to a *trans* position and then disperse at the TGN. Transport vesicles carry resident Golgi enzymes (indicated by the colored vesicles) in a retrograde direction. The red lens-shaped objects represent large cargo materials, such as procollagen complexes of fibroblasts. (c) Electron micrograph of an area of Golgi complex in a thin frozen section of a cell that had been infected with vesicular stomatitis virus (VSV). The black dots are nanosized gold particles bound by means of antibodies to VSVG protein, an anterograde cargo molecule. The cargo is restricted to the cisternae and does not

appear in nearby vesicles (arrows). (d) Electron micrograph of similar nature to that of *c* but, in this case, the gold particles are not bound to cargo, but to mannosidase II, a resident enzyme of the *medial* Golgi cisternae. The enzyme appears in both a vesicle (arrow) and cisternae. The labeled vesicle is presumably carrying the enzyme in a retrograde direction, which compensates for the anterograde movement of the enzyme as the result of cisternal maturation. Bar, 0.2 μm . (A third model for intra-Golgi transport is discussed in *Cell* 133:951, 2008.) (C: FROM ALEXANDER A. MIRONOV ET AL., COURTESY OF ALBERTO LUINI, *J. CELL BIOL.* 155:1234, 2001; D: FROM JOSE A. MARTINEZ-MENÁRGUEZ ET AL., COURTESY OF JUDITH KLUMPERMAN, *J. CELL BIOL.* 155:1214, 2001; BOTH REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

compatible with the vesicular transport model. Whether or not these results on yeast can be extrapolated to a mammalian Golgi complex, which has a more complex, stacked structure, remains to be determined.

A current version of the cisternal maturation model is depicted in Figure 8.23*b*. Unlike the original versions of the cisternal maturation model, the version shown in Figure 8.23*b* acknowledges a role for transport vesicles, which have been clearly shown to bud from Golgi membranes. In this model, however, these transport vesicles do not shuttle cargo in an anterograde direction, but instead carry resident Golgi enzymes in a retrograde direction. Instead, it is the Golgi cisternae themselves that serve as the primary anterograde Golgi carriers. This model of intra-Golgi transport is supported by electron micrographs of the type illustrated in Figure 8.23*c,d*. These micrographs depict ultrathin sections of cultured mammalian cells that were cut from a frozen block. In both cases, the frozen sections were treated with antibodies that were linked to gold particles prior to examination in the electron microscope. Figure 8.23*c* shows a section through a Golgi complex after treatment with gold-labeled antibodies that bind to a cargo protein, in this case the viral protein VSVG

(page 274). The VSVG molecules are present within the cisternae, but are absent from the nearby vesicles (arrows), indicating that cargo is carried in an anterograde direction within maturing cisternae but not within small transport vesicles. Figure 8.23*d* shows a section through a Golgi complex after treatment with gold-labeled antibodies that bind to a Golgi resident protein, in this case the processing enzyme mannosidase II. Unlike the VSVG cargo protein, mannosidase II molecules are found in both the cisternae and associated vesicles (arrow), which strongly supports the proposal that these vesicles are utilized to carry Golgi resident enzymes in a retrograde direction. Golgi resident proteins may also move in a retrograde direction through tubules that have been seen to connect different Golgi cisternae.

The cisternal maturation model depicted in Figure 8.23*b* explains how different Golgi cisternae in a stack can have a unique identity. An enzyme such as mannosidase II, for example, which removes mannose residues from oligosaccharides and is largely restricted to the *medial* cisternae (Figure 8.21), can be recycled backward in transport vesicles as each cisterna moves toward the *trans* end of the stack. It should be noted that a number of prominent researchers continue to argue, based on other experimental results, that cargo can be carried

by transport vesicles between Golgi cisternae in an anterograde direction. Thus, the matter remains to be settled.

REVIEW

1. Describe the steps that occur as a soluble secretory protein, such as a digestive enzyme in a pancreas cell, moves from the RER to the *cis* Golgi cisterna; from a *cis* cisterna to the TGN.
2. What is the role of dolichol phosphate in the synthesis of membrane glycoproteins? How is the sequence of sugars attached to the protein determined?
3. How does the process of glycosylation in the Golgi complex compare to that in the RER?
4. How can the cisternal maturation model of Golgi activity be reconciled with the presence of transport vesicles in the Golgi region?

8.5 | Types of Vesicle Transport and Their Functions

The biosynthetic pathway of a eukaryotic cell consists of a series of distinct membrane-bound organelles that function in the synthesis, modification, and delivery of soluble and membrane proteins to their appropriate destination in the cell. As was illustrated in Figure 8.2*a*, materials are carried between compartments by vesicles (or other types of membrane-bound carriers) that bud from donor membranes and fuse with acceptor membranes. If one scrutinizes electron micrographs for vesicles caught in the act of budding, one finds that most of these membranous buds are covered on their cytosolic surface by a “fuzzy,” electron-dense layer. Further analysis reveals that the dark-staining layer consists of a protein coat formed from soluble proteins that assemble on the cytosolic surface of the donor membrane at sites where budding takes place. Each coated bud pinches off to form a **coated vesicle** such as those shown in Figure 8.24. Vesicles of similar size and structure can be formed in cell-free sys-

tems as illustrated in Figure 8.6. (The discovery of coated vesicles is discussed in the Experimental Pathways on page 319.)

Protein coats have at least two distinct functions: (1) they act as a mechanical device that causes the membrane to curve and form a budding vesicle, and (2) they provide a mechanism for selecting the components to be carried by the vesicle. Selected components include (a) cargo consisting of secretory, lysosomal, and membrane proteins to be transported and (b) the machinery required to target and dock the vesicle to the correct acceptor membrane (page 300). In the best understood cases (see Figures 8.26 and 8.40), the vesicle coat is composed of two distinct protein layers: an outer cage or scaffolding that forms the framework for the coat and an inner layer of adaptors that binds both to the outer surface of the lipid bilayer and the membrane’s cargo. As discussed below, the adaptors are able to select specific cargo molecules by virtue of their specific affinity for the cytosolic “tails” of integral proteins that reside in the donor membrane (see Figure 8.25*b*).

Several distinct classes of coated vesicles have been identified; they are distinguished by the proteins that make up their coat, their appearance in the electron microscope, and their role in cell trafficking. The three best studied coated vesicles are the following:

1. **COPII-coated vesicles** (Figure 8.24*a*) move materials from the ER “forward” to the ERGIC and Golgi complex. (Recall from page 289 that the ERGIC is the intermediate compartment situated between the ER and Golgi complex.) (COP is an acronym for coat proteins.)
2. **COPI-coated vesicles** (Figure 8.24*b*) move materials in a retrograde direction (1) from the ERGIC and Golgi stack “backward” toward the ER and (2) from *trans* Golgi cisternae “backward” to *cis* Golgi cisternae (see Figure 8.25*a*). Additional roles for COPI vesicles have been debated.
3. **Clathrin-coated vesicles** move materials from the TGN to endosomes, lysosomes, and plant vacuoles. They also move materials from the plasma membrane to cytoplasmic compartments along the endocytic pathway. They have also been implicated in trafficking from endosomes and lysosomes.

Figure 8.24 Coated vesicles. These electron micrographs show the membranes of these vesicles to be covered on their outer (cytosolic) surface by a distinct protein coat. The micrograph on the left (a) shows a COPII-coated vesicle, whereas the micrograph on the right (b) shows a COPI-coated vesicle. (COURTESY OF RANDY SCHEKMAN AND LELIO ORCI.)

We will consider each type of coated vesicle in the following sections. A summary of the various transport steps along the biosynthetic or secretory pathway that is mediated by each of these coated vesicles is indicated in Figure 8.25*a*.

COPII-Coated Vesicles: Transporting Cargo from the ER to the Golgi Complex

COPII-coated vesicles mediate the first leg of the journey through the biosynthetic pathway—from the ER to the ERGIC and Golgi complex (Figure 8.25*a,b*). The COPII coat contains a number of proteins that were first identified in mutant yeast cells that were unable to carry out transport from the ER to the Golgi complex. Homologues of the yeast proteins were subsequently found in the coats of vesicles budding from the ER in mam-

malian cells. Antibodies to COPII-coat proteins block budding of vesicles from ER membranes but have no effect on movement of cargo at other stages in the secretory pathway.

COPII coats select and concentrate certain components for transport in vesicles. Certain integral membrane proteins of the ER are selectively captured because they contain “ER export” signals as part of their cytosolic tail. These signals interact specifically with COPII proteins of the vesicle coat (Figure 8.25*b*). Proteins selected by COPII-coated vesicles include (1) enzymes that act at later stages in the biosynthetic pathway, such as the glycosyltransferases of the Golgi complex (indicated as orange membrane proteins in Figure 8.25*b*), (2) membrane proteins involved in the docking and fusion of the vesicle with the target compartment, and (3) membrane proteins that are able to bind soluble cargo (such as the secretory proteins, indicated by the red spheres in Figure 8.25*b*). Cells lacking a specific cargo receptor typically fail to transport a specific subset of proteins from the ER to the Golgi complex. For example, mutations in one cargo receptor (ERGIC-53) have been linked to an inherited bleeding disorder. Persons with this disorder fail to secrete certain coagulation factors that promote blood clotting.

Among the COPII coat proteins is a small G protein called Sar1, which is recruited specifically to the ER membrane. Like other G proteins, Sar1 plays a regulatory role, in this case by initiating vesicle formation and by regulating the

Figure 8.25 Proposed movement of materials by vesicular transport between membranous compartments of the biosynthetic/secretory pathway. (a) The three different types of coated vesicles indicated in this schematic drawing are thought to have distinct transport roles. COPII-coated vesicles mediate transport from the ER to the ERGIC and Golgi complex. COPI-coated vesicles return proteins from the ERGIC and Golgi complex to the ER. COPI-coated vesicles also transport Golgi enzymes between cisternae in a retrograde direction. Clathrin-coated vesicles mediate transport from the TGN to endosomes and lysosomes. Transport of materials along the endocytic pathway is not shown in this drawing. (b) Schematic drawing of the assembly of a COPII-coated vesicle at the ER. Assembly begins when Sar1 is recruited to the ER membrane and activated by exchange of its bound GDP with a bound GTP. These steps are shown in Figure 8.26. Cargo proteins of the ER lumen (red spheres and diamonds) bind to the luminal ends of transmembrane cargo receptors. These receptors are then concentrated within the coated vesicle through interaction of their cytosolic tails with components of the COPII coat. ER resident proteins (e.g., BiP) are generally excluded from the coated vesicles. Those that do happen to become included in a coated vesicle are returned to the ER as described later in the text.

Figure 8.26 Proposed roles of the COPII coat proteins in generating membrane curvature, assembling the protein coat, and capturing cargo. In step 1, Sar1-GDP molecules have been recruited to the ER membrane by a protein called a GEF (guanine-exchange factor) that catalyzes the exchange of the bound GDP with a bound GTP. In step 2, each Sar1-GTP molecule has extended a finger-like α helix along the membrane within the cytosolic leaflet. This event expands the leaflet and induces the curvature of the lipid bilayer at that site. In step 3, a dimer composed of two COPII polypeptides (Sec23 and Sec24) has been recruited by the bound Sar1-GTP. The Sec23-Sec24 heterodimer is thought to further induce the curvature of the membrane in the formation of a vesicle. Both Sar1 and Sec23-Sec24 can bring

about membrane curvature when incubated with synthetic liposomes in vitro. Transmembrane cargo accumulates within the forming COPII vesicle as their cytosolic tails bind to the Sec24 polypeptide of the COPII coat. Sec24 can exist in at least four different isoforms. It is likely that different isoforms of this protein recognize and bind membrane proteins with different sorting signals, thus broadening the specificity in types of materials that can be transported by COPII vesicles. In step 4, the remaining COPII polypeptides (Sec13 and Sec31) have joined the complex to form an outer structural scaffold of the coat. (REPRINTED FROM STEPHAN FATH ET AL., COURTESY OF JONATHAN GOLDBERG, CELL 129:1333, 2007, WITH PERMISSION FROM ELSEVIER.)

assembly of the vesicle coat. These activities are illustrated in Figure 8.26. In step 1 of Figure 8.26, Sar1 is recruited to the ER membrane in the GDP-bound form and is induced to exchange its GDP for a molecule of GTP. Upon binding of GTP, Sar1 undergoes a conformational change that causes its N-terminal α helix to insert itself into the cytosolic leaflet of the ER bilayer (step 2). This event has been demonstrated to bend the lipid bilayer, which is an important step in the conversion of a flattened membrane into a spherical vesicle. Membrane bending is probably aided by a change in packing of the lipids that make up the two leaflets of the bilayer. In step 3, Sar1-GTP has recruited two additional polypeptides of the COPII coat, Sec23 and Sec24, which bind as a “banana-shaped” dimer. Because of its curved shape (Figure 8.27), the Sec23-Sec24 dimer provides additional pressure on the membrane surface to help it further bend into a curved bud. Sec24 also functions as the primary adaptor protein of the COPII coat that interacts specifically with the ER export signals in the cytosolic tails of membrane proteins that are destined to traffic on to the Golgi complex. In Figure 8.26, step 4, the remaining subunits of the COPII coat, Sec13 and Sec31, bind to the membrane to form the outer structural cage of the protein coat. Figure 8.27 shows a representation of a 40-nm vesicle with the COPII coat bound to its surface. The Sec13-Sec31 cage assembles into a relatively simple lattice in which each vertex is formed by the convergence of four Sec13-Sec31 legs (Figure 8.27). A certain degree of flexibility is built into the hinge between the Sec13-Sec31 subunits that allow them to form cages of varying diameter, thus accommodating vesicles of varying size.

Once the entire COPII coat has assembled, the bud is separated from the ER membrane in the form of a COPII-coated vesicle. Before the coated vesicle can fuse with a target membrane, the protein coat must be disassembled and its

components released into the cytosol. Disassembly is triggered by hydrolysis of the bound GTP to produce a Sar1-GDP subunit, which has decreased affinity for the vesicle

Figure 8.27 A molecular model of the outer Sec13-Sec31 cage of the COPII coat as it would assemble around the surface of a 40-nm “vesicle.” Each edge or leg of the lattice that makes up the cage consists of a heterotetramer (two Sec31 subunits seen as dark green and light green and two Sec13 subunits seen as orange and red). Four such legs converge to form each vertex of the lattice. Two copies of the Sar1-Sec23-Sec24 complex (shown in red, magenta, and blue, respectively) that would form the inner layer of the COPII coat are also shown in this model. It can be seen how the inner surface of the Sec23-Sec24 complex conforms to the curvature of the vesicle. Inset shows a COPII lattice, which is comprised of triangular and square, pentagonal, and/or hexagonal faces. (FROM STEPHAN FATH ET AL., COURTESY OF JONATHAN GOLDBERG, CELL 129:1333, 2007, BY PERMISSION OF ELSEVIER.)

membrane. Dissociation of Sar1-GDP from the membrane is followed by the release of the other COPII subunits.

COPI-Coated Vesicles: Transporting Escaped Proteins Back to the ER

COPI-coated vesicles were first identified in experiments in which cells were treated with molecules similar in structure to GTP (GTP analogues) but, unlike GTP, cannot be hydrolyzed. Under these conditions, COPI-coated vesicles accumulated within the cell and could be isolated from homogenized cells by density gradient centrifugation (Section 18.6). COPI-coated vesicles accumulate in the presence of a nonhydrolyzable GTP analogue because, similar to their COPII counterparts, the coat contains a small membrane-bending GTP-binding protein, called Arf1, whose bound GTP must be hydrolyzed before the coat can disassemble. COPI-coated vesicles have been most clearly implicated in the retrograde transport of proteins, including the movement of (1) Golgi resident enzymes in a *trans*-to-*cis* direction (as indicated in Figure 8.23*d*, which shows a gold-labeled mannosidase II molecule in a COPI vesicle) and (2) ER resident enzymes from the ERGIC and the Golgi complex back to the ER (Figure 8.25*a*). To understand the role of COPI-coated vesicles in retrograde transport, we have to consider a more general subject.

Retaining and Retrieving Resident ER Proteins If vesicles continually bud from membrane compartments, how does each compartment retain its unique composition? What determines, for example, whether a particular protein in the membrane of the ER remains in the ER or proceeds on to the Golgi complex? Studies suggest that proteins are maintained in an organelle by a combination of two mechanisms:

1. *Retention* of resident molecules that are excluded from transport vesicles. Retention may be based primarily on the physical properties of the protein. For example, soluble proteins that are part of large complexes or membrane proteins with short transmembrane domains are not likely to enter a transport vesicle.
2. *Retrieval* of “escaped” molecules back to the compartment in which they normally reside.

Proteins that normally reside in the ER, those both in the lumen and in the membrane, contain short amino acid sequences at their C-terminus that serve as *retrieval signals*, ensuring their return to the ER if they should be accidentally carried forward to the ERGIC or Golgi complex. The retrieval of “escaped” ER proteins from these compartments is accomplished by specific receptors that capture the molecules and return them to the ER in COPI-coated vesicles (Figures 8.25*a*, 8.28). Soluble resident proteins of the ER lumen (such as protein disulfide isomerase and the molecular chaperones that facilitate folding) typically possess the retrieval signal “lys-asp-glu-leu” (or KDEL in single-letter nomenclature). As shown in Figure 8.28, these proteins are recognized and returned to the ER by the *KDEL receptor*, an integral membrane protein that shuttles between the *cis* Golgi and the ER compartments. If the KDEL sequence is deleted from an ER protein, the escaped proteins are not returned to the ER

Figure 8.28 Retrieving ER proteins. Resident proteins of the ER contain amino acid sequences that lead to their retrieval from the Golgi complex if they are accidentally incorporated into a Golgi-bound transport vesicle. Soluble ER proteins bear the retrieval signal KDEL. Retrieval is accomplished as soluble ER proteins bind to KDEL receptors residing in the membranous wall of *cis* Golgi compartments. The KDEL receptors, in turn, bind to proteins of the COPI coat, which allows the entire complex to be recycled back to the ER.

but instead are carried forward through the Golgi complex. Conversely, when a cell is genetically engineered to express a lysosomal or secretory protein that contains an added KDEL C-terminus, that protein is returned to the ER rather than being sent on to its proper destination. Membrane proteins that reside in the ER also have a retrieval signal that binds to the COPI coat, facilitating their return to the ER. The most common retrieval sequences for ER membrane proteins involve two closely linked basic residues, most commonly KKXX (where K is lysine and X is any residue). Each membrane compartment in the biosynthetic pathway may have its own retrieval signals, which helps explain how each compartment can maintain its unique complement of proteins despite the constant movement of vesicles in and out of that compartment.

Beyond the Golgi Complex: Sorting Proteins at the TGN

Despite all the discussion of transport vesicles, we have yet to examine how a particular protein that has been synthesized in the ER is targeted toward a particular cellular destination. It is

important that a cell be able to distinguish among the various proteins that it manufactures. A pancreatic cell, for example, has to segregate newly synthesized digestive enzymes that will be secreted into a duct, from newly synthesized cell-adhesion molecules that will ultimately reside in the plasma membrane, from lysosomal enzymes that are destined for lysosomes. This is accomplished as the cell sorts proteins destined for different sites into different membrane-bound carriers. The *trans* Golgi network (TGN), which is the last stop in the Golgi complex, functions as a major sorting station, directing proteins to various destinations. The best understood of the post-Golgi pathways is one that carries lysosomal enzymes.

Sorting and Transport of Lysosomal Enzymes Lysosomal proteins are synthesized on membrane-bound ribosomes of the ER and carried to the Golgi complex along with other types of proteins. Once in the Golgi cisternae, soluble lysosomal enzymes are specifically recognized by enzymes that catalyze the two-step addition of a phosphate group to certain mannose sugars of the *N*-linked carbohydrate chains (Figure 8.29a). Thus, unlike other glycoproteins sorted at the TGN, lysosomal enzymes possess phosphorylated mannose residues, which act as sorting signals. This mechanism of protein sorting was discovered through studies on cells from humans that lacked one of the enzymes involved in phosphate addition (discussed in the Human Perspective on page 306). Lysosomal enzymes carrying a mannose 6-phosphate signal are recognized and captured by *mannose 6-phosphate receptors* (MPRs), which are integral membrane proteins that span the TGN membranes (Figure 8.29b).

Lysosomal enzymes are transported from the TGN in clathrin-coated vesicles (which are the third and last type of coated vesicles to be discussed). The structure of clathrin-coated vesicles is described in detail on page 308 in connection with endocytosis, a process that is better understood than budding at the TGN. It will suffice at this point to note that

the coats of these vesicles contain (1) an outer honeycomb-like lattice composed of the protein clathrin, which forms a structural scaffold, and (2) an inner shell composed of protein adaptors, which covers the surface of the vesicle membrane that faces the cytosol (Figure 8.30). The term *adaptor* describes a molecule that physically links two or more components. Lysosomal enzymes are escorted from the TGN by a family of adaptor proteins called **GGAs**.

Figure 8.29 Targeting lysosomal enzymes to lysosomes. (a) Lysosomal enzymes are recognized by an enzyme in the *cis* cisternae that transfers a phosphorylated *N*-acetylglucosamine from a nucleotide sugar donor to one or more mannose residues of *N*-linked oligosaccharides. The glucosamine moiety is then removed in a second step by a second enzyme, leaving mannose 6-phosphate residues as part of the oligosaccharide chain. (b) Schematic diagram showing the pathways followed by a lysosomal enzyme (black) from its site of synthesis in the ER to its delivery to a lysosome. The mannose residues of the lysosomal enzyme are phosphorylated in the Golgi cisternae (step 1) and then selectively incorporated into a clathrin-coated vesicle at the TGN (step 2). The mannose 6-phosphate receptors are thought to have a dual role (step 3): they interact specifically with the lysosomal enzymes on the luminal side of the vesicle, and they interact specifically with adaptors on the cytosolic surface of the vesicle (shown in Figure 8.30). The mannose 6-phosphate receptors separate from the enzymes (step 4) and are returned to the Golgi complex (step 5). The lysosomal enzymes are delivered to an endosome (step 6) and eventually to a lysosome. Mannose 6-phosphate receptors are also present in the plasma membrane, where they capture lysosomal enzymes that are secreted into the extracellular space and return the enzymes to a pathway that directs them to a lysosome (step 7).

Figure 8.30 The formation of clathrin-coated vesicles at the TGN. Clathrin-coated vesicles that bud from the TGN contain GGA, an adaptor protein consisting of several distinct domains. One of the GGA domains binds to the cytosolic domains of membrane proteins, including those that will ultimately reside in the boundary membrane of the lysosome and also the MPR that transports lysosomal enzymes. Other GGA domains bind to Arf1 and to the surrounding cytosolic network of clathrin molecules.

As indicated in the inset of Figure 8.30, a GGA molecule has several domains, each capable of grasping a different protein involved in vesicle formation. The outer ends of the GGA adaptors bind to clathrin molecules, holding the clathrin scaffolding onto the surface of the vesicle. On their inner surface, the GGA adaptors bind to a sorting signal in the cytosolic tails of the mannose 6-phosphate receptors. The MPRs, in turn, bind to soluble lysosomal enzymes within the vesicle lumen (Figure 8.30, inset). As a result of these interactions with GGA adaptors, the MPRs in the TGN membrane and lysosomal enzymes within the TGN lumen become concentrated into clathrin-coated vesicles. As in the formation of COPI and COPII vesicles, production of clathrin-coated vesicles at the TGN begins with the recruitment to the membrane of a small GTP-binding protein, in this case Arf1, which sets the stage for the binding of the other coat proteins. Like Sar1 (Figure 8.26), Arf1 extends a membrane-bending α helix that acts in conjunction with the clathrin coat to initiate formation of the budding vesicle. After the vesicle has budded from the TGN, the clathrin coat is lost and the uncoated vesicle proceeds to its destination, which may be an early endosome, late endosome, or plant vacuole. Before they reach one of these organelles, the MPRs dissociate from the lysosomal enzymes and return to the TGN (Figure 8.29*b*) for another round of lysosomal enzyme transport.

Sorting and Transport of Nonlysosomal Proteins Lysosomal proteins are not the only materials that are exported from the TGN. As indicated in Figure 8.2, membrane proteins destined for the plasma membrane and secretory materials destined for export from the cell are also transported from the TGN, but the mechanisms are poorly understood. According to one

model, membranous carriers are produced as the TGN fragments into vesicles and tubules of various size and shape. This concept fits with the cisternal maturation model, which proposes that the cisternae of the Golgi complex move continually toward the TGN, where they would have to disperse to allow continued maturation of the Golgi stack. Proteins that are discharged from the cell by a process of regulated secretion, such as digestive enzymes and hormones, are thought to form selective aggregates that eventually become contained in large, densely packed secretory granules. These aggregates are apparently trapped as immature secretory granules bud from the rims of the *trans* Golgi cisternae and TGN. In some cells, long tubules are seen to be pulled out of the TGN by motor proteins that operate along microtubular tracks. These tubules are then split into a number of vesicles or granules by membrane fission. Once they have departed from the TGN, the contents of the secretory granules become more concentrated. Eventually, the mature granules are stored in the cytoplasm until their contents are released following stimulation of the cell by a hormone or nerve impulse.

The targeted delivery of integral proteins to the plasma membrane appears to be based largely on sorting signals in the cytoplasmic domains of the membrane proteins. Considerable research has focused on polarized cells, such as those depicted in Figure 8.11. In these cells, membrane proteins destined to reside in the apical portion of the plasma membrane contain different sorting signals from those destined for the lateral or basal portion. These two groups of plasma membrane proteins are clustered into different TGN membrane domains and transported to the cell surface in separate carriers. Plasma membrane proteins of nonpolarized cells, such as fibroblasts and white blood cells, may not require special sorting signals. Such proteins may simply be carried from the TGN to the cell surface in vesicles of the constitutive secretory pathway (Figure 8.2*b*).

Targeting Vesicles to a Particular Compartment

Vesicle fusion requires specific interactions between different membranes. Vesicles from the ER, for example, fuse with the ERGIC or *cis* Golgi network and not with a *trans* cisterna. Selective fusion is one of the factors that ensures a directed flow through the membranous compartments of the cell. Despite a major research effort, we still do not fully understand the mechanisms by which cells target vesicles to particular compartments. It is thought that a vesicle contains specific proteins associated with its membrane that govern the movements and fusion potential of that vesicle. To understand the nature of these proteins, we will consider the steps that occur between the stages of vesicle budding and vesicle fusion.

1. **Movement of the vesicle toward the specific target compartment.** In many cases, membranous vesicles must move considerable distances through the cytoplasm before reaching their eventual target. These types of movement are mediated largely by microtubules, which act like railroad tracks carrying cargo containers along a defined pathway to a predetermined destination. The membranous carriers seen in Figure 8.19, for example, were observed to move from the ERGIC to the Golgi complex over microtubules.

2. **Tethering vesicles to the target compartment.** The initial contacts between a transport vesicle and its target membrane, such as a Golgi cisterna, are thought to be mediated by a diverse collection of “tethering” proteins. Two groups of tethering proteins have been described (Figure 8.31*a*): rod-shaped, fibrous proteins that are capable of forming a molecular bridge between the two mem-

branes over a considerable distance (50–200 nm) and large multiprotein complexes that appear to hold the two membranes in closer proximity. Different tethering proteins initiate fusion between different types of membranes. For example, one class of fibrous tethering proteins, called golgins, act in and around the Golgi complex. Among various proposed functions, golgins may serve as

(a) Tethering

(c) Docking

(b)

(d)

Figure 8.31 Proposed steps in the targeting of transport vesicles to target membranes. (a) According to this model, Rab proteins on the vesicle and target membrane are involved in recruiting tethering proteins that mediate initial contact between the two membranes. Two types of tethering proteins are depicted: highly elongated fibrous proteins (e.g., golgins and EEA1) and multiprotein complexes (e.g., the exocyst and TRAPPI). (b) Electron tomographic image of a slice through a mammalian nerve terminus showing the network of synaptic vesicles that are present in close association with the presynaptic plasma membrane (page 169). The left insets (corresponding to the white box on the right) show the presence of filamentous connectors between a pair of synaptic vesicles (upper inset) and between one of the synaptic vesicles and the adjacent plasma membrane (lower inset). Bars: main panel, 100 nm; insets, 50 nm. (c) During the docking stage leading up to membrane fusion, a v-SNARE in the vesicle membrane interacts with the t-SNAREs in the target membrane to form a four-stranded

α -helical bundle that brings the two membranes into intimate contact (see next figure). In the cases described in the text, SNAP-25, one of the t-SNAREs, is a peripheral membrane protein that is bound to the lipid bilayer by a lipid anchor rather than a transmembrane domain. SNAP-25 contributes two helices to the four-helix SNARE bundle. (d) A model of a synaptic vesicle showing the distribution of only one of its constituent proteins, the SNARE synaptobrevin. The surface density and structures of the synaptobrevin molecules are based on calculations of the number of these proteins per vesicle and the known structure of the molecule. A complete portrait of the proteins on the surface of a synaptic vesicle is shown in the image in Figure 4.4*d*. (B: FROM RUBÉN FERNÁNDEZ-BUSNADIEGO, ET AL., COURTESY OF WOLFGANG BAUMEISTER, J. CELL BIOL. 188, 147, 2010, REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS; D: FROM SHIGEO TAKAMORI ET AL., CELL 127:841, 2006, COURTESY OF REINHARD JAHN, WITH PERMISSION FROM ELSEVIER.)

“tentacles” to reach out and capture transport vesicles carrying Golgi-bound cargo. Several different tethering complexes have been visualized with the electron microscope. Figure 8.31*b* shows tomographic images of the presynaptic zone of a mammalian nerve terminal. These 3D images reveal the presence of filamentous structures—presumably constructed of tethering proteins—connecting synaptic vesicles both to one another and to the adjacent plasma membrane with which these vesicles would have fused. Much of the specificity between vesicle and target may be conferred by a family of small G proteins called **Rabs**, which cycle between an active GTP-bound state and an inactive GDP-bound state. GTP-bound Rabs associate with membranes by a lipid anchor. With over 60 different Rab genes identified in humans, these proteins constitute the most diverse group of proteins involved in membrane trafficking. More importantly, different Rabs become associated with different membrane compartments. This preferential localization gives each compartment a unique surface identity, which is required to recruit the proteins involved in targeting specificity. In their GTP-bound state, Rabs play a key role in vesicle targeting by recruiting specific cytosolic tethering proteins to specific membrane surfaces (Figure 8.31*a*). Rabs also play a key role in recruiting numerous proteins involved in other aspects of membrane trafficking, including the motor proteins that move membranous vesicles through the cytoplasm (shown in Figure 9.52*c*).

3. **Docking vesicles to the target compartment.** At some point during the process leading to vesicle fusion, the membranes of the vesicle and target compartment come into close contact with one another as the result of an interaction between the cytosolic regions of integral proteins of the two membranes. The key proteins that engage in these interactions are called **SNAREs**, and they constitute a family of more than 35 membrane proteins whose members are localized to specific subcellular compartments. Although SNAREs vary considerably in structure and size, all contain a segment in their cytosolic domain called a *SNARE motif* that consists of 60–70 amino acids capable of forming a complex with another SNARE motif. SNAREs can be divided functionally into two categories, **v-SNAREs**, which become incorporated into the membranes of transport vesicles during budding, and **t-SNAREs**, which are located in the membranes of target compartments (Figure 8.31*c*). The best studied SNAREs are those that mediate docking of synaptic vesicles with the presynaptic membrane during the regulated release of neurotransmitters (page 169). In this case, the plasma membrane of the nerve cell contains two t-SNAREs, syntaxin and SNAP-25, whereas the synaptic vesicle membrane contains a single v-SNARE, synaptobrevin. The distribution of synaptobrevin molecules on a representative synaptic vesicle is shown in Figure 8.31*d*. As the synaptic vesicle and presynaptic membrane approach one another, the SNARE motifs of t- and v-SNARE molecules from apposing membranes interact to form four-stranded bundles as shown in Figure 8.32*a*. Each bundle

consists of four α helices, two donated by SNAP-25 and one each donated by syntaxin and synaptobrevin. These parallel α helices zip together to form a tightly interwoven complex that pulls the two apposing lipid bilayers into very close association (Figures 8.31*c* and 8.32*a*). The formation of similar four-stranded helical bundles occurs among other SNAREs at other sites throughout the cell, wherever membranes are destined to fuse. It is interesting to note that the SNAREs of the synaptic vesicle and presynaptic membrane are the targets of two of the most potent bacterial toxins; those responsible for botulism and tetanus. These deadly toxins act as proteases whose only known substrates are SNAREs. Cleavage of the neuronal SNAREs by the toxins blocks the release of neurotransmitters, which causes paralysis.

4. **Fusion between vesicle and target membranes.** When artificial lipid vesicles (liposomes) containing purified t-SNAREs are mixed with liposomes containing purified v-SNAREs, the two types of vesicles fuse with one another, but not with themselves. This finding indicates that interactions between t- and v-SNAREs are capable of pulling two lipid bilayers together with sufficient force to cause them to fuse (Figure 8.32*b,c*). However, a large body of evidence suggests that, although interaction between v- and t-SNAREs is required for membrane fusion, it is not sufficient by itself to bring about fusion *within a cell*. According to the prevailing view regarding the regulated secretion of neurotransmitter molecules, the four-stranded SNARE bundle remains locked in an arrested state by interaction with accessory proteins. Vesicles at this stage remain docked at the membrane and ready to discharge their contents almost instantaneously once they receive an activating signal, in the form of a rise in Ca^{2+} concentration (as discussed below). Regardless of how it is regulated, once the lipid bilayers of the two membranes merge, the SNAREs that previously projected from separate membranes now reside in the same membrane (Figure 8.32*c*). Dissociation of the four-stranded SNARE complex is achieved by a doughnut-shaped, cytosolic protein called NSF that attaches to the SNARE bundle and, using energy from ATP hydrolysis, twists it apart.

Now that we have described the events that occur during the fusion of a vesicle with a target membrane, we can return to the question: How is the specificity of this interaction determined? According to current consensus, the ability of a particular vesicle and target membrane to fuse is determined by the specific combination of interacting proteins, including tethering proteins, Rabs, and SNAREs that can be assembled at that site in the cell. Taken together, these multiple interactions between several types of proteins provide a high level of specificity, ensuring that each membrane compartment can be selectively recognized.

Exocytosis The fusion of a secretory vesicle or secretory granule with the plasma membrane and subsequent discharge of its contents is called **exocytosis**. Exocytosis probably occurs on a rather continual basis in most cells, as proteins and other

Figure 8.32 A model of the interactions between v- and t-SNAREs leading to membrane fusion and exocytosis. (a) The synaptic vesicle has become docked to the plasma membrane through the formation of four-stranded bundles comprising α helices donated by syntaxin (red), synaptobrevin (blue), and SNAP-25 (green). SNAP-25 contributes two helices and lacks a transmembrane domain (yellow). (b) A speculative transition state in the fusion of the two membranes. A small water-filled cavity is shown at the center of the transmembrane helix bundle. (c) The transmembrane helices that previously resided in the two separate membranes are now present in the same bilayer, and a fusion pore has opened between the vesicle and target membrane. The neurotransmitter contents of the vesicle can now be discharged by exocytosis. (d) Scanning electron micrograph of the extracellular surface of a pair of cultured alveolar (lung) cells stimulated to discharge proteins that had been stored in secretory granules. Material is seen being expelled from the cell through smooth, circular openings that are presumed to be dilated fusion pores. The arrow shows a fusion pore that has not dilated, which is readily distinguished from holes (arrowhead) accidentally formed during specimen preparation. (A–C: REPRINTED FROM PEHR A B HARBURY, *STRUCTURE* 6:1490, 1998, WITH PERMISSION FROM ELSEVIER. D: FROM THOMAS HALLER ET AL., *J. CELL BIOL.* 155:286, 2001; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

materials are delivered to both the plasma membrane and extracellular space. However, the best studied examples of exocytosis are those that occur during regulated secretion, most notably the release of neurotransmitters into the synaptic cleft. In these cases, membrane fusion produces an opening through which the contents of the vesicle or granule are released into the extracellular space. It was noted on page 169 that the arrival of a nerve impulse at the terminal knob of a neuron leads to an increase in the influx of Ca^{2+} and the subsequent discharge of neurotransmitter molecules by exocytosis. In this case, fusion is regulated by a calcium-binding protein (synaptotagmin) present in the membrane of the synaptic vesicle. In other types of cells, exocytosis is generally triggered by release of Ca^{2+} from cytoplasmic stores. Contact between the vesicle and plasma membranes is thought to lead to the formation of a small, protein-lined “fusion pore” (Figure 8.32c). Some fusion pores may simply re-close, but in most cases, the pore rapidly dilates to form an opening for discharge of the vesicle contents (Figure 8.32d). Regardless of the mechanism, when a cytoplasmic vesicle fuses with the plasma membrane, the luminal surface of the vesicle membrane becomes part of the outer surface of the plasma membrane, whereas the cytosolic surface of the vesicle membrane becomes part of the inner (cytosolic) surface of the plasma membrane (Figure 8.14).

4. How do retrieval signals ensure that proteins are kept as residents of a particular membrane compartment?

8.6 | Lysosomes

Lysosomes are an animal cell’s digestive organelles. A typical lysosome contains at least 50 different hydrolytic enzymes (Table 8.1) produced in the rough ER and targeted to these organelles. Taken together, lysosomal enzymes can hydrolyze virtually every type of biological macromolecule. The enzymes of a lysosome share an important property: all have their

Phospholipase	Phospholipids

optimal activity at an acid pH and thus are **acid hydrolases**. The pH optimum of these enzymes is suited to the low pH of the lysosomal compartment, which is approximately 4.6. The high internal proton concentration is maintained by a proton pump (a V-type H⁺-ATPase, page 160) present in the organelle's boundary membrane. Lysosomal membranes also contain a variety of highly glycosylated integral proteins whose carbohydrate chains are thought to form a protective lining that shields the membrane from attack by the enclosed enzymes.

Although lysosomes house a predictable collection of enzymes, their appearance in electron micrographs is neither distinctive nor uniform. Figure 8.33 shows a small portion of a Kupffer cell, a phagocytic cell in the liver that engulfs aging red blood cells. The lysosomes of a Kupffer cell exhibit an irregular shape and variable electron density, illustrating how difficult it is to identify these organelles on the basis of morphology alone.

0.3 μ m

Figure 8.33 Lysosomes. Portion of a phagocytic Kupffer cell of the liver showing at least 10 lysosomes of highly variable size. (FROM HANS GLAUMANN ET AL., J. CELL BIOL. 67:887, 1975; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

The presence within a cell of what is, in essence, a bag of destructive enzymes suggests a number of possible functions. The best studied role of lysosomes is the breakdown of materials brought into the cell from the extracellular environment. Many single-celled organisms ingest food particles, which are then enzymatically disassembled in a lysosome. The resulting nutrients pass through the lysosomal membrane into the cytosol. In mammals, phagocytic cells, such as macrophages and neutrophils, function as scavengers that ingest debris and potentially dangerous microorganisms (page 315). Ingested bacteria are generally inactivated by the low pH of the lysosome and then digested enzymatically. As shown in Figure 17.24, peptides produced by this digestive process are “posted” on the cell surface where they alert the immune system to the presence of a foreign agent.

Autophagy

Lysosomes also play a key role in organelle **turnover**, that is, the regulated destruction of the cell's own organelles and their replacement. During this process, which is called **autophagy**, an organelle, such as the mitochondrion shown in Figure 8.34,

Figure 8.34 Autophagy. Electron micrograph of a mitochondrion and peroxisome enclosed in a double membrane wrapper. This autophagic vacuole (or autophagosome) would have fused with a lysosome and its contents digested. (DON FAWCETT AND DANIEL FRIEND/PHOTO RESEARCHERS INC.)

is surrounded by a double membrane structure (or *phagophore*) to produce a double-membrane sequestering vesicle called an *autophagosome* (Figure 8.35). The origin of the double membrane in mammalian cells is unclear, with possibilities ranging from the ER to the outer mitochondrial membrane. Once formed, the outer membrane of the autophagosome fuses with a lysosome, generating a structure called an *autolysosome*, in which both the inner membrane of the autophagosome and the enclosed contents are degraded. The products of these degradative reactions are made available to the cell. It is estimated that 1 to 1.5 percent of the proteins within a healthy liver cell are degraded via autophagy per hour as part of a normal process of cellular renovation. Enclosure within autophagosomal vesicles is thought to be relatively selective rather than simply a random process. Autophagy probably evolved in early eukaryotic organisms as a response to nutrient deprivation. If a population of cells—whether derived from yeast, plants or animals—is placed under starvation conditions, a marked increase in autophagy is observed. Under these conditions, cells acquire energy to maintain their life by cannibalizing their own organelles. The same autophagic process is induced in the cells of a mammalian embryo before it has implanted in the uterus and thus before it can take advantage of nutrients delivered via the mother's bloodstream.

Our understanding of the importance of autophagy in animals has coincided with the discovery and analysis of a host of genes (known as *Atg* genes) that are required for various steps in the autophagic pathway. Deletion of certain of these autophagy genes can have serious consequences for embryonic development or adult physiology of model organisms, whether it is a worm or a mouse. It has been shown, for example, that autophagy helps protect an organism against intracellular threats ranging from abnormal protein aggregates to invading bacteria and parasites. Autophagy has also been implicated in the prevention of neurodegeneration. If autophagy is blocked in a particular portion of the brain of a laboratory

Figure 8.35 A summary of the autophagic pathway. The steps are described in the text.

animal, that region of the nervous system experiences massive loss of nerve cells. These findings reveal the importance of autophagy in protecting brain cells from the continuous damage to proteins and organelles that is experienced by these long-lived cells. Autophagy may even play a role in the prevention of certain types of cancers and slowing the body's aging process.

The role of lysosomes in autophagy is summarized in Figure 8.35. Once the digestive process in the autolysosome has been completed, the organelle is termed a *residual body*. Depending on the type of cell, the contents of the residual body may be eliminated from the cell by exocytosis, or they may be retained within the cytoplasm indefinitely as a *lipofuscin granule*. Lipofuscin granules increase in number as an individual becomes older; accumulation is particularly evident in long-lived cells such as neurons, where these granules are considered a major characteristic of the aging process. The role of lysosomes in various diseases is discussed in the accompanying Human Perspective.

REVIEW

1. Describe three distinct roles of lysosomes.
2. Describe the events that occur during the autophagic destruction of a mitochondrion.

THE HUMAN PERSPECTIVE

Disorders Resulting from Defects in Lysosomal Function

Our understanding of the mechanisms by which proteins are targeted to particular organelles began with the discovery that the mannose 6-phosphate residues in lysosomal enzymes act as an “address” for delivery of these proteins to lysosomes. The discovery of the lysosome address was made in studies of patients with a rare and fatal inherited condition known as *I-cell disease*. Many cells in these patients contain lysosomes that are bloated with undegraded materials. Materials accumulate in the lysosomes because of the absence of hydrolytic enzymes. When fibroblasts from these patients were studied in culture, it was found that lysosomal enzymes are synthesized at normal levels but are secreted into the medium and not targeted to lysosomes. Further analysis revealed that the secreted enzymes lacked the mannose phosphate residues that are present on the lysosomal enzymes of cells from normal individuals. The I-cell defect was soon traced to the deficiency of an enzyme (*N*-acetylglucosamine phosphotransferase) required for mannose phosphorylation in the Golgi complex (see Figure 8.29*a*).

In 1965, H. G. Hers of the University of Louvain in Belgium offered an explanation as to how the absence of a seemingly unimportant lysosomal enzyme, α -glucosidase, could lead to the development of a fatal inherited condition known as Pompe disease. Hers suggested that, in the absence of α -glucosidase, undigested glycogen accumulated in lysosomes, causing swelling of the organelles and irreversible damage to the cells and tissues. Diseases of this type, characterized by the deficiency of a single lysosomal enzyme and the corresponding accumulation of undegraded substrate (Figure 1), are called **lysosomal storage disorders**. Over 40 such diseases have been described, affecting approximately 1 in 8000 infants. Those diseases resulting from an accumulation of undegraded sphingolipids are listed in Table 1. The symptoms of lysosomal storage diseases can range from very severe to barely detectable, depending primarily on the degree of enzyme dysfunction. Several diseases have also been traced to mutations in lysosomal membrane proteins that impair the transport of substances from the lumen of the lysosome to the cytosol.

Among the best studied lysosomal storage diseases is Tay-Sachs disease, which results from a deficiency of the enzyme β -*N*-hexosaminidase A, an enzyme that degrades the ganglioside

G_{M2} (Figure 4.6). G_{M2} is a major component of the membranes of brain cells, and in the absence of the hydrolytic enzyme, the ganglioside accumulates in the bloated lysosomes of brain cells (Figure 1), causing dysfunction. In its severe form, which strikes during infancy, the disease is characterized by progressive mental and motor retardation, as well as skeletal, cardiac, and respiratory abnormalities. The disease is very rare in the general population but reached an

Figure 1 Lysosomal storage disorders. Electron micrograph of a section through a portion of a neuron of a person with a lysosomal storage disease characterized by an inability to degrade G_{M2} gangliosides. These cytoplasmic vacuoles stain for both lysosomal enzymes and the ganglioside, indicating they are lysosomes in which undigested glycolipids have accumulated. (COURTESY OF KINUKO SUZUKI.)

Table 1 Sphingolipid Storage Diseases

Disease	Enzyme deficiency	Principal storage substance	Consequences
G_{M1} Gangliosidosis	G_{M1} β -Galactosidase	Ganglioside G_{M1}	Mental retardation, liver enlargement, skeletal involvement, death by age 2
Tay-Sachs disease	Hexosaminidase A	Ganglioside G_{M2}	Mental retardation, blindness, death by age 3
Fabry's disease	α -Galactosidase A	Trihexosylceramide	Skin rash, kidney failure, pain in lower extremities
Sandhoff's disease	Hexosaminidases A and B	Ganglioside G_{M2} and globoside	Similar to Tay-Sachs disease but more rapidly progressing
Gaucher's disease	Glucocerebrosidase	Glucocerebroside	Liver and spleen enlargement, erosion of long bones, mental retardation in infantile form only
Niemann-Pick disease	Sphingomyelinase	Sphingomyelin	Liver and spleen enlargement, mental retardation
Farber's lipogranulomatosis	Ceramidase	Ceramide	Painful and progressively deformed joints, skin nodules, death within a few years
Krabbe's disease	Galactocerebrosidase	Galactocerebroside	Loss of myelin, mental retardation, death by age 2
Sulfatide lipidosis	Arylsulfatase A	Sulfatide	Mental retardation, death in first decade

incidence up to 1 in 3600 newborns among Jews of eastern European ancestry. The incidence of the disease has dropped dramatically in this ethnic population in recent years as the result of identification of carriers, genetic counseling of parents at risk, and prenatal diagnosis by amniocentesis. In fact, all of the known lysosomal storage diseases can be diagnosed prenatally.

In the past few years, the prospects for treatment of lysosomal storage diseases have improved with the demonstration that the symptoms of Gaucher's disease, a deficiency of the lysosomal enzyme glucocerebrosidase, can be alleviated by *enzyme replacement therapy*. Infants with Gaucher's disease accumulate large quantities of glucocerebroside lipids in the lysosomes of their macrophages, causing spleen enlargement and anemia. Initial attempts to correct the disease by infusing a solution of the normal human enzyme into the bloodstream were unsuccessful because the enzyme was taken up by liver cells, which are not seriously affected by the deficiency. To target macrophages, the enzyme was purified from human placental tissue and treated with three different glycosidases to remove terminal sugars on the enzyme's oligosaccharide chains, which exposed underlying mannose residues (see Figure 8.22). Following infusion into the bloodstream, this modified enzyme (marketed under the name Cerezyme) is recognized by mannose receptors on the surface of macrophages and rapidly taken up by receptor-mediated endocy-

tosis (page 308). Because lysosomes are the natural target site of materials brought into the macrophage by endocytosis, the enzymes are efficiently delivered to the precise sites in the cell where the deficiency is manifested. Thousands of victims of this disease have been successfully treated in this way. Enzyme replacement therapy for the treatment of several other lysosomal storage diseases has either been approved or is being investigated in clinical trials. (The movie *Extraordinary Measures* is based on the search for a replacement enzyme to treat Pompe disease.) Unfortunately, many of these diseases affect the central nervous system, which is unable to take up circulating enzymes because of the blood–brain barrier (page 262).

An alternate approach that has shown some promise in preclinical trials is referred to as *substrate reduction therapy*, in which small-molecular-weight drugs (e.g., Zavesca) are administered to inhibit the synthesis of the substances that accumulate in the disease. Finally it can be noted that, although it is accompanied by considerable risk to the patient, bone marrow (or cord blood) transplantation has proven relatively successful in treating some of these diseases. It is thought that the foreign transplanted cells, which contain normal copies of the gene in question, secrete a limited amount of the normal lysosomal enzyme. Some of these enzyme molecules are then taken up by the patient's own cells, which lessens the impact of the enzyme deficiency.

8.7 | Plant Cell Vacuoles

As much as 90 percent of the volume of many plant cells is occupied by a single membrane-bound, fluid-filled central **vacuole** (Figure 8.36). While simple in structure, plant

vacuoles carry out a wide spectrum of essential functions. Many of a cell's solutes and macromolecules, including ions, sugars, amino acids, proteins, and polysaccharides, are stored temporarily in the vacuole. Vacuoles may also store a host of toxic compounds. Some of these compounds (such

(a)

leaf mesophyll cells showing the large central vacuole and thin layer of surrounding cytoplasm. (A: M. I. WALKER/PHOTO RESEARCHERS, INC.; B: BIOPHOTO ASSOCIATES/PHOTO RESEARCHERS, INC.)

as cyanide-containing glycosides and glucosinolates) are part of an arsenal of chemical weapons that are released when the cell is injured by an herbivore or fungus. Other toxic compounds are simply the by-products of metabolic reactions; because plants lack the type of excretory systems found in animals, they utilize their vacuoles to isolate these by-products from the rest of the cell. Some of these compounds, such as digitalis, have proven to have important clinical value.

The membrane that bounds the vacuole, the **tonoplast**, contains a number of active transport systems that pump ions into the vacuolar compartment to a concentration much higher than that in the cytoplasm or the extracellular fluid. Because of its high ion concentration, water enters the vacuole by osmosis. Hydrostatic (turgor) pressure exerted by the vacuole not only provides mechanical support for the soft tissues of a plant (page 150), it also stretches the cell wall during cell growth.

Plant vacuoles are also sites of intracellular digestion, not unlike lysosomes, which are absent in plants. In fact, plant vacuoles have some of the same acid hydrolases found in lysosomes. The pH of the vacuole is maintained at a low value by a V-type H^+ -ATPase within the tonoplast that pumps protons into the vacuolar fluid. Like the proteins of the lysosome, many of the proteins of a plant vacuole are synthesized on membrane-bound ribosomes of the RER, transported through the Golgi complex, and sorted at the *trans* face of the Golgi before being targeted to the vacuole.

REVIEW

1. Describe three distinct roles of plant vacuoles.
2. In what ways is a plant vacuole similar to a lysosome? In what ways is it different?

8.8 | The Endocytic Pathway: Moving Membrane and Materials into the Cell Interior

We have described at length how a cell transports materials from the RER and Golgi to the plasma membrane and extracellular space. We can now turn to the movement of materials in the opposite direction. We considered in Chapter 4 how low-molecular-weight solutes pass through the plasma membrane. But how are cells able to take in materials that are too large to penetrate this membrane regardless of its permeability properties? And how are proteins that reside in the plasma membrane recycled to the cell's internal compartments? Both of these requirements are met by the endocytic pathway, in which segments of the plasma membrane invaginate to form cytoplasmic vesicles that are transported into the cell interior. We will consider two basic processes in this section of the chapter, endocytosis and phagocytosis, which occur by different mechanisms. **Endocytosis** is primarily a process by which the cell internalizes cell-surface receptors and bound extracellular ligands. **Phagocytosis** describes the uptake of particulate matter.

Endocytosis

Endocytosis can be divided broadly into two categories: bulk-phase endocytosis and receptor-mediated endocytosis. *Bulk-phase endocytosis* (also known as *pinocytosis*) is the nonspecific uptake of extracellular fluids. Any molecules, large or small, that happen to be present in the enclosed fluid also gain entry into the cell. Bulk-phase endocytosis can be visualized by adding a substance to the culture medium, such as the dye lucifer yellow or the enzyme horseradish peroxidase, that is taken up by cells nonspecifically. Bulk-phase endocytosis also removes portions of the plasma membrane and may function primarily in the recycling of membrane between the cell-surface and interior compartments. **Receptor-mediated endocytosis (RME)**, in contrast, brings about the uptake of specific extracellular macromolecules (ligands) following their binding to receptors on the external surface of the plasma membrane.⁵

Receptor-Mediated Endocytosis and the Role of Coated Pits

Receptor-mediated endocytosis provides a means for the selective and efficient uptake of macromolecules that may be present at relatively low concentrations in the extracellular fluid. Cells have receptors for the uptake of many different types of ligands, including hormones, growth factors, enzymes, and blood-borne proteins carrying certain nutrients. Substances that enter a cell by means of clathrin-mediated RME become bound to receptors that collect in specialized domains of the plasma membrane, known as **coated pits**. Receptors are concentrated in coated pits at 10–20 times their level in the remainder of the plasma membrane. Coated pits (Figure 8.37*a*) are recognized in electron micrographs as sites where the surface is indented and the plasma membrane is covered on its cytoplasmic face by a bristly, electron-dense coat containing clathrin. Coated pits invaginate into the cytoplasm (Figure 8.37*b*) and then pinch free of the plasma membrane to form coated vesicles (Figure 8.37*c,d*). To understand the mechanism of coated vesicle formation, we need to examine the molecular structure of the clathrin coat.

Figure 8.38 shows a coated pit as seen from the extracellular and cytoplasmic surfaces of the plasma membranes of cells that had been engaged in receptor-mediated endocytosis. When viewed from its cytoplasmic surface (Figure 8.38*b,c*), the bristly coat appears as a network of polygons (hexagons and pentagons) resembling a honeycomb. The geometric construction of the coat is derived from the structure of its clathrin building blocks. Each clathrin molecule consists of three heavy chains and three light chains, joined together at the center to form a three-legged assembly called a *triskelion*

⁵Over the years, several distinct mechanisms of receptor-mediated endocytosis have been described, although some of these proposed mechanisms remain controversial. For our purpose, we will discuss only one mechanism of endocytosis—that which is accomplished by means of clathrin-containing coats, the same type of protein coat discussed on page 299 in connection with vesicles formed at the TGN. (Discussions of clathrin-independent endocytosis can be found in *Ann. Rev. Biochem.* 78, 857, 2009; *J. Cell Sci.* 122: 1713, 2009; and *Curr. Opin. Cell Biol.* 22, 519, 2010 & 23:413, 2011.)

Figure 8.37 Receptor-mediated endocytosis. This sequence of micrographs shows the steps in the uptake of yolk lipoproteins by the hen oocyte. (a) The proteins to be taken into the cell are concentrated on the extracellular surface of an indented region of the plasma membrane, forming a coated pit. The cytosolic surface of the plasma membrane of the coated pit is covered with a layer of bristly, electron-dense material containing the protein clathrin. (b) The coated pit has sunk inward to form a coated bud. (c) The plasma membrane is about to

pinch off as a vesicle containing the yolk protein on its luminal (previously extracellular) surface and clathrin on its cytosolic surface. (d) A coated vesicle that is no longer attached to the plasma membrane. The next step in the process is the release of the clathrin coat. (FROM M. M. PERRY AND A. B. GILBERT, *J. CELL SCIENCE* 39:257, 1979, BY PERMISSION OF THE COMPANY OF BIOLOGISTS, LTD. <http://jcs.biologists.org/content/39/1/257.full.pdf+html?sid=2493468d-1f02-467a-a192-c2c876bd98b9>)

(Figure 8.39). The overlapping arrangement of the triskelions within the clathrin scaffold of a coated vesicle is shown in Figure 8.40. Each leg of a clathrin triskelion extends outward

along two edges of a polygon. The clathrin molecules overlap in such a way that each vertex of a polygon contains a center of one of the component triskelions.

Figure 8.40 Molecular organization of a coated vesicle.

(a) Schematic drawing of the surface of a coated vesicle showing the arrangement of triskelions and adaptors in the outer clathrin coat. The sides of the polygons are formed by parts of the legs of overlapping triskelions. The N-terminus of each clathrin heavy chain forms a “hook” that projects toward the surface of the membrane where it engages an adaptor. Each adaptor, which consists of four different polypeptide subunits, can bind a diverse array of accessory proteins that are not shown in this illustration. Both the hooks and adaptors are situated at the vertices of the polyhedrons. (*Note:* Not all of the triskelions of the lattice are shown in this figure; if they were, every vertex would have a clathrin hub, hook, and associated adaptor.) (b) Schematic drawing of a cross section through the surface of a coated vesicle showing the interactions of the AP2 adaptor complexes with both the clathrin coat and membrane receptors. Recruitment of AP2 adaptors to the plasma membrane is facilitated by the presence of PI(4,5)P₂ molecules in the inner (cytosolic) leaflet of the membrane as shown in Figure 8.42. Each receptor is bound to a ligand being internalized. (c) Reconstruction of a clathrin cage containing 36 triskelions showing the overlapping arrangement of several of these trimeric molecules (shown in different colors). (An animation can be found at <http://iwasa.hms.harvard.edu>) (A: ANNUAL REVIEW OF BIOCHEMISTRY. VOLUME 66 BY RICHARDSON, CHARLES C.; ABELSON, JOHN N.; RAETZ, CHRISTIAN R. H. HARRISON; © 2004. REPRINTED WITH PERMISSION FROM MACMILLAN PUBLISHERS LTD.)

Like the clathrin-coated vesicles that bud from the TGN (page 299), the coated vesicles that form during endocytosis also contain a layer of adaptors situated between the clathrin lattice and the surface of the vesicle facing the cytosol. The best studied adaptor operating in connection with clathrin-mediated endocytosis is AP2. Unlike the GGA adaptors utilized at the TGN, which consist of a single subunit with several domains (Figure 8.30), the AP2 adaptors that become incorporated into the vesicles that bud from the plasma membrane contain multiple subunits having different functions (Figure 8.40). The μ subunit of AP2 adaptors engages the cytoplasmic tails of specific plasma membrane receptors, leading to the concentration of these selected receptors—and their bound cargo molecules—into the emerging coated vesicle (discussed further in the Experimental Pathways on page 321). In contrast, the β -adaptein subunit of AP2 adaptors binds and recruits the clathrin molecules of the overlying lattice. A comparison of Figures 8.26 and 8.40 shows both marked differences and similarities between the coats of COPII- and clathrin-coated vesicles. Both coats contain two

distinct layers: an outer geometric scaffold and an inner layer of adaptor proteins. The structure of the outer scaffolds, however, are very different; the subunits of the clathrin lattice (three-legged clathrin complexes) overlap extensively, whereas those of the COPII lattice (rod-like Sec13–Sec31 complexes) do not overlap at all. In addition, each vertex of a COPII coat is formed by four edges rather than three as in a clathrin coat. Whether there is a functional basis for these two different types of construction strategies is unclear.

The structure depicted in Figure 8.40 is a greatly simplified version of an actual coated vesicle, which may contain upwards of two dozen different accessory proteins that form a dynamic network of interacting molecules. These proteins have roles in cargo recruitment, coat assembly, membrane bending and invagination, interaction with cytoskeletal components, vesicle release, and membrane uncoating. The best studied of these accessory proteins is dynamin.

Dynamin is a large GTP-binding protein that is required for the release of a clathrin-coated vesicle from the membrane on which it forms. Dynamin self-assembles into a helical collar around the neck of an invaginated coated pit (Figure 8.41), just before it pinches off from the membrane. In the model depicted in Figure 8.41*a*, steps 3–4, hydrolysis of the bound GTP by the polymerized dynamin molecules induces a twisting motion in the dynamin helix that severs the coated vesicle from the plasma membrane. According to this mechanism, dynamin acts as an enzyme capable of utilizing the chemical energy of GTP to generate mechanical forces. Dissociation of the clathrin coat from the vesicle requires the help of an additional protein, the ATPase Hsc70, which is recruited to the clathrin coat by a cofactor, auxilin.

The Role of Phosphoinositides in the Formation of Coated Vesicles Although this discussion emphasizes the protein molecules of the coat and vesicle, the phospholipids of the vesicle membrane also play an important role. As discussed in Chapter 15, phosphate groups can be added to different positions of the sugar ring of the phospholipid phosphatidylinositol (PI), converting them into phosphoinositides (see Figure 15.10). Seven distinct phosphoinositides are identified: PI(3)P, PI(4)P, PI(5)P, PI(3,4)P₂, PI(4,5)P₂, PI(3,5)P₂, and PI(3,4,5)P₃. The phosphorylated rings of these phosphoinositides reside at the surface of the membrane where they can be recognized and bound by particular proteins. Different phosphoinositides are concentrated in different membrane compartments, which helps give each compartment a unique “surface identity.” The inner leaflet of the plasma membrane, for example, tends to contain elevated levels of PI(4,5)P₂, which plays an important role in recruiting proteins involved in clathrin-mediated endocytosis, such as dynamin and AP2 (see Figure 8.40*b*). Not only can a phosphoinositide aid in recruiting specific proteins, it can also induce conformational changes in a bound protein that facilitate a molecular process. The clathrin adaptor AP2, for example, normally exists in the cytosol in a locked conformation. Binding of the AP2 complex to PI(4,5)P₂ sites in the plasma membrane induces a major conformational change in AP2 that opens a cargo binding site within the adaptor, allowing it to

(a)

(b)

Figure 8.41 The role of dynamin in the formation of clathrin-coated vesicles. (a) The clathrin lattice of the coated pit (step 1) undergoes rearrangement to form an invaginated vesicle connected to the overlying plasma membrane by a stalk (step 2). At this point, the dynamin subunits, which are concentrated in the region, undergo polymerization to form a ring around the stalk (step 3). Changes in the conformation of the ring, which are thought to be induced by GTP hydrolysis (step 4), lead to fission of the coated vesicle from the plasma membrane and disassembly of the dynamin ring (step 5a). If vesicle budding occurs in the presence of GTP γ S, a nonhydrolyzable analogue of GTP, dynamin polymerization continues beyond formation of a simple collar, producing a narrow tubule constructed from several turns of the dynamin helix (step 5b). Structural models of dynamin action can be found in *Nature* 477:556, 561, 2011. (b) Electron micrograph showing a coated vesicle forming in the presence of GTP γ S, which corresponds to the stage depicted in step 5b of part a. (A: REPRINTED FROM P. DE CAMILLI ET AL. CURRENT OPIN NEURO-BIOL. VOL 5, P. 562, 1995, WITH PERMISSION FROM ELSEVIER. B: FROM KOHJI TAKEI ET AL., NATURE VOL. 374, COVER 3/9/95; © 1995, REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LTD.)

interact with the cytoplasmic tails of specific membrane receptors. A structural model depicting this series of events is shown in Figure 8.42.

A lipid species such as PI(4,5)P₂ can have a dynamic regulatory role because it can be rapidly formed and destroyed by enzymes that are localized at particular places and times within the cell. In the example of endocytosis, PI(4,5)P₂

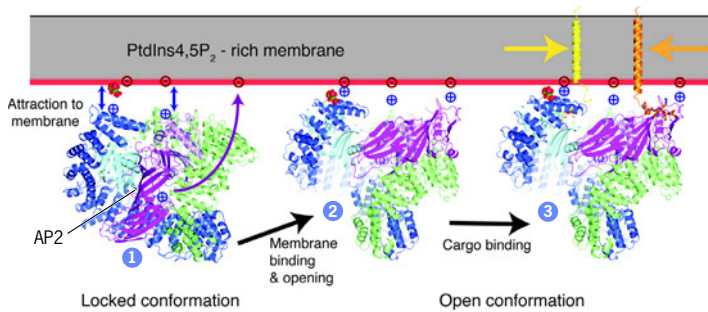

Figure 8.42 A structural model depicting the changes in protein conformation that occur upon AP2 binding to the plasma membrane. Binding of the AP2 adaptor is mediated by its interaction with PI(4,5)P₂ molecules in the inner leaflet of the plasma membrane (step 1). Binding of the adaptor to the membrane induces a large conformational change in the adaptor (step 2) that facilitates its interaction with specific motifs in the cytoplasmic tails of certain membrane receptors (shown in yellow and orange) (step 3). (FROM L. P. JACKSON, ET AL., COURTESY OF DAVID J. OWEN, CELL 141:1228, 2010, FIG. 7. © 2010, REPRINTED BY PERMISSION FROM ELSEVIER.) (SEE SUPPLEMENTAL MOVIE S3.)

disappears from a site of endocytosis about the time the coated vesicle is pinched away from the plasma membrane. Other PIs that are thought to serve as “landmarks” within the secretory/endocytic pathways include PI(3)P localized at early endosomes and intraluminal vesicles of late endosomes; PI(4)P localized at the TGN, secretory granules, and synaptic vesicles; and PI(3,5)P₂ localized at the late endosome boundary membrane.

The Endocytic Pathway Molecules taken into a cell by endocytosis are routed through a well-defined **endocytic pathway** (Figure 8.43a). Before describing events that occur along the endocytic pathway, it is worth considering two different types of receptors that are subjected to endocytosis. One group of receptors, which we will refer to as “housekeeping receptors,” is responsible for the uptake of materials that will be used by the cell. The best studied examples are the transferrin and LDL (low-density lipoprotein) receptors, which mediate the delivery to cells of iron and cholesterol, respectively. The LDL receptor is discussed in detail at the end of this section. The red-colored receptor of Figure 8.43a represents a housekeeping receptor. The second group of receptors, which we will refer to as “signaling receptors,” is responsible for binding extracellular ligands that carry messages that change the activities of the cell. These ligands, which include hormones such as insulin and growth factors such as EGF, bind to the surface receptor (shown in green in Figure 8.43a) and signal a physiologic response inside the cell (discussed at length in Chapter 15). Endocytosis of the first group of receptors leads typically to the delivery of the bound materials, such as iron and cholesterol, to the cell and the return of the receptor to the cell surface for additional rounds of uptake. Endocytosis of the second group of receptors often leads to the destruction of the receptor, a process called *receptor down-regulation*, which has the effect of reducing the sensitivity of the cell to further stimulation by the hormone or

growth factor. Receptor down-regulation is a mechanism by which cells regulate their ability to respond to extracellular messengers. “Signaling receptors” are typically marked for endocytosis and subsequent destruction by the covalent attachment of a “tag” to the cytoplasmic tail of the receptor while it resides at the cell surface. The tag is a small protein called ubiquitin, which is added enzymatically. Membrane proteins that are not normally subjected to endocytosis become internalized if they are made to carry an added ubiquitin.⁶

Following internalization, vesicle-bound materials are transported to a dynamic network of tubules and vesicles known collectively as **endosomes**, which represent distribution centers along the endocytic pathway. The fluid in the lumen of endosomes is acidified by a H⁺-ATPase in the boundary membrane. Endosomes are divided into two classes: **early endosomes**, which are typically located near the peripheral region of the cell, and **late endosomes**, which are typically located closer to the nucleus. According to the prevailing model, early endosomes progressively mature into late endosomes. This transformation from an early to a late endosome is characterized by a decrease in pH, an exchange of Rab proteins (e.g., from Rab5 to Rab7), and a major change in the internal morphology of the structures.

Receptors that are taken up by endocytosis are transported in vesicles to an early endosome, which serves as a sorting station that directs different types of receptors and ligands along different pathways (Figure 8.43a). “Housekeeping receptors” typically dissociate from their bound ligands as a result of the high H⁺ concentration of the early endosomes. The receptors are then concentrated into specialized tubular compartments of the early endosome, which represent recycling centers. Vesicles that bud from these tubules carry receptors back to the plasma membrane for additional rounds of endocytosis (Figure 8.43a). In contrast, released ligands (e.g., LDLs) become concentrated into a sorting compartment before being dispatched to a late endosome and ultimately to a lysosome, where final processing occurs. As noted above, “signaling receptors” with attached ubiquitin tags do not recycle back to the membrane. Instead, these ubiquitinated receptors are sequestered into a population of small, spherical vesicles that crowd the interior of the late endosome (Figure 8.43b). This vesiculation process (shown in the inset on the left side of Figure 8.43a) is orchestrated by a series of protein complexes (called ESCRT complexes). Four different ESCRT complexes act in sequence to (1) sort the ubiquitinated receptors into a cluster within the late endosomal membrane, (2) cause that patch of membrane to invaginate as a bud into the lumen of the late endosome, and (3) sever the neck of the invagination to release the newly formed intraluminal

⁶In its best-studied role, ubiquitin is attached to a protein to target that protein for degradation as discussed in Section 12.7. This type of degradation signal is composed of a number of ubiquitin molecules that are joined to one another (to form a polyubiquitin chain) by covalent linkages at a specific residue on each ubiquitin molecule, namely Lys48. In contrast, internalization of a membrane protein is thought to be triggered by attachment to that protein of either a single ubiquitin molecule or a short polyubiquitin chain in which the ubiquitin molecules are linked to one another at Lys63 rather than Lys48 (see *Trends Cell Biol.* 21:647.2011).

(c)

Figure 8.43 The endocytic pathway. The movement of materials from the extracellular space to early endosomes where sorting occurs. Endocytosis of two types of receptor–ligand complexes is shown. Housekeeping receptors, such as the LDL receptor (shown in red), are typically sent back to the plasma membrane, whereas their ligands (purple spheres) are transferred to late endosomes. Signaling receptors, such as the EGF receptor (shown in green), are typically transported to late endosomes along with their ligands (yellow). Late endosomes also receive newly synthesized lysosomal enzymes (red spheres) from the TGN. These enzymes are carried by mannose 6-phosphate receptors (MPRs), which return to the TGN. The contents of late endosomes are transferred to lysosomes by a number of routes (not shown). The inset on the left shows an enlarged view of a portion of a late endosome with an intraluminal vesicle budding inward from the outer membrane. The membranes of these vesicles contain receptors to be degraded. (b) Electron micrograph showing the internal vesicles within the lumen of a late endosome. A number of lysosomes are present in the vicinity. (c) The gold particles seen in this electron micrograph are bound to EGF receptors that were internalized by endocytosis and have become localized within the membranes of the internal vesicles of this late endosome. (B: FROM J. PAUL LUZIO, PAUL R. PRYOR, AND NICHOLAS A. BRIGHT, NATURE REV. MOL. CELL BIOL. 8:625, 2007; © 2007, REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LTD., C: COURTESY OF CLARE FUTTER.)

vesicle. The segregation of signaling receptors within the lumen of a late endosome is shown in Figure 8.43c. Because of these internal vesicles, late endosomes are also referred to as *multivesicular bodies (MVBs)*.

LDLs and Cholesterol Metabolism Among many examples of receptor-mediated endocytosis, the first studied and best understood is one that provides animal cells with exogenous cholesterol. Animal cells use cholesterol as an essential part of their plasma membranes and as a precursor to steroid hormones. Cholesterol is a hydrophobic molecule that is transported in the blood as part of huge lipoprotein complexes, such as the *low-density lipoprotein (LDL)* shown in Figure 8.44. Each LDL particle contains a central core of about 1500 cholesterol molecules esterified to long-chain fatty acids. The core is surrounded by a single layer of phospholipids that contains a single copy of a large protein, called *apolipoprotein B-*

100, which binds specifically to LDL receptors on the surfaces of cells.

LDL receptors are transported to the plasma membranes of cells, where they become concentrated in coated pits, even in the absence of LDL ligand. As a result, the receptors are on the cell surface ready to take up the blood-borne lipoproteins if they should become available. Once the LDL particles are bound to a coated pit, the pit invaginates to form a coated vesicle, the clathrin coat is disassembled, and the LDL receptors pass through the early endosomes and back to the plasma membrane, as depicted in Figure 8.43a. Meanwhile, the LDL particles are delivered to late endosomes and lysosomes, where the protein component is degraded and the cholesterol is deesterified and used by the cell in membrane assembly or other metabolic processes (e.g., steroid hormone formation). Persons with a rare inherited disorder called *Niemann-Pick type C disease* lack one of the proteins required to transfer

Figure 8.44 LDL cholesterol. Each particle consists of esterified cholesterol molecules, surrounded by a mixed monomolecular layer of phospholipids and cholesterol, and a single molecule of the protein apolipoprotein B-100, which interacts specifically with the LDL receptor projecting from the plasma membrane.

cholesterol out of lysosomes. The resulting accumulation of cholesterol in these organelles leads to nerve degeneration and death during early childhood. Studies of a different disease that led to the discovery of receptor-mediated endocytosis and LDL internalization are described in the accompanying Experimental Pathways.

The level of LDL in the blood has been related to the development of atherosclerosis, a condition characterized by formation of plaques in the inner lining of arteries that reduce the flow of blood through the vessel and act as sites for the formation of blood clots. Blood clots that block the coronary arteries are the leading cause of myocardial infarction (heart attack). Studies suggest that atherosclerosis results from a

chronic inflammatory response that is initiated by the deposition of LDL within the inner walls of blood vessels, as indicated in Figure 8.45. Lowering blood LDL levels is most readily accomplished by administration of drugs called *statins* (e.g., lovastatin and Lipitor) that block HMG CoA reductase, a key enzyme in the synthesis of cholesterol (page 319). When blood cholesterol levels are lowered, the risk of heart attack is reduced.

LDLs are not the only cholesterol-transporting agents in the blood. *HDLs* (*high-density lipoproteins*) have a similar construction but contain a different protein (apolipoprotein A-I) and play a different physiologic role in the body. LDL serves primarily to carry cholesterol molecules from the liver, where they are synthesized and packaged, through the blood to the body's cells. HDL carries cholesterol in the opposite direction. Excess cholesterol is transported out of the plasma membrane of the body's cells directly to circulating HDL particles, which carry cholesterol to the liver for excretion. Just as high blood levels of LDL are associated with increased risk of heart disease, high blood levels of HDL are associated with decreased risk, which has led to HDL being called the "good cholesterol." There is little doubt that lowering LDL levels is beneficial, but the consequences of raising HDL levels is less clear-cut. For example, cholesterol molecules can be transferred from HDL to other lipoprotein particles by an enzyme called cholesteryl ester transfer protein (CETP), an activity that tends to lower HDL cholesterol levels. CETP has become a focus of research following the discovery of a population of Japanese families whose members routinely live more than 100 years and carry mutations in the *CETP* gene. Several small-molecular-weight CETP inhibitors have been tested in clinical trials and found to increase HDL levels in the blood. One of these drug candidates (torcetrapib) was dropped from further study despite the fact that it raised HDL blood levels. For reasons that are unclear, subjects taking the drug and a statin were considerably more likely to die than those in the control group who took only the statin. Preliminary study of

Figure 8.45 A model of atherosclerotic plaque formation. According to this model, plaque formation is initiated by various types of injury to the endothelial cells that line the vessel, including damage inflicted by oxygen free radicals that chemically alter the LDL-cholesterol particles. The injured endothelium acts as an attractant for white blood cells (leukocytes) and macrophages, which migrate beneath the endothelium and begin a process of chronic inflammation. The macrophages ingest the oxidized LDL, which becomes deposited in the cytoplasm as

cholesterol-rich fatty droplets. These cells are referred to as macrophage foam cells and they are often already present in the blood vessels of adolescents and young adults. Substances released by the macrophages stimulate the proliferation of smooth muscle cells, which produce a dense, fibrous connective tissue matrix (fibrous cap) that bulges into the arterial lumen. Not only do these bulging lesions restrict blood flow, they are prone to rupture, which can trigger the formation of a blood clot and ensuing heart attack.

another CETP inhibitor (anacetrapib) did not show any evidence of harmful effects from the drug. Although anacetrapib raised HDL levels dramatically (by an average of more than 100 percent), it remains to be seen if this response will translate into increased long-term survival of patients at risk for heart disease. Another cholesterol-lowering drug target is PCSK9, a proteolytic enzyme that destroys LDL receptors in the liver. Persons that carry inactivating mutations in the gene encoding PCSK9 have reduced LDL cholesterol levels and

decreased heart disease. At least two PCSK9 inhibitors (REGN727 and AMG145) are in clinical trials.

Phagocytosis

Phagocytosis (“cell eating”) is carried out extensively by a few types of cells specialized for the uptake of relatively large particles ($>0.5 \mu\text{m}$ diameter) from the environment. Many single-celled protists, such as amoebas and ciliates, make their livelihood by trapping food particles and smaller organisms and enclosing them within folds of the plasma membrane. The folds fuse to produce a vacuole (or *phagosome*) that pinches off inwardly from the plasma membrane. The phagosome fuses with a lysosome, and the material is digested within the resulting *phagolysosome*.

In most animals, phagocytosis is a protective mechanism rather than a mode of feeding. Mammals possess a variety of “professional” phagocytes, including macrophages and neutrophils, that wander through the blood and tissues phagocytizing invading organisms, damaged and dead cells, and debris. These materials are recognized and bound by receptors on the surface of the phagocyte prior to uptake. Once inside the phagocyte, microorganisms may be killed by lysosomal enzymes or by oxygen free radicals generated within the lumen of the phagosome. The process of particle engulfment is pictured in the chapter-opening photograph and in Figure 8.46a. The steps in the digestion of engulfed materials are illustrated in Figure 8.46b. The engulfment of particulate material by phagocytosis is driven by contractile activities of the actin-containing microfilaments that underlie the plasma membrane.

Not all bacteria ingested by phagocytic cells are destroyed. In fact, some species hijack the phagocytic machinery to promote their own survival in the body. *Mycobacterium tuberculosis*, the agent responsible for tuberculosis, for example, is taken into the cytoplasm of a macrophage by phagocytosis, but the bacterium is able to inhibit the fusion of its phagosome with a lysosome. Even if the phagosome does become highly acidic, the bacterium appears able to maintain its own physiological pH despite the lowered pH of its surrounding medium. The bacterium responsible for Q fever, *Coxiella burnetii*, becomes enclosed in a phagosome that does fuse with a lysosome, but neither the acidic environment nor the lysosomal enzymes can destroy the pathogen. *Listeria monocytogenes*, a bacterium that causes meningitis, produces proteins that destroy the integrity of the lysosomal membrane, allowing the bacterium to escape into the cell’s cytosol (see Figure 9.67).

REVIEW

1. Describe the steps that occur between the binding of an LDL particle to the plasma membrane of a cell and the entry of cholesterol molecules into the cytosol.
2. Describe the molecular structure of clathrin and the relationship between its structure and function.
3. How does the role of phagocytosis in the life of an amoeba compare to its role in a multicellular animal? What are the major steps that occur during phagocytosis?

8.9 | Posttranslational Uptake of Proteins by Peroxisomes, Mitochondria, and Chloroplasts

The division of the contents of a cell into large numbers of compartments presents many organizational challenges to the cell's protein-trafficking machinery. We have seen in this chapter that protein trafficking within a eukaryotic cell is governed by (1) sorting signals, such as the signal peptide of secreted proteins or mannose-phosphate groups of lysosomal enzymes, and (2) receptors that recognize these signals and deliver proteins containing them to the proper compartment. Four of the cell's major organelles—nucleus, mitochondria, chloroplasts, and peroxisomes—import proteins through one or more outer boundary membranes. As in the case of the rough ER, proteins that are imported by these organelles contain amino acid sequences that serve as addresses that are recognized by receptors at the organelle's outer membrane. Unlike the rough ER, which generally imports its proteins cotranslationally, the proteins of these other organelles are imported posttranslationally, that is, following their complete synthesis on free ribosomes in the cytosol.

The import of proteins into the nucleus is a specialized topic and will be discussed separately in Section 12.2. Import of proteins into peroxisomes, mitochondria, and chloroplasts will be discussed in the following sections.

Uptake of Proteins into Peroxisomes

Peroxisomes are very simple organelles having only two subcompartments in which an imported protein can be placed: the boundary membrane and the internal matrix (page 206). Proteins destined for a peroxisome possess a *peroxisomal targeting signal*, either a *PTS* for a peroxisomal matrix protein or an *mPTS* for a peroxisomal membrane protein. Several different PTSs, mPTSs, and PTS receptors have been identified. PTS receptors bind to peroxisome-destined proteins in the cytosol and shuttle them to the surface of the peroxisome, where they can enter the organelle. Some evidence suggests that at least one of the PTS receptors (PEX5) moves from the cytosol into the peroxisomal membrane where it forms a transient pore that facilitates the movement of proteins into the peroxisome. Unlike mitochondria and chloroplasts, whose imported proteins must assume an unfolded state, peroxisomes are somehow able to import peroxisomal matrix proteins in their native, folded conformation, even those that consist of several subunits. The mechanism by which peroxisomes are able to accomplish this daunting assignment remains a matter of speculation.

Uptake of Proteins into Mitochondria

Mitochondria have four subcompartments into which proteins can be delivered: an outer mitochondrial membrane (OMM), inner mitochondrial membrane (IMM), intermembrane space, and matrix (see Figure 5.3c). Although mitochondria synthesize a few of their own integral membrane

polypeptides (13 in mammals), roughly 99 percent of the organelle's proteins are encoded by the nuclear genome, synthesized in the cytosol, and imported posttranslationally. We will restrict the present discussion to proteins of the mitochondrial matrix and inner mitochondrial membrane, which together constitute the vast majority of the proteins targeted to this organelle. As with peroxisomal proteins, and proteins of other compartments, mitochondrial proteins contain signal sequences that target them to their home base. Most mitochondrial matrix proteins contain a removable targeting sequence (called the *presequence*) located at the N-terminus of the molecule (step 1, Figure 8.47a). A presequence typically includes a number of positively charged residues on one face of the helix and hydrophobic residues on the opposite face. In contrast, most proteins destined for the IMM contain internal targeting sequences that remain as part of the molecule.

Before a protein can enter a mitochondrion, several events are thought to take place. First, the protein must be presented to the mitochondrion in a relatively extended, or unfolded, state (steps 1 and A, Figure 8.47a). Several different molecular chaperones (e.g., Hsp70 and Hsp90) have been implicated in preparing polypeptides for uptake into mitochondria, including ones that specifically direct mitochondrial proteins to the cytosolic surface of the OMM (Figure 8.47a). The OMM contains a protein-import complex, the *TOM complex*, which includes (1) receptors that recognize and bind mitochondrial proteins and (2) protein-lined channels through which unfolded polypeptides are translocated across the outer membrane (steps 2 and B).⁷ Proteins that are destined for the IMM or matrix must pass through the intermembrane space and engage a second protein-import complex located in the IMM, called a *TIM complex*. The IMM contains two major TIM complexes: TIM22 and TIM23. TIM22 binds integral proteins of the IMM that contain an internal targeting sequence and inserts them into the lipid bilayer (steps C–D, Figure 8.47a). TIM23, in contrast, binds proteins with an N-terminal presequence, which includes all of the proteins of the matrix (as well as a number of proteins of the IMM that will not be discussed). TIM23 recognizes and translocates the matrix proteins completely through the IMM and into the inner aqueous compartment (step 3, Figure 8.47a). Translocation occurs at sites where the outer and inner mitochondrial membranes come into close proximity so that the imported protein can cross both membranes simultaneously. Movement into the matrix is powered by the electric potential across the IMM acting on the positively charged targeting signal; if the potential is dissipated by addition of a drug such as DNP (page 198), translocation ceases.

As it enters the matrix, a polypeptide interacts with mitochondrial chaperones, such as mtHsp70 (step 4, Figure 8.47a),

⁷It is interesting to note that, unlike the translocon of the ER or peroxisome, the pore-forming protein of the TOM complex (Tom 40) is a β -barrel protein, like the other integral proteins of the OMM (page 182), reflecting its evolution from the outer membrane of an ancestral bacterium. This has functional consequences, as the β -barrel protein cannot open laterally to allow integral proteins to insert into the OMM. As a result, OMM proteins have to pass into the intermembrane space before entering the OMM bilayer.

Figure 8.47 Importing proteins into a mitochondrion. (a) Proposed steps taken by proteins imported posttranslationally into either the mitochondrial matrix or inner mitochondrial membrane. The polypeptide is targeted to a mitochondrion by a targeting sequence, which is located at the N-terminus in the matrix protein (step 1) and is located internally in most inner membrane proteins (step A). Cytosolic Hsp70 molecules unfold the polypeptides prior to their entry into the mitochondrion. The proteins are recognized by membrane receptors (red transmembrane proteins) and translocated through the OMM by way of pores in the TOM complex of the OMM (step 2 or B). Most integral proteins of the IMM are directed to the TIM22 complex of the IMM (step C), which steers them into the lipid bilayer of the IMM (step D). Mitochondrial matrix proteins are translocated through the TIM23 complex of the IMM (step 3). Once the protein enters the matrix, it is

that mediate entry into the aqueous compartment. Two mechanisms have been proposed to explain the general action of molecular chaperones involved in the movement of proteins across membranes, which is a widespread phenomenon. According to one view, the chaperones act as force-generating motors that use energy derived from ATP hydrolysis to actively “pull” the unfolded polypeptide through the translocation pore. According to the alternate view, the chaperones aid in the diffusion of the polypeptide across the membrane. Diffusion is a random process in which a molecule can move in any available direction. Consider what would happen if an unfolded polypeptide had entered a translocation pore in the mitochondrial membrane and had “poked its head” into the matrix. Then consider what would happen if a chaperone re-

bound by a mitochondrial chaperone (step 4), which may either pull the polypeptide into the matrix or act like a Brownian ratchet to ensure that it diffuses into the matrix (these alternate chaperone mechanisms are discussed in the text). Once in the matrix, the unfolded protein assumes its native conformation (step 5a) with the help of Hsp60 chaperones (not shown). The presequence is removed enzymatically (step 5b). (b) A three-dimensional model of the mitochondrial protein-import machinery, showing the number, relative size, and topology of the various proteins involved in this activity. The TOM complex is a reddish color, the TIM23 complex is yellow-green, the TIM22 complex is green, and the cooperating chaperones are blue. (B: FROM TOSHIYA ENDO, HAYASHI YAMAMOTO, AND MASATOSHI ESAKI, J. CELL SCIENCE, COVER OF VOL. 116, #16, 2003; REPRODUCED BY PERMISSION OF THE COMPANY OF BIOLOGISTS, LTD. <http://jcs.biologists.org/content/116/16.cover-expansion>)

siding on the inner surface of the membrane were able to bind the protruding polypeptide in such a way that it blocked the diffusion of the polypeptide back through the pore and into the cytosol, but did not block its diffusion further into the matrix. As the polypeptide diffused further into the matrix, it would be bound repeatedly by the chaperone and at each stage prevented from diffusing backward. This mechanism of chaperone action is referred to as *biased diffusion*, and the chaperone is said to be acting as a “Brownian ratchet”; the term *Brownian* implies random diffusion, and a “ratchet” is a device that allows movement in only one direction. Recent studies suggest that both mechanisms of chaperone action are probably utilized and act cooperatively. Regardless of the mechanism of entry, once in the matrix the polypeptide achieves its

native conformation (step 5a, Figure 8.47a) following enzymatic removal of the presequence (step 5b).

Uptake of Proteins into Chloroplasts

Chloroplasts have six subcompartments into which proteins can be delivered: an inner and outer envelope membrane and intervening intermembrane space, as well as the stroma, thylakoid membrane, and thylakoid lumen (Figure 8.48). Chloroplast and mitochondrial import mechanisms exhibit many similarities, although their translocation machineries have evolved independently. As in the mitochondria,

1. the vast majority of chloroplast proteins (approximately 3000 in higher plants) are imported from the cytosol,
2. the outer and inner envelope membranes contain distinct translocation complexes (*Toc* and *Tic* complexes, respectively) that work together during import,

Figure 8.48 Importing proteins into a chloroplast. Proteins encoded by nuclear genes are synthesized in the cytosol and imported through protein-lined pores in both membranes of the outer chloroplast envelope (step 1). Proteins destined for the stroma (step 1a) contain a stroma-targeting domain at their N-terminus, whereas proteins destined for the thylakoid (step 1b) contain both a stroma-targeting domain and a thylakoid-transfer domain at their N-terminus. Stromal proteins remain in the stroma (step 2) following translocation through the outer envelope and removal of their single targeting sequence. The presence of the thylakoid transfer domain causes thylakoid proteins to be translocated either into or completely through the thylakoid membrane (step 3). A number of the proteins of the thylakoid membrane are encoded by chloroplast genes and synthesized by chloroplast ribosomes that are bound to the outer surface of the thylakoid membrane (step 4).

3. chaperones aid in the unfolding of the polypeptides in the cytosol and folding of the proteins in the chloroplast, and
4. most proteins destined for the chloroplast are synthesized with a removable N-terminal sequence (termed the *transit peptide*) that is highly variable in length and sequence.

The transit peptide does more than simply target a polypeptide to a chloroplast: it provides an “address” that localizes the polypeptide to one of several possible subcompartments within the organelle (Figure 8.48). All proteins translocated through the chloroplast envelope contain a *stroma targeting domain* as part of their transit peptide, which guarantees that the polypeptide will enter the stroma. Once in the stroma, the stroma targeting domain is removed by a processing peptidase located in that compartment. Those polypeptides that belong in a thylakoid membrane or thylakoid lumen bear an additional segment in their transit peptide, called the *thylakoid transfer domain*, that dictates entry into the thylakoids. Several distinct pathways have been identified by which proteins are either inserted into the thylakoid membrane or translocated into the thylakoid lumen. These pathways exhibit striking similarities to transport systems in bacterial cells, the presumed ancestors of chloroplasts. Many of the proteins that reside within the thylakoid membrane are encoded by chloroplast genes and synthesized on membrane-bound ribosomes of the chloroplast, as illustrated in Figure 8.48, step 4.

2. What is the role of cytosolic and mitochondrial chaperones in the process of mitochondrial import?
3. Distinguish between two possible import mechanisms: biased diffusion and force-generating motors.
4. Describe the steps by which a polypeptide would move from the cytosol where it is synthesized to the thylakoid lumen.

EXPERIMENTAL PATHWAYS

Receptor-Mediated Endocytosis

Embryonic development begins with the fusion of a minuscule sperm and a much larger egg. Eggs develop from oocytes, which accumulate yolk that has been synthesized elsewhere in the body of the female. How are the high-molecular-weight yolk proteins able to enter the oocyte? In 1964, Thomas Roth and Keith Porter of Harvard University reported on the mechanism by which yolk proteins might be taken into the oocytes of mosquitoes.¹ They noticed that during stages of rapid oocyte growth, there was a dramatic increase in the number of pitlike depressions seen on the surface of the oocyte. The pits, which were formed by invaginations of the plasma membrane, were covered on their inner surface by a bristly coat. In a farsighted proposal, Roth and Porter postulated that yolk proteins were specifically adsorbed onto the outer surface of the membrane of the coated pits, which would then invaginate as coated vesicles. The coated vesicles would lose their bristly coats and fuse with one another to produce the large, membrane-bound yolk bodies characteristic of the mature oocyte.

The first insight into the structure of coated vesicles was obtained in 1969 by Toku Kanaseki and Ken Kadota of the University of Osaka.² Electron microscopic examination of a crude vesicle fraction isolated from guinea pig brains showed that coated vesicles were covered by a polygonal basketwork (Figure 1). These investigators suggested that the coatings were an apparatus to control the infolding of the plasma membrane during vesicle formation.

The first studies of the biochemical nature of the vesicle coat were published in 1975 by Barbara Pearse of the Medical Research Council in Cambridge, England.³ Pearse developed a procedure in which membrane vesicles from pig brains were centrifuged through a succession of sucrose density gradients until a purified fraction of coated vesicles was obtained. Protein from the coated vesicles was solubilized and fractionated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE, Section 18.7). The results indicated that the coat contained one predominant protein species having a molecular mass of approximately 180,000 daltons. Pearse named the protein clathrin. She found the same protein (based on molecular mass and peptide mapping) in prepa-

Figure 1 (a) A handmade model of an "empty basket" that would form the surface lattice of a coated vesicle. (b) A high-power electron micrograph of an empty proteinaceous basket. The numbers 5 and 6 refer to pentagonal and hexagonal elements of the lattice, respectively. (A-B: FROM TOKU KANASEKI AND KEN KADOTA, J. CELL BIOL. 42:216, 1969; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

rations of coated vesicles that were isolated from several different types of cells obtained from more than one animal species.⁴

As the research described above was being conducted, an apparently independent line of research was begun in 1973 in the laboratories of Michael Brown and Joseph Goldstein of the University of Texas Medical School in Dallas. Brown and Goldstein had become interested in the inherited condition *familial hypercholesterolemia (FH)*. People who were homozygous for the defective gene (the *FH* allele) had profoundly elevated levels of serum cholesterol (800 mg/dl vs. 200 mg/dl for a normal person), invariably developed severely blocked (atherosclerotic) arteries, and usually died from heart attack before the age of 20. At the time, very little was known about the fundamental physiologic or biochemical defects in this disorder.

Brown and Goldstein began their studies of FH by examining cholesterol metabolism in cultured fibroblasts derived from the skin of normal and FH-afflicted individuals. They found that the rate-controlling enzyme in cholesterol biosynthesis, HMG CoA reductase, could be inhibited in normal fibroblasts by cholesterol-containing lipoproteins (such as LDL) placed in the medium (Figure 2).⁵ Thus, the addition of LDL to the culture medium in which normal fibroblasts were growing led to a decreased level of activity of HMG CoA reductase and a corresponding decrease in the synthesis of cholesterol by the fibroblasts. When HMG CoA reductase levels were measured in FH-derived fibroblasts, they were found to be 40 to 60 times that of normal fibroblasts.⁶ In addition, enzyme activity in the FH fibroblasts was totally unaffected by the presence of LDL in the medium (Figure 3).

How could lipoproteins in the medium affect the activity of an enzyme in the cytoplasm of cultured cells? To answer this question, Brown and Goldstein initiated studies on the interaction between the cells and the lipoproteins. They added radioactively labeled LDL to culture dishes containing a single layer of fibroblasts derived from either FH-afflicted or normal human subjects.⁷ The normal fibroblasts bound the labeled LDL molecules with high affinity and specificity, but the mutant cells showed virtually no ability to bind

Figure 2 HMG CoA reductase activity in normal fibroblasts was measured following addition of the lipoprotein fraction of calf serum (open squares), unfractionated calf serum (closed circles), or nonlipoprotein fraction of calf serum (open triangles). It is evident that the lipoproteins greatly depress the activity of the enzyme, while the nonlipoproteins have little effect. (FROM M. S. BROWN ET AL., PROC. NAT'L. ACAD. SCI. U.S.A. 70:2166, 1973.)

Figure 3 Fibroblast cells from either a control subject (closed circles) or a patient with homozygous FH (open circles) were grown in dishes containing fetal calf serum. On day 6 (which corresponds to 0 hours on the graph), the medium was replaced with fresh medium containing lipoprotein-deficient plasma. At the indicated time, extracts were prepared, and HMG CoA reductase activity was measured. If we look at the control cells, it is apparent that at the beginning of the monitoring period the cells have very little enzyme activity because the medium had contained enough cholesterol-containing lipoproteins that the cells did not need to synthesize their own. Once the medium was changed to the lipoprotein-deficient plasma, the cells were no longer able to use cholesterol from the medium and thus increased the amount of enzyme within the cell. In contrast, the cells from the FH patients showed no response to either the presence or absence of lipoproteins in the medium. (FROM J. L. GOLDSTEIN AND M. S. BROWN, *PROC. NAT'L. ACAD. SCI. U.S.A.* 70:2805, 1973.)

these lipoprotein molecules (Figure 4). These results indicated that normal cells have a highly specific receptor for LDL and that this receptor was defective or missing in cells from patients with FH.

To visualize the process of receptor binding and internalization, Brown and Goldstein teamed up with Richard Anderson, who had been studying cellular structure with the electron microscope. The group incubated fibroblasts from normal and FH subjects with LDL that had been covalently linked to the iron-containing protein ferritin. Because of the iron atoms, ferritin molecules are able to scatter a beam of electrons and thus can be visualized in the electron microscope. When normal fibroblasts were incubated with LDL-ferritin at 4°C, a temperature at which ligands can bind to the cell surface but cannot be internalized, LDL-ferritin particles were seen to be bound to the cell surface. Close examination revealed that the LDL particles

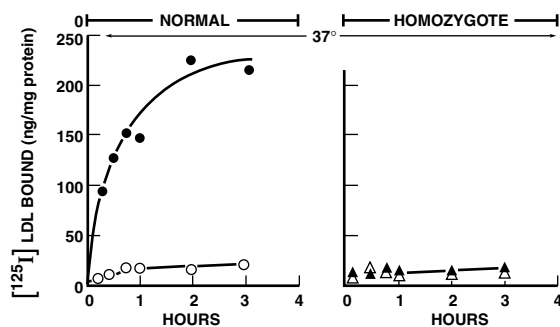

Figure 4 Time course of radioactive [¹²⁵I]-labeled LDL binding to cells from a normal subject (circles) and a homozygote with FH (triangles) at 37°C. The cells were incubated in a buffer containing 5 mg/ml [¹²⁵I] LDL in the presence (open circles and triangles) and absence (closed circles and triangles) of 250 mg/ml of nonradioactive LDL. It is evident that in the absence of added nonradioactive LDL, the normal cells bind significant amounts of the labeled LDL, while the cells from the FH patients do not. The binding of labeled LDL is greatly reduced in the presence of nonradioactive LDL because the nonlabeled lipoproteins compete with the labeled ones for binding sites. Thus, the binding of the lipoprotein to the cells is specific (i.e., it is not the result of some nonspecific binding event). (FROM M. S. BROWN AND J. L. GOLDSTEIN, *PROC. NAT'L. ACAD. SCI. U.S.A.* 71:790, 1974.)

were not randomly scattered over the cell surface but were localized to short segments of the plasma membrane where the membrane was indented and coated by a “fuzzy” material (Figure 5).⁸ These segments of the membrane were similar to the coated pits originally described by Roth and Porter and had since been seen in a variety of cell types. Although cells from patients with FH were found to have a similar number of coated pits on their surface, no LDL-ferritin was bound to these mutant cells. The results supported the proposal that the mutant FH allele encoded a receptor that was unable to bind LDL. Subsequent electron microscopic studies on the internalization of LDL-ferritin revealed the endocytic pathway by which these lipoprotein particles were internalized, as described in the chapter.⁹

Based on these results, the group postulated that the rapid internalization of receptor-bound LDL is strictly dependent on the localization of LDL receptors in coated pits. It follows from this postulate that, if an LDL receptor failed to become localized within a coated pit, it would be unable to deliver its bound ligand to cellular lysosomes and thus would be unable to affect cholesterol biosynthesis within the cell. At about this time, an LDL receptor with a different type of mutation was discovered. LDL receptors bearing this new defect (known as the J. D. mutation after the patient in which it occurred) bound normal amounts of radioactively labeled LDL, yet the receptor-bound lipoprotein failed to be internalized and consequently was not delivered to cytoplasmic lysosomes for processing.¹⁰ Anderson and co-workers postulated that the LDL receptor was a transmembrane protein that normally became localized in coated pits because its cytoplasmic domain was specifically bound by a component of the coated pits, possibly clathrin (but later identified as a likely subunit of an AP adaptor, as discussed below). Because of a defect in its cytoplasmic domain, the J. D. mutant receptor was unable to become localized in a cell's coated pits. People with this mutation exhibit the same phenotype as patients whose receptors are unable to bind LDL. Some of the historical background to the work just described can be found in reference 11.

Subsequent studies determined that the normal LDL receptor is a transmembrane glycoprotein of 839 amino acids, with the 50 amino acids at the C-terminal end of the protein extending inward from the membrane as a cytoplasmic domain. Analysis of the J. D. mutant receptor revealed that the protein contained a single amino acid substitution: a tyrosine residue normally located at position 807 was replaced by a cysteine.¹² This single alteration in amino acid sequence obliterated the ability of the protein to become concentrated in coated pits.

Figure 5 Electron micrograph showing the binding of LDL to a coated pit of a human fibroblast. The LDL is made visible by conjugating the particles to electron-dense, iron-containing ferritin. Bar: 100 nm. (FROM R. G. W. ANDERSON, M. S. BROWN, AND J. L. GOLDSTEIN, *CELL* 10:356, 1977; REPRINTED BY PERMISSION OF ELSEVIER.)

Over the next few years, attention turned to the amino acid sequences of the cytoplasmic tails of other receptors that became localized in coated pits. Studies on a diverse array of membrane receptors turned up several internalization signals that were shared by numerous membrane proteins. The two most common such signals are: (1) a YXX ϕ signal (as in the transferrin receptor) where Y is tyrosine, X can be any amino acid and ϕ is an amino acid with a bulky hydrophobic side chain and (2) an acidic dileucine signal containing two adjacent leucine residues (as in the CD4 protein which serves as the receptor for HIV on the surface of T lymphocytes). The YXX ϕ sequence of the receptor binds to the μ subunit of the AP2 adaptors, and the dileucine motif binds to the σ subunit of the AP2 adaptors (Figure 8.40).¹³ X-ray crystallographic studies have revealed the nature of the interactions between the adaptor and these internalization signals. Included within the μ subunit are two hydrophobic pockets, one that binds the tyrosine residue and the other that binds the bulky hydrophobic side chain of the YXX ϕ internalization signal.¹⁴ Similarly, the dileucine signal binds to a hydrophobic pocket in the σ subunit.¹⁵ Meanwhile, the AP2 adaptor complex binds to the clathrin coat by means of its β subunit (Figure 8.40). As a result of these various intermolecular contacts, the adaptor complex and the receptor are trapped in coated pits prior to endocytosis.^{Reviewed in 16–18}

Over the past decade, many different lines of investigation of clathrin-mediated endocytosis have been followed. One of the most rewarding experimental approaches has been to label two or more components of the endocytic machinery with different fluorescent markers and follow their movements over time within a living cell. Using this approach, researchers have watched dynamin, AP2 adaptors, or various types of cargo receptors bind to clathrin-coated pits, become enveloped within a clathrin-coated vesicle, which then buds off into the cytoplasm and disappears. Figure 6 depicts an example of this type of experiment.¹⁹ The fluorescence micrographs show the surface of a cultured mammalian epithelial cell that is expressing a clathrin light chain that is fused to a variant of the green fluorescent protein. The green patches, for the most part, represent clathrin-coated pits situated at the cell surface. The red-staining spots are individual fluorescently labeled LDL particles that were added to the medium in which the cells were growing. The series of images illustrate a particular clathrin-coated pit (indicated by the green arrow in the second frame marked -3) that has captured a particular LDL particle (indicated by the red arrows in these same early frames). Once the LDL particle has been bound to an LDL receptor in the coated pit, the overlap of the two fluorescent dyes produces a yellow-orange spot (indicated by the yellow arrows in the frames marked T_2 and T_3). The remaining frames (marked T_4) show the uncoated vesicle containing the red fluorescent LDL particle moving into the adjacent cytoplasm.

Synopsis

The cytoplasm of eukaryotic cells contains a system of membranous organelles, including the endoplasmic reticulum, Golgi complex, and lysosomes, that are functionally and structurally related to one another and to the plasma membrane. These various membranous organelles are part of a dynamic, integrated endomembrane network in which materials are shuttled back and forth as part of transport vesicles that form by budding from one compartment and fusing with another. A biosynthetic (secretory) pathway moves proteins from their site of synthesis in the ER through the Golgi complex to their final destination (an organelle, the plasma membrane, or the extracellular space), whereas an endocytic pathway moves material in the opposite direction from the plasma membrane or extracellular space to the cell interior. Cargo is directed to its proper destination by specific targeting signals that are part of the proteins themselves. (p. 271)

The endoplasmic reticulum (ER) is a system of tubules, cisternae, and vesicles that divides the cytoplasm into a luminal space within the ER membranes and a cytosolic space outside the membranes. The ER is divided into two broad types: the rough ER (RER), which occurs typically as flattened cisternae and whose membranes have attached ribosomes, and the smooth ER (SER), which occurs typically as tubular compartments and whose membranes lack ribosomes. The functions of the SER vary from cell to cell and include the synthesis of steroid hormones, detoxification of a wide variety of organic compounds, and sequestration of calcium ions. The functions of the RER include the synthesis of secreted proteins, lysosomal proteins, and integral membrane proteins. (p. 279)

Proteins to be synthesized on membrane-bound ribosomes of the RER are recognized by a hydrophobic signal sequence, which is usually situated near the N-terminus of the nascent polypeptide. As the signal sequence emerges from the ribosome, it is bound by a signal recognition particle (SRP) that arrests further synthesis and mediates the binding of the complex to the RER membrane. Following binding, the SRP is released from the membrane, and the nascent polypeptide passes through a protein-lined pore in the ER membrane and into the ER lumen. Lysosomal and secretory proteins are translocated into the lumen in their entirety, whereas membrane proteins become embedded in the lipid bilayer by virtue of one or more hydrophobic transmembrane sequences. Proteins that are not folded correctly are dislocated back into the cytosol and destroyed. Once a newly synthesized protein is situated in either the lumen or the membrane of the RER, the protein can be moved from that location to specific destinations along the biosynthetic pathway. If the lumen of the ER becomes “choked” by an overabundance of newly synthesized proteins, a comprehensive response called the UPR stops further synthesis of ER proteins and promotes removal of those already present. (p. 282)

Most of the lipids of a cell’s membranes are also synthesized in the ER and moved from that site to various destinations. Phospholipids are synthesized at the cytosolic face of the ER and inserted into the outer leaflet of the ER membrane. Some of these molecules are subsequently flipped into the opposite leaflet. The lipid composition of membranes is subject to modification in a number of ways. For example, phospholipids may be selectively transported from the membrane of one organelle to another, or the head groups of specific lipids may be modified enzymatically. (p. 285)

The addition of sugars (glycosylation) to the asparagine residues of proteins begins in the rough ER and continues in the Golgi complex. The sequences of sugars that make up the oligosaccharide chains of glycoproteins are determined by the types and locations of members of a large family of glycosyltransferases, enzymes that transfer a specific sugar from a nucleotide sugar donor to a specific

acceptor. The carbohydrate chains are assembled in the ER one sugar at a time and then transferred as a unit from the dolichol carrier to an asparagine residue of the polypeptide. Almost as soon as the carbohydrate block is transferred, it begins to be modified—first by removal of the terminal glucose residues. Membrane vesicles, with their enclosed cargo, bud from the edges of the ER and are targeted to the Golgi complex. (p. 286)

The Golgi complex functions as a processing plant, modifying the membrane components and cargo synthesized in the ER before it moves on to its target destination. The Golgi complex is also the site of synthesis of the complex polysaccharides that make up the matrix of the plant cell wall. Each Golgi complex consists of a stack of flattened, platelike cisternae with dilated rims and associated vesicles and tubules. Materials enter the stack at the *cis* face and are modified as they move by vesicle transport toward the opposite, or *trans*, face. As they traverse the stack, sugars are added to the oligosaccharide chains by glycosyltransferases located in particular Golgi cisternae. Once the proteins reach the *trans* Golgi network (TGN) at the end of the stack, they are ready to be sorted and targeted for delivery to their ultimate cellular or extracellular destination. (p. 290)

Most, if not all, of the vesicles that transport material through the endomembrane system are encased initially in a protein coat. Several distinct types of coated vesicles have been identified. COPII-coated vesicles carry materials from the ER to the Golgi complex. COPI-coated vesicles carry materials in the opposite (retrograde) direction, from the Golgi back to the ER. Clathrin-coated vesicles carry materials from the TGN to the endosomes, lysosomes, and plant vacuole. Clathrin-coated vesicles are also part of the endocytic pathway, carrying materials from the plasma membrane to endosomes and lysosomes. (p. 295)

Each compartment along the biosynthetic or endocytic pathway has a characteristic protein composition. Resident proteins tend to be retained in that particular compartment and retrieved if they escape to other compartments. The sorting of proteins in the biosynthetic pathway occurs to a large extent in the last of the Golgi compartments, the TGN. The TGN is the source of vesicles that contain particular membrane proteins that target the vesicle to a particular destination. Lysosomal enzymes produced in the rough ER are sorted in the TGN and targeted for lysosomes in clathrin-coated vesicles. Lysosomal enzymes are enclosed in these budding vesicles because they possess phosphorylated mannose residues on their core oligosaccharides. These modified oligosaccharides are recognized by membrane receptors (MPRs), which in turn are bound to a class of adaptors (GGA proteins) that form a layer between the outer clathrin coat and the vesicle membrane. (p. 298)

Vesicles that bud from a donor compartment possess specific proteins in their membrane that recognize proteins located in the target (acceptor) compartment. The docking of the two membranes is mediated by tethering proteins and regulated by a large family of G proteins called Rabs. Fusion of donor and acceptor membranes is mediated by v-SNAREs and t-SNAREs, which interact to form four-stranded bundles. (p. 300)

Lysosomes are diverse-appearing, membrane-bound organelles that contain an array of acid hydrolases capable of digesting virtually every type of biological macromolecule. Among their numerous roles, lysosomes degrade materials, such as bacteria and debris, that are brought into the cell by phagocytosis; they degrade aging cytoplasmic organelles by a process called autophagy; and they digest various macromolecules that are delivered by way of endosomes by receptor-mediated endocytosis. In vertebrates, lysosomes play a key role in immunologic defense. (p. 303)

The vacuoles of plants carry out a diverse array of activities. Vacuoles serve as a temporary storehouse for solutes and macromolecules; they contain toxic compounds used in defense; they provide a container for cellular wastes; they maintain a hypertonic compartment that exerts turgor pressure against the cell wall; and they are sites of intracellular digestion mediated by acid hydrolases. (p. 307)

Endocytosis facilitates the uptake of fluid and suspended macromolecules, the internalization of membrane receptors and their bound ligands, and functions in the recycling of membrane between the cell surface and cytoplasm. Phagocytosis is the uptake of particulate matter. In receptor-mediated endocytosis, specific ligands are bound to plasma membrane receptors. The receptors collect in pits of the membrane that are coated on their cytoplasmic surface by a polygonal scaffold of clathrin molecules. The coated pits give rise

to coated vesicles, which lose their coat, and deliver their contents to an endosome and ultimately to a lysosome. Phagocytosis can function as a feeding mechanism or as a cellular system of defense. (p. 308)

Proteins within peroxisomes, mitochondria, or chloroplasts that are encoded by nuclear genes must be imported into the organelle posttranslationally. In all of these cases, the proteins to be imported carry signal sequences that interact with receptors responsible for protein import. All three of these organelles contain protein-lined channels in their membranes that promote the translocation of either folded polypeptides (in peroxisomes) or unfolded polypeptides (in mitochondria and chloroplasts) into the organelle. Mitochondria and chloroplasts contain several different compartments into which newly translocated proteins are directed. (p. 316)

Analytic Questions

- Which, if any, of the following polypeptides would be expected to lack a signal peptide: collagen, acid phosphatase, hemoglobin, ribosomal proteins, glycophorin, proteins of the tonoplast?
- Suppose you suspected that a patient might be suffering from I-cell disease (page 306). How could you decide if this diagnosis was accurate using cells that were cultured from the patient?
- In what cellular compartment would a glycoprotein be expected to have its greatest mannose content? its greatest *N*-acetylglucosamine content? its greatest sialic acid content?
- It was noted on page 316 that peroxisomes are able to import folded proteins. Yet, these same organelles are impermeable to relatively small molecules such as NADH and acetyl-CoA. How is it possible to be permeable to one and not the other?
- Name two proteins you would expect to find as integral components of the RER membrane that would be absent from the SER? Name two proteins of the SER that would not be present in the RER?
- Suppose you wanted to study the process of regulated secretion in a cell that lacked mature secretory granules, that is, vesicles containing secretory material that was ready to be discharged. How might you obtain a cell that lacked such granules?
- It was described on page 307 how glucocerebrosidase could be prepared that bore mannose residues at the end of its surface oligosaccharides rather than the usual sugar, sialic acid. A similar version of glucocerebrosidase with exposed mannose residues is being produced by recombinant DNA technology using a special line of cells. What characteristics do you think these cells might exhibit? Clue: Information to answer this question is provided in Figure 8.22.
- Autoradiography depends on particles emitted from radioactive atoms striking a photographic emulsion that lies on top of the tissue section. When the emulsion is developed, the site where the particle struck the emulsion appears as a silver grain, as in Figure 8.3a. How do you think the thickness of the section might affect the resolution of the technique, that is, the ability to locate the precise site in the cell where radioactivity is incorporated?
- In which part of a cell would you expect the following compounds to be first incorporated: [³H]leucine, [³H]sialic acid, [³H]mannose, [³H]choline, [³H]glucuronic acid (a precursor of GAGs), [³H]pregnenolone (a precursor of steroid hormones), [³H]rhamnose in a plant cell (rhamnose is a precursor of pectins)?
- Which of the following cells would you expect to be engaged most heavily in bulk-phase endocytosis: (a) an erythrocyte, (b) a pancreatic acinar cell, (c) a skeletal muscle cell? Why?
- Would you expect the properties of the cisternal side of Golgi membranes to be more similar to the extracellular or cytosolic side of the plasma membrane? Why?
- Which compartment(s) of a cell is associated with each of the following: clathrin, calcium ions in a skeletal muscle cell, dolichol phosphate, ribonuclease and lipase, digitalis, LDL receptors, COPI proteins, COPII proteins, unbound SRPs?
- If a slice of pancreatic tissue had been incubated in [³H]leucine continuously for 2 hours, where in the acinar cells would you expect to find incorporated radioactivity?
- If you were to add a drug that interfered with the ability of ribosomes to bind to mRNA, what effect would this be expected to have on the structure of the RER?
- Not all receptors that carry out RME are located in coated pits prior to binding ligand, yet they too become concentrated in coated pits prior to internalization. How do you suppose the binding of a ligand to a receptor would cause it to become concentrated into a coated pit?
- It was noted in the text that lysosomes lack a distinctive appearance in the electron microscope. How might you determine whether a particular vacuole is in fact a lysosome?
- Studies of a rare inherited disorder, Dent's disease, revealed that these individuals lacked a chloride ion channel in the endosomes of the cells of their kidney tubules. These patients suffered from a variety of symptoms that suggested that their endosomal compartments were not as acidic as those of normal individuals. How do you suppose that a defect in a chloride channel could account for this condition?
- Examine the fluorescence micrograph in Figure 8.20d. Although the Golgi complex is brightly stained, there is scattered red fluorescence in other parts of the cell. How can you explain the presence of this dispersed staining?
- Figure 8.8b shows the localization of GFP-labeled mannosidase II in a cell treated with an siRNA against an mRNA encoding a protein involved in an early step in the secretory pathway. How would you expect the fluorescence pattern to appear in a cell that had been treated with an siRNA against an mRNA encoding the protein GGA? Or the protein clathrin? Or a protein of the signal recognition particle?

THE HUMAN PERSPECTIVE: The Role of Cilia in Development and Disease

The skeleton of a vertebrate is a familiar organ system consisting of hardened elements that support the soft tissues of the body and play a key role in mediating bodily movements. Eukaryotic cells also possess a “skeletal system”—a **cytoskeleton**—that has analogous functions. The cytoskeleton is composed of three well-defined filamentous structures—microtubules, microfilaments, and intermediate filaments—that together form an elaborate interactive network. Each of the three types of cytoskeletal filaments is a polymer of protein subunits held together by weak, noncovalent bonds. This type of construction lends itself to rapid assembly and disassembly, which is dependent on complex cellular regulation. Each cytoskeletal element has distinct properties. **Microtubules** are long, hollow, unbranched tubes composed of subunits of the protein tubulin. **Microfilaments** are solid, thinner structures, often organized into a branching network and composed of the protein actin. **Intermediate filaments** are tough, ropelike fibers composed of a variety of related proteins. The properties of microtubules, intermediate filaments, and actin filaments are summarized in Table 9.1. Although the components of the cytoskeleton appear stationary in micrographs, in reality they are highly dynamic structures capable of dramatic reorganization. For many years, it was widely held that the cytoskeleton was strictly a eukaryotic innovation

The cytoskeleton is constructed from three major types of filaments, which are shown imaged separately in parts a–c. The distribution of each type of filament within a cultured liver cell (hepatocyte) is revealed by a fluorescent probe that binds specifically to that type of filament. The distribution of microfilaments (a) is revealed by fluorescent phalloidin binding; the distribution of microtubules (b) by fluorescent anti-tubulin antibodies; and the distribution of intermediate filaments (c) by fluorescent anti-keratin antibodies. The image in d is a composite of the three previous images and demonstrates that the cytoplasmic organization of each filament type is distinct. Bar equals 10 μm .

Table 9.1 Properties of Microtubules, Intermediate Filaments, and Actin Filaments

	Microtubules	Intermediate filaments	Actin filaments
Subunits incorporated into polymer	GTP- $\alpha\beta$ -tubulin heterodimer	~70 different proteins, likely incorporated as tetramers	ATP-actin monomers
Preferential site of incorporation	+ End (β -tubulin)	Internal	+ End (barbed)
Polarity	Yes	No	Yes
Enzymatic activity	GTPase	None	ATPase
Motor proteins	Kinesins, dyneins	None	Myosins
Major group of associated proteins	MAPs	Plakins	Actin-binding proteins
Structure	Stiff, hollow, inextensible tube	Tough, flexible, extensible filament	Flexible, inextensible helical filament
Dimensions	25 nm outer diam.	10–12 nm diam.	8 nm diam.
Distribution	All eukaryotes	Animals	All eukaryotes
Primary functions	Support, intracellular transport, cell organization	Structural support, mechanical strength	Motility, contractility, intracellular transport
Subcellular distribution	Cytoplasm	Cytoplasm + nucleus	Cytoplasm

that was absent from prokaryotic cells. We now know that numerous prokaryotes contain tubulin- and actin-like proteins that polymerize into cytoplasmic filaments that carry out cytoskeletal-like activities. Proteins distantly related to those of intermediate

filaments have also been discovered in certain prokaryotes, so it is apparent that all three types of cytoskeletal elements had their evolutionary roots in prokaryotic structures. We will begin with a brief overview of major cytoskeletal activities.

9.1 | Overview of the Major Functions of the Cytoskeleton

An overview of the major activities of the cytoskeleton in three different nonmuscle cells is shown in Figure 9.1. The cells depicted in this schematic illustration include a polarized

epithelial cell, the tip of an elongating nerve cell, and a dividing cultured cell. As will be discussed in this chapter, the cytoskeleton of these cells functions as

1. A dynamic scaffold providing structural support that can determine the shape of the cell and resist forces that tend to deform it.

Figure 9.1 An overview of the structure and functions of the cytoskeleton. Schematic drawings of (a) an epithelial cell, (b) a nerve cell, and (c) a dividing cell. The microtubules of the epithelial and nerve cells function primarily in support and organelle transport, whereas the microtubules of the dividing cell form the mitotic spindle

required for chromosome segregation. Intermediate filaments provide structural support for both the epithelial cell and nerve cell. Microfilaments support the microvilli of the epithelial cell and are an integral part of the motile machinery involved in nerve cell elongation and cell division.

- An internal framework responsible for positioning the various organelles within the interior of the cell. This function is particularly evident in polarized epithelial cells, such as those depicted in Figure 8.11, in which certain organelles are arranged in a defined order from the apical to the basal end of the cell.
- A network of tracks that direct the movement of materials and organelles within cells. Examples of this function include the delivery of mRNA molecules to specific parts of a cell, the movement of membranous carriers from the endoplasmic reticulum to the Golgi complex, and the transport of vesicles containing neurotransmitters down the length of a nerve cell. Figure 9.2 shows a small portion of a cultured cell, and it is evident that most of the fluorescent green organelles, which are labeled peroxisomes (page 206), are closely associated with the microtubules (red) of the cell's cytoskeleton. Microtubules are the tracks over which the peroxisomes are transported in mammalian cells.
- The force-generating apparatus that moves cells from one place to another. Single-celled organisms move either by "crawling" over the surface of a solid substratum or by propelling themselves through their aqueous environment with the aid of specialized, microtubule-containing locomotor organelles (cilia and flagella) that protrude from the cell's surface. Multicellular animals have a variety of cells that are capable of independent locomotion, including sperm, white blood cells, and fibroblasts (Figure 9.3). The tip of a growing axon is also highly motile (Figure 9.1), and its movement resembles a crawling cell.
- An essential component of the cell's division machinery. Cytoskeletal elements make up the apparatus responsible for separating the chromosomes during mitosis and

5 μm

Figure 9.2 An example of the role of microtubules in transporting organelles. The peroxisomes of this cell (shown in green and indicated by arrows) are closely associated with microtubules of the cytoskeleton (shown in red). Peroxisomes appear green because they contain a peroxisomal protein fused to the green fluorescent protein (page 273). Microtubules appear red because they are stained with a fluorescently labeled antibody. (FROM E. A. C. WIEMER ET AL., J. CELL BIOL. 136:78, 1997, COURTESY OF S. SUBRAMANI, FIG. 6. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

meiosis and for splitting the parent cell into two daughter cells during cytokinesis. These events are discussed at length in Chapter 14.

9.2 | The Study of the Cytoskeleton

The cytoskeleton is currently one of the most actively studied subjects in cell biology, due in large part to the development of techniques that allow investigators to pursue a coordinated morphological, biochemical, and molecular approach. As a result, we know a great deal about the families of proteins that make up the cytoskeleton; how the subunits are organized into their respective fibrous structures; the molecular "motors" that move along these filaments and generate the forces required for motile activities; and the dynamic qualities that control the spatial organization, assembly, and disassembly of the various elements of the cytoskeleton. A few of the most important approaches to the study of the cytoskeleton will be briefly surveyed.

The Use of Live-Cell Fluorescence Imaging

The concept that eukaryotic cells contained a network of cytoskeletal elements was first derived from studies of tissue sections with the electron microscope in the 1950s and 1960s. But the electron microscope produces only static images and failed to provide much insight into the dynamic structure and function of the various components of the cytoskeleton. Our appreciation of the dynamic character of the cytoskeleton has increased greatly over the past few decades as the result of a revolution in light microscopy. The fluorescence microscope (Section 18.1) has played a leading part in this revolution by allowing researchers to directly observe molecular processes in living cells—an approach known as *live-cell imaging*.

In the most widely used strategy, fluorescently labeled proteins are synthesized within a cell as a fusion protein con-

Figure 9.3 The capability of the cytoskeleton to change its three-dimensional organization is apparent in this mouse fibroblast that is migrating over the 90° edge of a coverslip. Bar, 30 μm. (FROM GUENTER ALBRECHT-BUEHLER, INT. REV. CYTOL. 120:211, 1990. © 1990, WITH PERMISSION FROM ELSEVIER.)

taining GFP. This technique was discussed in the previous chapter (page 273) and an example is shown in Figure 9.2. In an alternate approach, the protein subunits of cytoskeletal structures (e.g., purified tubulin or keratin) are fluorescently labeled *in vitro* by covalent linkage to a small fluorescent dye. The labeled subunits are then microinjected into a living cell where they are incorporated into the polymeric form of the protein, such as a microtubule or an intermediate filament. The dynamic behavior of the fluorescent structure can be followed over time as the cell participates in its normal activities. Figure 9.4 shows the dramatic changes in length and orientation of individual microtubules at the leading

Figure 9.4 Dynamic changes in length of microtubules within an epithelial cell. The cell was injected with a small volume of tubulin that had been covalently linked to the fluorescent dye rhodamine. After allowing time for the cell to incorporate the labeled tubulin into microtubules, a small portion of the edge of the living cell was examined with the fluorescence microscope. The elapsed time is shown at the lower right of each image. The microtubules have been false-colored to increase their contrast. A “pioneering” microtubule (arrowhead) can be seen to grow out to the leading edge of the cell, where it becomes bent and then continues its growth in a direction parallel to the cell’s edge. The rate of growth of bent parallel microtubules was much greater than those growing perpendicular to the cell’s edge. Bar, 10 μm (FROM CLARE M. WATERMAN-STORER AND E. D. SALMON, J. CELL BIOL. 139:423, 1997, FIG. 3A. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

edge of a cell that had been injected with fluorescently labeled tubulin.

If particularly small amounts of fluorescently labeled protein are injected, the cytoskeletal filaments are no longer uniformly labeled as in Figure 9.4, but instead contain irregularly spaced fluorescent speckles. These fluorescent speckles serve as fixed markers to follow dynamic changes in length or orientation of the filament. An example of this technique, which is known as *fluorescence speckle microscopy*, is illustrated in Figure 9.27.

Fluorescence microscopy can also be used to reveal the location within a cell of a protein present in very low concentration. This type of experiment is best carried out with fluorescently labeled antibodies that bind with high affinity to the protein being sought. Antibodies are particularly useful because they can distinguish between closely related variants (isoforms) of a protein. The protein can be localized by injecting the labeled antibody into a living cell, which may also reveal the function of the target protein because attachment of the antibody generally destroys the ability of the protein to perform its normal activity. Alternatively, the location of the target protein can be determined by adding the fluorescent antibody to fixed cells or tissue sections, as illustrated in Figure 9.5.

The Use of In Vitro and In Vivo Single-Molecule Assays

The digital images captured by modern video cameras possess exceptional contrast and can be enhanced by computer-assisted image processing. These features allow objects that

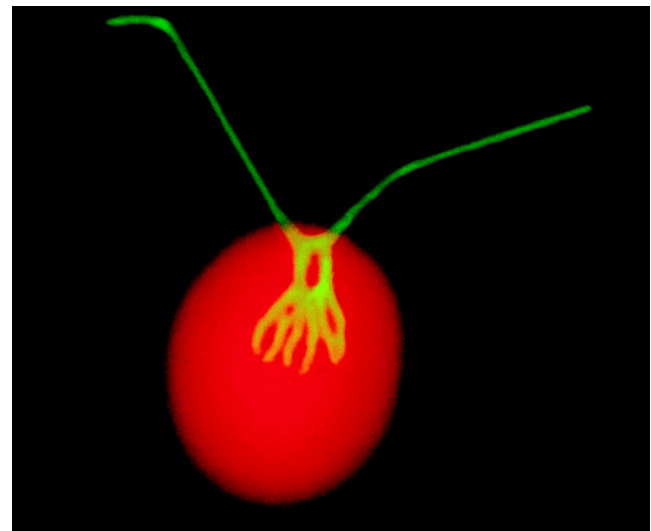

Figure 9.5 The localization of a protein within a cell using fluorescent antibodies. This algal cell was stained with fluorescent antibodies (yellow-green color) directed against a protein called centrin. Centrin is seen to be localized within the cell’s flagella and the rootlike structure at the base of the flagella. The red color of the cell results from autofluorescence of chlorophyll molecules of this photosynthetic alga. (FROM MARK A. SANDERS AND JEFFREY L. SALISBURY OF THE MAYO CLINIC, FROM CELL 70:533, 1992; REPRODUCED WITH PERMISSION OF ELSEVIER.)

are ordinarily invisible in the light microscope, such as 25-nm microtubules or 40-nm membrane vesicles, to be observed and photographed. The advent of high-resolution video microscopy has led to the development of *in vitro motility assays*. These assays make it possible to detect the activity of an individual protein molecule acting as a molecular motor in “real time.”¹ For example, single-molecule assays have allowed researchers to follow the sequence of events that occur as a motor molecule moves along its track. Such observations were not possible with standard biochemical techniques that average the results obtained from large numbers of molecules. In some of the earlier assays, microtubules were attached to a glass coverslip. Then, micron-sized beads containing attached motor proteins were placed directly onto the microtubules using aimed laser beams. The laser beams are shone through the objective lens of a microscope, producing a weak attractive force near the point of focus. Because it can grasp microscopic objects, this apparatus is referred to as *optical tweezers*. When ATP is present as an energy source, the movements of a bead along a microtubule can be followed by a video camera, revealing the size of individual steps taken by the motor protein. Focused laser beams can also be used to “trap” a single bead and determine the minute forces (measured as a few piconewtons, pN) generated by a single motor protein as it “tries” to move the bead against the force exerted by the optical trap (see Figure 11.5 for an illustration of this type of experiment).

While the optical trap experiments make it possible to detect the motility of motor proteins *in vitro*, these measurements

are indirect because the researchers are monitoring the motility of beads, not protein molecules. By combining fluorescence microscopy with specialized imaging techniques, scientists have been able to directly visualize the movement of individual motor molecules both *in vitro* and *in vivo*. Examples of this experimental approach are illustrated in Figure 9.6. For the *in vitro* assays, the gene for the kinesin motor was fused to a GFP variant called mCit (as discussed in Section 18.1), the fusion gene was introduced into cultured cells, and the cells were allowed to produce the labeled kinesin protein, which was then purified. This procedure provided the researchers with green fluorescent motor molecules. Meanwhile, the team prepared microtubules that were labeled with a red fluorescent dye. When these two preparations were combined under the appropriate conditions, the researchers were able to follow the movements of an individual fluorescently labeled kinesin molecule down the length of a single microtubule, as seen in the subsequent frames of Figure 9.6*a*. The clarity of these images is made possible by the use of a specialized type of laser-based fluorescence microscopy called TIRF (total internal reflection microscopy), which allows the observer to focus on a very thin plane that is just above the surface on which the microtubules are lying. As a result, fluorescent light rays from other areas in the field of view do not obscure the information that emanates from the individual protein molecules whose activities are being monitored. Using this type of experimental approach, scientists can compare the properties of different motor proteins, measure the properties of individual motors under different experimental conditions, or ask how a specific mutation of a motor protein affects its motility properties.

¹Background information on molecular motors can be found on page 334.

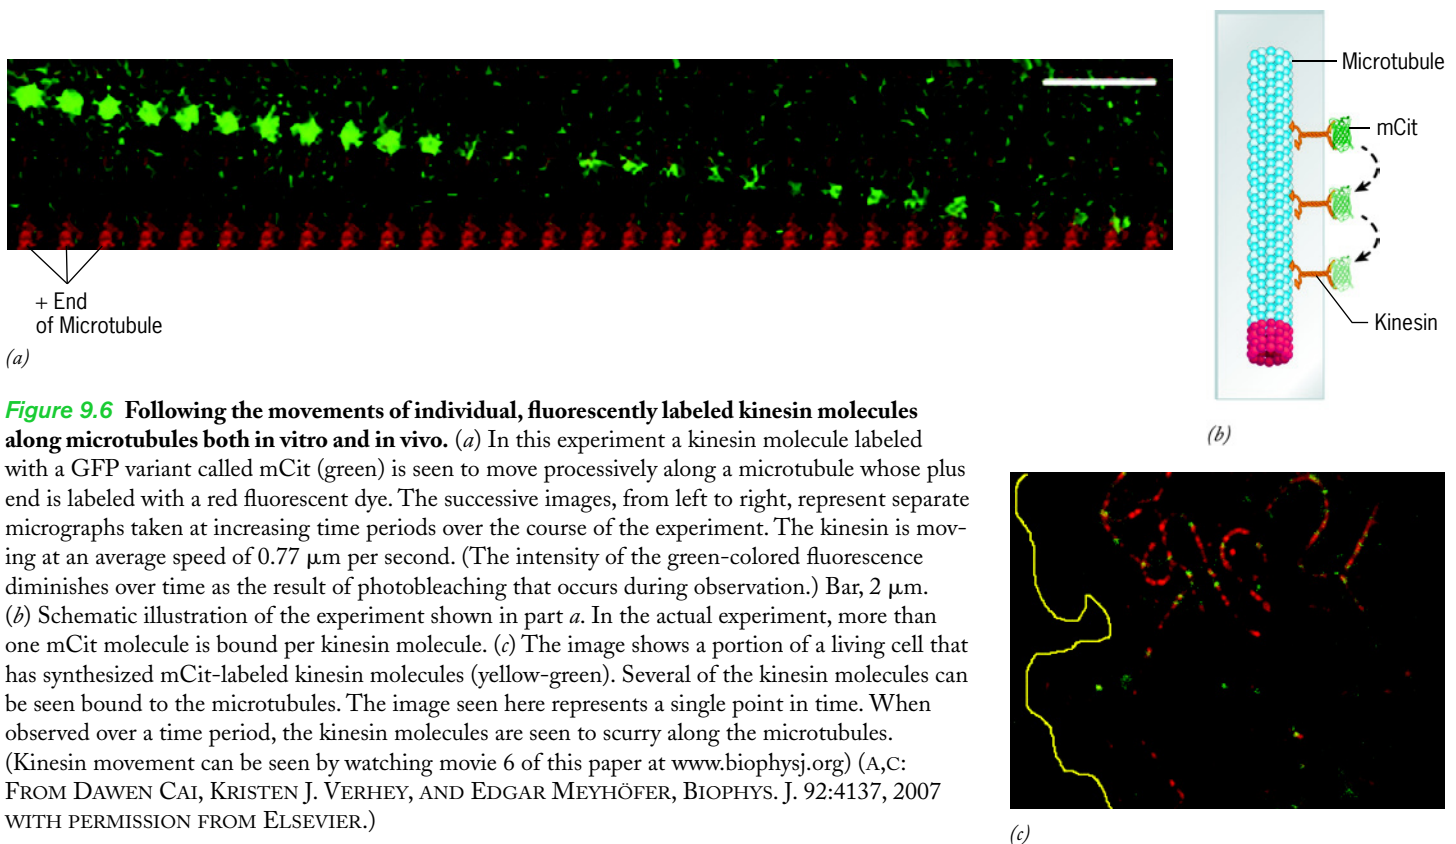

Figure 9.6 Following the movements of individual, fluorescently labeled kinesin molecules along microtubules both *in vitro* and *in vivo*. (a) In this experiment a kinesin molecule labeled with a GFP variant called mCit (green) is seen to move processively along a microtubule whose plus end is labeled with a red fluorescent dye. The successive images, from left to right, represent separate micrographs taken at increasing time periods over the course of the experiment. The kinesin is moving at an average speed of $0.77 \mu\text{m}$ per second. (The intensity of the green-colored fluorescence diminishes over time as the result of photobleaching that occurs during observation.) Bar, $2 \mu\text{m}$. (b) Schematic illustration of the experiment shown in part a. In the actual experiment, more than one mCit molecule is bound per kinesin molecule. (c) The image shows a portion of a living cell that has synthesized mCit-labeled kinesin molecules (yellow-green). Several of the kinesin molecules can be seen bound to the microtubules. The image seen here represents a single point in time. When observed over a time period, the kinesin molecules are seen to scurry along the microtubules. (Kinesin movement can be seen by watching movie 6 of this paper at www.biophysj.org) (A,C: FROM DAWEN CAI, KRISTEN J. VERHEY, AND EDGAR MEYHÖFER, BIOPHYS. J. 92:4137, 2007 WITH PERMISSION FROM ELSEVIER.)

Using similar technology, scientists have been able to visualize the movement of individual kinesins inside living cells. An example of this type of experiment is shown in Figure 9.6c. To carry out this experiment, cells are genetically engineered to synthesize both fluorescently labeled microtubule polymers and fluorescently labeled kinesin molecules. Researchers can then watch the interaction of the two types of labeled proteins as they take place within the cell's cytoplasm under various physiological conditions. As in the *in vitro* experiments, the movement of individual kinesin molecules are followed using TIRF microscopy. Together these techniques are giving scientists a detailed look at motor proteins in action.

Although light-microscopic fluorescence techniques can allow researchers to follow the movements of individual protein molecules, they cannot resolve the molecules themselves. Consequently, these optical techniques do not tell us much about the molecular mechanisms by which these proteins actually operate. On the other hand, electron microscopic and X-ray crystallographic techniques are well-suited for revealing the structure of the molecules but can only provide snapshots of the molecule at a single stage in its operation. In the past few years, a new technique has emerged that can provide both the high resolution of electron microscopy and the ability to observe a continuing process in real time. This technique employs the atomic force microscope (AFM, Section 18.3), which is an instrument that uses a nanosized tip to probe the surface of a macromolecular specimen. Use of the AFM to follow the movements of a single motor protein is shown in the images of Figure 9.52.

The AFM has also been used to measure the mechanical properties of cytoskeletal elements. One group of investigators has found that they can embed the tip of an AFM into a single intermediate filament and pull on the end or the middle of the filament to test its extensibility and tensile strength. Figure 9.7 shows the results of such an experiment in which a short section of an immobilized intermediate filament is being

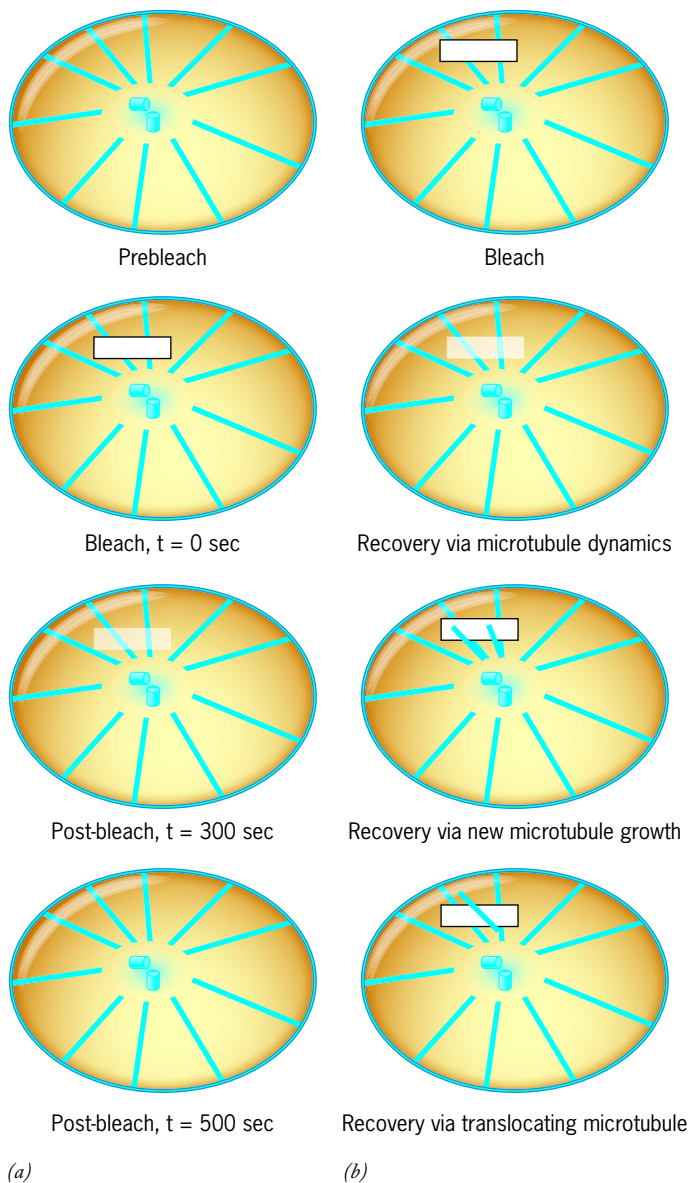

Figure 9.7 Determining the mechanical properties of single cytoskeletal filaments. These images show a single intermediate filament before and after it has been subjected to mechanical forces by the tip of an atomic force microscope. The tip is attached at one point along the filament (arrow) and has moved to the left, pulling on the affected segment. This segment has been stretched more than three times its original length (from 280 nm to a stretched length of 500 + 450 nm). (FROM LAURENT KREPLAK, ET AL., J. MOL. BIOL. 354:574, 2005, FIGURE 5A AND D. REPRODUCED WITH PERMISSION OF ACADEMIC PRESS.)

pulled out of its linear conformation. It is demonstrated in these experiments that a segment of filament can be mechanically stretched up to 3.5 times its normal length before it breaks into two pieces. These results confirm the suggestion that intermediate filaments are much more extensible than either microfilaments or microtubules.

The development of techniques for working with single molecules has coincided with the creation of a new field of mechanical engineering called **nanotechnology**. A goal of nanotechnologists is the development of tiny “nanomachines” (in the 10–100 nm size range) capable of performing specific activities in a submicroscopic world. There are many perceived uses of nanomachines, including a role in medicine. It is envisioned that, one day, such machines might be introduced into the human body where they could carry out a specific task, such as finding and destroying individual cancer cells. As it happens, nature has already evolved nanosized machines, including the motor proteins that will be discussed in this chapter. Not surprisingly, a number of nanotechnology labs have begun to use these nanosized “trucks” to haul molecular cargoes unlike any found within living organisms.

The Use of Fluorescence Imaging Techniques to Monitor the Dynamics of the Cytoskeleton

Within living cells, the microtubules and actin filaments of the cytoskeleton are both highly dynamic polymer systems. The word “dynamic” is used frequently in this text, and it is worthwhile to consider the term’s implications. To a cell biologist, “dynamic” implies “ever-changing.” Dynamic structures are continually undergoing some type of rebuilding, whether their old parts are being exchanged with new ones or they are being entirely broken down and rebuilt. Thus, even though a microtubule or actin filament appears unchanging from one moment to the next under a microscope, in reality, its molecular components are in a constant state of flux. Just as importantly, the dynamic properties of these structures are closely regulated by the cell and may change from one place in the cytoplasm to another or at different times during the cell cycle. Monitoring these changes requires the use of techniques that can measure polymer dynamics. One powerful technique is called *fluorescence recovery after photobleaching* (or *FRAP*) and was discussed earlier in conjunction with the movement of membrane proteins (page 142). Here we will examine its application to the study of the dynamic properties of microtubules. To carry out a FRAP experiment, a cell is either injected with tubulin coupled to a fluorescent dye or induced to express GFP-tubulin. Using a microscope equipped with a laser that can be focused on a small region of the cell, the fluorescence of the tubulin in that region is bleached by the laser beam. It is then possible to follow the specimen over time and measure the recovery of the fluorescent signal into the bleached zone (Figure 9.8a,c). As with most methods used in cell and molecular biology, there are often several possible interpretations of an experimental result. For example, the recovery of fluorescence can result from either the dynamics of the microtubules turning over in that bleached zone, growth of new microtubules into the bleached zone, or movement of microtubules through the bleached zone

(Figure 9.8*b*). Subsequent experiments are generally required to distinguish among these possible explanations.

REVIEW

1. Describe an example in which each of the following methodologies has contributed to our understanding of the nature of the cytoskeleton: fluorescence microscopy, *in vitro* motility assays, and atomic force microscopy.
2. List some of the major functions of the cytoskeleton.

9.3 | Microtubules

Structure and Composition

As the name implies, microtubules are hollow, relatively rigid, tubular structures, and they occur in nearly every eukaryotic cell.

(*c*)

Figure 9.8 The study of the cytoskeleton using FRAP. (*a*) A cell expressing GFP-tubulin incorporates the fluorescent tubulin into its microtubule array. When a laser is focused on a box on the array, the fluorescence is bleached ($t = 0$ sec). Over time the fluorescence is recovered in the bleached zone. (*b*) The fluorescence recovery can come from different properties of microtubules. The dynamic properties of the microtubules are very likely to contribute to fluorescence recovery. Alternatively, if new fluorescent microtubules grow from the centrosome, they can grow into the bleached zone. Finally, it is possible, that a fluorescent translocating microtubule can move through the bleached zone and be seen there at the time of observation. (*c*) Micrographs from a FRAP experiment performed on interphase (non-dividing) cells expressing GFP-tubulin. Two side-by-side cells were bleached in the boxed region with a laser, and the cells were then imaged over time. The fluorescence signal in the bleached region recovers over the time course of the experiment. (COURTESY OF CLAIRE WALCZAK AND RANIA RIZK.)

Microtubules are components of a diverse array of structures, including the mitotic spindle of dividing cells and the core of cilia and flagella. Microtubules have an outer diameter of 25 nm and a wall thickness of approximately 4 nm, and may extend across the length or breadth of a cell. The wall of a microtubule is composed of globular proteins arranged in longitudinal rows, termed **protofilaments**, that are aligned parallel to the long axis of the tubule (Figure 9.9*a*). When viewed in cross section, microtubules are seen to consist of 13 protofilaments aligned side by side in a circular pattern within the wall (Figure 9.9*b*). Noncovalent interactions between adjacent protofilaments are thought to play an important role in maintaining microtubule structure.

Each protofilament is assembled from dimeric building blocks consisting of one α -tubulin and one β -tubulin subunit. The two types of globular tubulin subunits have a similar three-dimensional structure and fit tightly together as shown in Figure 9.9*c*. The tubulin dimers are organized in a linear array along the length of each protofilament, as shown in Figure 9.9*d*. Because each assembly unit contains two nonidentical components (a heterodimer), the protofilament is asymmetric, with an α -tubulin at one end and a β -tubulin at the other end. All of the protofilaments of a microtubule have the same polarity. Consequently, the entire polymer has polarity. One end of a microtubule is known as the *plus end* and is terminated by a row of β -tubulin subunits (Figure 9.9*d*). The opposite end is the

The bumps at the surface of the microtubules are microtubule-associated proteins (MAPs), discussed later. (b) Electron micrograph of a cross section through a microtubule of a *Juniperus* root tip cell revealing the 13 subunits arranged within the wall of the tubule. The microtubules of these plant cells are most abundant in a cortical zone about 100 nm thick just beneath the plasma membrane (seen in the lower right of the micrograph). (c) A ribbon model showing the three-dimensional structure of the $\alpha\beta$ -tubulin heterodimer. Note the complementary shapes of the subunits at their interacting surfaces. The α -tubulin subunit has a bound GTP, which is not hydrolyzed and is nonexchangeable. The β -tubulin subunit has a bound GDP, which is exchanged for a GTP prior to assembly into a polymer (page 342). The plus end of the dimer is at the top. (d) Diagram of a longitudinal section of a microtubule shown in the B-lattice, which is the structure thought to occur in the cell. The wall consists of 13 protofilaments composed of $\alpha\beta$ -tubulin heterodimers stacked in a head-to-tail arrangement. Adjacent protofilaments are not aligned in register but are staggered about 1 nm so that the tubulin molecules form a helical array around the circumference of the microtubule. The helix is interrupted at one site where α and β subunits make lateral contacts. This produces a “seam” that runs the length of the microtubule. (A: FROM LINDA A. AMOS, *J. CELL BIOL.* 72:645, 1977, FIG. 2; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS; B: REPRINTED WITH PERMISSION OF MYRON C. LEDBETTER, *J. AGR. FOOD CHEM.* 13:406, 1965; © 1965, AMERICAN CHEMICAL SOCIETY; C: COURTESY OF EVA NOGALES AND KENNETH DOWNING.)

minus end and is terminated by a row of α -tubulin subunits. As discussed later in the chapter, the structural polarity of microtubules is an important factor in the growth of these structures and their ability to participate in directed mechanical activities.

Microtubule-Associated Proteins

Microtubules prepared from living tissue typically contain additional proteins, called **microtubule-associated proteins** (or **MAPs**). MAPs comprise a heterogeneous collection of proteins. The first MAPs to be identified are referred to as “classical MAPs” and typically have one domain that attaches to the side of a microtubule and another domain that projects outward as a tail from the microtubule’s surface. The binding of one of these MAPs to the surface of a microtubule is depicted in Fig-

ure 9.10. Some MAPs can be seen in electron micrographs as cross-bridges connecting microtubules to each other, thus maintaining their parallel alignment. MAPs generally increase the stability of microtubules and promote their assembly. The microtubule-binding activity of the various MAPs is controlled primarily by the addition and removal of phosphate groups from particular amino acid residues. An abnormally high level of phosphorylation of one particular MAP, called *tau*, has been implicated in the development of several fatal neurodegenerative disorders, including Alzheimer’s disease (page 67). The brain cells of people with these diseases contain strange, tangled filaments (called *neurofibrillary tangles*) consisting of tau molecules that are excessively phosphorylated and unable to bind to microtubules. The neurofibrillary filaments are thought to contribute to the death of nerve cells. Persons with one of these dis-

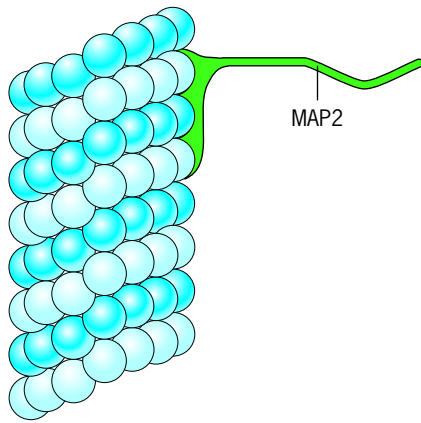

Figure 9.10 Microtubule-associated proteins (MAPs). Schematic diagram of a brain MAP2 molecule bound to the surface of a microtubule. The MAP2 molecule shown in this figure contains three tubulin-binding sites connected by short segments of the polypeptide chain. (An alternate isoform contains four binding sites). The binding sites are spaced at a sufficient distance to allow the MAP2 molecule to attach to three separate tubulin subunits in the wall of the microtubule. The tails of the MAP molecules project outward, allowing them to interact with other cellular components.

Figure 9.11 Localization of microtubules of a flattened, cultured mouse cell is revealed by fluorescent anti-tubulin antibodies. Microtubules are seen to extend from the perinuclear region of the cell in a radial array. Individual microtubules can be followed and are seen to curve gradually as they conform to the shape of the cell. (FROM MARY OSBORN AND KLAUS WEBER, *CELL* 12:563, 1977, WITH PERMISSION FROM ELSEVIER.)

eases, an inherited dementia called FTDP-17, carry mutations in the *tau* gene, indicating that alteration of the tau protein is the primary cause of this disorder.

Microtubules as Structural Supports and Organizers

Microtubules are stiff enough to resist forces that might compress or bend the fiber. This property enables them to provide mechanical support much as steel girders support a tall office building or poles support the structure of a tent. The distribution of cytoplasmic microtubules in a cell helps determine the shape of that cell. In cultured animal cells, the microtubules extend in a radial array outward from the area around the nucleus, giving these cells their round, flattened shape (Figure 9.11). In contrast, the microtubules of columnar epithelial cells are typically oriented with their long axis parallel to the long axis of the cell (Figure 9.1*a*). This configuration suggests that microtubules help support the cell's elongated shape. The role of microtubules as skeletal elements is particularly evident in certain highly elongated cellular processes, such as cilia and flagella and the axons of nerve cells.

In plant cells, microtubules play an indirect role in maintaining cell shape through their influence on the formation of the cell wall. During interphase, most of a plant cell's microtubules are located just beneath the plasma membrane (as in Figure 9.9*b*), forming a distinct cortical zone. The microtubules of the cortex are thought to influence the movement of the cellulose-synthesizing enzymes located in the plasma membrane (see Figure 7.37). As a result, the cellulose microfibrils of the cell wall are assembled in an orientation that is parallel to the underlying microtubules of the cortex (Figure 9.12). The orientation of these cellulose microfibrils plays an important role in determining the growth characteristics of the cell and thus its shape. In most cells, newly synthesized cellulose microfibrils and coaligned microtubules are arranged perpendicular to the long axis of the cell (transversely), like the hoops around a barrel (Figure 9.12). Because the cellulose microfibrils resist lateral expansion, the turgor pressure exerted by the fluid in the cell vacuole is directed to the ends of the cell, causing cell elongation.

Microtubules also play a key role in maintaining the internal organization of cells. Treatment of cells with microtubule-disrupting drugs can seriously affect the location of membranous organelles, including the ER and Golgi com-

Figure 9.12 Spatial relationship between microtubule orientation and cellulose deposition in plant cells. plex. The Golgi complex is typically organized as a single ribbon located near the center of a mammalian cell (see Figure 8.20c), just outside the nucleus. Treatment of cells with nocodazole or colchicine, which promote microtubule disassembly, can disperse the Golgi elements into separate Golgi stacks scattered throughout the cytoplasm. When the drug is removed and microtubules reassemble, the Golgi membranes return to their normal position in the cell interior.

Microtubules as Agents of Intracellular Motility

Living cells bristle with activity as macromolecules and organelles move in a directed manner from place to place. While this hustle and bustle can be appreciated by watching the movement of particulate materials in a living cell, the underlying processes are usually difficult to study because most cells lack a highly ordered cytoskeleton. We know, for example, that the transport of materials from one membrane compartment to another depends on the presence of microtubules because specific disruption of these cytoskeletal elements brings the movements to a halt. We will begin the study of intracellular motility by focusing on nerve cells whose intracellular movements rely on a highly organized arrangement of microtubules and other cytoskeletal filaments.

Figure 9.13 Axonal transport. (a) Schematic drawing of a nerve cell showing the movement of vesicles down the length of an axon along tracks of microtubules. Vesicles move in both directions within the axon. (b) Schematic drawing of the organization of the microtubules and intermediate filaments (neurofilaments) within an axon. Vesicles containing transported materials are attached to the microtubules by cross-linking proteins, including motor proteins, such as kinesin and dynein. (c) Electron micrograph of a portion of an axon from a cultured

Axonal Transport The axon of an individual motor neuron may stretch from the spinal cord to the tip of a finger or toe. The manufacturing center of this neuron is its cell body, a rounded portion of the cell that resides within the spinal cord. When labeled amino acids are injected into the cell body, they are incorporated into labeled proteins that move into the axon and gradually travel down its length. Many different materials, including neurotransmitter molecules, are compartmentalized within membranous vesicles in the ER and Golgi complex of the cell body and then transported down the length of the axon (Figure 9.13a). Non-membrane-bound cargo, such as RNAs, ribosomes, and even cytoskeletal elements are also transported along this vast stretch of extended cytoplasm. Different materials move at different rates, with the fastest axonal transport occurring at velocities of $5 \mu\text{m}$ per second. At this rate, an immature synaptic vesicle pulled by nanosized motor proteins can travel 0.4 meter in a single day, or about halfway from your spinal cord to the tip of your finger. Structures and materials traveling from the cell body toward the terminals of a neuron are said to move in an *anterograde* direction. Other structures, including endocytic vesicles that form at the axon terminals and carry regulatory factors from target cells, move in the opposite, or *retrograde*, direction—from the synapse toward the cell body. Defects in both anterograde and retrograde transport have been linked to several neurological diseases.

Axons are filled with cytoskeletal structures, including bundles of microfilaments, intermediate filaments, and micro-

nerve cell, showing the numerous parallel microtubules that function as tracks for axonal transport. The two membrane-bound organelles shown in this micrograph were seen under a light microscope to be moving along the axon at the time the nerve cell was fixed. (C: FROM A. C. BREUER, C. N. CHRISTIAN, M. HENKART, AND P. G. NELSON, J. CELL BIOL. 65:568, 1975, FIG. 3B. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

Figure 9.14 Visualizing axonal transport. (a–c) These video micrographs show the progression of a membranous organelle along a branched axon. The cell body is far out of the field to the upper left, while the termini (growth cones, page 379) are out of the field to the bottom right. The position of the organelle is indicated by the

arrowheads. The organelle being followed (an autophagic vacuole) moves in the retrograde direction across the branch point and continues to move toward the cell body. Bar, 10 μm . (FROM PETER J. HOLLENBECK, J. CELL BIOL. 121:307, 1993, FIG. 1. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

tubules interconnected in various ways (Figure 9.13b,c). Using video microscopy, investigators can follow individual vesicles as they move along the microtubules of an axon, either toward or away from the cell body (Figure 9.14). These movements are mediated primarily by microtubules (Figure 9.13c), which serve as tracks for a variety of **motor proteins** that generate the forces required to move objects within a cell. The study of motor proteins has become a major focus in cell and molecular biology, and a great deal of information has been collected about the nature of these molecules and their mechanism of action, which are the subjects of the following section.

Motor Proteins that Traverse the Microtubular Cytoskeleton

The motor proteins of a cell convert chemical energy (stored in ATP) into mechanical energy, which is used to generate force, as occurs when a muscle cell contracts, or to move cellular cargo attached to the motor. Types of cellular cargo transported by these proteins include ribonucleoprotein particles, vesicles, mitochondria, lysosomes, chromosomes, and other cytoskeletal filaments. A single cell may contain a hundred different motor proteins, each presumably specialized for a distinct activity, such as the movement of particular types of cargo in a particular region of the cell. Collectively, motor proteins can be grouped into three broad superfamilies: kinesins, dyneins, and myosins. Kinesins and dyneins move along microtubules, whereas myosins move along microfilaments. No motor protein is known that uses intermediate filament tracks. This is not surprising considering that intermediate filaments are not polarized and thus would not provide directional cues to the motor.

Motor proteins move unidirectionally along their cytoskeletal track in a stepwise manner, from one binding site to the next. As the protein moves along, it undergoes a series of conformational changes that constitute a *mechanical cycle*. The steps of the mechanical cycle are coupled to the steps of a *chemical* (or *catalytic*) cycle, which provide the energy necessary

to fuel the motor's activity (see Figure 9.61 for an example). The steps in the chemical cycle include the binding of an ATP molecule to the motor, the hydrolysis of the ATP, the release of the products (ADP and P_i) from the motor, and the binding of a new molecule of ATP. The binding and hydrolysis of a single ATP molecule at the catalytic site is used to drive a power stroke that moves the motor a precise number of nanometers along its track. As the motor protein moves to successive sites along the cytoskeletal polymer, the mechanical and chemical cycles are repeated over and over again, pulling the cargo over considerable distances. Keep in mind, we are describing molecular-sized motors, which unlike human-made machines are greatly influenced by their environment. For example, motor proteins have virtually no momentum and are subjected to tremendous frictional resistance from their viscous environment. As a result, a motor protein comes to a stop almost immediately once energy input has ceased.

We will begin by examining the molecular structure and functions of kinesins, which are the smallest and best understood microtubular motors.

Kinesins In 1985, Ronald Vale and colleagues isolated a motor protein from the cytoplasm of squid giant axons that used microtubules as its track. They named the protein **kinesin**, which was subsequently found in virtually all eukaryotic cells. The kinesin molecule discovered in 1985, which is referred to as “conventional kinesin” or kinesin-1, is only one member of a superfamily of related proteins, called **KRPs (kinesin-related proteins)**. KRPs are classified into 14 different families (kinesin-1 to kinesin-14). In the following discussion the term *kinesin* will refer only to members of the kinesin-1 family.

Each kinesin-1 molecule is a tetramer constructed from two identical heavy chains and two identical light chains (Figure 9.15a). A kinesin molecule has several parts, including a pair of globular heads that bind a microtubule and act as ATP-hydrolyzing, force-generating “engines.” Each head (or *motor domain*) is connected to a neck, a rodlike stalk, and a

fan-shaped tail that binds cargo to be hauled (Figure 9.15*a*). The motor portions of all KRPs have related amino acid sequences, reflecting their common evolutionary ancestry and their similar role in moving along microtubules. In contrast, the tails of KRPs have diverse sequences, reflecting the variety of cargo these motors haul. A number of different proteins have been identified as potential adaptors that link specific KRPs and their cargoes. Surprisingly, the motor domains of kinesins are strikingly similar in structure to that of myosins, despite the fact that kinesins are much smaller proteins and the two types of motors operate over different tracks. Kinesins and myosins almost certainly evolved from a common ancestral protein present in a primitive eukaryotic cell.

When purified kinesin molecules are observed in an *in vitro* motility assay, the motor proteins move along microtubules toward their plus end (see Figure 9.6). Kinesin is therefore said to be a *plus end-directed microtubular motor*. In an axon, where all of the microtubules are oriented with their minus ends facing the cell body, kinesin transports vesicles

Figure 9.15 Kinesin. (a) Structure of a kinesin-1 molecule, which consists of two heavy chains that wrap around each other to form a single, common stalk and two light chains associated with the globular ends of the heavy chains. The human genome encodes three different heavy chains and four different light chains for kinesin-1. The force-generating heads bind to the microtubule, and the tail binds to the cargo being transported. Having a molecular mass of approximately 380 kDa, kinesin is considerably smaller than the other motor proteins, myosin (muscle myosin, 520 kDa) and dynein (over 1000 kDa). (b) Schematic diagram of a kinesin molecule moving along a microtubular track. In the alternate hand-over-hand model shown here, the two heads carry out equivalent but alternating movements, not unlike that of a person walking through a garden on a linear path of stepping stones. As with walking, the trailing head (leg) moves 16 nm forward alternately on the left and right side of the stalk (body). (c) The conformational

and other cargo toward the synaptic terminals. The discovery of kinesin is discussed in the Experimental Pathways, which can be found on the Web at www.wiley.com/college/karp.

A single kinesin molecule moves along a single protofilament of a microtubule at a velocity proportional to the ATP concentration (up to a maximal velocity of about 1 μm per second). At low ATP concentrations, kinesin molecules travel slowly enough for observers to conclude that the protein moves in distinct steps (Figure 9.15*b*). Each step of the molecule is approximately 8 nm in length, which is also the length of one tubulin dimer in a protofilament, and requires the hydrolysis of a single ATP molecule. It is now generally accepted that kinesin moves by a “hand-over-hand” mechanism depicted in Figure 9.15*b*. According to this model, which is basically similar to a person climbing a rope, the two heads alternate in taking the leading and lagging positions without an accompanying rotation of the stalk and cargo at every step.

The movement of kinesin molecules, both *in vitro* and *in vivo*, is highly **processive**, meaning that the motor protein

(c) The conformational changes that occur in the head (blue) and neck (red) portions of a monomeric kinesin molecule that drive the movement of the protein along a microtubule (yellow contour map). Rather than being connected to a stalk and to a second head, the neck of this truncated kinesin molecule is attached to a GFP molecule (green). The swinging movement of the neck would normally drive the forward motion of the partner head, enabling the dimer to walk toward the plus end of a protofilament. (B: C. L. ASBURY, CURRENT OPINION CELL BIOLOGY 17:91, 2005. COPYRIGHT 2005 WITH PERMISSION FROM ELSEVIER SCIENCE. CURRENT OPINION IN CELL BIOLOGY BY ELSEVIER LTD., CURRENT OPINION JOURNALS. REPRODUCED WITH PERMISSION OF ELSEVIER LTD., CURRENT OPINION JOURNALS IN THE FORMAT JOURNAL VIA COPYRIGHT CLEARANCE CENTER. C: FROM RYAN B. CASE ET AL., COURTESY OF RONALD D. VALE, CURR. BIOL., VOL. 10, #3 COVER, 2000, WITH PERMISSION FROM ELSEVIER.)

tends to move along an individual microtubule for considerable distances (over 1 μm) without falling off. A two-headed kinesin molecule can accomplish this feat because at least one of the heads is attached to the microtubule at all times (Figure 9.15*b*). A motor protein with this capability is well adapted for independent, long-distance transport of small parcels of cargo.

The two heads of a kinesin molecule behave in a coordinated manner, so that they are always present at different stages in their chemical and mechanical cycles at any given time. When one head binds to the microtubule, the resulting conformational changes in the adjacent neck region of the motor protein cause the other head to move forward toward the next binding site on the protofilament. The forward-moving head probably finds its precise binding site on the protofilament through a rapid, diffusional (random) search. These actions are illustrated in Figure 9.15*c*, which depicts the head and neck portions of a monomeric kinesin heavy chain associated with a microtubule. Catalytic activity of the head leads to a swinging movement of the neck which, in this illustration, is attached to a molecule of GFP (the green barrel-shaped protein) rather than to a stalk and the partner head in a dimer. The microtubule is not simply a passive track in these events but plays an active role in stimulating certain steps in the mechanical and chemical cycles of the kinesin molecule. Freely soluble kinesins adopt a folded, self-inhibited conformation and require interaction with cargo and a microtubule to become activated.

Like kinesin-1, most KRPs move toward the plus end of the microtubule to which they are bound. One small family

(called kinesin-14), however, including the widely studied Ncd protein of *Drosophila*, moves in the opposite direction, that is, toward the minus end of the microtubular track. One might expect that the heads of plus end-directed and minus end-directed KRPs would have a different structure because they contain the catalytic motor domains. But the heads of the two proteins are virtually indistinguishable. Instead, differences in directional movement have been traced to differences in the adjacent neck regions of the two proteins. When the head of a minus end-directed Ncd molecule is joined to the neck and stalk portions of a kinesin-1 molecule, the hybrid protein moves toward the plus end of the track. Thus, even though the hybrid has a catalytic domain that normally would move toward the minus end of a microtubule, as long as it is joined to the neck of a plus end motor, it moves in the plus direction.

A third small family (kinesin-13) of kinesin-like proteins are incapable of movement. The KRPs of this group bind to either end of a microtubule and bring about its depolymerization rather than moving along its length. These proteins are often referred to as microtubule *depolymerases*.² The important role of these and other KRPs during cell division will be explored in Chapter 14.

Kinesin-Mediated Organelle Transport We saw in Chapter 8 how vesicles move from one membranous compartment, such

²Members of the kinesin-8 family also act as depolymerases, but they reach the tip of the microtubule by processive movement.

Figure 9.16 Alteration in the phenotype of a cell lacking a member of the kinesin superfamily. (*a,c*) Control cell from the extraembryonic tissues of a normal 9.5-day mouse embryo stained in *a* for microtubules (green) and in *c* for mitochondria (red). A significant fraction of the cell's mitochondria are located along microtubules in the peripheral regions of the cell. (*b,d*) A corresponding cell obtained from an embryo

that lacked both copies of the gene encoding KIF5B, which is one of three kinesin-1 isoforms in mice and humans. All of the mitochondria are clustered in the central region of the cell, suggesting that KIF5B is responsible for transporting mitochondria in an outward direction. (FROM YOSUKE TANAKA ET AL., COURTESY OF NOBUTAKA HIROKAWA, CELL 93:1150, 1998, WITH PERMISSION FROM ELSEVIER.)

as the Golgi complex, to another, such as a lysosome. The routes followed by cytoplasmic vesicles and organelles are largely defined by microtubules (see Figure 9.1), and members of the kinesin superfamily are strongly implicated as force-generating agents that drive the movement of this membrane-bounded cargo. In most cells, as in axons, microtubules are aligned with their plus ends pointed away from the center of the cell. Therefore, members of the kinesin superfamily tend to move vesicles and organelles (e.g., peroxisomes and mitochondria) in an outward direction toward the cell's plasma membrane. This is illustrated in the micrographs in Figure 9.16. The pair of micrographs on the left shows a cell that was isolated from a normal 9.5-day mouse embryo and stained to reveal the location of its microtubules (green) and mitochondria (orange). The pair of micrographs on the right shows a cell that was isolated from a 9.5-day mouse embryo lacking both copies of the gene that encodes the KIF5B kinesin heavy chain (a kinesin-1 family member). The mitochondria of the KIF5B-deficient cell are absent from the peripheral regions of the cell, as would be expected if this plus end-directed kinesin is responsible for the outward movement of membranous organelles (see also Figure 9.17c).

Figure 9.17 Cytoplasmic dynein and organelle transport by microtubule-tracking motor proteins. (a) Structure of a cytoplasmic dynein molecule, which contains two dynein heavy chains and a number of smaller intermediate and light chains at the base of the molecule. Each dynein heavy chain contains a large, globular, force-generating head, a protruding stalk containing a binding site for the microtubule, and a stem. (b) Schematic diagram of two vesicles moving in opposite directions along the same microtubule, one powered by kinesin moving toward the plus end of the track, and the other by cytoplasmic dynein

Cytoplasmic Dynein The first microtubule-associated motor was discovered in 1963 as the protein responsible for the movement of cilia and flagella. The protein was named **dynein**. The existence of cytoplasmic forms was almost immediately suspected, but it took over 20 years before a similar protein was purified and characterized from mammalian brain tissue and called **cytoplasmic dynein**. Whereas each of us has many different kinesins (and myosins), each adapted for specific functions, we are able to manage with only two cytoplasmic dyneins, one of which appears responsible for most transport operations.

Cytoplasmic dynein is a huge protein (molecular mass of approximately 1.5 million daltons) composed of two identical heavy chains and a variety of intermediate and light chains (Figure 9.17a). Each dynein heavy chain consists of a large globular head with an elongated projection (stalk). The dynein head, which is an order of magnitude larger than a kinesin head, acts as a force-generating engine. Each stalk contains the all-important microtubule-binding site situated at its tip. The longer projection, known as the stem (or tail), binds the intermediate and light chains, whose functions are not

moving toward the minus end of the track. In the model shown here, each vesicle contains both types of motor proteins, but the kinesin molecules are inactivated in the upper vesicle and the dynein molecules are inactivated in the lower vesicle. Both motor proteins are attached to the vesicle membrane by an intermediary: kinesin can be attached to vesicles by a variety of integral and peripheral membrane proteins, and dynein by a soluble protein complex called dynactin. (c) Schematic illustration of kinesin-mediated and dynein-mediated transport of vesicles, vesicular-tubular clusters (VTCs), and organelles in a nonpolarized, cultured cell.

well defined. Structural analyses indicate that the dynein motor domain consists of a number of distinct modules organized in the shape of a wheel (see Figure 9.37), which makes it fundamentally different in both architecture and mode of operation from kinesin and myosin.

In vitro motility assays indicate that cytoplasmic dynein moves processively along a microtubule toward the polymer's minus end—opposite that of most kinesins (Figure 9.17*b*). Cytoplasmic dynein is present throughout the animal kingdom, but appears to be absent in higher plants, which are thought to have an expanded array of minus end-directed kinesins (kinesin-14 members). A body of evidence suggests at least two well-studied roles for cytoplasmic dynein:

1. As a force-generating agent in positioning the spindle and moving chromosomes during mitosis (discussed in Chapter 14).

2. As a minus end-directed microtubular motor with a role in positioning the centrosome and Golgi complex and moving organelles, vesicles, and particles through the cytoplasm.

In nerve cells, cytoplasmic dynein has been implicated in the retrograde movement of membranous organelles and the anterograde movement of microtubules. In fibroblasts and other nonneural cells, cytoplasmic dynein is thought to transport membranous organelles from peripheral locations toward the center of the cell (Figure 9.17*c*). Dynein-driven cargo includes endosomes and lysosomes, ER-derived vesicles heading toward the Golgi complex, RNA molecules, and the HIV virus which is transported to the nucleus of an infected cell. Cytoplasmic dynein does not interact directly with membrane-bounded cargo but requires an intervening adaptor—most often the multisubunit protein *dynactin*. Dynactin may also

regulate dynein activity and help bind the motor protein to the microtubule, which increases processivity.

According to the simplified model shown in Figure 9.17c, kinesins and cytoplasmic dynein move similar materials in opposite directions over the same railway network. As indicated in Figure 9.17b, individual organelles may bind kinesin and dynein simultaneously, which endows these organelles with the capability to move in opposite directions depending on conditions. It is not clear how the activity of opposing motors is regulated, but in vitro observations have shown that two opposing motors may engage in a type of tug-of-war, causing the object to which they are attached to move back and forth along the microtubule. As discussed on page 363, myosin may also be present on some of these organelles, which provides the opportunity for the organelles to move along actin filaments as well as microtubules.

Microtubule-Organizing Centers (MTOCs)

The function of a microtubule within a living cell depends on its location and orientation, which makes it important to understand why a microtubule assembles in one place as opposed to another. When studied in vitro, the assembly of microtubules from $\alpha\beta$ -tubulin dimers occurs in two distinct phases: a slow phase of *nucleation*, in which a small portion of the microtubule is initially formed, and a much more rapid phase of *elongation*. Unlike the case in vitro, nucleation of microtubules takes place rapidly inside a cell, where it occurs in association with a variety of specialized structures called **microtubule-organizing centers** (or **MTOCs**). The best studied MTOC is the centrosome.

Centrosomes In animal cells, the microtubules of the cytoskeleton are typically nucleated by the **centrosome**, a complex structure that contains two barrel-shaped **centrioles** surrounded by amorphous, electron-dense **pericentriolar material** (or **PCM**) (Figure 9.18a,b). Centrioles are cylindrical structures about 0.2 μm in diameter and typically about twice

as long. Centrioles contain nine evenly spaced fibrils, each of which appears in cross section as a band of three microtubules, designated the A, B, and C tubules. Only the A tubule is a complete microtubule (Figure 9.18a,b) and it is connected to the center of the centriole by a radial spoke. The three microtubules of each triplet are arranged in a pattern that gives a centriole a characteristic pinwheel appearance. Centrioles are nearly always found in pairs, with the members situated at right angles to one another (Figure 9.18a,c). Extraction of isolated centrosomes with 1.0 M potassium iodide removes about 90 percent of the protein of the PCM, leaving behind a spaghetti-like scaffold of insoluble fibers (Fig. 9.18d). As discussed below, the centrosome is the major site of microtubule initiation in animal cells and typically remains at the center of the cell's microtubular network (Figure 9.18e).

Figure 9.19a shows an early experiment that demonstrates the role of the centrosome in the initiation and organization of the microtubular cytoskeleton. The microtubules of a cultured animal cell were first depolymerized by incubating the cells in colcemid, a drug that binds to tubulin subunits and blocks their use by the cell. Microtubule reassembly was then monitored by removing the chemical, fixing cells at various time intervals, and treating the fixed cells with fluorescent anti-tubulin antibodies. Within a few minutes after removal of the inhibiting conditions, one or two bright fluorescent spots are seen in the cytoplasm of each cell. Within 15 to 30 minutes (Figure 9.19a), the number of labeled filaments radiating out of these foci increases dramatically. When these same cells are sectioned and examined in the electron microscope, the newly formed microtubules are found to radiate outward from a centrosome. Close examination shows that the microtubules do not actually penetrate into the centrosome and make contact with the centrioles, but terminate in the dense PCM that re-

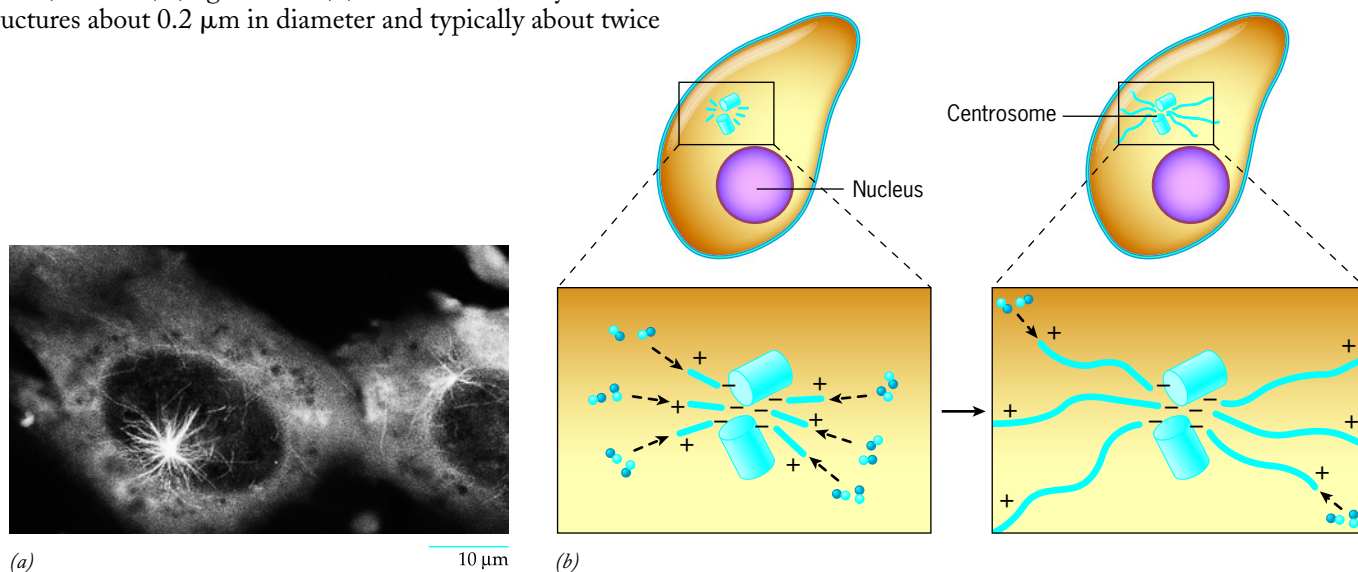

Figure 9.19 Microtubule nucleation at the centrosome. The bright starlike structure marks

the centrosome together with newly assembled microtubules that have begun to grow outward in all directions. (b) Schematic diagram of the re-growth of microtubules showing the addition of subunits at the plus end of the polymer away from the centrosome. (A: FROM MARY OSBORN AND KLAUS WEBER, PROC. NAT'L ACAD. SCI. U.S.A., 73:869, 1976.)

sides at the centrosome periphery. It is this material that initiates the formation of microtubules (see Figure 9.20*c*). Although centrioles are not directly involved in microtubule nucleation, they play a role in recruiting the surrounding PCM during assembly of the centrosome and in the general process of centrosome duplication (discussed in Section 14.2).

As illustrated by the experiment just described, centrosomes are sites of microtubule nucleation. The polarity of these microtubules is always the same: the minus end is associated with the centrosome, and the plus (or growing) end is situated at the opposite tip (Figure 9.19*b*). Thus, even though microtubules are nucleated at the MTOC, they are elongated at the opposite end of the polymer. The growing end of a microtubule may contain a host of specific proteins that help attach the microtubule to a particular target, such as an endosome or Golgi cisterna in an interphase cell or a condensed chromosome in a mitotic cell.

The fraction of microtubules that remain associated with the centrosome is highly variable from one cell type to another. The centrosome of a nonpolarized cell (e.g., a fibroblast) is typically situated near the center of the cell and tends to remain associated with the minus ends of a large number of microtubules (as in Figure 9.18*e*). In contrast, many of the microtubules in a polarized epithelial cell are anchored by their minus ends at dispersed sites near the apical end of the cell as their plus ends extend toward the cell's basal surface (Figure 9.1). Similarly, the axon of a nerve cell contains large numbers

of microtubules that have no association with the centrosome, which is located in the neuron's cell body. Many of these axonal microtubules are thought to form in conjunction with the centrosome, but are then severed from the MTOC and transported into the axon by motor proteins. Certain animal cells, including mouse oocytes, lack centrosomes entirely, yet they are still capable of forming complex microtubular structures, such as the meiotic spindle (as discussed in Chapter 14).

Basal Bodies and Other MTOCs Centrosomes are not the only MTOCs in cells. The outer microtubules in a cilium or flagellum are generated as outgrowths from the microtubules in a structure called a **basal body**, which resides at the base of the cilium or flagellum (see Figure 9.33). Basal bodies are identical in structure to centrioles, and in fact, basal bodies and centrioles can give rise to one another. For example, the basal body that gives rise to the flagellum of a sperm cell is derived from a centriole that had been part of the meiotic spindle of the spermatocyte from which the sperm arose. Conversely, the sperm basal body typically becomes a centriole during the first mitotic division of the fertilized egg. Plant cells lack both centrosomes and centrioles, or any other type of obvious MTOC. Instead, microtubules in a plant cell are nucleated around the surface of the nucleus and widely throughout the cortex (see Figure 9.22).

Microtubule Nucleation Regardless of their diverse appearance, all MTOCs play similar roles in all cells: they con-

Figure 9.20 The role of γ -tubulin in centrosome function. (a) A dividing fibroblast that has been double stained with antibodies against γ -tubulin (red) and β -tubulin (green). Orange staining is due to the coincidence of the two types of tubulin, which occurs in the two centrosomes located at opposite poles of a dividing cell. (b) A reconstruction based on electron micrographs of a portion of a centrosome that had been incubated with purified tubulin *in vitro* and then labeled with antibodies against γ -tubulin. The antibodies were linked to gold particles to make them visible (as white dots) in the reconstruction. During the incubation with tubulin, the centrosome served as an MTOC to nucleate microtubules whose minus ends are seen to be labeled with clusters of gold, which are often arranged in semicircles or

rings. The accompanying drawing shows the outline of the microtubule seen in the reconstruction. (c) A model for γ -tubulin function during the assembly of microtubules. Nucleation begins as $\alpha\beta$ -tubulin dimers bind to an open ring of γ -tubulin molecules (brown), which are held in place by a number of non-tubulin proteins (green) that make up the large γ -TuRC. Nucleation by the γ -TuRC defines microtubule polarity with a ring of α -tubulin monomers situated at the minus end of the structure. (A: COURTESY OF M. KATHERINE JUNG AND BERL R. OAKLEY; B: FROM MICHELLE MORITZ ET AL., NATURE 378:639, 1995, FIG. 1B. PHOTO COURTESY OF DAVID A. AGARD; © 1995. REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LIMITED.)

control the number of microtubules, their polarity, the number of protofilaments that make up their walls, and the time and location of their assembly. In addition, all MTOCs share a common protein component—a type of tubulin discovered in the late 1980s, called γ -tubulin. Unlike the α - and β -tubulins, which make up about 2.5 percent of the protein of a non-neural cell, γ -tubulin constitutes only about 0.005 percent of the cell's total protein. Fluorescent antibodies to γ -tubulin stain all types of MTOCs, including the pericentriolar material of centrosomes (Figure 9.20a), suggesting that γ -tubulin is a critical component in microtubule nucleation. This conclusion is supported by other studies. For example, microinjection of anti- γ -tubulin antibodies into a living cell blocks the reassembly of microtubules following their depolymerization by drugs or cold temperature.

To understand the mechanism of microtubule nucleation, researchers have focused on the structure and composition of the pericentriolar material (PCM) at the periphery of centrosomes. The insoluble fibers of the PCM (Figure 9.18d) are thought to serve as attachment sites for ring-shaped structures that have the same diameter as microtubules (25 nm) and contain γ -tubulin. These ring-shaped structures were discovered when centrosomes were purified and incubated with gold-labeled antibodies that bound to γ -tubulin. The gold particles were seen in the electron microscope to be clustered in semicircles or rings situated at the minus ends of microtubules (Figure 9.20b). These are the ends of the microtubules that are embedded in the PCM of the centrosome where nucleation occurs. Similar γ -tubulin ring complexes (or γ -TuRCs) have been isolated from cell extracts and shown to nucleate microtubule assembly *in vitro*. These and other studies have suggested the model shown in Figure 9.20c in which a helical array of γ -tubulin (brown) subunits forms an open, ring-shaped template on which the first row of $\alpha\beta$ -tubulin dimers assemble. In this model, only the α -tubulin of the heterodimer can bind to a ring of γ -subunits. Thus the γ -TuRC determines the polarity of the entire microtubule and also forms a cap at its minus end, preventing the gain or loss of tubulin subunits.

The Dynamic Properties of Microtubules

Although all microtubules appear quite similar morphologically, there are marked differences in their stability. Microtubules are stabilized by the presence of bound MAPs (page 331) and, likely, by other factors, including posttranslational modifications to the tubulin subunits. Microtubules of the mitotic spindle or the cytoskeleton are extremely labile, that is, sensitive to disassembly. Microtubules of mature neurons are much less labile, and those of centrioles, cilia, and flagella are highly stable. Living cells can be subjected to a variety of treatments that lead to the disassembly of labile cytoskeletal microtubules without disrupting other cellular structures. Disassembly can be induced by cold temperature; hydrostatic pressure; elevated Ca^{2+} concentration; and a variety of chemicals, including colchicine, vinblastine, vincristine, nocodazole, and podophyllotoxin. The drug taxol stops the dynamic activities of microtubules by a very different mechanism. Taxol binds to the microtubule polymer, inhibiting its disassembly, thereby preventing the cell from assembling new microtubular structures as required. Many of these compounds, including taxol, are used in chemotherapy against cancer because they preferentially kill tumor cells.

The lability of cytoskeletal microtubules reflects the fact that they are polymers formed by the noncovalent association of protein building blocks. The microtubules of the cytoskeleton are normally subject to depolymerization and repolymerization as the requirements of the cell change from one time to another. The dynamic character of the microtubular cytoskeleton is well illustrated by plant cells. If a typical plant cell is followed from one mitotic division to the next, four distinct arrays of microtubules appear, one after another (Figure 9.21).

1. During most of interphase, the microtubules of a plant cell are distributed widely throughout the cortex, as depicted in Figure 9.21, stage 1. A search for γ -tubulin shows this nucleation factor to be localized along the lengths of the cortical microtubules, suggesting that new microtubules might form directly on the surface of existing microtubules. This idea is supported by studies of

Figure 9.21 Four major arrays of microtubules present during the cell cycle of a plant cell. The organization of the microtubules at each stage are described in the text. (R. H. GODDARD ET AL, PLANT PHYSIOL. 104:2, 1994. PLANT PHYSIOLOGY BY AMERICAN SOCIETY

Figure 9.22 Nucleation of plant cortical microtubules. (a) The micrographs show a portion of a live cultured tobacco cell that is expressing fluorescently labeled GFP-tubulin. During the period of observation, an existing microtubule of the cortex nucleates the assembly of a daughter microtubule, which grows outward forming a Y-shaped branch. The end of a newly formed microtubule is indicated by the arrowhead, the branchpoint by the arrow. (b) Electron micrograph of a microtubule with two daughter microtubules branching from its surface. The branched microtubules were assembled in a cell-free system containing tubulin subunits. Bar, 10 μm . (c) A schematic model showing how new microtubules are nucleated at the sites of γ -tubulin present on the surface of an existing microtubule. (A,B: FROM TAKASHI MURATA ET AL., NATURE CELL BIOL. 7:961, 2005. REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD.)

tubulin incorporation in living cells (Figure 9.22a) and by in vitro assays (Figure 9.22b) that show newly formed microtubules branching at an angle off the sides of preexisting microtubules. Once formed, the daughter microtubules are likely severed from the parent microtubule and incorporated into the parallel bundles that encircle the cell (Figures 9.12a, 9.21).

2. As the cell approaches mitosis, the microtubules disappear from most of the cortex, leaving only a single transverse band, called the *preprophase band*, that encircles the cell like a belt (Figure 9.21, stage 2). The preprophase band marks the site of the future division plane.

3. As the cell progresses into mitosis, the preprophase band is lost and microtubules reappear in the form of the mitotic spindle (Figure 9.21, stage 3).
4. After the chromosomes have been separated, the mitotic spindle disappears and is replaced by a bundle of microtubules called the *phragmoplast* (Figure 9.21, stage 4), which plays a role in the formation of the cell wall that separates the two daughter cells (see Figure 14.38).

These dramatic changes in the spatial organization of microtubules are thought to be accomplished by a combination of two separate mechanisms: (1) the rearrangement of existing microtubules and (2) the disassembly of existing microtubules and reassembly of new ones in different regions of the cell. In the latter case, the microtubules that make up the preprophase band are formed from the same subunits that a few minutes earlier were part of the cortical array or, before that, the phragmoplast.

The Underlying Basis of Microtubule Dynamics Insight into factors that influence the rates of microtubule assembly and disassembly came initially from studies carried out in vitro. The first successful approach to the in vitro assembly of microtubules was taken in 1972 by Richard Weisenberg of Temple University. Reasoning that cell homogenates should possess all the macromolecules required for the assembly process, Weisenberg obtained tubulin polymerization in crude brain homogenates at 37°C by adding Mg^{2+} , GTP, and EGTA (which binds Ca^{2+} , an inhibitor of polymerization). Weisenberg found that microtubules could be disassembled and reassembled over and over simply by lowering and raising the temperature of the incubation mixture. Figure 9.23 shows three microtubules that were assembled in the test tube from purified tubulin. One of the three microtubules in this figure contains only 11 protofilaments (as indicated by its thinner diameter). It is not unexpected that microtubules assembled in vitro might have abnormal protofilament numbers because they lack a proper template (Figure 9.20c) normally provided by the γ -tubulin ring complexes in vivo. In vitro assembly of microtubules is aided greatly by the addition of MAPs or by pieces of microtubules or structures that contain microtubules (Figure 9.24), which serve as templates for the addition of free subunits. In these in vitro studies, tubulin subunits are added primarily to the plus end of the existing polymer.

Early in vitro studies established that GTP is required for microtubule assembly. Assembly of tubulin dimers requires that a GTP molecule be bound to the β -tubulin subunit.³ As it turns out, β -tubulin is not only a structural protein, it is also an enzyme; a GTPase. GTP hydrolysis is not required for the actual incorporation of the dimer onto the end of a microtubule. Rather, the GTP is hydrolyzed to GDP shortly *after* the dimer is incorporated into a microtubule, and the resulting GDP remains bound to the assembled polymer. After a dimer is released from a microtubule during disassembly and enters

³A molecule of GTP is also bound to the α -tubulin subunit, but it is not exchangeable and it is not hydrolyzed following subunit incorporation. The positions of the guanine nucleotides in the $\alpha\beta$ -tubulin heterodimer are shown in Figure 9.9c.

Figure 9.23 Microtubules assembled in the test tube. Electron micrograph of frozen, unfixed microtubules that had polymerized in vitro. The individual protofilaments and their globular tubulin subunits are visible. Note that the middle of the three microtubules contains only 11 protofilaments. (COURTESY OF R. H. WADE, INSTITUT DE BIOLOGIE STRUCTURALE, GRENOBLE, FRANCE.)

the soluble pool, the GDP is replaced by a new GTP. This nucleotide exchange “recharges” the dimer, allowing it to serve once again as a building block for polymerization.

Because it includes GTP hydrolysis, assembly of a microtubule is not an inexpensive cellular activity. Why has such a

Figure 9.24 The assembly of tubulin onto an existing microtubular structure. Electron micrograph showing the in vitro assembly of brain tubulin onto the plus ends of the microtubules of an axoneme from a *Chlamydomonas* flagellum. (COURTESY OF L. I. BINDER AND JOEL L. ROSENBAUM.)

costly polymerization pathway evolved? To answer this question, it is useful to consider the effect of GTP hydrolysis on microtubule structure. When a microtubule is growing, the plus end is seen under the electron microscope as an open sheet to which GTP-dimers are added (step 1, Figure 9.25a, 9.25b).

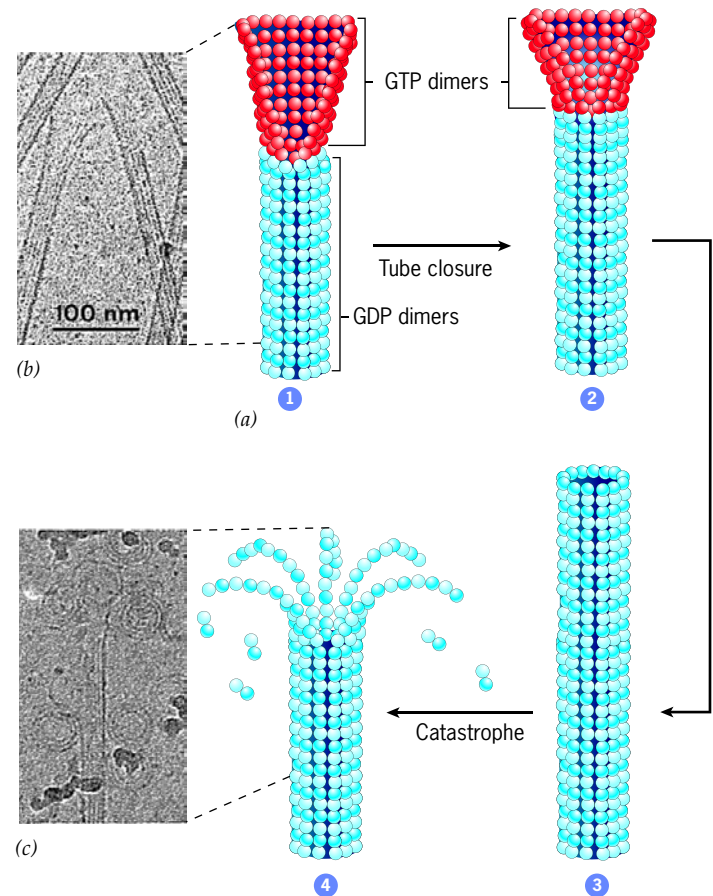

Figure 9.25 The structural cap model of dynamic instability.

According to the model, the growth or shrinkage of a microtubule depends on the state of the tubulin dimers at the plus end of the microtubule. Tubulin-GTP dimers are depicted in red. Tubulin-GDP dimers are depicted in blue. In a growing microtubule (step 1), the tip consists of an open sheet containing tubulin-GTP subunits. In step 2, the tube has begun to close, forcing the hydrolysis of the bound GTP. In step 3, the tube has closed to its end, leaving only tubulin-GDP subunits. GDP-tubulin subunits have a curved conformation compared to their GTP-bound counterparts, which makes them less able to fit into a straight protofilament. The strain resulting from the presence of GDP-tubulin subunits at the plus end of the microtubule is released as the protofilaments curl outward from the tubule and undergo catastrophic shrinkage (step 4). (b) Cryo-EM image of the growing end of a microtubule showing a curved, open sheet. (c) Cryo-EM image of the shrinking end of a microtubule showing outwardly curved protofilaments. (A: A. A. Figure 9.26 Microtubule dynamics in living cells. This cultured fibroblast was injected with a small volume of tubulin that had been covalently linked to biotin, a small molecule whose location in the cell is readily determined using fluorescent anti-biotin antibodies. Approximately one minute following injection, the cells were fixed, and the location of biotinylated tubulin that had been incorporated into insoluble microtubules was determined. It is evident from this fluorescence micrograph that, even during periods as short as one minute, tubulin subunits are widely incorporated at the growing ends of cytoskeletal microtubules. (FROM MARC KIRSCHNER, *J. CELL BIOL.* 102, COVER OF NO. 3, 1986; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

During times of rapid microtubule growth, tubulin dimers are added more rapidly than their GTP can be hydrolyzed. The presence of a cap of tubulin-GTP dimers at the plus ends of the protofilaments is thought to favor the addition of more subunits and the growth of the microtubule. However, micro-

tubules with open ends, as in step 1, Figure 9.25*a*, are thought to undergo a spontaneous reaction that leads to closure of the tube (steps 2 and 3). In this model, tube closure is accompanied by the hydrolysis of the bound GTP, which generates subunits that contain GDP-bound tubulin. GDP-tubulin subunits have a different conformation from their GTP-tubulin precursors and are less suited to fit into a straight protofilament. The resulting mechanical strain destabilizes the microtubule. The strain energy is released as the protofilaments curl outward from the plus end of the tubule and undergo catastrophic depolymerization (Figure 9.25*a*, step 4; 9.25*c*). Thus, it would appear that GTP hydrolysis is a fundamental component of the dynamic quality of microtubules. The strain energy stored in a microtubule as a result of GTP hydrolysis makes the microtubule inherently unstable and—in the absence of other stabilizing factors such as MAPs—capable of disassembling soon after its formation. Microtubules can shrink remarkably fast, especially *in vivo*, which allows a cell to disassemble its microtubular cytoskeleton very rapidly.

The dynamic character of the microtubular cytoskeleton inside a cell can be revealed by microinjecting labeled tubulin into a cultured cell. The labeled subunits are rapidly incorporated into the preexisting microtubules of the cytoskeleton, even in the absence of morphological change (Figure 9.26). If individual microtubules are observed under a fluorescence microscope, they appear to grow slowly for a period of time and then shrink rapidly and unexpectedly, as illustrated by the microtubule being followed in Figure 9.27. Because the switch from growth to shrinkage (an event termed *catastrophe*) occurs with high frequency *in vivo*, most microtubules disappear from the cell in a matter of minutes and are replaced by new microtubules that grow out from the centrosome.

In 1984, Timothy Mitchison and Marc Kirschner of the University of California, San Francisco, reported on the properties of individual microtubules and proposed that microtubule behavior *in vivo* could be explained by a phenomenon they termed **dynamic instability**. Dynamic instability ex-

Figure 9.27 Dynamic instability. This series of photographs shows the changes in length of a single microtubule in the growth cone of a neuron. The cell was microinjected with fluorescently labeled tubulin at sufficiently low concentration to produce green fluorescent speckles along the length of microtubules. As discussed on page 327, such speckles provide fixed reference points that can be followed over time. Each of the yellow horizontal lines connects one of these speckles from one time point to another. The blue line indicates the approximate plus

end of the microtubule at various time points. From 0 to about 200 seconds, the microtubule undergoes a gradual addition of tubulin subunits at its plus end. Then, from about 200 to 240 seconds the microtubule experiences rapid shrinkage. (FROM ANDREW W. SCHAEFER, NURUL KABIR, AND PAUL FORSCHER, *YALE UNIVERSITY. J. CELL BIOL.* 158:145, 2002, FIG. 5, REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

plains the observation (1) that growing and shrinking microtubules can coexist in the same region of a cell, and (2) that a given microtubule can switch back and forth unpredictably (*stochastically*) between growing and shortening phases, as in Figure 9.27. Dynamic instability is an inherent property of the microtubule itself and, more specifically, of the plus end of the microtubule. As indicated in Figure 9.25, it is the plus end where subunits are added during growth and lost during shrinkage. This does not mean that dynamic instability cannot be influenced by external factors. For example, cells contain a diverse array of proteins (called +TIPs) that bind to the dynamic plus ends of microtubules (Figure 9.28). Some of these +TIPs regulate the rate of the microtubule's growth or shrinkage or the frequency of interconversion between the two phases. Other +TIPs mediate the attachment of the plus end of the microtubule to a specific cellular structure, such as the kinetochore of a mitotic chromosome during cell division or the actin cytoskeleton of the cortex during vesicle transport. Once a subcellular structure is attached to the plus end of a microtubule, the dynamic properties of the microtubule can exert force on that structure. Polymerization of a microtubule can push on an attached object, whereas depolymerization of a microtubule can pull on an attached object. For instance, this type of pulling force plays a major role in the segregation of chromosomes during cell division (Section 14.2).

Dynamic instability provides a mechanism by which the plus ends of microtubules can rapidly explore the cytoplasm for appropriate sites of attachment. Attachment temporarily stabilizes microtubules and allows the cell to build the com-

Figure 9.28 Binding of a microtubule plus-end tracking protein (+TIP). The micrograph shows a live image of a human lung fibroblast expressing mCherry-labeled tubulin (generating red microtubules) and GFP-labeled EB3, a +TIP (appearing green). EB3 is seen to bind to the plus ends of the microtubules. (FROM ANNA AKHMANOVA AND MICHEL O. STEINMETZ, J. CELL SCIENCE 123, 3415, 2010; BY PERMISSION OF THE COMPANY OF BIOLOGISTS. COURTESY ANNA AKHMANOVA AND ILYA GRIGORIEV, UTRECHT UNIVERSITY, THE NETHERLANDS. <http://jcs.biologists.org/content/123/20/3415.full?sid=f97c0f52-c919-4739-a062-0d83b8e8f68b>)

plex cytoskeletal networks discussed in this chapter. Dynamic instability also allows cells to respond rapidly to changing conditions that require remodeling of the microtubular cytoskeleton. One of the most dramatic examples of such remodeling occurs at mitosis when the microtubules of the cytoskeleton are disassembled and remodeled into a bipolar mitotic spindle. This reorganization is associated with a marked change in microtubule stability; microtubules in interphase cells have half-lives that are 5–10 times longer than microtubules in mitotic cells. Unlike the microtubules of the mitotic spindle or cytoskeleton, the microtubules of the organelles to be discussed below lack dynamic activity and, instead, are highly stable.

Cilia and Flagella: Structure and Function

Anyone who has placed a drop of pond water under the lens of a microscope and tried to keep a protozoan from swimming out of the field of view can appreciate the activity of cilia and flagella. **Cilia** and **flagella** are hairlike, motile organelles that project from the surface of a variety of eukaryotic cells. Bacteria also possess structures referred to as *flagella*, but prokaryotic flagella are simple filaments that bear no evolutionary relationship to their eukaryotic counterparts (see Figure 1.14). The discussion that follows pertains only to the eukaryotic organelles.

Cilia and flagella are essentially the same structure. Most biologists use one or the other term based on the type of cell from which the organelle projects and its pattern of movement. According to this distinction, a cilium can be likened to an oar as it moves the cell in a direction perpendicular to the cilium itself. In its power stroke, the cilium is maintained in a rigid state (Figure 9.29a) as it pushes against the surrounding medium. In its recovery stroke, the cilium becomes flexible, offering little resistance to the medium. Cilia tend to occur in large numbers on a cell's surface, and their beating activity is usually coordinated (Figure 9.29b). In multicellular organisms, cilia move fluid and particulate material through various tracts (Figure 9.29c). In humans, for example, the ciliated epithelium lining the respiratory tract propels mucus and trapped debris away from the lungs. Not all cilia are motile: many cells of the body contain a single nonmotile cilium (called a *primary cilium*) that is thought to have a sensory function, monitoring the mechanical and chemical properties of extracellular fluids. Some of the roles of single motile and nonmotile cilia are discussed in the accompanying Human Perspective.

Flagella typically occur singly or in pairs and exhibit a variety of different beating patterns (*waveforms*), depending on the cell type. For example, the single-celled alga pictured in Figure 9.30a pulls itself forward by waving its two flagella in an asymmetric manner that resembles the breaststroke of a human swimmer (Figure 9.30b). This same algal cell can also push itself through the medium using a symmetric beat resembling that of a sperm (shown in Figure 9.35). The degree of asymmetry in the pattern of the beat in the algal cell is regulated by the internal calcium ion concentration.

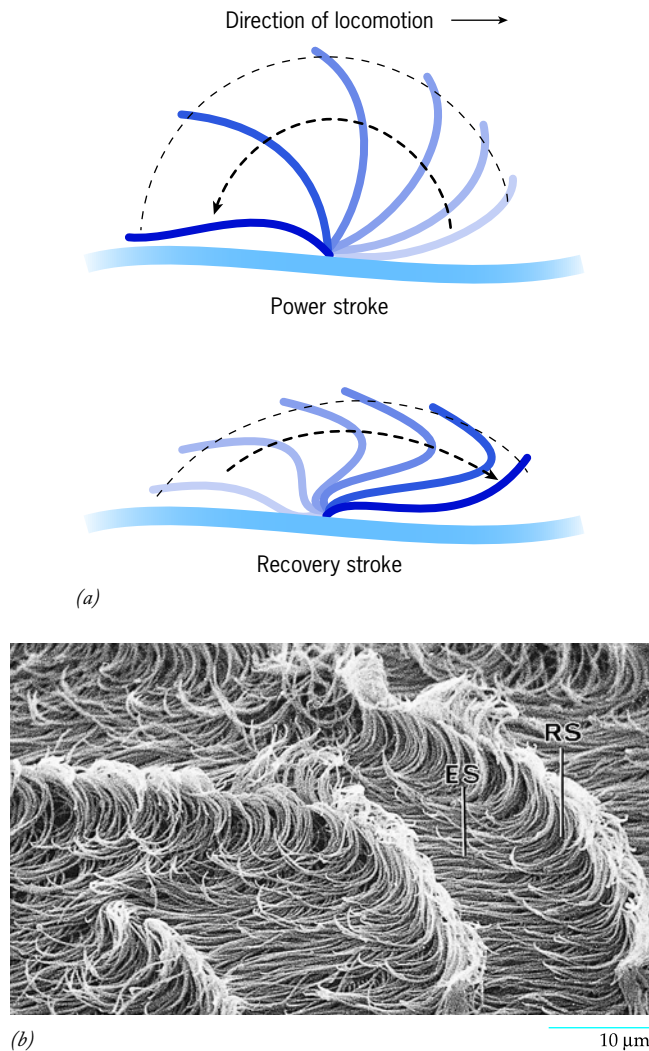

Figure 9.29 Ciliary beat. (a) The various stages in the beat of a cilium. (b) The cilia on the surface of a ciliated protozoan beat in metachronal waves in which the cilia in a given row are in the same stage of the beat cycle, but those in adjacent rows are in a different stage. (B: FROM G. A. HORRIDGE AND S. L. TAMM, *SCIENCE* 163:818, 1969. REPRINTED WITH PERMISSION FROM AAAS; C: FROM SEIKO F. OKADA, ET AL., *J. BIOL. CHEM.* 281: 22995, 2006, FIG. 2C, © 2006. THE AMERICAN SOCIETY FOR BIOCHEMISTRY AND MOLECULAR BIOLOGY.)

An electron micrograph of a cross section of a cilium or flagellum is one of the most familiar images in cell biology (Figure 9.31a). The entire ciliary or flagellar projection is covered by a membrane that is continuous with the plasma membrane of the cell. The core of the cilium, called the **axoneme**, contains an array of microtubules that runs longitudinally through the entire organelle. With rare exceptions, the axoneme of a motile cilium or flagellum consists of nine peripheral doublet microtubules surrounding a central pair of single microtubules. This same microtubular structure, which is known as the 9 + 2 array, is seen in axonemes from protists to mammals and serves as another of the many reminders that all living eukaryotes have evolved from a common ancestor. All microtubules of the axoneme have the same polarity: their plus ends are at the tip of the projection and their minus ends are at the base. Each peripheral doublet consists of one complete microtubule, the *A tubule*, and one incomplete microtubule, the *B tubule*, the latter containing 10 or 11 subunits rather than the usual 13.

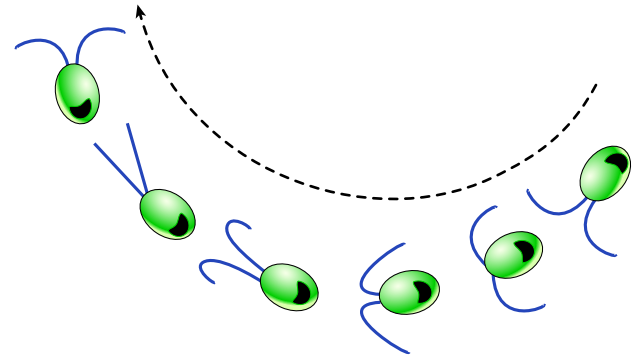

The basic structure of the axoneme was first described in 1952—in plants by Irene Manton and in animals by Don Fawcett and Keith Porter. (Flagella were lost during the evolution of higher plants.) As the resolving power of electron microscopes improved, certain of the less obvious components became visible (Figure 9.31b). The central tubules were seen to be enclosed by the *central sheath*, which is connected to the A tubules of the peripheral doublets by a set of *radial spokes*. The doublets are connected to one another by an *interdoublet bridge* composed of an elastic protein, nexin. Of particular importance was the observation that a pair of “arms”—an *inner arm* and an *outer arm*—project from the A tubule (Figure 9.31a). A longitudinal section, that is, one cut through the axoneme parallel to its long axis, reveals the continuous nature of the microtubules and the discontinuous nature of the other elements (Figure 9.32a).

As noted earlier, a cilium or flagellum emerges from a *basal body* (Figure 9.33a) similar in structure to the centriole of Figure 9.18a. The A and B tubules of the basal body elongate to

(a)

Figure 9.30 Eukaryotic flagella. (a) The unicellular alga *Chlamydomonas reinhardtii*. The two flagella appear green after binding a fluorescent antibody directed against a major flagellar membrane protein. The red color results from autofluorescence of the cell's chlorophyll. Unlike many flagellated organisms, *Chlamydomonas* does not need its flagella to survive and reproduce, so that mutant strains

exhibiting various types of flagellar defects can be cultured. (b) The forward movement of *Chlamydomonas* is accomplished by an asymmetric waveform that resembles the breast stroke. A different type of flagellar waveform is shown in Figure 9.35. (A: COURTESY OF ROBERT BLOODGOOD, UNIVERSITY OF VIRGINIA.)

form the doublets of the cilium or flagellum (Figure 9.33b). If a cilium or flagellum is sheared from the surface of a living cell, a new organelle is regenerated as an outgrowth of the basal body. As with other microtubular structures, the growth of an ax-

oneme occurs at the plus (outer) ends of its microtubules. How does a cell organize and maintain a construction site at the outer tip of an axoneme situated micrometers from the body of the cell where the synthesis of building materials takes place?

the cytoplasm and migrate to sites beneath the plasma membrane. (b) Schematic diagram of the structural relationship between the microtubules of the basal body and the axoneme of a cilium or flagellum. (A: COURTESY OF R. G. W. ANDERSON.)

THE HUMAN PERSPECTIVE

The Role of Cilia in Development and Disease

When you look into a mirror, you see a relatively symmetrical organism, one whose left half is essentially a mirror image of the right half. Surgeons, on the other hand, see a strikingly asymmetric organism when they open a person's thoracic or abdominal cavity. The stomach, heart, and spleen, for example, are shifted to the left side of the body, whereas the liver is largely on the right side. On occasion, a physician will see a patient in which the left–right asymmetry of the visceral organs is reversed (a condition called *situs inversus*).

Situs inversus is seen in persons with Kartagener syndrome, which is also characterized by recurrent sinus and respiratory infections and infertility in males. The first clues to the underlying cause of this disorder came in the 1970s when it was discovered that the immotile sperm from these individuals had an abnormal axonemal structure. Depending on the patient, the axonemes may be missing outer or inner dynein arms, central microtubules, or radial spoke structures (see Figure 9.31). Subsequent studies have shown that mutations in a number of genes, including those encoding dynein heavy and intermediate chains, can cause this syndrome. It is understandable that such patients would suffer from respiratory infections, which depend on the clearance of debris and bacteria by respiratory-tract cilia, and from male infertility, but why would roughly half of them exhibit a reversed left–right asymmetry?

The basic body plan of a mammal is laid down during gastrulation in association with a structure called the *embryonic node*. Each cell that makes up the node has a single cilium. These cilia have unusual properties; they are missing the two central microtubules (they have a 9 + 0 axonemal structure) and exhibit an unusual rotary (twirling) motion. If the motility of these cilia is impaired, as happens in mice harboring mutations in a flagellar dynein gene, roughly half of the animals develop reversed asymmetry, suggesting that left–right asymmetry in these mutants is determined by chance.

The rotation of the nodal cilia moves the surrounding fluid to the left side of the embryonic midline, as was demonstrated by tracking the movement of microscopic fluorescent beads. It was proposed that the extracellular fluid moved by the nodal cilia contains morphogenetic substances (i.e., substances that direct embryonic development) that become concentrated on the left side of the embryo, leading to the eventual formation of different organs on different sides of the midline. This proposal is strongly supported by experimental studies in which mouse embryos were raised in miniaturized chambers in which an artificial flow of fluid across the node could be imposed. When embryos were subjected to a flow of fluid in a direction opposite to that occurring during normal development, the embryos developed with reversed left–right asymmetry.^a

Many cells of the body have a single, nonmotile primary cilium that is lacking both central microtubules and dynein arms. These cilia were ignored by researchers for years, but more recent studies suggest that they have important functions as “antennae” that sense the chemical and mechanical properties of the fluids into which they project. Consider the primary cilia (Figure 1) on the epithelial cells that line the lumen of microscopic kidney tubules in which urine for-

mation occurs. The importance of these cilia was revealed when it was discovered that a pair of membrane proteins called polycystin 1 and 2 (PC1 and PC2) are localized on the surface of these kidney cilia. PC1 and PC2 form a complex in which PC1 serves as a sensor for fluid flow in the kidney tubules and PC2 serves as an associated Ca^{2+} ion channel. Mutations in *PKD1* and *PKD2*, the genes that encode PC1 and PC2, lead to polycystic kidney disease, in which the kidney develops multiple cysts that destroy kidney function. Polycystic kidney disease is thought to be a condition that results from a breakdown in the regulation of cell division because the cysts are the result of an abnormally high level of proliferation of the epithelial cells that line parts of the kidney tubules. According to one model, mutations in the polycystins alter the response of the primary cilia to fluid flow, which leads to a disturbance in calcium flux across the ciliary membrane, which in turn impairs the transmission of signals to the body of the cell and the nucleus, resulting in abnormal cell proliferation. The movement of calcium ions is only one type of signal that is transmitted by the membranes of primary cilia. The primary ciliary membranes of different types of cells contain unique sets of proteins that sense and respond to a variety of extracellular signals. These proteins play an important role in both embryonic development and the maintenance of healthy adult tissues.

Figure 1 Primary cilia. Immunofluorescence image showing a single primary cilium (green) projecting from the apical surface of each epithelial cell of the collecting duct of the kidney. The intercellular junctions between the epithelial cells are shown in red. (FROM HIROAKI ISHIKAWA AND WALLACE F. MARSHALL, *NATURE REVIEWS. MOL. CELL BIOL.* 12:223, 2011; REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS, LTD.)

^aAn alternate but related hypothesis holds that the embryonic node contains two different types of cilia, a population of motile cilia located in the center of the node and nonmotile primary cilia distributed around the node periphery. According to this hypothesis, the motile cilia generate the leftward flow and the nonmotile cilia act as sensory structures that detect the movement and transmit signals that lead to asymmetry.

The importance of cilia in human development is well illustrated by the discovery that Bardet-Biedl syndrome (BBS) is caused by mutations in any one of a number of genes that affect the assembly of basal bodies and cilia. Persons afflicted with BBS exhibit a remarkable range of abnormalities, including polydactyly (extra fingers or toes), situs inversus, obesity, kidney disease, heart defects, mental retardation, genital abnormalities, retinal degeneration, loss of hearing and smell, diabetes, and high blood pressure.

The fact that all of these dysfunctions can be traced to abnormalities in basal bodies and cilia illustrates the widespread importance of these cellular structures in organ development and function. Many of the genes responsible for these various cilia-based disorders (“ciliopathies”) were first identified in model organisms such as *Chlamydomonas* or *C. elegans*, which provides another example of the importance of basic research on nonvertebrate organisms in furthering our understanding of human disease.

Intraflagellar Transport Biologists had been watching the flagella of living cells for over a hundred years, but it wasn't until 1993 that Joel Rosenbaum and colleagues at Yale University observed the movement of particles in the space be-

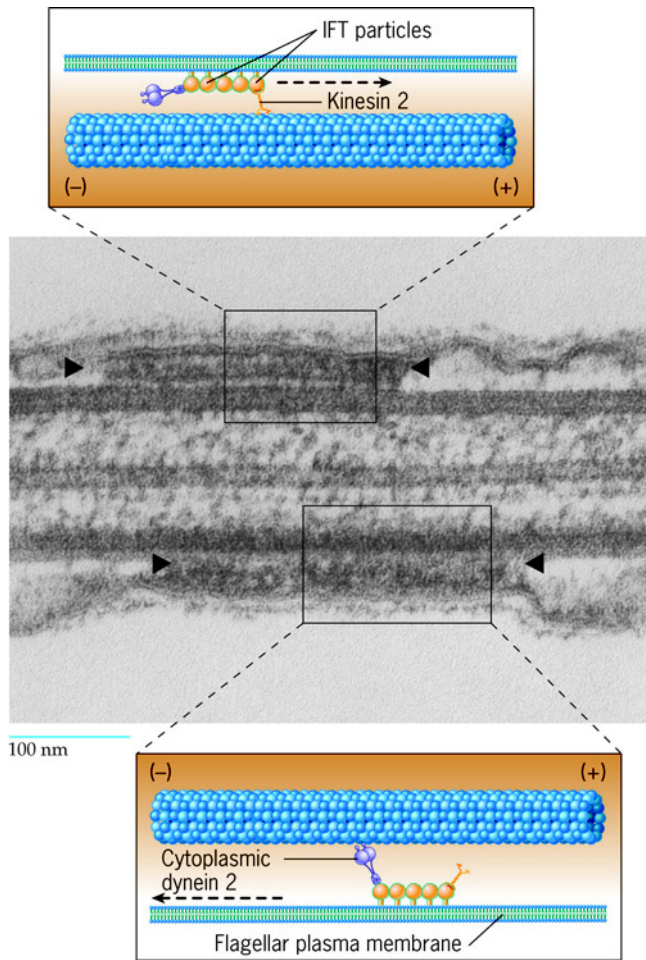

Figure 9.34 Intraflagellar transport (IFT). Electron micrograph of a longitudinal section of a *Chlamydomonas* flagellum showing two rows of protein particles (bounded by arrowheads) situated between the outer doublet microtubules and the flagellar plasma membrane. As illustrated in the insets, each row of particles and its associated cargo of axonemal proteins are moved along the outer doublet microtubule by a motor protein, either cytoplasmic dynein 2 if they are moving toward the flagellar base or kinesin 2 if the particles are moving toward the tip of the flagellum. (MICROGRAPH FROM KEITH G. KOZMINSKI ET AL., *J. CELL BIOL.* 131:1520, 1995, FIG. 1. COURTESY OF JOEL L. ROSENBAUM; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

tween the peripheral doublets and the surrounding plasma membrane. Subsequent studies revealed a process known as **intraflagellar transport (IFT)**, which is responsible for assembling and maintaining these organelles. IFT depends on the activity of both plus end- and minus end-directed movement along microtubules (Figure 9.34). Kinesin 2 moves complex arrays of IFT particles, together with associated building materials, along protofilaments of the peripheral doublets to the assembly site at the tip of the growing axoneme. Kinesin 2 molecules (and recycled axonemal proteins) are transported back toward the basal body along the same flagellar microtubules by a cytoplasmic dynein-powered mechanism. Recent studies have also implicated IFT in the transport of a number of important signaling molecules. Several of the characteristic features of Bardet-Biedel syndrome, including obesity and extra digits, can be traced to disturbances in the transport of these signaling molecules.

The Dynein Arms The machinery for ciliary and flagellar locomotion resides within the axoneme. This is illustrated in the experiment shown in Figure 9.35 in which a sperm tail axoneme devoid of its overlying membrane is still capable of normal, sustained beating in the presence of added Mg^{2+} and ATP. The greater the ATP concentration, the faster the beat frequency of these “reactivated” organelles.

The protein responsible for conversion of the chemical energy of ATP into the mechanical energy of ciliary locomotion was isolated in the 1960s by Ian Gibbons of Harvard University. Gibbons' experiments provide an elegant example

Figure 9.35 A sea urchin sperm reactivated with 0.2 mM ATP following demembration with the detergent Triton X-100. This multiple-exposure photomicrograph was obtained with five flashes of light and shows the reactivated flagellum at different stages of its beat. (FROM CHARLES J. BROKAW AND T. F. SIMONICK, *J. CELL BIOL.* 75:650, 1977, FIG. 4B. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

of the relationship between structure and function in biological systems and the means by which the relationship can be revealed by experimental analysis. Using various solutions capable of solubilizing different components, Gibbons carried out a chemical dissection of cilia from the protozoan *Tetrahymena* (Figure 9.36). An intact cilium is shown in cross section in step 1. The dissection began by dissolving the enclosing plasma membrane in the detergent digitonin (step 2). The isolated axonemes of the insoluble fraction were then immersed in a solution containing EDTA, a compound that binds and removes (chelates) divalent ions. When EDTA-treated axonemes were examined in the electron microscope,

Figure 9.36 Steps in the chemical dissection of cilia from the protozoan *Tetrahymena*. The numbered steps are described in the text.

the central tubules were missing, as were the arms projecting from the A tubules (step 3). Simultaneous with the loss of these structures, the insoluble axonemes lost their ability to hydrolyze ATP, while the supernatant gained it. The ATPase found in the supernatant was a huge protein (up to 2 million daltons) that Gibbons named *dynein* (from the words *dyne*, meaning “force,” and *protein*). This protein is now referred to as **ciliary** (or **axonemal**) **dynein** to distinguish it from cytoplasmic dynein, a related protein involved in organelle and particle transport. When the insoluble parts of the axoneme were mixed with the soluble protein in the presence of Mg^{2+} , much of the ATPase activity once again became associated with the insoluble material in the mixture (step 4). Examination of the insoluble fraction showed that the arms had reappeared on the A tubules of the axonemes. Gibbons concluded that the arms seen in the micrographs were equivalent to the dynein ATPase molecules recovered in the EDTA-containing solution, and thus it was the arms that released the energy required for locomotion.

In subsequent investigations it was found that treatment of isolated sperm axonemes with high salt (0.6 M NaCl) would selectively remove the outer arms, leaving the inner arms in place (step 5). When ATP was added to axonemes lacking outer arms, they beat at about half the rate of the intact axoneme, though they beat with a normal waveform.

An electron micrograph of an outer dynein molecule (i.e., outer dynein arm) from a *Tetrahymena* axoneme is shown in Figure 9.37a. This dynein molecule consists of three heavy chains and a number of intermediate and light chains. As discussed on page 337, each dynein heavy chain is composed of a long stem, a wheel-shaped head, and a stalk. Figure 9.37b,c show high-resolution electron micrographs of single dynein heavy chains from *Chlamydomonas* flagella prepared under two different conditions. The difference in conformation between the molecules in these two micrographs (shown merged in Figure 9.37d) is proposed to represent the power stroke of a flagellar dynein motor protein. In this model, the rotation of the head depicted in Figure 9.37b',c' serves as the basic driving force for ciliary/flagellar motion. To understand the mechanism responsible for this type of motility, we have to reconsider the structure of the axoneme.

The Mechanism of Ciliary and Flagellar Locomotion

As will be discussed later in this chapter, the contraction of muscle results from the sliding of actin filaments over adjacent myosin filaments. The sliding force is generated by ratchet-like cross-bridges that reside in the head of the myosin molecule. With the muscle system as a model, it was proposed that ciliary movement could be explained by the sliding of adjacent microtubular doublets relative to one another. According to this proposal, the dynein arms pictured in Figure 9.37 act as swinging cross-bridges that generate the forces required for ciliary or flagellar movement. The sequence of events is shown in Figure 9.38.

In the intact axoneme, the stem of each dynein molecule (with its associated intermediate and light chains) is tightly anchored to the outer surface of the A tubule, with the globular heads and stalks projecting toward the B tubule of the

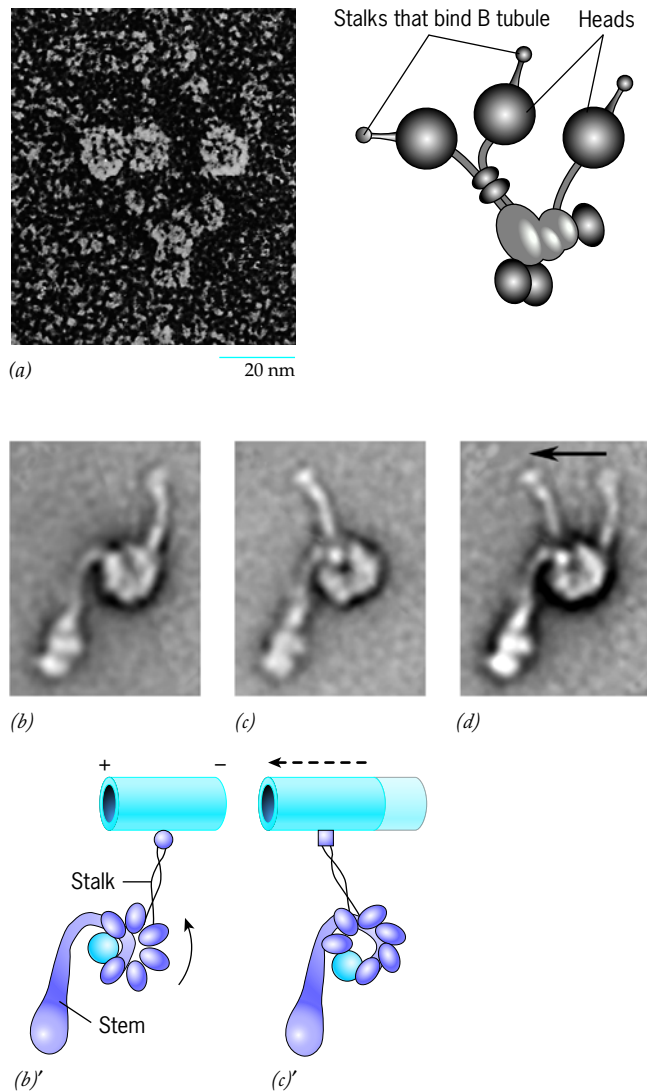

Figure 9.37 A model of the structure and function of flagellar/ciliary dynein. (a) Platinum replica of a rotary-shadowed, flagellar outer-arm dynein molecule prepared by rapid-freeze, deep-etch electron microscopy. Each of the three heavy chains forms a prominent globular head with an extension (stalk) that functions in linking the dynein arm to the neighboring doublet. An interpretive drawing is shown on the right. (b–d) High-resolution micrographs (with *b'*, *c'* interpretive models below) of a flagellar dynein heavy chain before (b) and after (c) its power stroke. The motor domain, which consists of a number of modules arranged in a wheel, is seen to have rotated, which has caused the stalk to move in a leftward direction. The image shown in (d) is a composite of molecules showing the position of the stalk before and after the power stroke. The power stroke causes the microtubule bound to the tip of the stalk to slide 15 nm in a leftward direction relative to the motor domain. In vitro motility assays suggest that dynein may be capable of “shifting gears” so that it can take shorter, more powerful steps as it moves a load of increasing mass. (Note: An alternate model of dynein function is discussed in *Science* 322:1647, 2008.) (A: COURTESY OF JOHN E. HEUSER AND URSULA W. GOODENOUGH; B–D: FROM STAN A. BURGESS, M. L. WALKER, M. SAKAKIBARA, P. J. KNIGHT, AND K. OIWA, *NATURE* 421:717, 2003, FIG. 4. REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LIMITED.)

Figure 9.38 Schematic representation of the forces that drive ciliary or flagellar motility. The steps are described in the text. A true representation of the power stroke is shown in the previous figure.

neighboring doublet. In step 1 of Figure 9.38, the dynein arms anchored along the A tubule of the lower doublet attach to binding sites on the B tubule of the upper doublet. In step 2, the dynein molecules undergo a conformational change, or power stroke, that causes the lower doublet to slide toward the basal end of the upper doublet. This conformational change in a dynein heavy chain is depicted in Figure 9.37*b–d*. In step 3 of Figure 9.38, the dynein arms have detached from the B tubule of the upper doublet. In step 4, the arms have reattached to the upper doublet so that another cycle can begin. (An electron micrograph of an axoneme showing the dynein arms from one doublet attached to the adjacent doublet is shown in Figure 18.18.)

Nexin is an elastic protein that connects adjacent doublets (Figure 9.31). These nexin bridges play an important role in ciliary/flagellar movement by limiting the extent that adjacent doublets can slide over one another. The resistance to sliding provided by the nexin bridges causes the axoneme to bend in response to the sliding force. Sliding on one side of the axoneme alternates with sliding on the other side so that a part of the cilium or flagellum bends first in one direction and then in the opposite direction (Figure 9.39). This requires that, at any given time, the dynein arms on one side of the axoneme are active, while those on the other side are inactive. As a result of this difference in dynein activity, the doublets on the

inner side of the bend (at the top and bottom of Figure 9.39) extend beyond those on the opposite side of the axoneme.

Evidence has steadily accumulated in favor of the sliding-microtubule theory and the role of the dynein arms. Microtubule sliding in beating flagellar axonemes has been directly visualized, as illustrated in the photographs of Figure 9.40. In this experiment, isolated axonemes were incubated with tiny gold beads that became attached to the exposed outer surface of the peripheral doublets. The beads served as fixed markers of specific sites on the doublets. The relative position of the beads was then monitored as the axonemes were stimulated to beat by addition of ATP. As the axonemes bent back and forth, the distances between the beads on different doublets increased and decreased in an alternating manner (Figure 9.40) as would be expected if neighboring doublets slid up and down over one another.

REVIEW

1. Describe three functions of microtubules.
2. Contrast the apparent roles of kinesin and cytoplasmic dynein in axonal transport.
3. What is an MTOC? Describe the structure of three different MTOCs and how each of them functions.
4. What is the role of GTP in the assembly of microtubules? What is meant by the term *dynamic instability*? What role does it play in cellular activity?
5. Contrast the movements of a flagellum and a cilium. Describe the power stroke of a dynein heavy chain. Describe the mechanism by which cilia and flagella are able to undergo their bending movements.

Figure 9.39 The sliding-microtubule mechanism of ciliary or flagellar motility.

Schematic diagram of the sliding of neighboring microtubules relative to one another. When the cilium is straight, all the outer doublets end at the same level (*center*). Cilium bending occurs when the doublets on the inner side of the bend slide beyond those on the outer side (*top and bottom*). The movement of the dynein arms responsible for the sliding of neighboring microtubules was shown in the previous figures. (FROM D. VOET & J. G. Figure 9.40 Experimental demonstration of microtubule sliding. Sea urchin sperm were demembrated, reactivated with ATP, and photographed by multiple exposure as in Figure 9.35. In this experiment, gold beads were attached to the exposed outer doublet microtubules, where they could serve as markers for specific sites along different doublets. As the flagellum underwent beating, the relative

positions of the beads were monitored. As shown here, the beads moved farther apart and then closer together as the flagellum undulated, indicating that the doublets are sliding back and forth relative to one another. (FROM CHARLES J. BROKAW, *J. CELL BIOL.* 114, COVER OF NO. 6, 1991. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

9.4 | Intermediate Filaments

The second of the three major cytoskeletal elements to be discussed was seen in the electron microscope as solid, unbranched filaments with a diameter of 10–12 nm. They were named **intermediate filaments** (or **IFs**). To date, intermediate filaments have only been identified in animal cells. Intermediate filaments are strong, flexible, ropelike fibers that provide mechanical strength to cells that are subjected to physical stress, including neurons, muscle cells, and the epithelial cells that line the body's cavities. Unlike microfilaments and microtubules, IFs are a chemically heterogeneous group of structures that, in humans, are encoded by approximately 70 different genes. The polypeptide subunits of IFs can be divided into five major classes based on the type of cell in which they are found (Table 9.2) as well as biochemical, genetic, and immunologic criteria. We will restrict the present discussion to classes I–IV, which are found in the construction of cytoplasmic filaments, and consider type V IFs (the lamins), which are present as part of the inner lining of the nuclear envelope, in Section 12.2.

IFs radiate through the cytoplasm of a wide variety of animal cells and are often interconnected to other cytoskeletal filaments by thin, wispy cross-bridges (Figure 9.41). In many cells, these cross-bridges consist of an elongated dimeric protein called *plectin* that can exist in numerous isoforms. Each plectin molecule has a binding site for an intermediate filament at one end and, depending on the isoform, a binding site for another intermediate filament, microfilament, or microtubule at the other end.

Although IF polypeptides have diverse amino acid sequences, all share a similar structural organization that allows them to form similar-looking filaments. Most notably, the polypeptides of IFs all contain a central, rod-shaped, α -helical

Figure 9.41 Cytoskeletal elements are connected to one another by protein cross-bridges. Electron micrograph of a replica of a small portion of the cytoskeleton of a fibroblast after selective removal of actin filaments. Individual components have been digitally colored to assist visualization. Intermediate filaments (blue) are seen to be connected to microtubules (red) by long wispy cross-bridges consisting of the fibrous protein plectin (green). Plectin is localized by antibodies linked to colloidal gold particles (yellow). (COURTESY OF TATYANA SVITKINA AND GARY BORISY.)

domain of similar length and homologous amino acid sequence. This long fibrous domain makes the subunits of intermediate filaments very different from the globular tubulin and actin subunits of microtubules and microfilaments. The central fibrous domain is flanked on each side by globular domains of variable size and sequence (step 1, Figure 9.42). Two such polypeptides spontaneously interact as their α -helical rods wrap around each other to form a ropelike dimer approximately 45 nm in length (step 2). Because the two polypeptides are aligned parallel to one another in the same orientation, the dimer has polarity, with one end defined by the C-termini of the polypeptides and the opposite end by their N-termini.

Intermediate Filament Assembly and Disassembly

The basic building block of IF assembly is thought to be a rod-like tetramer formed by two dimers that become aligned side by side in a staggered fashion with their N- and C-termini pointing in opposite (antiparallel) directions, as shown in Figure 9.42, step 3 and in Figure 9.42*b*. Because the dimers point in opposite directions, the tetramer itself lacks polarity. Recent studies of the self-assembly of IFs in vitro suggest that 8 tetramers associate with one another in a side-by-side (lateral) arrangement to form a filament that is one unit in length (about 60 nm) (step 4). Subsequent growth of the polymer is accomplished as these unit lengths of filaments associate with one another in an end-to-end fashion to form the highly elongated intermediate filament (step 5). None of these assembly steps is thought to require the direct involvement of either ATP or GTP. Because the tetrameric building blocks lack polarity, so too does the assembled filament, which is another important feature that distinguishes IFs from other cytoskeletal elements.

Table 9.2 Properties and Distribution of the Major Mammalian Intermediate Filament Proteins

IF protein	Sequence type	Primary tissue distribution
Keratin (acidic) (28 different polypeptides)	I	Epithelia
Keratin (basic) (26 different polypeptides)	II	Epithelia
Vimentin	III	Mesenchymal cells
Desmin	III	Muscle
Glial fibrillary acidic protein (GFAP)	III	Astrocytes
Peripherin	III	Peripheral neurons
Neurofilament proteins		Neurons of central and peripheral nerves
NF-L	IV	
NF-M	IV	
NF-H	IV	
Nestin	IV	Neuroepithelia
Lamin proteins		All cell types
Lamin A	V	(Nuclear envelopes)
Lamin B	V	
Lamin C	V

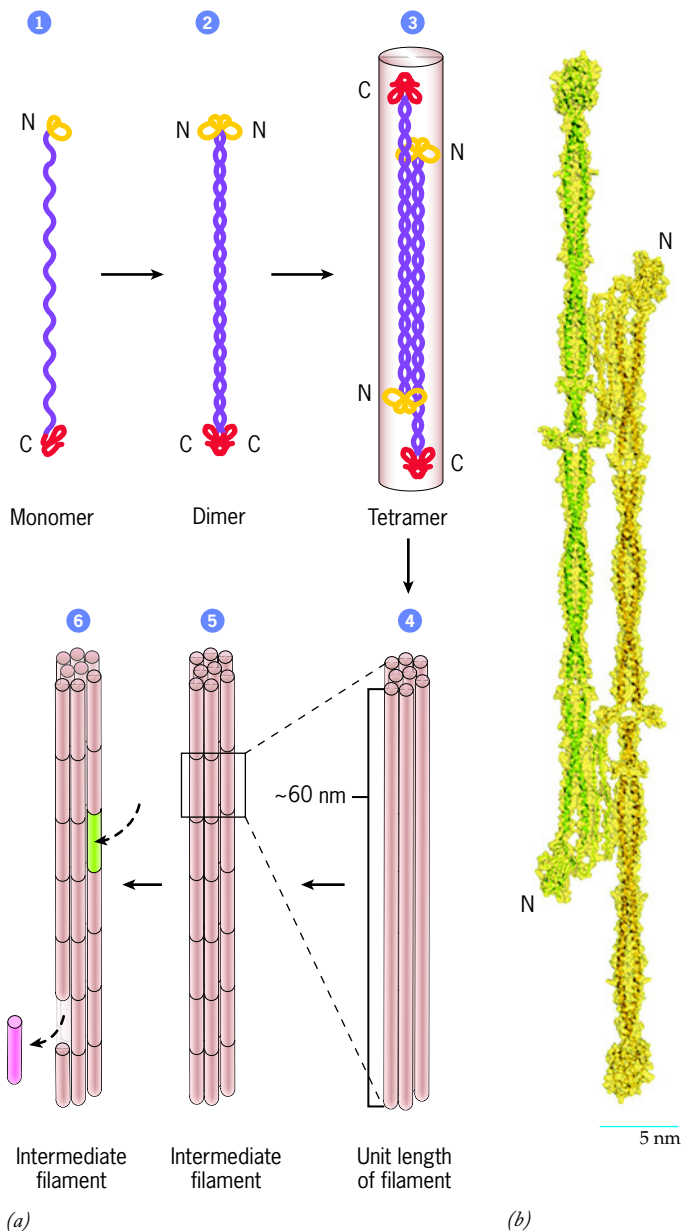

Figure 9.42 A model of intermediate filament assembly and architecture. Each monomer has a pair of globular terminal domains (red or yellow) separated by a long α -helical region (step 1). Pairs of monomers associate in parallel orientation with their ends aligned to form dimers (step 2). Depending on the type of intermediate filament, the dimers may be composed of identical monomers (homodimers) or nonidentical monomers (heterodimers). Dimers in turn associate in an antiparallel, staggered fashion to form tetramers (step 3), which are thought to be the basic subunit in the assembly of intermediate filaments. In the model shown here, 8 tetramers associate laterally to form a unit length of the intermediate filament (step 4). Highly elongated intermediate filaments are then formed from the end-to-end association of these unit lengths (step 5). Once formed, intermediate filaments undergo a process of dynamic remodeling that is thought to involve the intercalation of unit lengths of filament into the body of an existing filament (step 6). (b) A model of a tetramer of the IF protein vimentin. (B: FROM ANNA V. SOKOLOVA, ET AL., COURTESY OF SERGEI V. STRELKOV, PNAS 103; 16209, 2006, FIG. 3A. © 2006 NATIONAL ACADEMY OF SCIENCES, U.S.A.)

Intermediate filaments tend to be less sensitive to chemical agents than other types of cytoskeletal elements and more difficult to solubilize. In fact, treatment of a cell with ionic de-

Figure 9.43 Experimental demonstration of the dynamic character of intermediate filaments. These photographs show the results of an experiment in which biotin-labeled type I keratin was microinjected into cultured epithelial cells and localized 20 minutes later using immunofluorescence. The photograph in *a* shows the localization of the injected biotinylated keratin (as revealed by fluorescent anti-biotin antibodies) that had become incorporated into filaments during the 20-minute period following injection. The photograph in *b* shows the distribution of intermediate filaments in the cell as revealed by anti-keratin antibodies. The dotlike pattern of fluorescence in *a* indicates that the injected subunits are incorporated into the existing filaments at sites throughout their length, rather than at their ends. (Compare with a similar experiment with labeled tubulin in Figure 9.26.) (FROM RITA K. MILLER, KAREN VIKSTROM, AND ROBERT D. GOLDMAN, J. CELL BIOL. 113:848, 1991, FIG. 4. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

tergents extracts just about everything except the cell's intermediate filaments. Because of their insolubility, IFs were initially thought to be permanent, unchanging structures, so it came as a surprise to find that they behave dynamically in vivo. When labeled keratin subunits are injected into cultured skin cells, they are rapidly incorporated into existing IFs. Surprisingly, the subunits are not incorporated at the ends of the filament, as might have been expected by analogy with microtubule and microfilament assembly, but rather into the filament's interior (Figure 9.43). The results depicted in Figure 9.43 might reflect the exchange of unit lengths of filament

directly into an existing IF network (as shown in step 6, Figure 9.42a). Unlike the other two major cytoskeletal elements, assembly and disassembly of IFs are controlled primarily by phosphorylation and dephosphorylation of the subunits. For example, phosphorylation of vimentin filaments by protein kinase A leads to their disassembly.

Types and Functions of Intermediate Filaments

Keratin filaments constitute the primary structural proteins of epithelial cells (including epidermal cells, liver hepatocytes, and pancreatic acinar cells). Figure 9.44a shows a schematic view of the spatial arrangement of the keratin filaments of a generalized epithelial cell, and Figure 9.44b shows the actual arrangement within a pair of cultured epidermal cells. Keratin-containing IFs radiate through the cytoplasm, tethered to the nuclear envelope in the center of the cell and anchored at the outer edge of the cell by connections to the cytoplasmic plaques of desmosomes and hemidesmosomes (pages 257 and 249). Figure 9.44a also depicts the interconnections between IFs and the cell's microtubules and microfilaments, which transforms these otherwise separate elements into an integrated cytoskeleton. Because of these various physical connections, the IF network is able to serve as a scaffold for organizing and maintaining cellular architecture and for absorbing mechanical stresses applied by the extracellular environment.

The cytoplasm of neurons contains loosely packed bundles of intermediate filaments whose long axes are oriented parallel to that of the nerve cell axon (see Figure 9.13b). These IFs, or **neurofilaments**, as they are called, are composed of three distinct proteins: NF-L, NF-H, and NF-M, all of the type IV group of Table 9.2. Unlike the polypeptides of other IFs, NF-H and NF-M have sidearms that project outward from the neurofilament. These sidearms are thought to maintain the proper spacing between the parallel neurofilaments of the axon (see Figure 9.13b). In the early stages of differentiation when the axon is growing toward a target cell, it contains very few neurofilaments but large numbers of supporting microtubules. Once the nerve cell has become fully extended, it becomes filled with neurofilaments that provide support as the axon increases dramatically in diameter. Aggregation of NFs is seen in several human neurodegenerative disorders, including ALS and Parkinson's disease. These NF aggregates may block axonal transport, leading to the death of neurons.

Efforts to probe IF function have relied largely on genetically engineered mice that fail to produce a particular IF polypeptide (a gene knockout) or produce an altered IF polypeptide. These studies have revealed the importance of intermediate filaments in particular cell types. For example, mice carrying deletions in the gene encoding K14, a type I keratin polypeptide normally synthesized by cells of the basal epidermal layer, have serious health problems. These mice are so sensitive to mechanical pressure that even mild trauma, such as that occurring during passage through the birth canal or during nursing by the newborn, can cause severe blistering of the skin or tongue. This phenotype bears strong resemblance to a rare skin-blistering disease in humans, called *epi-*

dermolysis bullosa simplex (EBS).⁴ Subsequent analysis of EBS patients has shown that they carry mutations in the gene that encodes the homologous K14 polypeptide (or the K5 polypeptide, which forms dimers with K14). These studies confirm the role of IFs in imparting mechanical strength to cells situated in epithelial layers. Similarly, knockout mice that fail to produce the desmin polypeptide exhibit serious cardiac and skeletal muscle abnormalities. Desmin plays a key structural role in maintaining the alignment of the myofibrils of a muscle cell, and the absence of these IFs makes the cells extremely fragile. An inherited human disease, named *desmin-related myopathy*, is caused by mutations in the gene that encodes desmin. Persons with this disorder suffer from skeletal muscle weakness, cardiac arrhythmias, and eventual congestive heart failure. Not all IF polypeptides have such essential functions. For example, mice that lack the vimentin gene, which is expressed in fibroblasts, macrophages, and white blood cells, show relatively minor abnormalities, even though the affected cells lack cytoplasmic IFs. It is evident from these studies that IFs have tissue-specific functions, which are more important in some cells than in others.

REVIEW

1. Give some examples that reinforce the suggestion that intermediate filaments are important primarily in tissue-specific functions rather than in basic activities that are common to all cells.
2. Compare and contrast microtubule assembly and intermediate filament assembly.

9.5 | Microfilaments

Cells are capable of remarkable motility. The neural crest cells in a vertebrate embryo leave the developing nervous system and migrate across the entire width of the embryo, forming such diverse products as the pigment cells of the skin, teeth, and the cartilage of the jaws (see Figure 7.11). Legions of white blood cells patrol the tissues of the body searching for debris and microorganisms. Certain parts of cells can also be motile; broad projections of epithelial cells at the edge of a wound act as motile devices that pull the sheet of cells over the damaged area, sealing the wound. Similarly, the leading edge of a growing axon sends out microscopic processes that survey the substratum and guide the cell toward a synaptic target. All of these various examples of motility share at least one component: they all depend on microfilaments, the third major type of cytoskeletal element. Microfilaments are also involved in intracellular motile processes, such as the movement of vesicles, phagocytosis, and cytokinesis. In fact, plant cells rely primarily on microfilaments, rather than microtubules, to serve as tracks for the long-distance transport of cytoplasmic vesicles and organelles. This bias toward microfilament-based

⁴As mentioned in Chapter 7, similar types of blistering diseases can be caused by defects in proteins of the hemidesmosome, which holds the basal layer of the epidermis to the basement membrane.

(a)

(b)

Figure 9.44 The organization of intermediate filaments (IFs) within an epithelial cell. (a) In this schematic drawing, IFs are seen to radiate throughout the cell, being anchored at both the outer surface of the nucleus and the inner surface of the plasma membrane. Connections to the nucleus are made via proteins that span both membranes of the nuclear envelope and to the plasma membrane via specialized sites of adhesion such as desmosomes and hemidesmosomes. IFs are also seen to be interconnected to both of the other types of cytoskeletal fibers. Connections to microtubules (MTs) and microfilaments (MFs) are made primarily by members of the plakin family of proteins, such as the dimeric plectin molecule shown in Figure 9.41. (b) Distribution of keratin-containing intermediate filaments in cultured skin cells (keratinocytes). The filaments are seen to form a cage-like network around the nucleus and also extend to the cell periphery (A: REPRINTED WITH PERMISSION FROM H. HERRMANN ET AL., NATURE REVIEWS MOL. CELL BIOL. 8:564, 2007; COPYRIGHT 2007, MACMILLAN MAGAZINES LTD. NATURE REVIEWS MOLECULAR CELL BIOLOGY BY NATURE PUBLISHING GROUP. REPRODUCED WITH PERMISSION OF NATURE PUBLISHING GROUP IN THE FORMAT JOURNAL VIA COPYRIGHT CLEARANCE CENTER. B: FROM PIERRE A. COULOMBE AND M. BISHR OMARY, CURR. OPIN. CELL BIOL. 14:111, 2002, WITH PERMISSION FROM ELSEVIER.)

motility reflects the rather restricted distribution of microtubules in many plant cells (see Figure 9.12). Microfilaments also play an important role in determining the shapes of cells and can provide structural support for various types of cellular projections (as in Figure 9.66).

Microfilaments are approximately 8 nm in diameter and composed of globular subunits of the protein **actin**, which is the most abundant protein in most cells. In the presence of ATP, actin monomers polymerize to form a flexible, helical filament. As a result of its subunit organization (Figure 9.45*a*), an actin filament is essentially a two-stranded structure with two helical grooves running along its length (Figure

Figure 9.45 Actin filament structure. (a) A model of an actin filament. The actin subunits are represented in three colors to distinguish the consecutive subunits more easily. The subdomains in one of the actin subunits are labeled 1, 2, 3, and 4 and the ATP-binding cleft in each subunit is evident. Actin filaments have polarity, which is denoted as a plus and minus end. The cleft (in the upper red subunit) is present at the minus end of the filament. (b) Electron micrograph of a replica of an actin filament showing its double-helical architecture. (A: FROM MICHAEL F. SCHMID ET AL., COURTESY OF WAH CHIU, J. CELL BIOL. 124:346, 1994, FIG. 4. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS; B: FROM ROBERT H. DEPUE, JR. AND ROBERT V. RICE, J. MOL. BIOL. 12:302, 1965. REPRODUCED WITH PERMISSION OF ELSEVIER.)

9.45*b*). The terms *actin filament*, *F-actin*, and *microfilament* are basically synonyms for this type of filament. Because each actin subunit has polarity and all the subunits of an actin filament are pointed in the same direction, the entire microfilament has polarity. Consequently, the two ends of an actin filament have different structures and dynamic properties. Depending on the type of cell and the activity in which it is engaged, actin filaments can be organized into highly ordered arrays, loose ill-defined networks, or tightly anchored bundles.

The identification of actin filaments in a given cell can be made with certainty using a cytochemical test that takes advantage of the fact that actin filaments, regardless of their source, will interact in a highly specific manner with the protein myosin. To facilitate the interaction, purified myosin (obtained from muscle tissue) is cleaved into fragments by a proteolytic enzyme. One of these fragments, called S1 (see Figure 9.49), binds to the actin molecules all along the microfilament. In addition to identifying the filaments as actin, the bound S1 fragments reveal the filament's polarity. When S1 fragments are bound, one end of the microfilament appears *pointed* like an arrowhead, while the other end looks *barbed*. An example of this arrowhead “decoration” is shown in the microvilli of intestinal epithelial cells of Figure 9.46. The orientation of the arrowheads formed by the S1–actin complex provides information as to the direction in which the microfilaments are likely to be moved by a myosin motor protein. Actin can also be localized by light microscopy using fluorescently labeled phalloidin (Figure 9.74*a*), which binds to actin filaments, or by fluorescently labeled anti-actin antibodies.

Actin was identified more than 50 years ago as one of the major contractile proteins of muscle cells. Since then, it has been identified as a major protein in virtually every type of eukaryotic cell that has been examined. Higher plant and animal species possess a number of actin-coding genes whose encoded products are specialized for different types of motile processes. Actins have been remarkably conserved during the evolution of eukaryotes. For example, the amino acid sequences of actin molecules from a yeast cell and from rabbit skeletal muscle are 88 percent identical. In fact, actin molecules from diverse sources can copolymerize to form hybrid filaments. Although actin filaments can generate forces on their own (page 374), most processes involving actin require the activity of motor proteins, specifically those of the myosin superfamily.

Microfilament Assembly and Disassembly

Before it is incorporated into a filament, an actin monomer binds a molecule of ATP. Actin is an ATPase, just as tubulin is a GTPase, and the role of ATP in actin assembly is similar to that of GTP in microtubule assembly (page 342). The ATP associated with the actin monomer is hydrolyzed to ADP at some time after it is incorporated into the growing actin filament. As a consequence, the bulk of an actin filament consists of ADP-actin subunits.

Actin polymerization is readily demonstrated *in vitro* in solutions containing ATP-actin monomers. As in the case of microtubules, the initial stage in filament formation (i.e., *nucleation*) occurs slowly *in vitro*, whereas the subsequent stage of filament *elongation* occurs much more rapidly. The

Figure 9.46 Determining the location and polarity of actin filaments using the S1 subunit of myosin. Electron micrograph of a replica showing the microfilament bundles in the core of the microvilli of an intestinal epithelial cell. The cell had been fixed, treated with S1 myosin fragments, freeze fractured, and deep etched to expose the filamentous components of the cytoplasm. The intermediate filaments (IFs) at the bottom of the micrograph do not contain actin and therefore do not bind the S1 myosin fragments. These intermediate filaments originate at the desmosomes of the lateral surfaces of the cell. (FROM N. HIROKAWA, L. G. TILNEY, K. FUJIWARA, AND J. E. HEUSER, J. CELL BIOL. 94:430, 1982, FIG. 3. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

nucleation stage of filament formation can be bypassed by including preformed actin filaments in the reaction mixture. When preformed actin filaments are incubated with a high concentration of labeled ATP-actin monomers, both ends of the microfilament become labeled, but one end has a higher affinity for monomers and incorporates them at a rate approximately 10 times that of the other end. Decoration with the S1 myosin fragment reveals that the barbed (or plus) end of the microfilament is the fast-growing end, while the pointed (or minus) end is the slow-growing tip (Figure 9.47a).

Figure 9.47b illustrates how the events that occur during actin assembly/disassembly *in vitro* depend on the concentration of actin monomers. Suppose we were to begin by adding preformed actin filaments (seeds) to a solution of actin in the presence of ATP (step 1). As long as the concentration of ATP-actin monomers remains high, subunits will continue to

(a)

(b)

Figure 9.47 Actin assembly *in vitro*. (a) Electron micrograph of a short actin filament that was labeled with S1 myosin and then used to nucleate actin polymerization. The addition of actin subunits occurs much more rapidly at the barbed (plus) end than at the pointed (minus) end of the existing filament. (b) Schematic diagram of the kinetics of actin-filament assembly *in vitro*. All of the orange subunits are part of the original seed; red subunits were present in solution at the beginning of the incubation. The steps are described in the text. Once a steady-state concentration of monomers is reached, subunits are added to the plus end at the same rate they are released from the minus end. As a result, subunits treadmill through the filament *in vitro*. *Note:* No attempt is made to distinguish between subunits with a bound ATP versus ADP. (A: COURTESY OF M. S. RUNGE AND T. D. POLLARD.)

be added at both ends of the filament (step 2, Figure 9.47*b*). As the monomers in the reaction mixture are consumed by addition to the ends of the filaments, the concentration of free ATP-actin continues to drop until a point is reached where net addition of monomers continues at the plus end, which has a higher affinity for ATP-actin, but stops at the minus end, which has a lower affinity for ATP-actin (step 3). As filament elongation continues, the free monomer concentration drops further. At this point, monomers continue to be added to the plus ends of the filaments, but a net loss of subunits occurs at their minus end. As the free monomer concentration falls, a point is reached where the two reactions at opposite ends of the filaments are balanced so that both the lengths of the filaments and the concentration of free monomers remain constant (step 4). This type of balance between two opposing activities is an example of *steady state* (page 94) and occurs when the ATP-actin concentration is approximately 0.3 μM . Because subunits are being added to the plus ends and removed from the minus ends of each filament at steady state, the relative position of individual subunits within each filament is continually moving—a process known as “treadmilling” (steps 4–5). Studies on living cells containing fluorescently labeled actin subunits have supported the occurrence of treadmilling in vivo (see Figure 9.54*c*).

As discussed on page 372, the rate of assembly and disassembly of actin filaments in the cell can be influenced by a number of different “accessory” proteins. Changes in the local conditions in a particular part of the cell can push events there toward either the assembly or the disassembly of microfilaments. By controlling this dynamic behavior, the cell can reorganize its microfilament cytoskeleton. Such reorganization is required for dynamic processes such as cell locomotion, changes in cell shape, phagocytosis, and cytokinesis.

As noted above, actin filaments play a role in nearly all of a cell’s motile processes. The involvement of these filaments is most readily demonstrated by treating the cells with one of the following drugs that disrupt dynamic microfilament-based activities: cytochalasin, obtained from a mold, which blocks the plus ends of actin filaments, allowing depolymerization at the minus end; phalloidin, obtained from a poisonous mushroom, which binds to intact actin filaments and prevents their turnover; and latrunculin, obtained from a sponge, which binds to free monomers and blocks their incorporation into the polymer. Microfilament-mediated processes rapidly grind to a halt when cells contain one of these compounds.

Myosin: The Molecular Motor of Actin Filaments

We have previously examined the structure and actions of two molecular motors—kinesin and dynein—that operate in opposite directions over tracks of microtubules. To date, all of the motors known to operate in conjunction with actin filaments are members of the myosin superfamily. Myosins—with the major exception of myosin VI, which is discussed below—move toward the plus end of an actin filament.

Myosin was first isolated from mammalian skeletal muscle tissue and subsequently from a wide variety of eukaryotic cells, including protists, plants, nonmuscle cells of animals,

and vertebrate cardiac and smooth muscle tissues. All myosins share a characteristic motor (head) domain. The head contains a site that binds an actin filament and a site that binds and hydrolyzes ATP to drive the myosin motor. Whereas the head domains of various myosins are similar, the tail domains are highly divergent. Myosins also contain a variety of low-molecular-weight (light) chains. Myosins are generally divided into two broad groups: the **conventional** (or **type II**) **myosins**, which were first identified in muscle tissue, and the **unconventional myosins**. The unconventional myosins are subdivided on the basis of amino acid sequence into at least 17 different classes (type I and types III–XVIII). Some of these classes are expressed widely among eukaryotes, whereas others are restricted. Myosin X, for example, is found only in vertebrates, and myosins VIII and XI are present only in plants. Humans contain about 40 different myosins from at least 12 classes, each presumed to have its own specialized function(s). Of the various myosins, type II molecules are best understood.

Conventional (Type II) Myosins Proteins of the myosin II class are the primary motors for muscle contraction but are also found in a variety of nonmuscle cells. The human genome encodes 16 different myosin II heavy chains, 3 of which function in nonmuscle cells. All myosin IIs move toward the plus (barbed) end of an actin filament. Among their nonmuscle activities, type II myosins are required for splitting a cell in two during cell division, generating tension at focal adhesions, cell migration, and the turning behavior of growth cones (see Figure 9.76). The effect of inhibiting myosin II activity in an advancing growth cone is demonstrated in Figure 9.48.

An electron micrograph of a pair of myosin II molecules is shown in Figure 9.49*a*. Each myosin II molecule is composed of six polypeptide chains—one pair of heavy chains and two pairs of light chains—organized in such a way as to produce a highly asymmetric protein (Figure 9.49*a*). Examination of the molecule in Figure 9.49*b* shows it to consist of (1) a pair of globular heads that contain the catalytic site of the molecule; (2) a pair of necks, each consisting of a single, uninterrupted α helix and two associated light chains; and (3) a single, long, rod-shaped tail formed by the intertwining of long α -helical sections of the two heavy chains.

Isolated myosin heads (S1 fragments of Figure 9.49*b*) that have been immobilized on the surface of a glass coverslip are capable of sliding attached actin filaments in an in vitro assay such as that shown in Figure 9.50. Thus, all of the machinery required for motor activity is contained in a single head. The mechanism of action of the myosin head, and the key role played by the neck, are discussed on page 369. The fibrous tail portion of a myosin II molecule plays a structural role, allowing the protein to form filaments. Myosin II molecules assemble so that the ends of the tails point toward the center of the filament and the globular heads point away from the center (Figures 9.51 and 9.57). As a result, the filament is described as *bipolar*, indicating a reversal of polarity at the filament’s center. Because they are bipolar, the myosin heads at the opposite ends of a myosin filament have the ability to pull actin filaments toward one another, as occurs in a muscle cell. As described in the following section, the myosin II filaments that assemble in

Figure 9.48 Experimental demonstration of a role for myosin II in the directional movement of growth cones. (a) Fluorescence micrograph showing fine processes (neurites) growing out from a microscopic fragment of mouse embryonic nervous tissue. The neurites (stained green) are growing outward on a glass coverslip coated with strips of laminin (stained red). Laminin is a common component of the extracellular matrix (page 243). The tip of each nerve process contains a motile growth cone. When the growth cones reach the border of the laminin strip (indicated by the line with arrowheads), they turn sharply

and continue to grow over the laminin-coated surface. Bar, 500 μm . (b) The tissue in this micrograph was obtained from a mouse embryo lacking myosin IIB. The growth cones no longer turn when they reach the edge of the laminin-coated surface, causing the neurites to grow forward onto a surface (black) lacking laminin. Bar, 80 μm . (FROM STEPHEN G. TURNEY AND PAUL C. BRIDGMAN, *NATURE NEUROSCI.* 8:717, 2005; © 2005, REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LTD.)

Figure 9.49 Structure of a myosin II molecule. (a) Electron micrograph of negatively stained myosin molecules. The two heads and tail of each molecule are clearly visible. (b) A highly schematic drawing of a myosin II molecule (molecular mass of 520,000 daltons). The molecule consists of one pair of heavy chains (purple) and two pairs of light chains, which are named as indicated. The paired heavy chains consist of a rod-shaped tail in which portions of the two polypeptide chains wrap

around one another to form a coiled coil and a pair of globular heads. When treated with a protease under mild conditions, the molecule is cleaved at the junction between the neck and tail, which generates the S1 fragment. (A: FROM S. A. BURGESS, M. L. WALKER, H. D. WHITE, AND J. TRINICK, *J. CELL BIOL.* 139:676, 1997, FIG. 1. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

(B: COURTESY OF HUGH HUXLEY.)

transient construction, assembling when and where they are needed and then disassembling after they have acted.

Unconventional Myosins In 1973, Thomas Pollard and Edward Korn of the National Institutes of Health described a unique myosin-like protein that was extracted from the protist *Acanthamoeba*. Unlike muscle myosin, this smaller unconventional myosin had only a single head and was unable to assemble into filaments in vitro; the protein became known as myosin I. As reflected in the drawing of a microvillus in Figure 9.66, myosin I often serves as a cross-link between actin filaments of the cytoskeleton and the lipid bilayer of the plasma membrane. It has been suggested that myosin I can exert tension on the plasma membrane, which could play a role in processes that require movement or deformation of the membrane.

None of the unconventional myosins are capable of filament formation and instead appear to operate primarily as individual protein molecules. The best-studied unconventional myosins are capable of moving processively along actin filaments in a manner analogous to the way that kinesins and cytoplasmic dynein move along microtubules. The steps taken by one of these myosins—myosin V—have been revealed in a remarkable series of atomic force micrographs that capture a single molecule as it moves rapidly along an actin filament in vitro (Figure 9.52a). In order to visualize the various steps in the protein's mechanical cycle, these researchers placed molecular obstacles in the path of the moving motor protein, which slowed the rate at which the protein was able to travel. Figure 9.52b shows a series of images that reveal the movements of the molecule during a single mechanical cycle. (Keep in mind that myosin V normally has a sizeable tail segment, as de-

skeletal muscle cells are highly stable components of the contractile apparatus. However, the smaller myosin II mini-filaments that form in most nonmuscle cells often display

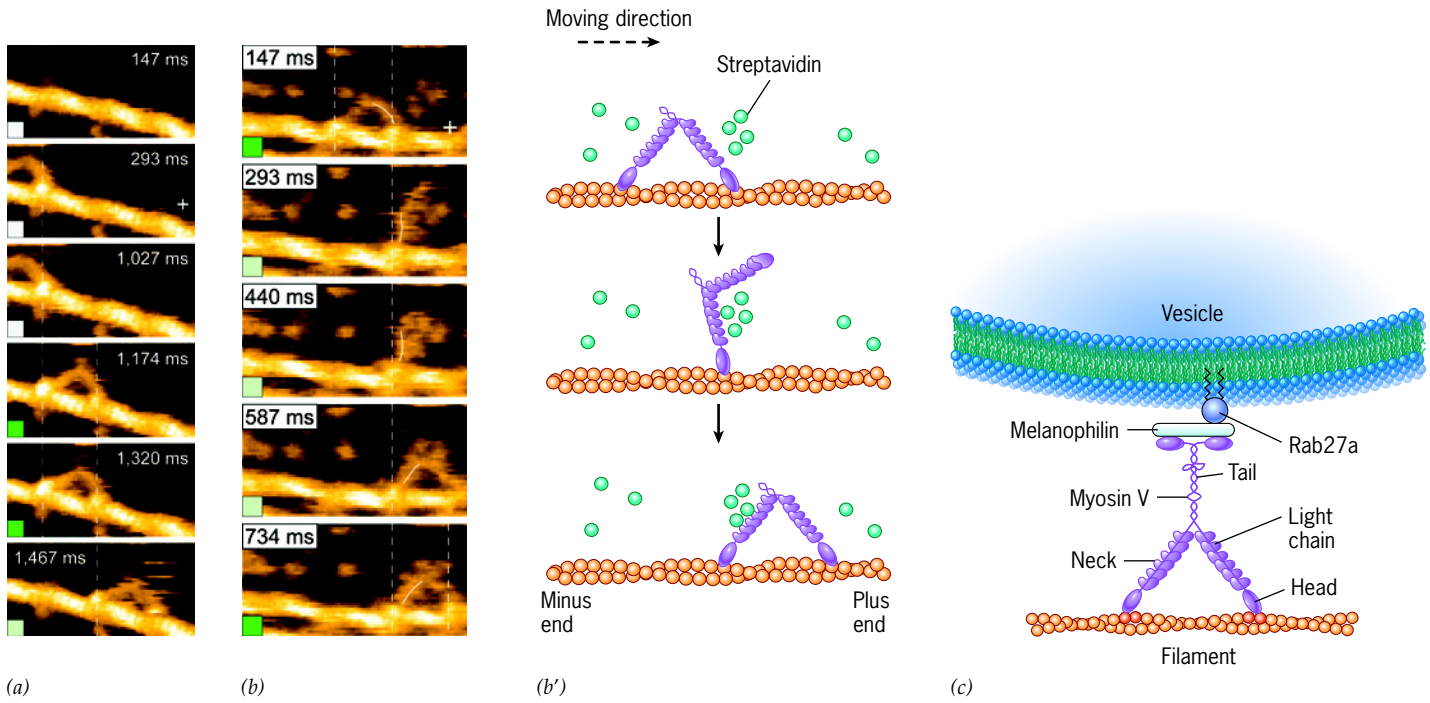

Figure 9.52 Myosin V—a two-headed unconventional myosin involved in organelle transport. (a) Direct visualization of a single myosin V molecule (one that is lacking its normal tail domain) as it moves along an actin filament in vitro in the presence of ATP. Using high-speed atomic force microscopy (HS-AFM), this series of images shows the movement of the molecule over a period of about one second. (b) Successive HS-AFM images showing the hand-over-hand movement of a single myosin V molecule as it passes through a cluster of obstacles (consisting of streptavidin protein molecules). The swinging neck (or lever arm) is highlighted with a thin white line. Interpretive drawings (b') depict the motor protein as seen in several of the

corresponding HS-AFM images. A continuous movie of the protein's movement can be seen in the supplement to this article. (c) Schematic drawing of a complete dimeric myosin V molecule, including its numerous light chains, with both heads bound to an actin filament and its tail domain bound to a vesicle. Rab27a and melanophilin serve as adaptors that link the globular ends of the tail to the vesicle membrane. The long neck of myosin V binds 6 light chains. picted in Figure 9.52c, that has been removed for these particular experiments.)

In the first frame of Figure 9.52b, both heads of the dimeric protein are seen to be attached to the underlying filament, and a cluster of obstacles are seen in the path of the motor. In the second frame, the trailing head of the myosin V molecule has detached from the filament and is in the process of moving forward through the roadblocks in its path. By the fourth frame, this swinging head has made contact with the filament at a forward position along the filament and thus has become the new leading head. These images provide visual confirmation that myosin V moves in a hand-over-hand fashion similar to that of the kinesin molecule in the drawing of Figure 9.15b. To accomplish this type of movement, at least one of the two heads must be bound to its polarized track at all times. Figure 9.52c shows an illustration of an intact myosin V molecule. As seen in this illustration, myosin V is noteworthy for the length of each neck, which at 23 nm is about three times that of myosin II.

Because of its long necks, which act as swinging arms (or levers) during movement, myosin V can take very large steps. This is very important for a motor protein that moves proces-

sively along an actin filament made up of *helical* strands of subunits. The actin helix repeats itself about every 13 subunits (36 nm), which is just about the step size of a myosin V molecule (Figure 9.52b). To accomplish this type of movement, each myosin head must move a distance of 72 nm, twice the distance between two successive binding sites on the actin filament (Figure 9.52b). As a result of its giant strides, myosin V can walk along the filament in a straight path even though the underlying “roadway” spirals 360° between its “feet.”

Several unconventional myosins (including myosin I, V, and VI) are associated with various types of cytoplasmic vesicles and organelles. In some cases these myosins may act primarily as organelle tethers and in other cases as organelle transporters. Some vesicles have been shown to contain microtubule-based motors (kinesins and/or cytoplasmic dynein) and microfilament-based motors (unconventional myosins) and, in fact, the two types of motors may be physically linked to one another. The movement of vesicles and other membranous carriers over long distances within animal cells occurs on microtubules, as previously described. However, once they approach the end of the microtubule, these membranous vesicles are often thought to switch over to microfilament tracks for

Figure 9.53 The contrasting roles of microtubule- and microfilament-based motors in intracellular transport. Most vesicle transport is thought to be mediated by members of the kinesin and dynein families, which carry their cargo over relatively long distances. It is thought that some vesicles also carry myosin motors, such as myosin Va, which transport their cargo over microfilaments, including those present in the peripheral (cortical) regions of the cell. The two types of motors may act in a cooperative manner, as illustrated here in the case of a frog pigment cell in which pigment granules move back and forth within extended cellular processes. (AFTER X, WU, ET AL., COPYRIGHT 1998, ROCKEFELLER UNIVERSITY PRESS. ORIGINALLY PUBLISHED IN THE JOURNAL OF CELL BIOLOGY 143:1915.)

the local movement through the actin-rich periphery of the cell, which is mediated by myosins (Figure 9.53).

Cooperation between microtubules and microfilaments has been best studied in pigment cells (Figure 9.53). In mammals, pigment granules (melanosomes) are transported into fine peripheral processes of the pigment cell by one of the myosin V isoforms called Va. Melanosomes are then transferred to hair follicles where they become incorporated into a developing hair. Mice lacking myosin Va activity are unable to transfer melanosomes into hair follicles, causing their coat to have a much lighter color. Humans lacking a normal gene encoding myosin Va suffer from a rare disorder called Griscelli syndrome; these individuals exhibit partial albinism (lack of skin coloration) and suffer other symptoms thought to be related to defects in vesicle transport. In 2000 it was discovered that a subset of Griscelli patients had a normal myosin Va gene, but lacked a functional gene encoding a peripheral membrane protein called Rab27a. The Rab family of proteins was discussed on page 302 as molecules that regulate vesicle trafficking. Rabs are also involved in the attachment of myosin (and kinesin) motors to membrane surfaces (Figure 9.52c).

Hair cells, whose structure is shown in Figure 9.54a have been a particularly good system for studying the functions of unconventional myosins. Hair cells are named for the bundle of stiff, hairlike stereocilia that project from the apical surface of the cell into the fluid-filled cavity of the inner ear. Displacement of the stereocilia by mechanical stimuli leads to the opening of Ca^{2+} channels in the plasma membrane and the

subsequent generation of nerve impulses that we perceive as sound. Stereocilia have no relation to the true cilia discussed earlier. Instead of containing microtubules, each stereocilium is supported by a bundle of parallel actin filaments (Figure 9.54b) whose barbed ends are located at the outer tip of the projection and pointed ends at the base. Stereocilia have provided some of the most striking images of the dynamic nature of the actin cytoskeleton. While the stereocilia themselves are permanent structures, the actin bundles are in constant flux. Actin monomers continually bind to the barbed end of each filament, treadmill through the body of the filament, and dissociate from the pointed end. This process is captured in the fluorescence micrograph of Figure 9.54c, which shows the incorporation of GFP-labeled actin subunits at the barbed end of each filament. Several unconventional myosins (I, III, V, VI, VII, and XV) are localized at various sites within the hair cells of the inner ear; two of these are shown in Figure 9.54d and e. Mutations in myosin VIIa are the cause of Usher 1B syndrome, which is characterized by both deafness and blindness. The morphologic effects of mutations in the myosin VIIa gene on the hair cells of the inner ear of mice are shown in Figure 9.54f,g. As in humans, mice that are homozygous for the mutant allele encoding this motor protein are deaf.

Myosin VI, a processive organelle transporter in the cytoplasm of many cells, is distinguished by its movement in a “reverse direction,” that is, toward the pointed (minus) end of an actin filament. Myosin VI is located at the base of the stereocilia where it might connect the cytoskeleton to the overlying plasma membrane. In other types of cells, myosin VI is thought to be involved in the formation of clathrin-coated vesicles at the plasma membrane, the movement of uncoated vesicles to early endosomes, and the maintenance of Golgi morphology. Mutations in myosin VI are the cause of several inherited diseases.

Now that we have described the basics of actin and myosin structure and function, we can see how these two proteins interact to mediate a complex cellular activity.

REVIEW

1. Compare and contrast the characteristics of microtubule assembly versus actin filament assembly.
2. Compare the structure of a fully assembled microtubule, actin filament, and intermediate filament.
3. Describe three functions of actin filaments.
4. Contrast the structure and function of conventional myosin II and the unconventional myosin V.
5. How is it possible for the same vesicle to be transported along both microtubules and microfilaments?

9.6 | Muscle Contractility

Skeletal muscles derive their name from the fact that most of them are anchored to bones that they move. They are under voluntary control and can be consciously commanded to contract. Skeletal muscle cells have a highly unorthodox structure. A single, cylindrically shaped muscle cell is typically 10 to 100 μm thick, over 100 mm long, and contains hundreds of nuclei.

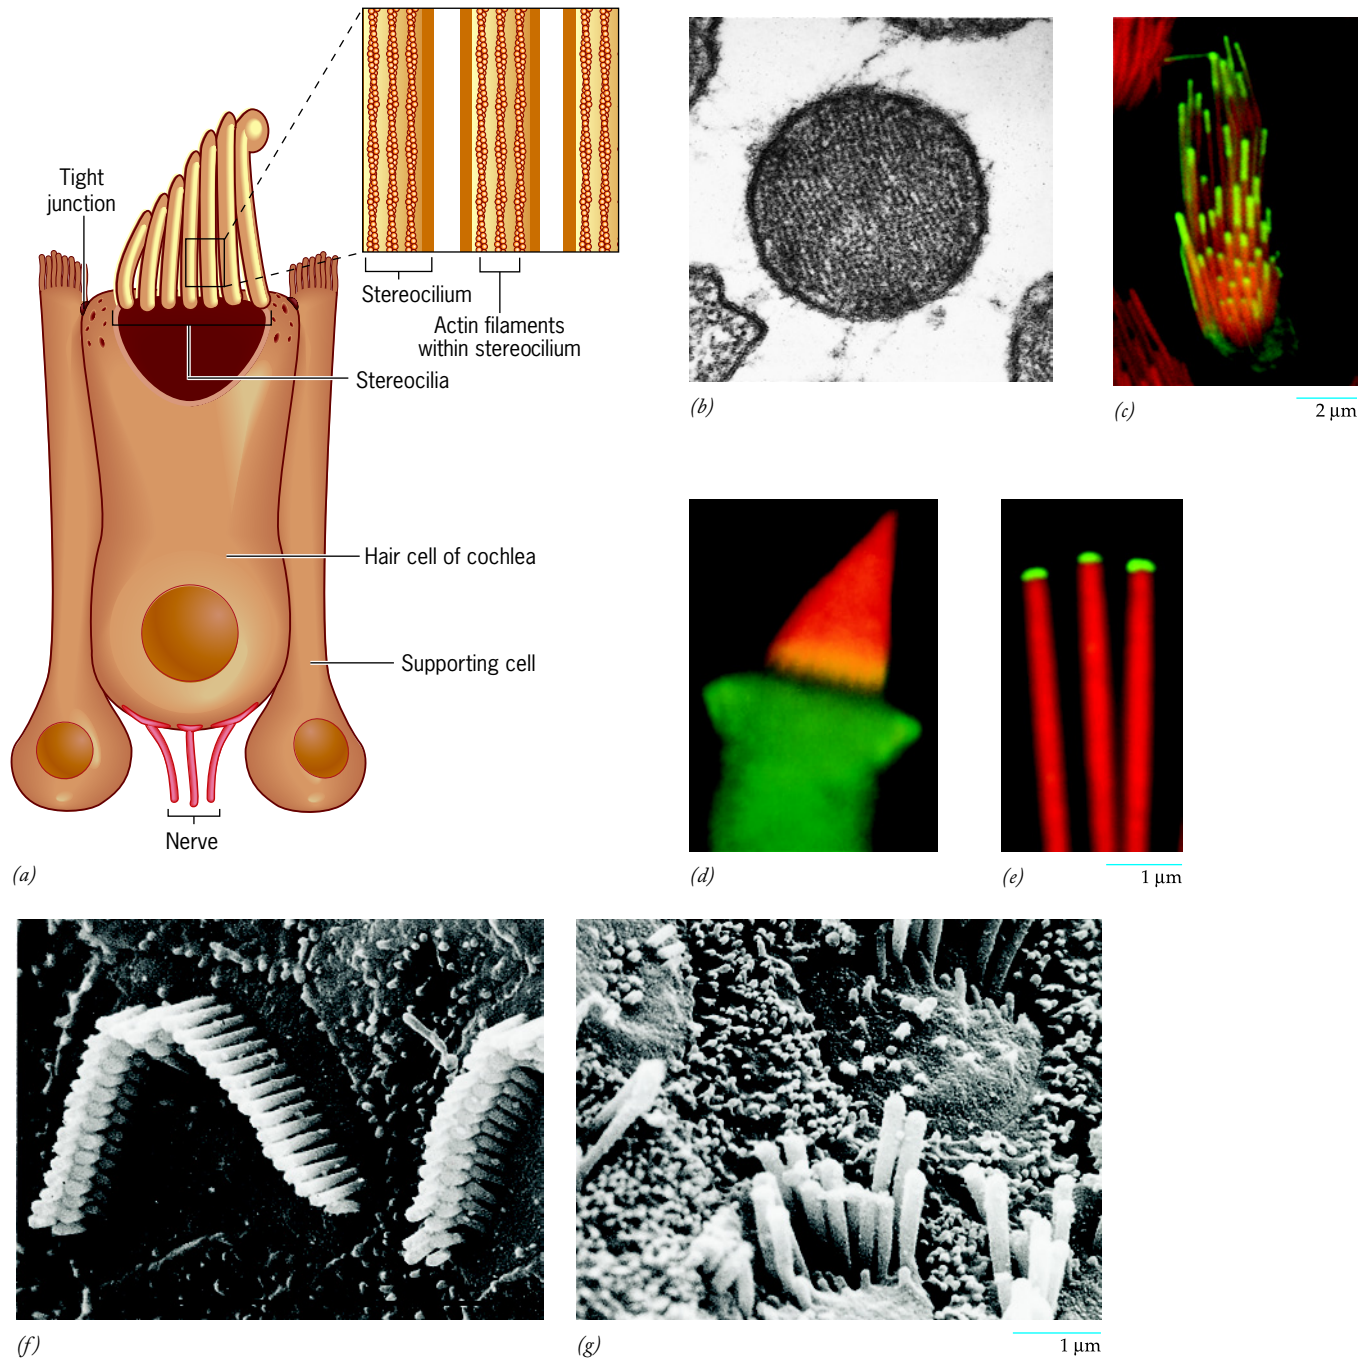

Figure 9.54 Hair cells, actin bundles, and unconventional myosins. (a) Drawing of a hair cell of the cochlea. The inset shows a portion of several of the stereocilia, which are composed of a tightly grouped bundle of actin filaments. (b) Transmission electron micrograph of a cross section of a stereocilium showing it is composed of a dense bundle of actin filaments. (c) Fluorescence micrograph of a hair cell from the vestibule of a rat inner ear. The tips of the stereocilia are labeled green due to the incorporation of GFP-actin monomers at their barbed ends. Taller stereocilia contain a longer column of GFP-labeled subunits, which reflects a more rapid incorporation of actin monomers. The stereocilia appear red due to labeling by rhodamine-labeled phalloidin, which binds to actin filaments. (d) A hair cell from the bullfrog inner ear. The localization of myosin VIIa is indicated in green. The orange bands near the bases of the stereocilia (due to red and green overlap) indicate a concentration of myosin VIIa. (e) Myosin XVa (green) is localized at the tips of the stereocilia of a rat auditory hair cell. (f)

STEEL, *DEVELOP.* 125:560, 1998; REPRODUCED BY PERMISSION OF THE COMPANY OF BIOLOGISTS, LTD. <http://dev.biologists.org/content/125/4/557.full.pdf+html?sid=1524ec24-e6c0-413f-9c05-ac2111083a85>)

Because of these properties, a skeletal muscle cell is more appropriately called a **muscle fiber**. Muscle fibers have multiple nuclei because each fiber is a product of the fusion of large numbers of mononucleated *myoblasts* (premuscle cells) in the embryo.

Skeletal muscle cells may have the most highly ordered internal structure of any cell in the body. A longitudinal section of a muscle fiber (Figure 9.55) reveals a cable made up of hundreds of thinner, cylindrical strands, called **myofibrils**. Each myofibril consists of a repeating linear array of contractile units, called **sarcomeres**. Each sarcomere in turn exhibits a characteristic banding pattern, which gives the muscle fiber a striped or *striated* appearance. Examination of stained muscle fibers in the electron microscope shows the banding pattern to be the result of the partial overlap of two distinct types of filaments, **thin filaments** and **thick filaments** (Figure 9.56*a*). Each sarcomere extends from one *Z line* to the next *Z line* and contains several dark bands and light zones. A sarcomere has a pair of lightly staining *I bands* located at its outer edges, a more densely staining *A band* located between the outer *I bands*, and a lightly staining *H zone* located in the center of the *A band*. A densely staining *M line* lies in the center of the *H zone*. The *I band* contains only thin filaments, the *H zone* only thick filaments, and that part of the *A band* on either side of the *H zone* represents the region of overlap and contains both types of filaments.

Figure 9.55 The structure of skeletal muscle. (a) Levels of organization of a skeletal muscle. (b) Light micrograph of a multinucleated muscle fiber. (c) Electron micrograph of a sarcomere with the bands

Cross sections through the region of overlap show that the thin filaments are organized in a hexagonal array around each thick filament, and that each thin filament is situated between two thick filaments (Figure 9.56*b*). Longitudinal sections show the presence of projections from the thick filaments at regularly spaced intervals. The projections represent cross-bridges capable of forming attachments with neighboring thin filaments.

The Sliding Filament Model of Muscle Contraction

All skeletal muscles operate by shortening; there is no other way they can perform work. The units of shortening are the sarcomeres, whose combined decrease in length accounts for the decrease in length of the entire muscle. The most important clue to the mechanism underlying muscle contraction came from observations of the banding pattern of the sarcomeres at different stages in the contractile process. As a muscle fiber shortened, the *A band* in each sarcomere remained essentially constant in length, while the *H band* and *I bands* decreased in width and then disappeared altogether. As shortening progressed, the *Z lines* on both ends of the sarcomere moved inward until they contacted the outer edges of the *A band* (Figure 9.57).

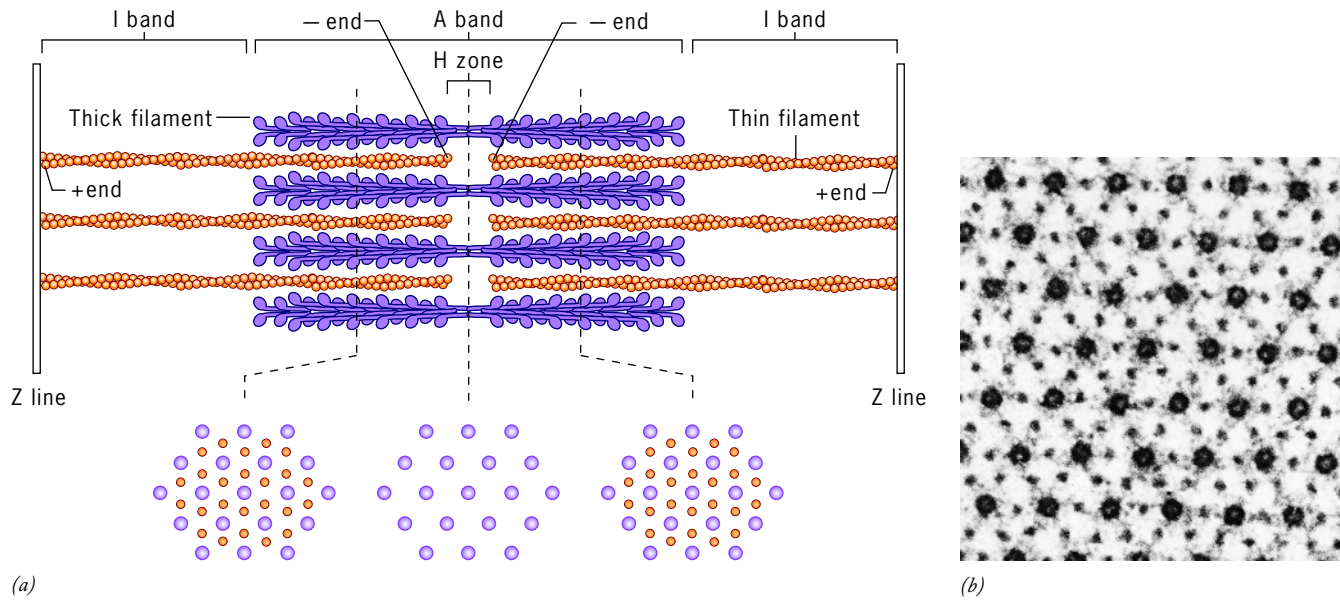

Figure 9.56 The contractile machinery of a sarcomere. (a) Diagram of a sarcomere showing the overlapping array of thin actin-containing (orange) and thick myosin-containing (purple) filaments. The small transverse projections on the myosin fiber represent the myosin heads

(cross-bridges). (b) Electron micrograph of a cross section through an insect flight muscle showing the hexagonal arrangement of the thin filaments around each thick filament. (J. AUBER/PHOTO RESEARCHERS, INC.)

Figure 9.57 The shortening of the sarcomere during muscle contraction. (a) Schematic diagram showing the difference in the structure of the sarcomere in a relaxed and contracted muscle. During contraction, the myosin cross-bridges make contact with the surrounding thin filaments, and the thin filaments are forced to slide toward the center of the sarcomere. Cross-bridges work asynchronously, so that

only a fraction are active at any given instant. (b) Electron micrographs of longitudinal sections through a relaxed (top) and contracted (bottom) sarcomere. The micrographs show the disappearance of the H zone as the result of the sliding of the thin filaments toward the center of the sarcomere. (B: TOP AND BOTTOM IMAGES FROM JAMES E. DENNIS/PHOTOTAKE.)

Based on these observations, two groups of British investigators, Andrew Huxley and Rolf Niedergerke, and Hugh Huxley and Jean Hanson, proposed a far-reaching model in 1954 to account for muscle contraction. They proposed that the shortening of individual sarcomeres did not result from the shortening of the filaments, but rather from their sliding over one another. The sliding of the thin filaments toward the center of the sarcomere would result in the observed increase in overlap between the filaments and the decreased width of the I and H bands (Figure 9.57). The *sliding-filament model* was rapidly accepted, and evidence in its favor continues to accumulate.

The Composition and Organization of Thick and Thin Filaments In addition to actin, the thin filaments of a skeletal muscle contain two other proteins, *tropomyosin* and *troponin* (Figure 9.58). Tropomyosin is an elongated molecule (approximately 40 nm long) that fits securely into the grooves and troponin molecules spaced at defined intervals, as described in the text. The positional changes in these proteins that trigger contraction are shown in Figure 9.63.

Each thick filament is composed of several hundred myosin II molecules together with small amounts of other proteins. Like the filaments that form in vitro (see Figure 9.51), the polarity of the thick filaments of muscle cells is reversed at the center of the sarcomere. The center of the filament is composed of the opposing tail regions of the myosin

Figure 9.58 The molecular organization of the thin filaments. Each thin filament consists of a helical array of actin subunits with rod-shaped tropomyosin molecules situated in the grooves and troponin molecules spaced at defined intervals, as described in the text. The positional changes in these proteins that trigger contraction are shown in Figure 9.63.

molecules and is devoid of heads. The myosin heads project from each thick filament along the remainder of its length due to the staggered position of the myosin molecules that make up the body of the filament (Figure 9.51).

The third most abundant protein of vertebrate skeletal muscles is *titin*, which is the largest protein yet to be discovered in any organism. The entire titin gene (which can give rise to isoforms of different length) encodes a polypeptide more than 3.5 million daltons in molecular mass and containing more than 38,000 amino acids. Titin molecules originate at the M line in the center of each sarcomere and extend along the myosin filament, continuing past the A band and terminating at the Z line (Figure 9.59). Titin is a highly elastic protein that stretches like a molecular spring as certain regions within the molecule become uncoiled. Titin is thought to prevent the sarcomere from becoming pulled apart during muscle stretching. Titin also maintains myosin filaments in their proper position within the center of the sarcomere during muscle contraction.

Figure 9.59 The arrangement of titin molecules within the sarcomere. These huge elastic molecules stretch from the end of the sarcomere at the Z line to the M band in the sarcomere center. Titin molecules are thought to maintain the thick filaments in the center of the sarcomere during contraction. The I-band portion of the titin molecule contains spring-like domains and is capable of great elasticity. The nebulin molecules (which are not discussed in the text) are

thought to act like a “molecular ruler” by regulating the number of actin monomers that are allowed to assemble into a thin filament. (T. C. S. KELLER, CURR. OPIN CELL BIOL. 7:33, 1995. CURRENT OPINION IN CELL BIOLOGY BY ELSEVIER LTD., CURRENT OPINION JOURNALS. REPRODUCED WITH PERMISSION OF ELSEVIER LTD., CURRENT OPINION JOURNALS IN THE FORMAT JOURNAL VIA COPYRIGHT CLEARANCE CENTER.)

The Molecular Basis of Contraction Following the formulation of the sliding-filament hypothesis, attention turned to the heads of the myosin molecules as the force-generating components of the muscle fiber. During a contraction, each myosin head extends outward and binds tightly to a thin filament, forming the cross-bridges seen between the two types of filaments (Figure 9.57). The heads from a single myosin filament interact with six surrounding actin filaments. While it is bound tightly to the actin filament, the myosin head undergoes a conformational change (described below) that moves the thin actin filament approximately 10 nm toward the center of the sarcomere. Unlike myosin V (depicted in Figure 9.52), muscle myosin (i.e., myosin II) is a *nonprocessive motor*. Muscle myosin remains in contact with its track, in this case a thin filament, for only a small fraction (less than 5 percent) of the overall cycle. However, each thin filament is contacted by a team of a hundred or so myosin heads that beat out of synchrony with one another (Figure 9.57a). Consequently, the thin filament undergoes continuous motion during each contractile cycle. It is estimated that a single thin filament in a muscle cell can be moved several hundred nanometers during a period as short as 50 milliseconds.

Muscle physiologists have long sought to understand how a single myosin molecule can move an actin filament approximately 10 nm in a single power stroke. The publication of the first atomic structure of the S1 myosin II fragment in 1993 by Ivan Rayment, Hazel Holden, and their colleagues at the University of Wisconsin focused attention on a proposal to explain its mechanism of action. In this proposal, the energy released by ATP hydrolysis induces a small (0.5 nm) conformational change within the head while the head is tightly bound to the actin filament. The small movement within the head is then amplified approximately 20-fold by the swinging movement of an adjoining α -helical neck (Figure 9.60). According to this hypothesis, the elongated myosin II neck acts as a rigid “lever arm” causing the attached actin filament to slide a much greater distance than would otherwise be possible. The two light chains, which are wrapped around the neck, are thought to provide rigidity for the lever.

Figure 9.60 Model of the swinging lever arm of a myosin II molecule. (a) During the power stroke, the neck of the myosin molecule moves through a rotation of approximately 70° , which would produce a movement of the actin filament of approximately 10 nm. (b) A model of the power stroke of the myosin motor domain consisting of the motor domain (or head) and adjoining neck (or lever arm). An attached actin filament is shown in gray/brown. The long helical neck is shown in two positions, both before and after the power stroke

Support for the “lever-arm” proposal was initially obtained through a series of experiments by James Spudich and colleagues at Stanford University. These researchers constructed genes that encoded altered versions of the myosin II molecule, which contained necks of different length. The genetically engineered myosin molecules were then tested in an *in vitro* motility assay with actin filaments, similar to that depicted in Figure 9.50. As predicted by the lever-arm hypothesis, the apparent length of the power stroke of the myosin molecules was directly proportional to the length of their necks. Myosin molecules with shorter necks generated smaller displacements, whereas those with longer necks generated greater displacements. Not all studies have supported the correlation between step size and neck length, so the role of the lever-arm remains a matter of controversy.

The Energetics of Filament Sliding Like the other motor proteins kinesin and dynein, myosin converts the chemical energy of ATP into the mechanical energy of filament sliding. Each cycle of mechanical activity of the myosin cross-bridge takes about 50 msec and is accompanied by a cycle of ATPase activity, as illustrated in the model shown in Figure 9.61. According to this model, the cycle begins as a molecule of ATP binds to the myosin head, an event that induces the dissociation of the cross-bridge from the actin filament (Figure 9.61, step 1). Binding of ATP is followed by its hydrolysis, which occurs before the myosin head makes contact with the actin

(depicted as the upper dark blue and lower light blue necks, respectively). It is this displacement of the neck region that is thought to power muscle movement. The essential and regulatory light chains, which wrap around the neck, are shown in yellow and magenta, respectively. (B: FROM MALCOLM IRVING ET AL., NATURE STRUCT. BIOL. 7:482, 2000; REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD. COURTESY OF MALCOLM IRVING, IVAN RAYMENT, AND CAROLYN COHEN.)

Figure 9.61 A schematic model of the actinomyosin contractile cycle. The movement of the thin filament by the force-generating myosin head occurs as the result of a linkage between a mechanical cycle involving the attachment, movement, and detachment of the head and a chemical cycle involving the binding, hydrolysis, and release of ATP, ADP, and P_i . In this model, the two cycles begin in step 1 with the binding of ATP to a cleft in the myosin head, causing the detachment of the head from the actin filament. The hydrolysis of the bound ATP (step 2) energizes the head, causing it to bind weakly to the actin filament (step 3). The release of P_i causes a tighter attachment of the myosin head to the thin filament and the power stroke (step 4) that moves the thin filament toward the center of the sarcomere. The release of the ADP (step 5) sets the stage for another cycle. (M. Y. JIANG & M. P. SHEETZ, *BIOESSAYS* 16:532, 1994.)

filament. The products of ATP hydrolysis, namely, ADP and P_i , remain bound to the active site of the enzyme, while the energy released by hydrolysis is absorbed by the protein as a whole (Figure 9.61, step 2). At this point, the cross-bridge is in an energized state, analogous to a stretched spring capable of spontaneous movement. The energized myosin then attaches to the actin molecule (step 3) and releases its bound phosphate, which triggers a large conformational change driven by the stored free energy (step 4). This conformational change shifts the actin filament toward the center of the sarcomere. This movement represents the power stroke of the myosin head as shown in Figure 9.60. The release of the bound ADP (step 5) is followed by the binding of a new ATP molecule so that a new cycle can begin. In the absence of ATP, the myosin head remains tightly bound to the actin filament. The inability of myosin cross-bridges to detach in the absence of ATP is the basis for the condition of *rigor mortis*, the stiffening of muscles that ensues following death.

Excitation–Contraction Coupling Muscle fibers are organized into groups termed *motor units*. All the fibers of a motor unit are jointly innervated by branches from a single motor

neuron and contract simultaneously when stimulated by an impulse transmitted along that neuron. The point of contact of a terminus of an axon with a muscle fiber is called a **neuromuscular junction** (Figure 9.62; see also Figure 4.56 for a closer view of the structure of the synapse). The neuromuscular junction is a site of transmission of the nerve impulse from the axon across a synaptic cleft to the muscle fiber, whose plasma membrane is also excitable and capable of conducting an action potential.

The steps that link the arrival of a nerve impulse at the muscle plasma membrane to the shortening of the sarcomeres deep within the muscle fiber constitute a process referred to as **excitation–contraction coupling**. Unlike a neuron, where an action potential remains at the cell surface, the impulse generated in a skeletal muscle cell is propagated into the interior of the cell along membranous folds called **transverse (T) tubules** (Figure 9.62). The T tubules terminate in very close proximity to a system of cytoplasmic membranes that make up the **sarcoplasmic reticulum (SR)**, which forms a membranous sleeve around the myofibril. Approximately 80 percent of the integral protein of the SR membrane consists of Ca^{2+} -ATPase molecules whose function is to transport Ca^{2+} out of the cytosol and into the lumen of the SR, where it is stored until needed.

The importance of calcium in muscle contraction was first shown in 1882 by Sydney Ringer, an English physician. Ringer found that an isolated frog heart would contract in a saline solution made with London tap water, but failed to contract in a solution made with distilled water. Ringer determined that calcium ions present in tap water were an essential factor in muscle contraction. In the relaxed state, the Ca^{2+} levels within the cytoplasm of a muscle fiber are very low (approximately 2×10^{-7} M)—below the threshold concentration required for contraction. With the arrival of an action potential by way of the transverse tubules, calcium channels in the SR membrane are opened, and calcium diffuses out of the SR compartment and over the short distance to the myofibrils. As a result, the intracellular Ca^{2+} levels rise to about 5×10^{-5} M. To understand how elevated calcium levels trigger contraction in a skeletal muscle fiber, it is necessary to reconsider the protein makeup of the thin filaments.

When the sarcomere is relaxed, the tropomyosin molecules of the thin filaments (see Figure 9.58) block the myosin-binding sites on the actin molecules. The position of the tropomyosin within the groove is under the control of the attached troponin molecule. When Ca^{2+} levels rise, these ions bind to one of the subunits of troponin (troponin C), causing a conformational change in another subunit of the troponin molecule. Like the collapse of a row of dominoes, the movement of troponin is transmitted to the adjacent tropomyosin, which moves approximately 1.5 nm closer to the center of the filament's groove (from position b to a in Figure 9.63). This shift in position of the tropomyosin exposes the myosin-binding sites on the adjacent actin molecules, allowing the myosin heads to attach to the thin filaments. Each troponin molecule controls the position of one tropomyosin molecule, which in turn controls the binding capacity of seven actin subunits in the thin filament.

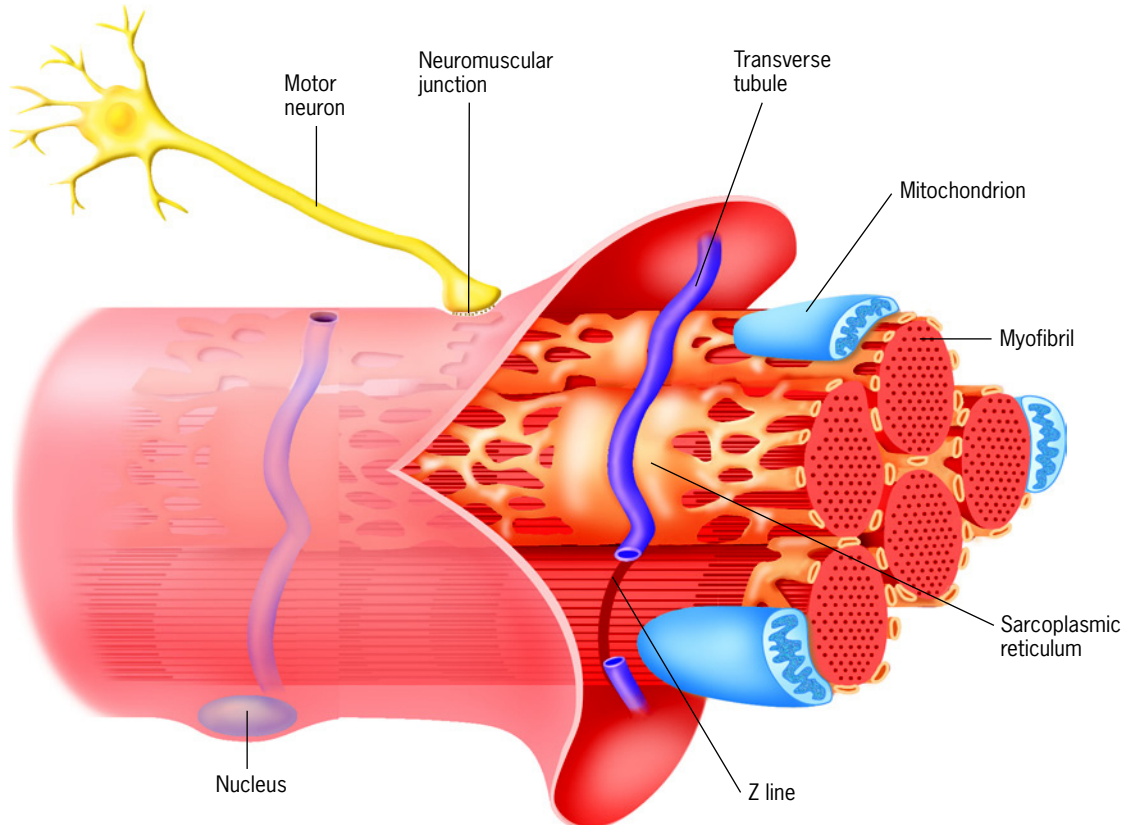

Figure 9.62 The functional anatomy of a muscle fiber. Calcium is housed in the elaborate network of internal membranes that make up the sarcoplasmic reticulum (SR). When an impulse arrives by means of a motor neuron, it is carried into the interior of the fiber along the

membrane of the transverse tubule to the SR. The calcium gates of the SR open, releasing calcium into the cytosol. The binding of calcium ions to troponin molecules of the thin filaments leads to the events described in the following figure and the contraction of the fiber.

Once stimulation from the innervating motor nerve fiber ceases, the Ca^{2+} channels in the SR membrane close, and the Ca^{2+} -ATPase molecules in that membrane remove excess calcium from the cytosol. As the Ca^{2+} concentration decreases, these ions dissociate from their binding sites on troponin, which causes the tropomyosin molecules to move back

to a position where they block the actin–myosin interaction. The process of relaxation can be thought of as a competition for calcium between the transport protein of the SR membrane and troponin. The transport protein has a greater affinity for the ion, so it preferentially removes it from the cytosol, leaving the troponin molecules without bound calcium.

Figure 9.63 The role of tropomyosin in muscle contraction. Schematic diagram of the steric hindrance model in which the myosin-binding site on the thin actin filaments is controlled by the position of the tropomyosin molecule. When calcium levels rise, the interaction between calcium and troponin (not shown) leads to a movement of the tropomyosin from position b to position a, which exposes the myosin-binding site on the thin filament to the myosin head.

REVIEW

1. Describe the structure of the sarcomere of a skeletal muscle myofibril and the changes that occur during its contraction.
2. Describe the steps that occur between the time that a nerve impulse is transmitted across a neuromuscular junction to the time that the muscle fiber begins to shorten. What is the role of calcium ions in this process?

9.7 | Nonmuscle Motility

Skeletal muscle cells are an ideal system for the study of contractility and movement because the interacting contractile proteins are present in high concentration and are part of defined cellular structures. The study of nonmuscle

motility is more challenging because the critical components tend to be present in less ordered, more labile, transient arrangements. Moreover, they are typically restricted to a thin *cortex* just beneath the plasma membrane. The cortex is an active region of the cell, responsible for such processes as the ingestion of extracellular materials, the extension of processes during cell movement, and the constriction of a single animal cell into two cells during cell division. All of these processes are dependent on the assembly of microfilaments in the cortex.

In the following pages, we will consider a number of examples of nonmuscle contractility and motility that depend on actin filaments and, in some cases, members of the myosin superfamily. First, however, it is important to survey the factors that govern the rates of assembly, numbers, lengths, and spatial patterns of actin filaments.

Actin-Binding Proteins

Purified actin can polymerize *in vitro* to form actin filaments, but such filaments cannot interact with one another or perform useful activities. Under the microscope, they resemble the floor of a barn covered by straw. In contrast, actin filaments in living cells are organized into a variety of patterns, including various types of bundles, thin (two-dimensional) networks, and complex three-dimensional gels (Figure 9.64). The organization and behavior of actin filaments inside cells are determined by interaction of actin with a remarkable vari-

Figure 9.64 Two different arrangements of actin filaments within a cell. As described later in the chapter, cells move across a substratum by extending various types of processes. This electron micrograph of the leading edge of a motile fibroblast shows the high density of actin filaments. These filaments are seen to be organized into two distinct arrays: as bundles in which the filaments are arranged parallel to one another (arrow) and as a cross-linked meshwork in which the filaments are arranged in various directions. (COURTESY OF J. VICTOR SMALL.)

ety of **actin-binding proteins**. These proteins affect the localized assembly or disassembly of the actin filaments, their physical properties, and their interactions with one another and with cellular organelles. More than 100 different actin-binding proteins belonging to numerous families have been isolated from different cell types. Actin-binding proteins can be divided into several categories based on their presumed function in the cell (Figure 9.65).⁵

1. **Nucleating proteins.** The slowest step in the formation of an actin filament is the first step, nucleation, which requires that at least two or three actin monomers come together in the proper orientation to begin formation of the polymer. This is a very unfavorable process for actin molecules left on their own. As noted earlier, the formation of an actin filament is accelerated by the presence of a preexisting seed or nucleus to which monomers can be added (as in Figure 9.47a). Several proteins have been identified that promote nucleation of actin filaments. The best studied is the *Arp2/3 complex*, which contains two “actin-related proteins,” that is, proteins that share considerable sequence homology with actins but are not considered “true” actins. Once the complex is activated, the two Arps adopt a conformation that provides a template to which actin monomers can be added, analogous to the way that γ -tubulin is proposed to form a template for microtubule nucleation (Figure 9.20c). As discussed on page 378, the Arp2/3 complex generates networks of short, branched actin filaments. Another family of nucleating proteins, the *formins*, generate unbranched filaments, such as those found at focal adhesions (page 248) and the contractile rings of dividing cells (Section 14.2). Unlike Arp2/3, which remains at the pointed end of the newly formed filament, formins track with the barbed end even as new subunits are inserted at that site. Thus not only do formins nucleate actin filaments, they can promote very rapid elongation of the filaments that they helped create.
2. **Monomer-sequestering proteins.** Thymosins (e.g., thymosin β_4) are proteins that bind to actin-ATP monomers (often called *G-actin*) and prevent them from polymerizing. Proteins with this activity are described as actin monomer-sequestering proteins. These proteins are believed responsible for the relatively high concentration of G-actin in nonmuscle cells (50–200 μ M). Without monomer-sequestering proteins, conditions within the cytoplasm would favor the near complete polymerization of soluble actin monomers into filaments. Because of their ability to bind G-actin and stabilize the monomer pool, changes in the concentration or activity of monomer-sequestering proteins can shift the monomer–polymer equilibrium in a certain region of a cell and determine whether polymerization or depolymerization is favored at the time.

⁵It should be noted that some of these proteins can carry out more than one of the types of activities listed, depending on the concentration of the actin-binding protein and the prevailing conditions (e.g., the concentration of Ca^{2+} and H^+). Most studies of these proteins are conducted *in vitro*, and it is often difficult to extend the results to activities within the cell.

Figure 9.65 The roles of actin-binding proteins.

3. **End-blocking (capping) proteins.** Proteins of this group regulate the length of actin filaments by binding to one or the other end of the filaments, forming a cap that blocks both loss and gain of subunits. If the fast-growing, barbed end of a filament is capped, depolymerization may proceed at the opposite end, resulting in the disassembly of the filament. If the pointed end is also capped, depolymerization is blocked. The thin filaments of striated muscle are capped at their barbed end at the Z line by a protein called capZ and at their pointed end by the protein tropomodulin. If the tropomodulin cap is disturbed by microinjection of antibodies into a muscle cell, the thin filaments add more actin subunits at their newly exposed pointed end and undergo dramatic elongation into the middle of the sarcomere.
4. **Monomer-polymerizing proteins.** Profilin is a small protein that binds to the same site on an actin monomer as does thymosin. However, rather than inhibiting polymerization, profilin promotes the growth of actin filaments. Profilin does this by attaching to an actin monomer and catalyzing the dissociation of its bound ADP, which is rapidly replaced with ATP. The profilin-ATP-actin monomer can then assemble onto the free barbed end of a growing actin filament, which leads to the release of profilin. Filament elongation at the barbed end is further promoted by members of the Ena/VASP protein family.
5. **Actin filament-depolymerizing proteins.** Members of the cofilin family of proteins (including cofilin, ADF, and depactin) bind to actin-ADP subunits present within the body and at the pointed end of actin filaments (see Figure 18.33). Cofilin has two apparent activities: it can fragment actin filaments, and it can promote their depolymerization at the pointed end. These proteins play a role in the rapid turnover of actin filaments at sites of dynamic changes in cytoskeletal structure. They are essential for cell locomotion, phagocytosis, and cytokinesis.
6. **Cross-linking proteins.** Proteins of this group are able to alter the three-dimensional organization of a population of actin filaments. Each of these proteins has two or more actin-binding sites and therefore can cross-link two or more separate actin filaments. Certain of these proteins (e.g., filamin) have the shape of a long, flexible rod and promote the formation of loose networks of filaments interconnected at near right angles to one another (as in Figure 9.64). Regions of the cytoplasm containing such networks have the properties of a three-dimensional elastic gel that resists local mechanical pressures. Other cross-linking proteins (e.g., villin and fimbrin) have a more globular shape and promote the bundling of actin filaments into tightly knit, parallel arrays. Such arrays are found in the microvilli that project from certain epithelial cells (Figure 9.66) and in the hairlike stereocilia (Figure 9.54) that project from receptor cells of the inner ear. Bundling filaments together adds to their rigidity, allowing them to act as a supportive internal skeleton for these cytoplasmic projections.
7. **Filament-severing proteins.** Proteins of this class have the ability to bind to the side of an existing filament and

Figure 9.66 Actin filaments and actin-binding proteins in a microvillus. Microvilli are present on the apical surface of epithelia that function in absorption of solutes, such as the lining of the intestine and wall of the kidney tubule. Actin filaments are maintained in a highly ordered arrangement by the bundling proteins villin and fimbrin. The role of myosin I, which is present between the plasma membrane of the microvillus and the peripheral actin filaments, remains unclear.

break it in two. Severing proteins (e.g., gelsolin) may also promote the incorporation of actin monomers by creating additional free barbed ends, or they may cap the fragments they generate. As indicated in Figure 9.71, cofilin is also capable of severing filaments.

8. **Membrane-binding proteins.** Much of the contractile machinery of nonmuscle cells lies just beneath the plasma membrane. During numerous activities, the forces generated by the contractile proteins act on the plasma membrane, causing it to protrude outward (as occurs, for example, during cell locomotion) or to invaginate inward (as occurs, for example, during phagocytosis or cytokinesis). These activities are generally facilitated by linking the actin filaments to the plasma membrane indirectly, by means of attachment to a peripheral membrane protein. Two examples were described in previous chapters: the inclusion of short actin polymers into the membrane skeleton of erythrocytes (see Figure 4.32*d*), and the attachment of actin filaments to the membrane at focal adhesions and adherens junctions (see Figures 7.17 and 7.26). Proteins that link membranes to actin include vinculin, members of the ERM family (ezrin, radixin, and moesin), and members of the spectrin family (including dystrophin, the protein responsible for muscular dystrophy).

Examples of Nonmuscle Motility and Contractility

Actin filaments, often working in conjunction with myosin motors, are responsible for a variety of dynamic activities in nonmuscle cells, including cytokinesis, phagocytosis, cytoplasmic streaming (the directed bulk flow of cytoplasm that occurs in certain large plant cells), vesicle trafficking, blood platelet activation, lateral movements of integral proteins within membranes, cell–substratum interactions, cell locomotion, axonal outgrowth, and changes in cell shape. Nonmuscle motility and contractility are illustrated by the following examples.

Actin Polymerization as a Force-Generating Mechanism

Some types of cell motility occur solely as the result of actin polymerization and do not involve the activity of myosin. Consider the example of *Listeria monocytogenes*, a bacterium that infects macrophages and can cause encephalitis or food poisoning. *Listeria* is propelled like a rocket through the cytoplasm of an infected cell by the polymerization of actin monomers just behind the bacterium (Figure 9.67). How is the bacterial cell able to induce the formation of actin filaments at a particular site on its surface? Questions about location are important in the study of any type of motile process because motility depends on a cell being able to assemble the necessary machinery at a particular site and a particular time. *Listeria* can accomplish this feat because it contains a surface protein called ActA that is present only at one end of the bacterium. When ActA is exposed within the host cytoplasm, it recruits and activates a number of host proteins (including the Arp2/3 complex, discussed below) that work together to direct the process of actin polymerization. The process of *Listeria* propulsion has been reconstituted *in vitro*, which has allowed researchers to demonstrate conclusively that actin polymerization by itself, that is, without the participation of myosin motors, is capable of providing the force required for motility.

The same events that occur during *Listeria* propulsion are utilized for normal cellular activities, ranging from the propulsion of cytoplasmic vesicles and organelles to the movement of cells themselves, which is the subject of the following section.

Cell Locomotion Cell locomotion is required for many activities in higher vertebrates, including tissue and organ development, formation of blood vessels, development of axons, wound healing, and protection against infection. Cell locomotion also contributes to the spread of cancerous tumors. In the following discussion, we will concentrate on studies of cultured cells moving over a flat (i.e., two-dimensional) substrate because these are the experimental conditions that have dominated this field of research. Keep in mind that cells in the body don't move over bare, flat substrates, and there is increasing evidence that some of the findings from these studies may not apply to cells traversing more complicated terrain. Researchers have recently begun to develop more complex substrata, including various types of three-dimensional extracellular matrices (see Figure 18.22), which may lead to

CYTOL.* 120:194, 1990.)

revision of some aspects of the mechanism of cell locomotion discussed below.

Figure 9.68 shows a single fibroblast that was in the process of moving toward the lower right corner of the field when it was prepared for microscopy. Cell locomotion, as ex-

hibited by the fibroblast in Figure 9.68, shares properties with other types of locomotion, for example, walking. As you walk, your body performs a series of repetitive activities: first, a leg is extended in the direction of locomotion; second, the bottom of your foot makes contact with the ground, which acts as a point of temporary adhesion; third, force is generated by the muscles of your legs that moves your entire body forward past the stationary foot, all the while generating traction against the point of adhesion; fourth, your foot—which is now behind your body rather than in front of it—is lifted from the ground in anticipation of your next step. Even though motile cells may assume very different shapes as they crawl over a substra-

Figure 9.69 The repetitive sequence of activities that occurs as a cell crawls over the substratum. Step 1 shows the protrusion of the leading edge of the cell in the form of a lamellipodium. Step 2 shows the adhesion of the lower surface of the lamellipodium to the substratum, an attachment that is mediated by integrins residing in the plasma membrane. The cell uses this attachment to grip the substratum. Step 3 shows the movement of the bulk of the cell forward over the site of attachment, which remains relatively stationary. This movement is accomplished by a contractile (traction) force exerted against the substratum. Step 4 shows the cell after the rear attachments with the substratum have been severed and the trailing portion of the cell has been pulled forward.

tum, they display a similar sequence of activities (Figure 9.69). (1) Movement is initiated by the protrusion of a part of the cell surface in the direction in which the cell is to move. (2) A portion of the lower surface of the protrusion attaches to the substratum, forming temporary sites of anchorage. (3) The bulk of the cell is pulled forward over the adhesive contacts, which eventually become part of the rear of the cell. (4) The cell breaks its rear contacts with the substratum, causing retraction of the trailing edge, or “tail.”

Cells that Crawl over the Substratum When a small piece of living tissue, such as skin or liver, is placed in a culture dish in an appropriate culture medium, individual cells migrate out of the specimen and onto the surface of the dish. Examination of these cells under the microscope typically shows them to be fibroblasts, which are the predominant cells present in connective tissue (see Figure 7.1). As it moves, a fibroblast flattens itself close to the substratum and becomes fan-shaped, with a broadened frontal end and a narrow “tail” (as in Figure 9.68). Its movement is erratic and jerky, sometimes advancing and other times withdrawing. On a good day, a fibroblast may move a distance of about 1 mm. The key to the fibroblast’s locomotion is seen by examining its leading edge, which is extended out from the cell as a broad, flattened, veil-like protrusion, called a **lamellipodium** (Figure 9.70a). Lamellipodia are typically devoid of cytoplasmic vesicles and other

(a)

(b)

Figure 9.70 The leading edge of a motile cell. (a) The leading edge of this motile fibroblast is flattened against the substratum and spread out into a veil-like lamellipodium. (b) Scanning electron micrograph of the leading edge of a cultured cell, showing the ruffled membranes of the lamellipodium. (A: COURTESY OF J. VICTOR SMALL; B: FROM JEAN PAUL REVEL, SYMP. SOC. EXP. BIOL. 28:447, 1974.)

particulate structures, and the outer edge often exhibits an undulating motion, giving it a ruffled appearance (Figure 9.70b). As a lamellipodium is extended from the cell, it adheres to the underlying substratum at specific points, providing temporary sites of anchorage for the cell to pull itself forward.

We saw on page 374 how the polymerization of actin monomers can provide the force that propels a *Listeria* bacterium through the cytoplasm. This type of intracellular movement is accomplished without the involvement of mo-

Figure 9.71 Directed cell motility. (a) Micrograph of a white blood cell (a neutrophil) that has responded to a chemoattractant being delivered by a pipette (seen on the right). The cell has become polarized and is moving toward the source of the stimulus. (b) A proposed mechanism for the movement of a cell in a directed manner. A stimulus is received at the cell surface (step 1) that leads to the activation of Arp2/3 complex by a member of the WASP/WAVE family (step 2). Activated Arp2/3 complexes serve as nucleating sites for the formation of new actin filaments (step 3). Once filaments have formed, Arp2/3 complexes attach to the sides of the filaments (step 4), which stimulates their nucleating activity. As a result, the bound Arp2/3 complexes initiate side branches that extend outward (step 5) at an angle of about 70° relative to the existing filaments to which they are anchored. As these filaments polymerize, they are thought to push the plasma membrane outward, resulting in extension of the leading edge of the

lamellipodium. Meanwhile, the barbed end of previously formed filaments are bound by a capping protein, which prevents further growth of these filaments, keeping them short and rigid. Eventually, the pointed ends of the older, preexisting actin filaments undergo depolymerization, releasing ADP-actin subunits (step 6). Depolymerization is promoted by cofilin, which binds to ADP-actin subunits within the filament and stimulates dissociation of the subunits from the pointed end of the filament. Released subunits bind profilin and become recharged by ATP/ADP exchange, which makes them ready to engage in actin polymerization (as in step 3). (A discussion of the validity of this model can be found in *Trends Cell Biol.* 21:2, 2011 and *Nature Cell Biol.* 13: 1012, 2011.) (A: FROM CAROLE A. PARENT, *CURR. OPIN. CELL BIOL.* 16:5, 2004; © 2004, WITH PERMISSION FROM ELSEVIER.)

lecular motors. A similar type of actin-polymerization mechanism is thought to provide the motile force required for the protrusion of the leading edge of a lamellipodium. This type of nonmuscle motility also demonstrates the importance of actin-binding proteins (depicted in Figure 9.65) in orchestrating the assembly and disassembly of actin-filament networks at a particular site within the cell at a particular time.

Suppose we begin with a rounded white blood cell that receives a chemical signal coming from one particular direction where the body has been wounded. Once the stimulus is received at the plasma membrane, it triggers the localized polymerization of actin, which leads to the polarization of the cell and its movement toward the source of the stimulus (Figure 9.71a).⁶ Just as *Listeria* has a protein (ActA) that activates polymerization at the bacterial cell surface, mammalian cells

have a family of proteins (the WASP/WAVE family) that activates the Arp2/3 complex at the site of stimulation near the plasma membrane. WASP, the founding member of the family, was discovered as the product of a gene responsible for Wiskott-Aldrich syndrome. Patients with this disorder have a crippled immune system because their white blood cells lack a functional WASP protein and consequently fail to respond to chemotactic signals.

Figure 9.71b depicts a model for the major steps in formation of a lamellipodium that would guide a cell in a particular direction. A stimulus is received at one end of the cell (step 1, Figure 9.71b), which leads to the activation of Arp2/3 protein complexes by activated WASP proteins (step 2). In its activated state, the Arp2/3 complex adopts a conformation that resembles the free surface at the barbed end of an actin filament. As a result, free ATP-actin monomers bind to the Arp2/3 template, leading to the nucleation of actin filaments (step 3). Polymerization of ATP-bound actin monomers onto the free barbed ends of the growing filaments is promoted by

⁶This type of response can be seen in a remarkable film on the Web showing a neutrophil chasing a bacterium. It can be found using the search words: “neutrophil crawling.”

profilin molecules (page 373). Once new actin filaments have formed, Arp2/3 complexes bind to the sides of these filaments (step 4) and nucleate the formation of additional actin filaments that form as branches (step 5). The Arp2/3 complexes remain at the pointed ends, which are situated at the branch-points. Meanwhile, growth of the barbed ends of older filaments is blocked by the addition of capping protein (step 5). In contrast, addition of actin subunits to the barbed ends of more recently formed filaments of the network pushes the membrane of the lamellipodium outward in the direction of the attractive stimulus (steps 5 and 6). As newer filaments are growing by addition of subunits to their barbed ends, the older capped filaments undergo disassembly from their pointed ends (step 6). Disassembly is promoted by cofilin, which binds to actin-ADP subunits along the filaments (step 6). Actin-ADP subunits released from the disassembling filaments are recharged by conversion into profilin-ATP-actin monomers, which can be reutilized in the assembly of actin filaments at the leading edge.

Figure 9.72 illustrates some of the major structural features of cell locomotion. The electron micrograph of Figure 9.72 shows the branched, cross-linked nature of the filamentous actin network that resides just beneath the plasma membrane of an advancing lamellipodium. The circular insets in Figure 9.72 show a succession of short actin-filament branches, with Arp2/3 complexes highlighted by immunogold labeling. The Arp2/3 complexes are seen to reside at the Y-shaped junctions where the newly polymerized filaments have branched off of preexisting filaments.

Figure 9.72 The structural basis of lamellipodial extension. Electron micrograph of a replica of the cytoskeleton at the leading edge of a motile mouse fibroblast. The actin filaments are seen to be arranged in a branched network, which has been colorized to indicate individual “trees.” The circular insets show a succession of Y-shaped junctions between branched actin filaments. Arp2/3 complexes are localized at the base of each branch by antibodies linked to colloidal gold particles (yellow). (FROM TATYANA M. SVITKINA AND GARY G. BORISY, FROM *J. CELL BIOL.*, VOL. 145, #5, 1999; REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS.)

Lamellipodial movement is a dynamic process. As actin filament polymerization and branching continue at the very front edge of the lamellipodium, assembled actin filaments flow in a rearward direction and then depolymerize toward the back of the lamellipodium (step 6, Figure 9.71). Thus taken as a whole, the entire actin-filament array undergoes a type of treadmilling (page 360) in which actin subunits are added to barbed ends of the array at its front end and lost from pointed ends of the array toward the rear.

According to the sequence of events depicted in Figure 9.69, protrusion of the leading edge is followed by movement of the bulk of the cell. The major forces involved in cell locomotion are those generated at sites of adhesion that are required to pull or “tow” the main body of the cell forward (step 3 of Figure 9.69). They are often described as “traction forces” because they occur at sites where the cell grips the substrate.

When cells are allowed to migrate over a thin sheet of elastic material, movements of the cell are accompanied by deformation of the underlying substratum (see Figure 7.18). The magnitude of the traction forces exerted at various locations within a live migrating cell can be calculated from the dynamic patterns of substrate deformation and portrayed as shown in Figure 9.73*a*. As seen by examination of this computerized image of a migrating fibroblast, the greatest traction forces are exerted just behind the cell’s leading edge where the cell adheres strongly to the underlying substratum. The presence of these sites of attachment is best revealed by following the localization of fluorescently labeled vinculin within a living cell. This allows investigators to specifically visualize structures where the cell makes contact with the underlying substratum. Figure 9.73*b* is a fluorescence micrograph showing the presence of red fluorescent vinculin molecules concentrated just behind the leading edge of a migrating cell. Vinculin is a major component of focal adhesions, the actin-containing sites illustrated in Figure 7.17. The vinculin-containing sites where the leading edge of a migrating cell adheres to the substratum tend to be smaller and simpler than the mature focal adhesions seen in highly spread, stationary cultured cells and are often referred to as *focal complexes*. Traction forces are thought to be generated in the actin cytoskeleton associated with these adhesion sites and then transmitted to the extracellular substrate by way of the transmembrane integrin molecules that connect the inside and outside of the cell. The focal complexes that form near the leading edge of a motile cell either disassemble as the cell moves forward or mature into larger, more contractile focal adhesions. Maturation of focal complexes is probably stimulated by tension exerted on these adhesion sites.

A large body of evidence indicates that actin polymerization is responsible for pushing the leading edge of a cell outward (step 1, Figure 9.69), whereas myosin (in conjunction with actin filaments) is responsible for pulling the remainder of the cell forward (step 3, Figure 9.69). These contrasting roles of actin and myosin are best illustrated in studies on fish keratocytes, which are cells derived from the epidermis that covers the fish’s scales. Keratocytes have been a favored system for studying locomotion because their rapid gliding movement depends on the formation of a very broad, thin lamel-

Figure 9.73 Distribution of traction forces within a migrating fibroblast. (a) As a cell migrates it generates traction (pulling) forces against its substrate. The present image shows the traction forces generated per unit area by the surface of a migrating fibroblast. Traction forces were calculated at different sites on the surface based on the degree of substrate deformation (see Figure 7.18). The magnitude of the traction forces are expressed by varying colors with red representing the strongest forces. The largest forces are generated at sites of small focal complexes that form transiently behind the leading edge of the cell where the lamellipodium is being extended (arrow). Deformation at the rear of the cell (shown in red) occurs as the front end actively pulls against the tail, which is passively anchored. (b) A living, migrating fibroblast exhibiting a well-developed lamellipodium

that is adhering to the underlying substratum at numerous sites (red). This cell is expressing GFP-actin (green) and had been injected with rhodamine-tagged vinculin (red). The fluorescently labeled vinculin is incorporated into dot-like focal complexes near the leading edge of the cell. Some of these focal complexes disassemble, whereas others mature into focal adhesions, which are situated farther from the advancing edge. (A: FROM KAREN A. BENINGO, MICAH DEMBO, AND YU-LI WANG, *J. CELL BIOL.* 153:885, 2001, FIG. 3. REPRODUCED WITH PERMISSION OF THE ROCKEFELLER UNIVERSITY PRESS; B: FROM J. VICTOR SMALL, ET AL., IMAGE COURTESY OF OLGA KRYLYSHKINA, *NATURE REV. MOL. CELL BIOL.* 3:957, 2002; © 2002, REPRINTED WITH PERMISSION FROM MACMILIAN PUBLISHERS LTD.)

lipodium. Figure 9.74 shows a moving keratocyte that has been fixed and stained for actin (Figure 9.74a) and myosin II (Figure 9.74b). As expected from the previous discussion, the advancing edge of the lamellipodium is filled with actin. Myosin, on the other hand, is concentrated in a band where the rear of the lamellipodium joins the remainder of the cell. Electron micrographs of this region show the presence of clusters of small, bipolar myosin II filaments bound to the actin network (Figure 9.74c). Contractile forces generated by these myosin molecules are presumed to pull the bulk of the cell along behind the advancing lamellipodium. Myosin I and other unconventional myosins are also thought to generate forces for cell locomotion in some organisms.

Axonal Outgrowth In 1907, Ross Harrison of Yale University performed one of the classic experiments in biology. Harrison removed a small piece of tissue from the developing nervous system of a frog embryo and placed the fragment into a tiny drop of lymphatic fluid. Harrison watched the tissue under a microscope over the next few days and found that the

nerve cells not only remained healthy, but many of them sprouted processes that grew out into the surrounding medium. Not only was this the first time that cells had been kept alive in tissue culture, the experiment provided strong evidence that axons develop by a process of active outgrowth and elongation.

The tip of an elongating axon is very different from the remainder of the cell (see Figure 9.1b). Although the bulk of the axon shows little outward evidence of motile activity, the tip, or **growth cone**, resembles a highly motile, crawling fibroblast. Close examination of a living growth cone reveals several types of locomotor protrusions: a broad, flattened lamellipodium that creeps outward over the substratum; short, stiff *microspikes* (Figure 9.75a) that point outward to the edge of the lamellipodium; and highly elongated *filopodia* that extend and retract in a continuous display of motile activity. Fluorescence microscopy shows all of these structures in the peripheral domain of the growth cone to be filled with actin filaments (shown in green, Figure 9.75b). These actin filaments are presumed to be responsible for the motile activities

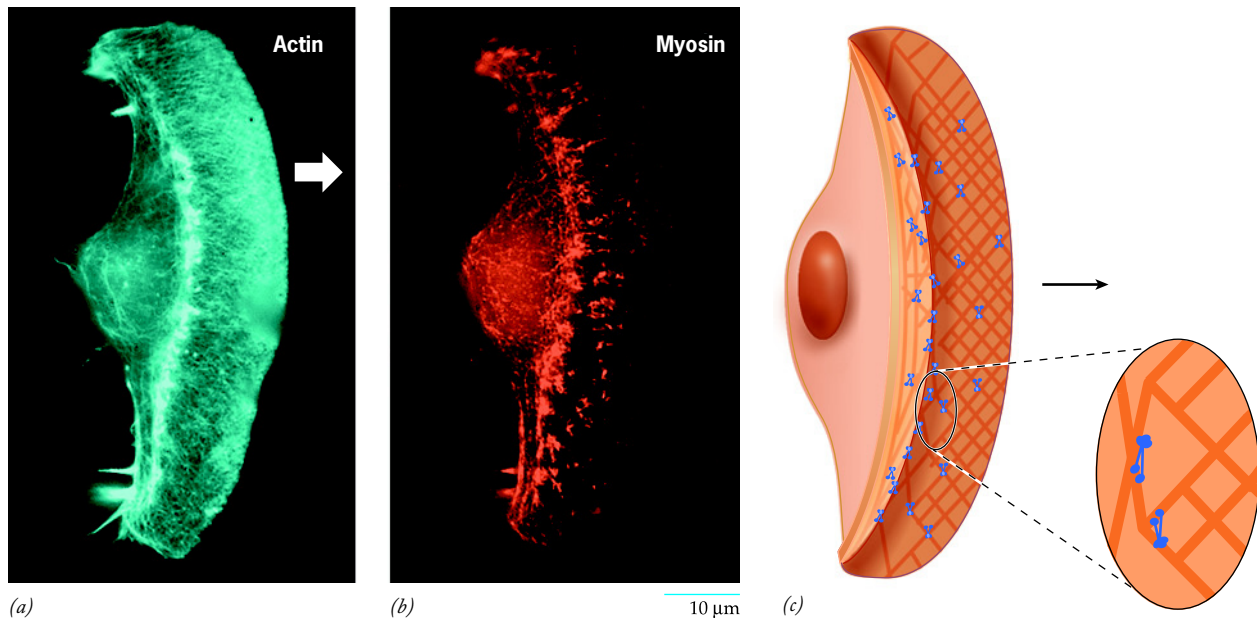

Figure 9.74 The roles of actin and myosin in the lamellipodial-based movement of fish keratocytes. (a,b)

Fluorescence micrographs of a fish keratocyte moving over a culture dish by means of a broad, flattened lamellipodium. The arrow shows the direction of movement, which can occur at rates of 10 μm/min. The distribution of filamentous actin is revealed in part *a*, which shows the localization of fluorescently labeled phalloidin, which binds only to actin filaments. The distribution of myosin in the same cell is revealed in part *b*, which shows the localization of fluorescent antimyosin antibodies. It is evident that the body of the lamellipodium contains actin

filaments but is virtually devoid of myosin. Myosin is concentrated, instead, in a band that lies just behind the lamellipodium, where it merges with the body of the cell. (c) A schematic drawing depicting the filamentous actin network of the lamellipodium and the actin–myosin interactions toward the rear of the lamellipodium. The actin network is shown in red, myosin molecules in blue. (BY ALEXANDER B. VERKHOVSKY, FROM TATYANA M. SVITKINA ET AL., *J. CELL BIOL.* 139:397, 1997, FIG. 1. cell that is expressing the neuronal guidance factor ephrin (red). (A: FROM ELKE STEIN AND MARC TESSIER-LAVIGNE, *SCIENCE* 291:1929, 2001. REPRINTED WITH PERMISSION FROM AAAS; B: COURTESY OF IRINA DUDANOVA.)

of the growth cone. Microtubules, on the other hand, fill the axon and the central domain of the growth cone, providing support for the thin, elongating axon. A number of individual microtubules are seen to penetrate into the actin-rich periphery (shown in orange, Figure 9.75*b*). These penetrating microtubules are highly dynamic and are thought to play an important role in steering the growth cone in the appropriate direction.

The growth cone is a highly motile region of the cell that explores its environment and elongates the axon. Within the embryo, the axons of developing neurons grow along defined paths, following certain topographical features of the substratum or responding to the presence of certain chemicals that diffuse into their path. The lamellipodia and filopodia from the growth cone respond to the presence of these physical and chemical stimuli, causing the pathfinding axons to turn toward attractive factors and away from repulsive factors. Figure 9.76*a* shows a cultured neuron whose advancing tip has made a direct turn toward a diffusible protein called netrin, which acts as an attractant for axons growing within the early embryo. Figure 9.76*b* shows a growth cone (green) making contact with a cell that is expressing another protein called ephrin (red) that also acts as a neuronal guidance factor. Unlike netrin, ephrin is a non-diffusible, integral protein of the plasma membrane that binds to an ephrin receptor on the surface of the growth cone. The growth cone is making contact with the ephrin-expressing cell by means of its long filopodia, which serve a sensory function. Ultimately, the correct wiring of the entire nervous system depends on the uncanny ability of embryonic growth cones to make the proper steering “decisions” that lead them to the target organ they must innervate.

Changes in Cell Shape during Embryonic Development Each part of the body has a characteristic shape and

internal architecture that arises during embryonic development: the spinal cord is basically a hollow tube, the kidney consists of microscopic tubules, each lung is composed of microscopic air spaces, and so forth. Numerous cellular activities are necessary for the development of the characteristic morphology of an organ, including programmed changes in cell shape. Changes in cell shape are brought about largely by changes in the orientation of cytoskeletal elements within the cells. One of the best examples of this phenomenon is seen in the early stages of the development of the nervous system.

Toward the end of gastrulation in vertebrates, the outer (ectodermal) cells situated along the embryo’s dorsal surface elongate and form a tall epithelial layer called the *neural plate* (Figure 9.77*a,b*). The cells of the neural plate elongate as microtubules become oriented with their long axes parallel to that of the cell (inset, Figure 9.77*b*). Following elongation, the cells of the neural epithelium become constricted at one end, causing them to become wedge shaped and the entire layer of cells to curve inward (Figure 9.77*c*). This latter change in cell shape is brought about by the contraction of a band of microfilaments that assemble in the cortical region of the cells just beneath the apical cell membrane (inset, Figure 9.77*c*). Eventually, the curvature of the neural tube causes the outer edges to contact one another, forming a cylindrical, hollow tube (Figure 9.77*d,e*) that will give rise to the animal’s entire nervous system.

REVIEW

1. List the various types of actin-binding proteins and one function of each type.
2. Describe the steps taken by a mammalian cell crawling over a substratum.
3. Describe the role of actin filaments in the activities of the growth cone of a neuron.

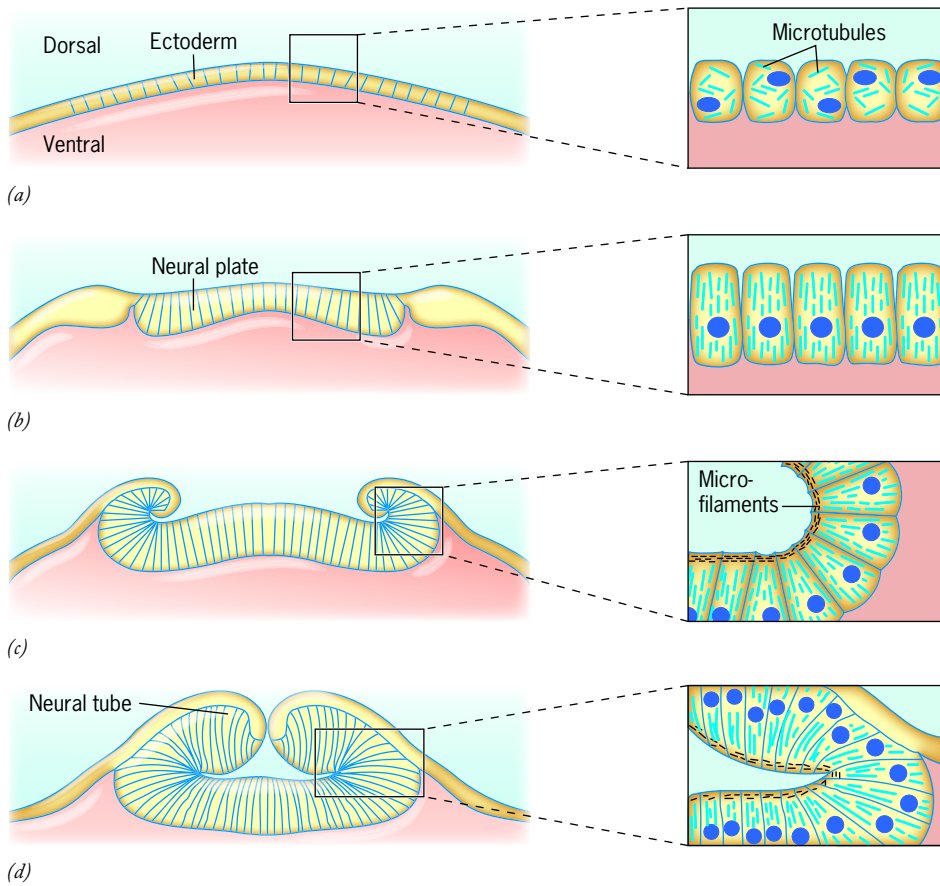

Figure 9.77 Early stages in the development of the vertebrate nervous system. (a–d) Schematic drawings of the changes in cell shape that cause a layer of flattened ectodermal cells at the mid-dorsal region of the embryo to roll into a neural tube. The initial change in height of the cells is thought to be driven by the orientation and elongation of microtubules, whereas the rolling of the plate into a tube is thought to be driven by contractile forces generated by actin filaments at the apical ends of the cells. Synopsis

The cytoskeleton is composed of three distinct types of fibrous structures: microtubules, intermediate filaments, and microfilaments (actin filaments), which participate in a number of cellular activities. Collectively, the elements of the cytoskeleton function as a structural support that helps maintain the shape of the cell; as an internal framework responsible for positioning the various organelles within the cell interior; as part of the machinery required for the movement of materials and organelles within cells; and as force-generating elements responsible for the movement of cells from one place to another. (p. 324)

Microtubules are hollow, tubular structures 25 nm in diameter that are assembled from the protein tubulin and, in addition to the cytoskeleton, form part of the mitotic spindle, centrioles, and the core of cilia and flagella. Microtubules are polymers assembled from $\alpha\beta$ -tubulin heterodimers that are arranged in rows, or protofilaments. Many of the properties of microtubules, including their stability and capabilities for interaction, are influenced by members of a group of microtubule-associated proteins (MAPs). Because of their stiffness, microtubules often act in a supportive capacity not unlike the way that steel girders provide support for a tall building. The structural role of

microtubules is most evident on examination of highly elongated processes, such as axons, which are filled with microtubules oriented parallel to the long axis of the process. Microtubules also function in such diverse activities as influencing the deposition of cellulose in a plant cell wall; maintaining the position of the membranous organelles of the biosynthetic pathway including the ER and Golgi complex; and the movement of vesicles and other materials between the cell body and axon terminals of a nerve cell. (p. 330)

Three families of motor proteins have been identified and characterized: kinesins and dyneins, which move along microtubules, and myosins, which move along microfilaments. These motor proteins are able to convert chemical energy stored in ATP into mechanical energy that is used to move cellular cargo attached to the motor. Forces are generated as conformational changes in the motor protein are coupled to a chemical cycle involving the binding and hydrolysis of nucleotides and the release of the bound products. (p. 334)

In most cases, kinesins and cytoplasmic dynein move materials along microtubules in opposite directions. Both kinesin and cytoplasmic dyneins are motor proteins with globular heads that interact with microtubules and act as force-generating engines and an opposite end that binds to specific types of cargo to be transported. Kinesin moves materials toward the plus end of a microtubule, cytoplasmic dynein toward the minus end. Kinesin has been implicated in the movement of ER-derived vesicles, endosomes, lysosomes, and secretory granules and is the primary motor protein mediating anterograde transport in an axon (from cell body to axon terminus). (p. 334)

The nucleation of microtubules in vivo occurs in association with a variety of MTOCs (microtubule organizing centers). In animal cells, the microtubules of the cytoskeleton typically form in association with the centrosome, a complex structure that contains two barrel-shaped centrioles surrounded by amorphous, electron-dense pericentriolar material. Centrioles contain nine evenly spaced fibrils, each of which is composed of three microtubules, and they usually occur in pairs whose members are oriented at right angles to one another. Microtubules typically radiate outward from the pericentriolar material, which contains the components required for microtubule nucleation. The microtubules that form the fibers of a cilium or flagellum originate from a basal body, which has essentially the same structure as a centriole. Centrosomes, basal bodies, and other MTOCs, share a common protein component called γ -tubulin, which plays a key role in nucleation of microtubules. (p. 339)

The microtubules of the cytoskeleton are dynamic polymers that are subject to shortening, lengthening, disassembly, and reassembly. Disassembly of the microtubular cytoskeleton can be induced by a number of agents including colchicine, cold temperature, and elevated Ca^{2+} concentration. The microtubules of the cytoskeleton are normally disassembled prior to cell division, and the tubulin subunits are reassembled as part of the mitotic spindle. This process of disassembly and reassembly is reversed following division. At any given moment, some microtubules of the cytoskeleton are growing in length while others are shrinking. When individual microtubules are followed over time, they are seen to switch back and forth between growing and shrinking phases, a phenomenon known as dynamic instability. Both growth and shrinkage occur predominantly, if not exclusively, at the plus end of the polymer—the end opposite the MTOC. Tubulin dimers that are polymerized into a microtubule contain a GTP molecule that is hydrolyzed soon after its incorporation into the polymer. During periods of rapid polymerization, the hydrolysis of GTP bound to incorporated tubulin dimers lags behind the incorporation of new dimers, so that the end of the microtubule contains a cap of tubulin-GTP dimers that favors the addition of

subunits and growth of the microtubule. Assembly and disassembly may also be governed by Ca^{2+} concentration, +TIP-binding proteins, and the presence of specific MAPs. (p. 341)

Cilia and flagella contain a core structure, the axoneme, that is composed of an array of microtubules that support the organelle as it projects from the cell surface and provide the machinery for generating the forces required for locomotion. In cross section, an axoneme is seen to consist of nine outer doublet microtubules (a complete A microtubule and an incomplete B microtubule) surrounding a pair of single microtubules. A pair of arms projects from the A microtubule of each doublet. The arms are composed of ciliary dynein, a motor protein that uses the energy released by ATP hydrolysis to generate the forces required for ciliary or flagellar bending. This is accomplished as the dynein arms of one doublet attach to the B microtubule of the neighboring doublet and then undergo a conformational change that causes the A microtubule to slide a perceptible distance. Sliding on one side of the axoneme alternates with sliding on the other side so that a part of the cilium or flagellum first bends in one direction and then in the opposite direction. Microtubule sliding has been demonstrated directly by attaching beads to the doublets of demembrated axonemes and following their relative movements during reactivation. (p. 345)

Intermediate filaments (IFs) are ropelike cytoskeletal structures approximately 10 nm in diameter that, depending on the cell type, may be composed of a variety of different protein subunits capable of assembling into similar types of filaments. Unlike microtubules, intermediate filaments are composed of symmetric building blocks (tetrameric subunits), which assemble into filaments that lack polarity. IFs are resistant to tensile forces and relatively insoluble; yet, like the other two types of cytoskeletal elements, they are dynamic structures that rapidly incorporate labeled subunits that are injected into a cell. Assembly and disassembly are thought to be controlled primarily by phosphorylation and dephosphorylation. IFs provide mechanical stability to cells and are required for specialized, tissue-specific functions. (p. 354)

Actin filaments (or microfilaments) are 8 nm in diameter, composed of a double-helical polymer of the protein actin, and play a key role in virtually all types of contractility and motility within cells. Depending on the type of cell and the activity, actin filaments can be organized into highly ordered arrays, loose ill-defined networks, or tightly held bundles. Actin filaments are often identified by their ability to bind to the S1 myosin fragment, which also reveals the polarity of the filament. Although both ends of an actin filament can gain or lose subunits, the barbed (or plus end) is the preferred site of subunit addition, and the pointed (or minus end) is the preferred site of subunit loss. To be incorporated onto the growing end of a filament, an actin subunit must be bound to an ATP, which is hydrolyzed soon after its incorporation. Cells maintain a dynamic equilibrium between the monomeric and polymeric forms of actin, which can be altered by changes in a variety of local conditions. The role of actin filaments in a particular process is readily tested by treating the cells with cytochalasin, which promotes the depolymerization of the filament, or with phalloidin, which prevents it from disassembling and participating in dynamic activities. (p. 356)

The forces responsible for microfilament-dependent processes may be generated by the assembly of the actin filament or, more often, as the result of interaction with the motor protein myosin. The propulsion of certain bacteria through the cytoplasm of an infected phagocyte is driven by actin polymerization. Myosins are divided into two classes: conventional (type II) myosins and unconventional (types I and III–XVIII) myosins. Myosin II is the molecular motor that generates force in the various types of muscle

tissues and also a variety of nonmuscle activities, including cytokinesis. Myosin II molecules contain a long, rod-shaped tail attached at one end to two globular heads. The heads bind the actin filament, hydrolyze ATP, and undergo the conformational changes required for force generation. The neck is thought to act as a lever arm that amplifies conformational changes of the head. The fibrous tail mediates the assembly of myosin into bipolar filaments. Most unconventional myosins have a single head and variable tail domains; they are implicated in cell motility and organelle transport. (p. 360)

The contraction of a skeletal muscle fiber results from the sliding of actin-containing thin filaments toward the center of the individual sarcomeres of a myofibril, and it is driven by forces generated in the myosin cross-bridges that extend outward from the thick filaments. Changes that occur during the shortening of a muscle fiber are reflected in changes in the banding pattern of the sarcomeres as the Z lines at the ends of the sarcomere are moved toward the outer edges of the A bands. Contraction is triggered as an impulse penetrates into the interior of the muscle fiber along the membranous transverse tubules, stimulating the release of Ca^{2+} from storage sites in the sarcoplasmic reticulum (SR). The binding of calcium ions to troponin molecules of the thin filaments causes a change in conformation that moves the tropomyosin molecules to a position that exposes the myosin-binding sites on the actin subunits of the thin filament. The subsequent interaction between myosin and actin triggers filament sliding. (p. 364)

Nonmuscle motility and contractility depend on some of the same proteins found in muscle cells, but they are arranged in less ordered, more labile, and transient configurations. Nonmuscle

motility depends on actin, usually in conjunction with myosin. The organization and behavior of actin filaments are determined by a variety of actin-binding proteins that affect the assembly of the actin filaments, their physical properties, and their interactions with one another and with other cellular organelles. Included on the list are proteins that nucleate actin filaments; proteins that sequester actin monomers and prevent their polymerization; proteins that form a cap at one end of an actin filament, which may block filament growth or lead to filament disassembly; proteins that cross-link actin filaments into bundles, loose meshworks, or three-dimensional gels; proteins that sever actin filaments; and proteins that link actin filaments to the inner surface of the plasma membrane. (p. 371)

Examples of nonmuscle motility and contractility include the crawling of cells over a substratum and axonal outgrowth. Cell crawling is typically accomplished by a flattened, veil-like projection, or lamellipodium, that forms at the cell's leading edge. As a lamellipodium extends from the cell, it adheres to the underlying substratum at specific points, providing temporary sites of anchorage for the cell to crawl over. The protrusion of a lamellipodium is associated with the nucleation and polymerization of actin filaments and their association with various types of actin-binding proteins. The forces required for lamellipodial protrusion result from actin polymerization. The tip of an elongating axon consists of a growth cone, which resembles a highly motile, crawling fibroblast and contains several types of locomotor protrusions, including a lamellipodium, microspikes, and filopodia. The growth cone acts both to explore the environment and to elongate the axon along an appropriate pathway. (p. 374)

Analytic Questions

1. If a myofibril were pulled so that the sarcomeres increased in length by approximately 50 percent, what effect would you expect this to have on the contractile ability of the myofibril? Why? What effects would this have on the H, A, and I bands?
2. What are three different radioactively or fluorescently labeled substances that you might inject into a cell that would label the microtubules of a cell without labeling the other cytoskeletal elements?
3. What are two types of nonmuscle motility that might be unaffected by antibodies against both myosin I and myosin II? Why?
4. A centriole contains _____ complete microtubules, and a cilium contains _____ complete microtubules.
5. Microtubules can be formed *in vitro* from tubulin that is bound to GTP analogues that (unlike GTP) cannot be hydrolyzed. What properties would you expect these microtubules to possess?
6. List two things you could do that would shift the dynamic equilibrium of an *in vitro* preparation of tubulin and microtubules toward the formation of microtubules. List two treatments that would shift the equilibrium in the opposite direction.
7. It was noted that a demembrated ciliary or flagellar axoneme is able to beat with a normal frequency and pattern. Can you conclude that the plasma membrane is not important in ciliary or flagellar function?
8. Because cytoplasmic vesicles are seen to move in both directions within an axon, can you conclude that some microtubules are oriented with their plus end facing the axon terminus and others oriented with the opposite polarity? Why or why not?
9. Would you agree with the statement that the centrosome plays a key role in determining the rates of lengthening and shortening of the microtubules of an animal cell? Why or why not?
10. If you were comparing the molecular structure of kinesin and myosin, which are thought to have been derived from a common ancestral protein, which part (heads or tails) would you expect to be most similar between them? Why?
11. Figure 9.31a shows the appearance of a cross section of a ciliary axoneme cut at an interior portion of the cilium. How might the image of a cross section differ if it had been cut very near the tip of a cilium at the beginning of the recovery stroke?
12. If an individual kinesin molecule can move at a rate of 800 nm/sec in an *in vitro* motility assay, what is the maximal turnover rate (ATP molecules hydrolyzed per second) by one of the molecule's motor domains?
13. Why do you suppose more can be learned about microtubule dynamics by injecting fluorescent tubulin into a cell than radioactively labeled tubulin? Can you think of a question that would be better answered by radioactively labeled tubulin?
14. Suppose you discovered that a mouse lacking copies of one of the conventional kinesin genes appeared to show no ill effects and lived to a ripe old age. What could you conclude about the role of this kinesin in intracellular locomotion?
15. Which type of vertebrate tissue would you expect to be an excellent source of tubulin? of actin? of keratin? Which protein would you expect to be the least soluble and most difficult to extract? What types of protein would you expect as contaminants in a preparation of tubulin? Which in a preparation of actin?

16. Actin is one of the most evolutionarily conserved proteins. What does this tell you about the structure and function of this protein in eukaryotic cells?
17. According to data from genome sequences, cytoplasmic dynein is absent in some plants (e.g., *Arabidopsis*) and present in others (e.g., rice). Does this finding surprise you? What else might you do to confirm or refute such a statement? How is it possible that higher plant cells could operate without cytoplasmic dynein?
18. Myosin II action (Figure 9.61) differs from that of kinesin (Figure 9.15) in that one of the kinesin heads is always in contact with a microtubule, whereas both myosin heads become completely detached from the actin filament. How are these differences correlated with the two types of motor activities in which these proteins engage?
19. The microtubules of an axon are thought to be nucleated at the centrosome, then severed from their nucleation site and moved into the axon. It was noted in the text that cytoplasmic dynein is responsible for the retrograde movement of organelles in axons, yet this same motor is thought to mediate the anterograde movement of microtubules in these same cellular processes. How is it possible that the same minus end-directed motor can be involved in both anterograde and retrograde movements?
20. Motor proteins are often described as mechanoenzymes. Why? Could this same term be applied to virtually all enzymes? Why or why not?

EXPERIMENTAL PATHWAYS: The Chemical Nature of the Gene

Our concept of the gene has undergone a remarkable evolution as biologists have learned more and more about the nature of inheritance. The earliest studies revealed genes to be discrete factors that were retained throughout the life of an organism and then passed on to each of its progeny. Over the following century, these hereditary factors were shown to reside on chromosomes and to consist of DNA, a macromolecule with extraordinary properties. Figure 10.1 provides an overview of some of the early milestones along this remarkable journey of discovery, capped by the description of the double helical structure of DNA in 1953. In the decades that followed this turning point, a major branch of molecular biology began to focus on the **genome**, which is the collective body of genetic information that is present in a species. A genome contains all of the genes required to “build” a particular organism. During the past decade or so, collaborations by laboratories around the world have uncovered the complete nucleotide sequences of many different genomes, including that of our own species and the chimpanzee, our closest living relative. For the first time in human history, we have the means to reconstruct the genetic path of human evolution by comparing corresponding regions of the genome in related organisms. We can learn which regions of our genome have been duplicated and which have been lost since our split from a common ancestor; we can observe which nucleotides in a

Model of DNA built by James Watson and Francis Crick at Cambridge University, 1953. Inset shows a photograph taken by Rosalind Franklin of the X-ray diffraction pattern of a DNA fiber that suggested the helical nature of DNA. (SCIENCE & SOCIETY/SUPERSTOCK; INSET: SCIENCE SOURCE/PHOTO RESEARCHERS, INC.)

particular gene or regulatory region have undergone change and which have remained constant; most important, we can infer which parts of our genome have been subject to natural selection and which have been free to drift randomly as time has

passed. We have also begun to use this information to learn more about our history as a species: when and where we arose, how we are related to one another, and how we came to occupy the regions of the Earth that we have.

10.1 | The Concept of a Gene as a Unit of Inheritance

The science of genetics began in the 1860s with the work of Gregor Mendel, a friar at the abbey of St. Thomas located in today's Czech Republic. Mendel's laboratory was a small garden plot on the grounds of the abbey. We don't know exactly what motivated Mendel to begin his studies, but he evidently had a clear experimental plan in mind: his goal was to mate, or *cross*, pea plants having different inheritable characteristics and to determine the pattern by which these characteristics were transmitted to the offspring. Mendel chose the garden pea for a number of practical reasons, not the least of which was that he could purchase a variety of seeds that would give rise to plants with distinct characteristics. Mendel chose to focus on seven clearly definable traits, including plant height and flower color, each of which occurred in two alternate and clearly identifiable forms (Table 10.1). Mendel crossbred plants through several generations and counted the number of individuals having various characteristics. After several years of research, Mendel drew the following conclusions, which are expressed below in modern genetic terminology.

1. The characteristics of the plants were governed by distinct factors (or units) of inheritance, which were later termed

genes. An individual plant possessed two copies of a gene that controlled the development of each trait, one derived from each parent. The two copies could be either identical to one another or nonidentical. Alternate forms of a gene are called **alleles**. For each of the seven traits studied, one of the two alleles was dominant over the other. When both were present together in the same plant, the existence of the recessive allele was masked by the dominant one.

2. Each reproductive cell (or *gamete*) produced by a plant contained only one copy of a gene for each trait. A particular gamete could have either the recessive or the

Table 10.1 Seven Traits of Mendel's Pea Plants

Trait	Dominant allele	Recessive allele
Height	Tall	Dwarf
Seed color	Yellow	Green
Seed shape	Round	Angular (wrinkled)
Flower color	Purple	White
Flower position	Along stem	At stem tips
Pod color	Green	Yellow
Pod shape	Inflated	Constricted

(See www.mendelweb.org for a discussion of Mendel's work.)

dominant allele for a given trait, but not both. Each plant arose by the union of a male and female gamete. Consequently, one of the alleles that governed each trait in a plant was inherited from the female parent, and the other allele was inherited from the male parent.

- Even though the pair of alleles that governed a trait remained together throughout the life of an individual plant, they became separated (or *segregated*) from one another during the formation of the gametes. This finding formed the basis of Mendel's law of segregation.
- The segregation of the pair of alleles for one trait had no effect on the segregation of alleles for another trait. A particular gamete, for example, could receive a paternal gene governing seed color and a maternal gene governing seed shape. This finding formed the basis of Mendel's law of independent assortment.

Mendel presented the results of his work to the members of the Natural History Society of Br \ddot{u} nn; the minutes of the meeting record no discussion of his presentation. Mendel's experiments were published in the Br \ddot{u} nn society's journal in 1866, where they generated no interest whatsoever until 1900, 16 years after his death. In that year, three European botanists *independently* reached the same conclusions, and all three rediscovered Mendel's paper, which had been sitting on the shelves of numerous libraries throughout Europe for 35 years.

10.2 | Chromosomes: The Physical Carriers of the Genes

Although Mendel provided convincing evidence that inherited traits were governed by discrete factors, or genes, his studies were totally unconcerned with the physical nature of these elements or their location within the organism. During the time between Mendel's work and its rediscovery, a number of biologists became concerned with this other aspect of heredity—its physical basis within the cell.

The Discovery of Chromosomes

By the 1880s, a number of European biologists were closely following the activities of cells and using rapidly improving light microscopes to observe newly discernible cell structures. None of these scientists was aware of Mendel's work, yet they understood that whatever it was that governed inherited characteristics would have to be passed from cell to cell and from generation to generation. This, by itself, was a crucial realization; all the genetic information needed to build and maintain a complex plant or animal had to fit within the boundaries of a single cell. Observations of dividing cells by the German biologist Walther Flemming in the early 1880s revealed that the cytoplasmic contents were shuttled into one daughter cell or the other as a matter of chance, depending on the plane through which the furrow happened to divide the cell. In contrast, the cell appeared to go to great lengths to divide the nuclear contents equally between the daughters. During cell division, the

material of the nucleus became organized into visible "threads," which were named **chromosomes**, meaning "colored bodies."

At about this time, the process of fertilization was observed, and the roles of the two gametes—the sperm and the egg—were described (Figure 10.2). Even though the sperm is a tiny cell, it was known to be as important genetically as the much larger egg. What was it that these two very different cells had in common? The most apparent feature was the nucleus and its chromosomes. The importance of the chromosomes contributed by the male became evident in a study by the German biologist Theodore Boveri on sea urchin eggs that had been fertilized by two sperm rather than just one, as is normally the case. This condition, referred to as *polyspermy*, is characterized by disruptive cell divisions and the early death of the embryo. Why should the presence of one extra tiny sperm nucleus within the very large egg have such drastic consequences? The second sperm donates an extra set of chromosomes and an extra centriole (page 339). These additional components lead to abnormal cell divisions in the embryo during which daughter cells receive variable numbers of chromosomes. Boveri concluded that the orderly process of normal development is "dependent upon a particular combination of chromosomes; and this can only mean that the individual chromosomes must possess different qualities." This was the first evidence of a *qualitative* difference among chromosomes.

Events occurring after fertilization were followed most closely in the roundworm *Ascaris*, whose few chromosomes are large and were as readily observed in the nineteenth century as in introductory biology laboratories today. In 1883, the Belgian biologist Edouard van Beneden noted that the cells of the worm's body had four large chromosomes, but that the male and female nuclei present in the egg just after fertilization (before the two

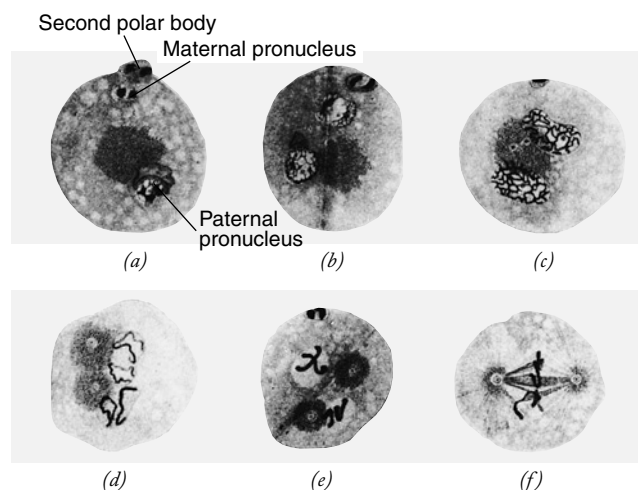

Figure 10.2 Events occurring in the roundworm *Ascaris* following fertilization, as reported in a classic nineteenth-century investigation. Both the male and female gamete are seen to contain two chromosomes. Fusion of the sperm and egg nuclei (called pronuclei) in the egg cytoplasm (between *e* and *f*) produces a zygote containing four chromosomes. The second polar body shown in *a* is a product of the previous meiosis as described in Section 14.3. (FROM T. BOVERI, JENAISCHE ZEIT 22:685, 1888.)

nuclei fuse with one another) had but two chromosomes apiece (Figure 10.2). About this same time, the process of meiosis was described, and in 1887 the German biologist August Weismann proposed that meiosis included a “reduction division” during which the chromosome number was reduced by half prior to formation of the gametes. If a reduction division did not occur, and each gamete contained the same number of chromosomes as an adult cell, then the union of two gametes would double the number of chromosomes in the cells of the progeny. The number of chromosomes would double with each and every generation, which obviously does not and cannot occur.¹

Chromosomes as the Carriers of Genetic Information

The rediscovery of Mendel’s work and its confirmation had an immediate influence on research in cell biology. Whatever their physical nature, the carriers of the hereditary units would have to behave in a manner consistent with Mendelian principles. In 1903, Walter Sutton, a graduate student at Columbia University, published a paper that pointed directly to the chromosomes as the physical carriers of Mendel’s genetic factors. Sutton followed the development of sperm cells in the grasshopper, which like *Ascaris*, has large, easily observable chromosomes. The cells that give rise to sperm are called spermatogonia, and they can undergo two very different types of cell division. A spermatogonium can divide by mitosis to produce more spermatogonia, or it can divide by meiosis to produce cells that differentiate into sperm (see Figure 14.41). On examination of the mitotic stages of grasshopper spermatogonia, Sutton counted 23 chromosomes. Careful examination of the shapes and sizes of the 23 chromosomes suggested that they were present in “look-alike” pairs. Eleven pairs of chromosomes could be distinguished together with one additional chromosome, termed an *accessory chromosome* (and later shown to be a sex-determining X chromosome), that was not part of an obvious pair. Sutton realized that the presence in each cell of pairs of chromosomes, or **homologous chromosomes**, as they were soon called, correlated perfectly with the pairs of inheritable factors uncovered by Mendel.

When Sutton examined the chromosomes in cells just beginning meiosis, he found that the members of each pair of chromosomes were associated with one another, forming a complex called a *bivalent*. Eleven bivalents were visible, each showing a cleft along its length where the two homologous chromosomes were associated (Figure 10.3). The ensuing first meiotic division separated the two homologous chromosomes into separate cells. This was the reduction division proposed 15 years earlier by Weismann on theoretical grounds. Here also was the physical basis for Mendel’s proposal that hereditary factors exist in pairs that remain together throughout the life of an individual and then separate from one another upon formation of the gametes. The reduction division observed by Sutton explained several of Mendel’s other findings: gametes could contain only one version (allele) of each gene; the num-

Figure 10.3 Homologous chromosomes. Sutton’s drawing of the homologous chromosomes of the male grasshopper that have associated during meiotic prophase to form bivalents. Eleven pairs of homologous chromosomes (*a–k*) and an unpaired X chromosome were observed. (W. S. SUTTON, BIOL. BULLETIN 4:24, 1902. BIOLOGICAL BULLETIN BY MARINE BIOLOGICAL LABORATORY (WOODS HOLE, MASS.) COPYRIGHT 1902. REPRODUCED WITH PERMISSION OF MARINE BIOLOGICAL LABORATORY IN THE FORMAT TEXTBOOK VIA COPYRIGHT CLEARANCE CENTER.)

ber of gametes containing one allele was equal to the number containing the other allele; and the union of two gametes at fertilization would produce an individual with two alleles for each trait. But many questions remained unanswered. For instance, how were the genes organized within the chromosomes, and could the location of specific genes be determined?

The Chromosome as a Linkage Group As clearly as Sutton saw the relationship between chromosome behavior and Mendel’s alleles, he saw one glaring problem. Mendel had examined the inheritance of seven traits and found that each was inherited independently of the others. This observation formed the basis of Mendel’s law of independent assortment. But if genes are packaged together on chromosomes, like beads on a string, then genes should be passed from parent to offspring in packages, just as intact chromosomes are passed to the next generation. Genes on the same chromosome should act as if they are *linked* to one another; that is, they should be part of the same **linkage group**.

How is it that all seven of Mendel’s traits assorted independently? Were they all on different linkage groups, that is, different chromosomes? As it happens, the garden pea has seven pairs of homologous chromosomes. The genes that govern each of Mendel’s traits either occur on different chromosomes or are so far apart from one another on the same chromosome that they act independently (page 391). Sutton’s prophecy of linkage groups was soon confirmed. Within a couple of years, genes for two traits in sweet peas (flower color and pollen shape) were shown to be linked; other evidence for chromosomal linkage rapidly accumulated.

¹Readers who have forgotten the events that occur during meiosis might want to read through Section 14.3, which discusses this pivotal event in the life cycle of eukaryotic organisms.

Genetic Analysis in *Drosophila*

Research in genetics soon came to focus on one particular organism, the fruit fly, *Drosophila* (Figure 10.4). Fruit flies have a generation time (from egg to sexually mature adult) of about 10 days and can produce up to 1000 eggs in a lifetime. In addition, fruit flies are very small, so a large number could be kept on hand; they were easy to house and breed; and they were very inexpensive to maintain. In 1909, fruit flies seemed like the ideal organism to Thomas Hunt Morgan of Columbia University, and he began what was to be the start of a new era in genetic research. There was one major disadvantage in beginning work with this insect—there was only one “strain” of fly available, the **wild type**. Whereas Mendel had simply purchased varieties of pea seeds, Morgan had to generate his own varieties of fruit flies. Morgan expected that variants from the wild type would appear if he bred sufficient numbers of flies. Within a year—after observing thousands of flies—he found his first **mutant**, that is, an individual having an inheritable characteristic that distinguished it from the wild type. The mutant had white eyes rather than the normal red-colored ones (Figure 10.4).

By 1915, Morgan and his students had found 85 different mutants with a wide variety of affected structures. It was apparent that on rare occasions a spontaneous change, or **mutation**, occurs within a gene, altering it permanently, so that the altered trait is passed from generation to generation. The demonstration of a spontaneous, inheritable alteration in a gene had consequences far beyond the study of *Drosophila* genetics. It suggested a mechanism for the origin of variation that exists within populations—evidence for a vital link in the theory of evolution. If variants of genes could arise spontaneously, then isolated populations could become genetically different from one another and ultimately give rise to new species.

Whereas mutations are a necessary occurrence for evolution, they are a tool for geneticists, because they provide contrast to the wild-type condition. As *Drosophila* mutants were isolated,

Figure 10.4 The fruit fly *Drosophila melanogaster*. Photograph of a wild-type female fruit fly and a mutant male that carries a mutation leading to white eyes. (COURTESY OF STANLEY J. P. IYADURAL.)

they were bred and crossbred and kept as stocks within the lab. As expected, the 85 mutations did not all assort independently; instead, Morgan found that they belonged to four different linkage groups, one of which contained very few mutant genes (only two in 1915). This finding correlated perfectly with the observation that *Drosophila* cells have four pairs of homologous chromosomes, one of which is very small (Figure 10.5). Little doubt remained that genes reside on chromosomes.

Crossing Over and Recombination

Even though the association of genes into linkage groups was confirmed, linkage between alleles on the same chromosome was found to be *incomplete*. In other words, alleles of two different genes, such as short wings and black body (as in Figure 10.7), that were originally present together on a given chromosome did not always remain together during the production of gametes. Thus maternal and paternal characteristics that were inherited by an individual on separate homologous chromosomes could be reshuffled so that they ended up on the same chromosome of a gamete. Conversely, two characteristics that were inherited together on the same chromosome could become separated from one another and end up in separate gametes.

In 1911, Morgan offered an explanation for the “breakdown” in linkage. Two years earlier, F. A. Janssens had observed that the homologous chromosomes of bivalents became wrapped around each other during meiosis (Figure 10.6). Janssens had proposed that this interaction between maternal and paternal chromosomes resulted in the breakage and exchange of pieces. Capitalizing on this proposal, Morgan suggested that this phenomenon, which he termed **crossing over** (or **genetic recombination**), could account for the appearance of offspring (*recombinants*) having unexpected combinations of genetic traits. An example of crossing over is shown in Figure 10.7.

Analyses of offspring from a large number of crosses between adults carrying a variety of alleles on the same chromosome indicated that (1) the percentage of recombination between a given pair of genes on a chromosome, such as eye color and wing length, was essentially constant from one ex-

Figure 10.5 Fruit flies have four pairs of homologous chromosomes, one of which is very small. The two dissimilar homologues are the chromosomes that determine sex. As in humans, male fruit flies are XY and females are XX.

Figure 10.6 Visualizing sites of crossing over. Homologous chromosomes wrap around each other during meiosis, as seen in this micrograph of a meiotic cell of a lily. The points at which the homologues are crossed are termed *chiasmata* (arrows) and (as discussed in Chapter 14) are sites at which crossing over had occurred at an earlier stage. (FROM A. H. SPARROW, ANNALS OF THE NEW YORK ACADEMY OF SCIENCES, 1508,1951. THIS MATERIAL IS USED BY PERMISSION OF JOHN WILEY & SONS.)

periment to another, and (2) the percentages of recombination between different pairs of genes, such as between eye color and wing length versus eye color and body color, could be very different.

The fact that a given pair of genes gave the same approximate frequency of recombination in every cross strongly suggested that the positions of the genes along the chromosome (their **loci**) were fixed and did not vary from one fly to the next. If the locus of each gene is fixed, then the frequency of recombination between two genes provides a measure of the distance that separates those two genes. The more room between two sites on a chromosome for breakage to occur, the more likely it is that a break would occur between those two sites and, therefore, the greater the recombination frequency. In 1911, Alfred Sturtevant, an undergraduate at Columbia University who was working in Morgan's laboratory, conceived the idea that recombination frequencies could be used to map the relative positions of individual genes along a given chromosome. An example of the underlying principles of this mapping procedure is illustrated in Figure 10.7. In this example, the genes for wing length and body color in *Drosophila* are situated at a considerable distance from one another on the chromosome and, therefore, are likely to become unlinked by an intervening breakage and crossover. In contrast, the genes for eye color and body color are situated very close to one another on the chromosome and consequently are less likely to become unlinked. Using recombination frequencies,

Figure 10.7 Crossing over provides the mechanism for reshuffling alleles between maternal and paternal chromosomes. (a) Simplified representation of a single crossover in a *Drosophila* heterozygote ($BbWw$) at chromosome number 2 and the resulting gametes. If either of the crossover gametes participates in fertilization, the offspring will have a chromosome with a combination of alleles that was not present on a single chromosome in the cells of either parent. (b) Bivalent (tetrad) formation during meiosis, showing three crossover intersections (chiasmata, indicated by red arrows).

Sturtevant—who became one of the century's most prominent geneticists—began to construct detailed maps of the serial order of genes along each of the four chromosomes of the fruit fly. Recombination frequencies have since been used to prepare chromosomal maps from viruses and bacteria as well as a large variety of eukaryotic species.

Mutagenesis and Giant Chromosomes

During the early period of genetics, the search for mutants was a slow, tedious procedure dependent on the *spontaneous* appearance of altered genes. In 1927, using a special strain of fruit flies designed to reveal the presence of recessive alleles, H. J. Muller found that flies subjected to a sublethal dose of X-rays displayed more than 100 times the spontaneous mutation rate exhibited by nonirradiated controls. This finding had important consequences. On the practical side, the use of mutagenic agents, such as X-rays and ultraviolet radiation, greatly increased the number of mutants available for genetic research. The finding also pointed out the hazard of the increasing use of radiation in the industrial and medical fields. Today, mutations in *Drosophila* are most often generated by adding a chemical mutagen (ethyl methane sulfonate) to the animals' feed.

The rediscovery in 1933 of giant chromosomes in certain insect cells by Theophilus Painter of the University of Texas illustrates a basic principle in biology. There is such remarkable variability among organisms, not only at the obvious macroscopic levels, but also at the cellular and subcellular levels, that often one particular type of cell may be much better suited for a particular type of research than others. Cells from the larval salivary gland of *Drosophila* contain chromosomes that are about 100 times thicker than the chromosomes found in most other cells of the organism (Figure 10.8a). During larval development, these cells cease dividing, but they keep growing. DNA replication continues, providing the additional genetic material needed to support the high level of secretory activity of these enormous cells. The duplicated DNA strands remain attached to each other in perfect side-by-side alignment (inset of Figure 10.8a), producing giant chromosomes with as many as 1024 times the number of DNA strands of normal chromosomes.

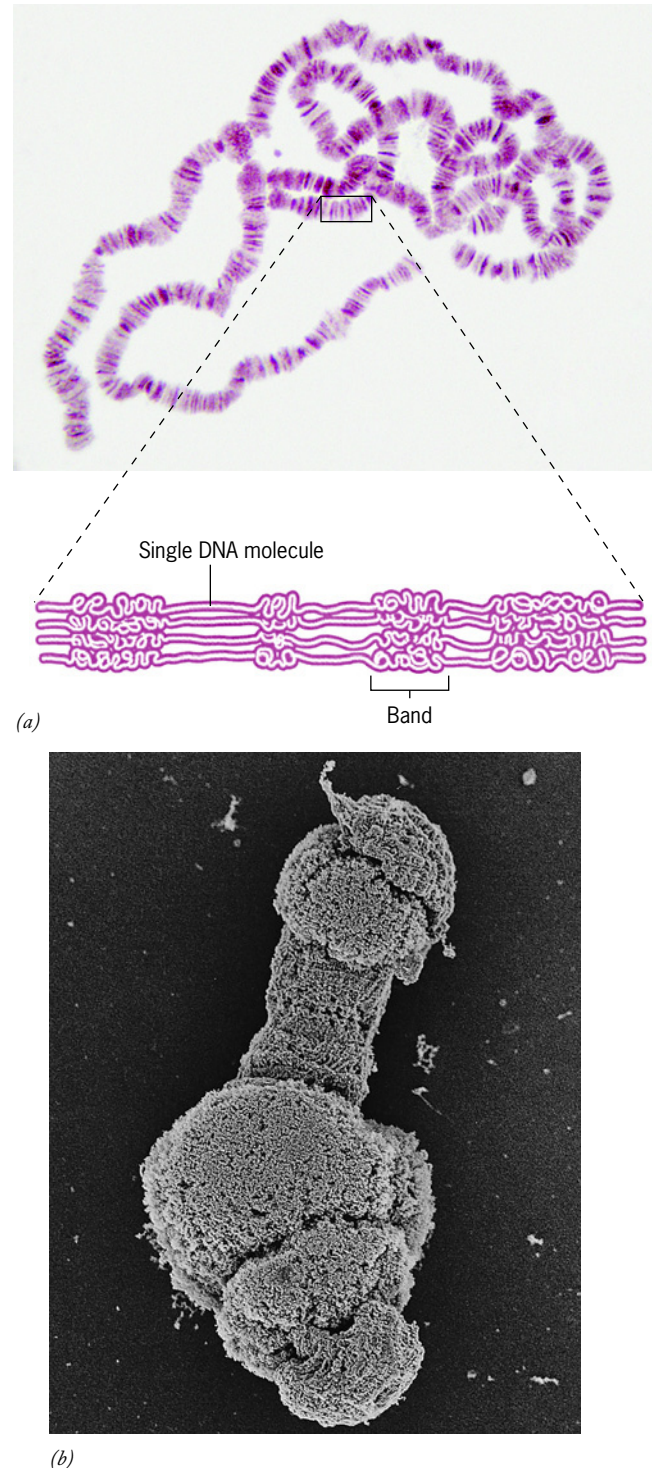

These unusual **polytene chromosomes**, as they are called, are rich in visual detail, displaying about 5000 bands when stained and examined microscopically. The banding pattern is essentially constant from one individual to the next, but considerable differences are observed between the chromosomes from flies of different species of the *Drosophila* genus. Painter soon found that individual bands could be correlated with specific genes. The relative positions of these genes on the giant chromosomes agreed with those predicted on the basis of genetic maps prepared from recombination frequencies, thus providing visual confirmation of the validity of the entire mapping procedure.

Figure 10.8 Giant polytene chromosomes of larval insects. (a)

These giant polytene chromosomes from the salivary gland of a larval fruit fly show several thousand distinct, darkly staining bands. The bands have been identified as the loci of particular genes. The inset shows how polytene chromosomes consist of a number of individual DNA molecules. The stained bands on the chromosomes correspond to sites where the DNA is more tightly compacted. (b) Scanning electron micrograph of a giant polytene chromosome from a *Chironomus* larva showing how specific sites are expanded to form a "puff." Chromosome puffs are sites where DNA is being very actively transcribed.

(A: ANDREW SYRED/PHOTO RESEARCHERS, INC.; B: FROM TERRY D. ALLEN AND CLAUS PELLING, J. CELL SCIENCE, COVER OF VOL. 93, PART 4, 1989. REPRODUCED WITH PERMISSION OF THE COMPANY OF BIOLOGISTS, LTD.)

Giant insect chromosomes have been useful in other ways. Comparisons of banding patterns among polytene chromosomes of different species have provided an unparalleled opportunity for the investigation of evolutionary changes at the chromosome level. In addition, these chromosomes are not inert cellular objects but dynamic structures in which certain regions become "puffed out" at particular stages of development (Figure 10.8b). These chromosome puffs are sites where DNA is being transcribed at a very high level, providing one of the best systems available for the direct visualization of gene expression.

REVIEW

1. What is a linkage group? What is its relationship to a chromosome? How can one determine the number of linkage groups in a species?
2. How do genetic mutations help in mapping the location of genes on a chromosome?
3. What is meant by incomplete linkage? What does this have to do with pairing of homologous chromosomes during meiosis?
4. How do polytene chromosomes of an insect differ from normal chromosomes?

10.3 | The Chemical Nature of the Gene

Classical geneticists uncovered the rules governing the transmission of genetic characteristics and the relationship between genes and chromosomes. In his acceptance speech for the Nobel Prize in 1934, T. H. Morgan stated, “At the level at which the genetic experiments lie, it does not make the slightest difference whether the gene is a hypothetical unit or whether the gene is a material particle.” By the 1940s, however, a new set of questions was being considered, foremost of which was, “What is the chemical nature of the gene?” The experiments answering this question are outlined in the Experimental Pathways at the end of this chapter. Once it became evident that genes are made of DNA, biologists were faced with a host of new questions. These questions will occupy us for the remainder of the chapter.

The Structure of DNA

To understand the workings of a complex macromolecule—whether it is a protein, polysaccharide, lipid, or nucleic acid—it is essential to know how that molecule is constructed. The mystery of DNA structure was investigated by a number of laboratories in both the United States and England in the early 1950s and was solved by James Watson and Francis Crick at Cambridge University in 1953. Before describing their proposed DNA structure, let us consider the facts available at the time.

Figure 10.9 The chemical structure of DNA. (a) Model of a DNA nucleotide containing the base thymine; the molecule is deoxythymidine 5'-monophosphate (dTMP). The netlike cage represents the electron density of the atoms that make up the molecule. (b) Chemical structure of a DNA nucleotide containing the base adenosine; the molecule is deoxyadenosine 5'-monophosphate (dAMP). A nucleotide is composed of a nucleoside linked to a phosphate; the nucleoside portion of the molecule (i.e., deoxyadenosine) is enclosed by the dashed line. (c) The chemical structure of a small segment of a single DNA strand showing all four nucleotides. (A: FROM ARNON LAVIE ET AL., NATURE STR. BIOL. 4:604, 1997, FIG. 2A. REPRINTED BY PERMISSION OF MACMILLAN PUBLISHERS LIMITED.)

Base Composition The basic building block of DNA was known to be a **nucleotide** (Figure 10.9a,b) consisting of the five-carbon sugar *deoxyribose* to which one phosphate is esterified at

(a)

Phosphate

(b)

3' end

(c)

the 5' position of the sugar ring and one nitrogenous base is attached at the 1' site.² Two types of nitrogenous bases are present in a nucleic acid: **pyrimidines**, which contain a single ring, and **purines**, which contain two rings (Figure 10.9c). DNA contains two different pyrimidines, *thymine* (*T*) and *cytosine* (*C*), and two different purines, *guanine* (*G*) and *adenine* (*A*). The nucleotides are covalently linked to one another to form a linear polymer, or *strand*, with a backbone composed of alternating sugar and phosphate groups joined by 3'-5'-*phosphodiester bonds* (Figure 10.9c). The bases attached to each sugar were thought to project from the backbone like a column of stacked shelves.

A nucleotide has a polarized structure: one end, where the phosphate is located, is called the 5' *end* (pronounced “five-prime end”), while the other end is the 3' *end* (Figure 10.9b). Because each of the stacked nucleotides in a strand faces the same direction, the entire strand has a direction. One end of the strand is the 3' end, the other is the 5' end (Figure 10.9c). X-ray diffraction analysis indicated that the distance between the nucleotides of the stack was 3.4 Å (0.34 nm) and suggested the presence of a large structural repeat every 3.4 nm.

As discussed on page 421, DNA was thought for many years to consist of a simple repeating tetranucleotide (e.g., —ATGCATGCATGC—), which made it unlikely to serve as an informational macromolecule. In 1950, Erwin Chargaff of Columbia University reported an important finding that delivered the final blow to the tetranucleotide theory and provided vital information about DNA structure. Chargaff, believing that the sequence of nucleotides of the DNA molecule held the key to its importance, determined the relative amounts of each base in various samples of DNA, that is, the **base composition** of the samples. Base composition analysis of a DNA sample was performed by hydrolyzing the bases from their attached sugars, separating the bases in the hydrolysate by paper chromatography, and determining the amount of material in each of the four spots to which the bases migrated.

If the tetranucleotide theory were correct, each of the four bases in a DNA sample would be present as 25 percent of the total number. Chargaff found that the ratios of the four component bases were quite variable from one type of organism to another, often being very different from the 1:1:1:1 ratio predicted by the tetranucleotide theory. For example, the A:G ratio of the DNA of a tubercle bacillus was 0.4, whereas the A:G ratio of human DNA was 1.56. It made no difference which plant or animal tissue was used as the source of the

²It is useful to introduce a bit of terminology at this point. A molecule consisting simply of one of the four nitrogenous bases of Figure 10.9 linked to a pentose sugar moiety is known as a nucleoside. If the sugar is deoxyribose, the nucleoside is a deoxyribonucleoside. There are four major deoxyribonucleosides distinguished by the attached base: deoxyadenosine, deoxyguanosine, deoxythymidine, and deoxycytidine. If the nucleoside has one or more attached phosphate groups (generally at the 5' position, but alternatively at the 3' position), the molecule is a nucleotide. There are nucleoside 5'-monophosphates, nucleoside 5'-diphosphates, and nucleoside 5'-triphosphates, depending on the number of phosphates in the molecule. Examples of each are deoxyadenosine 5'-monophosphate (dAMP), deoxyguanosine 5'-diphosphate (dGDP), and deoxycytidine 5'-triphosphate (dCTP). A similar set of nucleosides and nucleotides involved in RNA metabolism contain the sugar ribose rather than deoxyribose. The nucleotides employed in energy metabolism, such as adenosine triphosphate (ATP), are ribose-containing molecules.

DNA; the base composition remained constant for that species. Amid this great variability in base composition of different species' DNA, an important numerical relationship was discovered. The number of purines always equaled the number of pyrimidines in a given sample of DNA. More specifically, the number of adenines always equaled the number of thymines, and the number of guanines always equaled the number of cytosines. In other words, Chargaff discovered the following rules of DNA base composition:

$$[A] = [T], [G] = [C], [A] + [T] \neq [G] + [C]$$

Chargaff's findings put the DNA molecule in a new light, giving it specificity and individuality from one organism to another. The significance of the base equivalencies, however, remained obscure.

The Watson-Crick Proposal

When protein structure was discussed in Chapter 2, the importance of secondary and tertiary structure as determinants of the protein's activity was stressed. Similarly, information about the three-dimensional organization of DNA was needed if its biological activity was to be understood. Using X-ray diffraction data (obtained by Rosalind Franklin and Maurice Wilkins at King's College London) and models constructed from cutouts of the four types of nucleotides, Watson and Crick proposed a structure of DNA that included the following elements (Figure 10.10):

1. The molecule is composed of two chains of nucleotides. This conclusion followed on the heels of an erroneous proposal by Linus Pauling, who had suggested that DNA was composed of three nucleotide strands.
2. The two chains spiral around each other to form a pair of right-handed helices. In a right-handed helix, an observer looking down the central axis of the molecule would see that each strand follows a clockwise path, as it moves away from the observer. The helical nature of DNA was revealed in the pattern of spots produced by Franklin's X-ray diffraction image (seen on page 386), which was shown to Watson during a visit to King's College.

Figure 10.10 The double helix. (*opposite*) (a) Schematic representation of the DNA double helix. (b) Space-filling model of the B form of DNA. (c) The Watson-Crick base pairs. The original model showed both A-T and G-C pairs with two hydrogen bonds; the third hydrogen bond in the G-C pair was subsequently identified by Linus Pauling. (d) Electron micrograph of DNA being released from the head of a T2 bacteriophage. This linear DNA molecule (note the two free ends) measures 68 μm in length, approximately 60 times longer than the phage head in which it is contained. (B: COURTESY OF NELSON MAX, LAWRENCE LIVERMORE NATIONAL LABORATORY AND THE DEPARTMENT OF ENERGY. C: FIGURE 28.6 ON PAGE 854 FROM VOET & VOET, BIOCHEMISTRY, 2E; COPYRIGHT 1995, JOHN WILEY & SONS, INC. THIS MATERIAL IS REPRODUCED WITH PERMISSION OF JOHN WILEY & SONS, INC. D: FROM A. K. KLEINSCHMIDT, ET AL., BIOCHIM. BIOPHYS. ACTA 61:861, 1962, WITH PERMISSION FROM ELSEVIER.)

(a)

(b)

(c)

(d)

3. The two chains comprising one double helix run in opposite directions; that is, they are *antiparallel*. Thus, if one chain is aligned in the 5' → 3' direction, its partner must be aligned in the 3' → 5' direction.
4. The –sugar–phosphate–sugar–phosphate– backbone of each strand is located on the outside of the molecule with the two sets of bases projecting toward the center. The phosphate groups give the molecule a large negative charge.
5. The bases occupy planes that are approximately perpendicular to the long axis of the molecule and are, therefore, stacked one on top of another like a pile of plates. Hydrophobic interactions and van der Waals forces (page 36) between the stacked, planar bases provide stability for the entire DNA molecule. Together, the helical turns and planar base pairs cause the molecule to resemble a spiral staircase. This manner of construction is evident in the chapter-opening photograph, which shows the original Watson–Crick model.
6. The two strands are held together by hydrogen bonds between each base of one strand and an associated base on the other strand. Because individual hydrogen bonds are weak and easily broken, the DNA strands can become separated during various activities. But the strengths of hydrogen bonds are additive, and the large numbers of hydrogen bonds holding the strands together make the double helix a stable structure.
7. The distance from the phosphorus atom of the backbone to the center of the axis is 1 nm (thus the width of the double helix is 2 nm).
8. A pyrimidine in one chain is always paired with a purine in the other chain. This arrangement produces a molecule that is 2 nm wide along its entire length.
9. The nitrogen atoms linked to carbon 4 of cytosine and carbon 6 of adenine are predominantly in the amino (NH₂) configuration (Figure 10.9c) rather than the imino (NH) form. Similarly, the oxygen atoms linked to carbon 6 of guanine and carbon 4 of thymine are predominantly in a keto (C=O) configuration rather than the enol (C–OH) form. These structural restrictions on the configurations of the bases suggested that adenine was the only purine structurally capable of bonding to thymine and that guanine was the only purine capable of bonding to cytosine. Therefore, the only possible pairs were A–T and G–C (Figure 10.10c). This fit perfectly with the base composition analysis carried out by Chargaff whose results were communicated to Watson and Crick during a meeting of the three scientists in Cambridge in 1952. Because an A–T and G–C base pair had the same geometry (Figure 10.10c), there were no restrictions on the sequence of bases; a DNA molecule could have any one of an unlimited variety of nucleotide sequences.
10. The spaces between adjacent turns of the helix form two grooves of different width—a wider *major groove* and a more narrow *minor groove*—that spiral around the outer surface of the double helix. Proteins that bind to DNA often contain domains that fit into these grooves. In many cases, a protein bound in a groove is able to read

the sequence of nucleotides along the DNA without having to separate the strands.

11. The double helix makes one complete turn every 10 residues (3.4 nm), or 150 turns per million daltons of molecular mass.
12. Because an A on one strand is always bonded to a T on the other strand, and a G is always bonded to a C, the nucleotide sequences of the two strands are always fixed relative to one another. Because of this relationship, the two chains of the double helix are said to be **complementary** to one another. For example, A is complementary to T, 5'-AGC-3' is complementary to 3'-TCG-5', and one entire chain is complementary to the other. As we shall see, complementarity is of overriding importance in nearly all the activities and mechanisms in which nucleic acids are involved.

The Importance of the Watson-Crick Proposal From the time biologists first considered DNA as the genetic material, it was expected to fulfill three primary functions (Figure 10.11):

1. **Storage of genetic information.** As genetic material, DNA must contain a stored record of instructions that determine all the inheritable characteristics that an organism exhibits. In molecular terms, DNA must contain the information for the specific order of amino acids in all the proteins that are synthesized by an organism.
2. **Replication and inheritance.** DNA must contain the information for synthesis of new DNA strands (replication). DNA replication allows genetic instructions to be transmitted from one cell to its daughter cells and from one individual to its offspring.
3. **Expression of the genetic message.** DNA is more than a storage center; it is also a director of cellular activity. Consequently, the information encoded in DNA has to be expressed in some form that can take part in events that are taking place within the cell. More specifically, the information in DNA must be used to direct the order by which specific amino acids are incorporated into a polypeptide chain.

The Watson-Crick model of DNA structure suggested a way in which the first two of these three genetic functions might be accomplished. The model strongly supported the suspicion that the information content of DNA resided in the linear sequence of its bases. A given segment of DNA would correspond to each gene. The specific sequence of nucleotides in that segment would dictate the sequence of amino acids in a corresponding polypeptide. A change in the linear sequence of nucleotides within that segment would correspond to an inheritable mutation in that gene. Differences in nucleotide sequence were presumed to form the basis of genetic variation, whether between individuals of a species or between species themselves. As discussed in the next chapter, another decade would pass before biologists would learn the mechanism by which a sequence of amino acids is encoded by a sequence of DNA nucleotides.

As for the second function, Watson and Crick's initial publication of DNA structure included a proposal as to how such a molecule might replicate. This may have been the first time that

Figure 10.11 Three functions required of the genetic material.
 (a) DNA must contain the information that encodes inheritable traits.
 (b) DNA must contain the information that directs its own duplication.
 (c) DNA must contain the information that directs the assembly of specific proteins.

a study of molecular structure led directly to a hypothesis of a basic molecular mechanism. Watson and Crick proposed that during replication, the hydrogen bonds holding the two strands of the DNA helix were sequentially broken, causing the gradual separation of the strands much like the separation of two halves of a zipper. Each of the separated strands, with its nitrogenous bases exposed, would then serve as a *template* directing the order in which complementary nucleotides become assembled to form the complementary strand. When complete, the process would generate two double-stranded DNA molecules that were (1) identical to one another and (2) identical to the original DNA molecule. According to the Watson-Crick proposal, each DNA double helix would contain one strand from the original DNA molecule and one newly synthesized strand (see Figure 13.1). As we will see in Chapter 13, the Watson-Crick proposal fared quite well in predicting the mechanism of DNA replication. Of the three primary functions listed above, only the mechanism by which DNA governs the assembly of a specific protein remained a total mystery.

Not only was the elucidation of DNA structure important in its own right, it provided the stimulus for investigating all the activities in which the genetic material must take part. Once the model for its structure was accepted, any theory of a genetic code, DNA synthesis, or information transfer had to be consistent with that structure.

DNA Supercoiling

In 1963, Jerome Vinograd and his colleagues at the California Institute of Technology discovered that two closed, circular DNA molecules of identical molecular mass could exhibit very different rates of sedimentation during centrifugation (Section 18.9). Further analysis indicated that the DNA molecule sedimenting more rapidly had a more compact shape because the molecule was twisted upon itself (Figure 10.12*a,b*), much like a rubber band in which the two ends are twisted in opposite directions or a tangled telephone cord after extended use. DNA in this state is said to be **supercoiled**. Because supercoiled DNA is more compact than its relaxed counterpart, it occupies a smaller volume and moves more rapidly in response to a centrifugal force or an electric field (Figure 10.12*c*).

Figure 10.12 Supercoiled DNA. (a,b) Electron micrographs showing the differences in conformation between a relaxed, circular molecule of phage DNA (a) and the same type of molecule in a supercoiled state (b). (c) When a mixture of relaxed and supercoiled SV40 DNA molecules are subjected to gel electrophoresis, the highly compact, supercoiled form (seen at the bottom of the gel) moves much more rapidly than the relaxed form. The DNA molecules are visualized by staining the gel with ethidium bromide, a fluorescent molecule that inserts itself into the double helix. (A,B: COURTESY OF JAMES C. WANG; C: FROM WALTER KELLER, PROC. NAT'L. ACAD. SCI. U.S.A. 72:2553, 1975.)

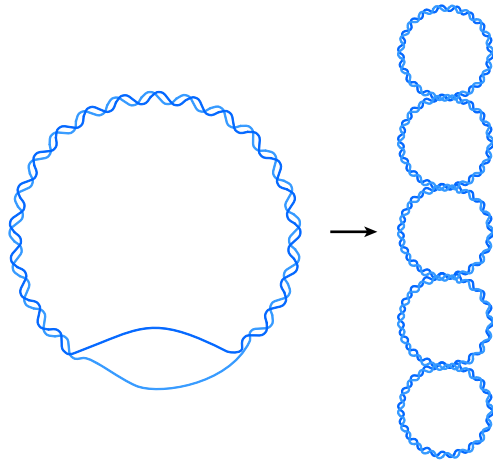

Figure 10.13 Underwound DNA. The DNA molecule at the left is underwound; that is, it has more than an average of 10 base pairs per turn of a helix. An underwound molecule spontaneously assumes a negatively supercoiled conformation, as shown on the right.

Supercoiling is best understood if one pictures a length of double-helical DNA lying free on a flat surface. A molecule in this condition has the standard number of 10 base pairs per turn of the helix and is said to be *relaxed*. The DNA would still be relaxed if both ends of the two strands were simply fused to form a circle. Consider, however, what would happen if the molecule were twisted *before* the ends were sealed. If the length of DNA were twisted in a direction opposite to that in which the duplex was wound, the molecule would tend to unwind. An *underwound* DNA molecule has a greater number of base pairs per turn of the helix (Figure 10.13). Because the molecule is most stable with 10 residues per turn, it tends to resist the strain of becoming underwound by becoming twisted upon itself into a supercoiled conformation (Figure 10.13).

DNA is referred to as *negatively supercoiled* when it is underwound and *positively supercoiled* when it is overwound. Circular DNAs found in nature (e.g., mitochondrial, viral, bacterial) are invariably negatively supercoiled. Supercoiling is not restricted to small, circular DNAs but also occurs in linear, eukaryotic DNA. For example, negative supercoiling plays a key role in allowing the DNA of the chromosomes to be compacted so as to fit inside the confines of a microscopic cell nucleus (Section 12.2). Because negatively supercoiled DNA is underwound, it exerts a force that helps separate the two strands of the helix, which is required during both replication (DNA synthesis) and transcription (RNA synthesis).

Cells rely on enzymes to change the supercoiled state of a DNA duplex. These enzymes are called **topoisomerases** because they change the *topology* of the DNA. Topoisomerases were discovered in 1971 by James Wang of the University of California, Berkeley. Cells contain a variety of topoisomerases, which can be divided into two classes. *Type I topoisomerases* change the supercoiled state of a DNA molecule by creating a transient break in one strand of the duplex. A model for the mechanism of action of human topoisomerase I is shown in Figure 10.14*a*. The enzyme cleaves one strand of the DNA and then allows the intact, complementary strand to undergo

a controlled rotation, which relaxes the supercoiled molecule. Topoisomerase I is essential for processes such as DNA replication and transcription. It functions in these activities by preventing excessive supercoiling from building up as the complementary strands of a DNA duplex separate and unwind (as in Figure 13.6). *Type II topoisomerases* make a transient break in both strands of a DNA duplex. Another segment of the DNA molecule (or a separate molecule entirely) is then transported through the break, and the severed strands are resealed. As expected, this complex reaction mechanism is accompanied by a series of dramatic conformational changes that are depicted in the model in Figure 10.14*b*. These enzymes are capable of some remarkable “tricks.” In addition to being able to supercoil and relax DNA (Figure 10.14*c*, panel 1), type II topoisomerases can tie a DNA molecule into knots or untie a DNA knot (Figure 10.14*c*, panel 2). They can also cause a population of independent DNA circles to become interlinked (*catenated*), or separate interlinked circles into individual components (Figure 10.14*c*(3),*d*). Topoisomerase II is required to disentangle DNA molecules before duplicated chromosomes can be separated during mitosis. Human topoisomerase II is a target for a number of drugs (e.g., etoposide and doxorubicin) that bind to the enzyme and prevent the cleaved DNA strands from being resealed. In doing so, these drugs preferentially kill rapidly dividing cells and are therefore used in the treatment of cancer.

REVIEW

1. What is meant by saying that a DNA strand has polarity? That the two strands are antiparallel? That the molecule has a major groove and a minor groove? That the strands are complementary to one another?
2. What is the relationship between Chargaff's analysis of DNA base composition and the structure of the double helix?
3. How do underwound and overwound DNAs differ from one another? How do the two classes of topoisomerases differ?

10.4 | The Structure of the Genome

DNA is a macromolecule—an assemblage of a large number of atoms bonded together in a defined arrangement whose three-dimensional structure can be described by techniques such as X-ray crystallography. But DNA is also an information repository, which is a property more difficult to describe in simple molecular terms. If, as noted above, a gene corresponds to a particular segment of DNA, then the sum of the genetic information that an individual organism inherits from its parents is equivalent to the sum of all of the DNA segments present in the fertilized egg at the start of life. All the individuals that make up a species population share the same set of genes, even though different individuals invariably possess slightly different versions (alleles) of many of

(d)

Figure 10.14 DNA topoisomerases. (a) A model depicting the action of human topoisomerase I. The enzyme (yellow) cuts one of the strands of the DNA (step 1), which rotates around a phosphodiester bond in the intact strand. The cut strand is then resealed (step 2). (Note: The drawing depicts a type IB topoisomerase; type IA enzymes found in bacteria act by a different mechanism.) (b) A molecular model based on X-ray crystallography depicting the action of topoisomerase II, a dimeric enzyme consisting of two identical halves. In step 1, the enzyme has bound the G-DNA segment, so named because it will form the gate through which the T-DNA (or transported DNA) segment will pass. In step 2, the dimeric enzyme has hydrolyzed two molecules of ATP and undergone a conformational change as the two ATPase domains close. In step 3, the G-segment is cleaved, and the T-segment is passed through the open “gate.” At this stage, both cut ends of the G-segment are covalently bound to the enzyme. In step 4, the two ends of the G-segment are rejoined, and the T-segment exits via the C gate. (c) Types of reactions that are catalyzed by topoisomerases. Part 1 shows supercoiling–relaxation reactions; part 2 shows knotting–unknotting reactions; part 3 shows catenation–decatenation reactions. (d) Electron micrograph of a pair of inter-connected (catenated) circular DNA molecules. Molecules of this type collect in bacteria lacking a specific topoisomerase. BERGER ET AL., NATURE 388:231, 1997; COPYRIGHT 1997; D: FROM N. COZZARELLI, CELL VOL. 71, COVER #2, 1992, WITH PERMISSION FROM ELSEVIER.)

these genes. Thus each species of organism has a unique content of genetic information, which is known as its **genome**. For humans, the genome is essentially equivalent to all of the genetic information that is present in a single (**haploid**) set of

human chromosomes, which includes 22 different autosomes and both the X and Y sex chromosomes.

The Complexity of the Genome

To understand how the complexity of the genome is determined, it is first necessary to consider one of the most important properties of the DNA double helix: its ability to separate into its two component strands, a property termed **denaturation**.

DNA Denaturation As first suggested by Watson and Crick, the two strands of a DNA molecule are held together

Figure 10.15 Thermal denaturation of DNA. A thermal denaturation curve for native bacteriophage T6 DNA in 0.3 M sodium citrate. The “melting” of the DNA (strand separation) occurs over a narrow range of temperature, particularly for the simpler DNAs of small viruses. The temperature corresponding to half the increase in absorbance is termed the T_m (J. MARMUR AND P. DOTY, JOURNAL OF MOLECULAR BIOLOGY 3:593, 1961; COPYRIGHT 1961. JOURNAL OF MOLECULAR BIOLOGY BY ACADEMIC PRESS. REPRODUCED WITH PERMISSION OF ACADEMIC PRESS IN THE FORMAT REUSE IN A BOOK/TEXTBOOK VIA COPYRIGHT CLEARANCE CENTER.)

by weak, noncovalent bonds. When DNA is dissolved in saline solution and the solution is slowly warmed, a temperature is reached when strand separation begins. Within a few degrees, the process is generally complete and the solution contains single-stranded molecules that are completely separated from their original partners. The progress of thermal denaturation (or *DNA melting*) is usually monitored by following the increase in absorbance of ultraviolet light by the dissolved DNA. Once the two DNA strands have separated, the hydrophobic interactions that result from base stacking are greatly decreased, which changes the electronic nature of the bases and increases their absorbance of ultraviolet radiation. The rise in absorbance that accompanies DNA denaturation is shown in Figure 10.15. The temperature at which the shift in absorbance is half completed is termed the *melting temperature* (T_m). The higher the GC content (%G + %C) of the DNA, the higher the T_m . This increased stability of GC-containing DNA reflects the presence of the extra hydrogen bond between the bases as compared with AT pairs (Figure 10.10c).

DNA Renaturation The separation of the two strands of the DNA duplex by heat is not an unexpected finding, but the *reassociation* of single strands into stable double-stranded molecules with correct base pairs seems almost inconceivable. However, in 1960, Julius Marmur and Paul Doty at Harvard University found that if they slowly cooled a solution of bacterial DNA that had been thermally denatured, the DNA regained the properties of the double helix; it absorbed less

ultraviolet light and once again behaved like genetic material in being able to transform bacterial cells (discussed on page 422). It became apparent from these studies that complementary single-stranded DNA molecules were capable of reassociating, an event termed **renaturation**, or **reannealing**. This finding has proved to be one of the most valuable observations ever made in molecular biology. On one hand, reannealing has served as the basis for an investigation into the complexity of the genome, a subject discussed in the following section. On the other hand, reannealing has led to the development of a methodology called *nucleic acid hybridization*, in which complementary strands of nucleic acids from different sources can be mixed to form double-stranded (hybrid) molecules. Examples of the types of questions that have been answered by allowing single-stranded nucleic acids to hybridize are discussed later in the chapter (page 403) and illustrated in Figure 10.19. Nucleic acid hybridization plays a key role in our most important modern biotechnologies, including DNA sequencing, DNA cloning, and DNA amplification.

The Complexity of Viral and Bacterial Genomes Several factors determine the rate of renaturation of a given preparation of DNA. They are (1) the ionic strength of the solution, (2) the incubation temperature, (3) the concentration of DNA, (4) the period of incubation, and (5) the size of the interacting molecules. With these factors in mind, consider what might happen if one were to compare the rate of renaturation of three different DNAs, each constituting the entire genome of (1) a small virus, such as MS-2 (4×10^3 nucleotide pairs); (2) a larger virus, such as T4 (1.8×10^5 nucleotide pairs); and (3) a bacterial cell, such as *E. coli* (4.5×10^6 nucleotide pairs). The primary difference between these DNAs is their length. To compare their renaturation, it is important that the reacting molecules are of equivalent length, typically about 1000 base pairs. DNA molecules can be fragmented into pieces of this length in various ways, one of which is to force them through a tiny orifice at high pressure.

When these three types of DNA—all present at the same lengths and DNA concentration (e.g., mg/ml)—are allowed to reanneal, they do so at distinctly different rates (Figure 10.16). The smaller the genome, the faster the renaturation. The reason becomes apparent when one considers the concentration of complementary sequences in the three preparations. Because all three preparations have the same amount of DNA in a given volume of solution, it follows that the smaller the genome size, the greater the number of genomes present in a given weight of DNA and the greater the chance of collision between complementary fragments.

The Complexity of Eukaryotic Genomes The renaturation of viral and bacterial DNAs occurs along single, symmetrical curves (Figure 10.16). Renaturation occurs along such curves because all of the sequences are present (with the exception of a very few sequences in bacterial DNA) at the same concentration. Consequently, every nucleotide sequence in the population is as likely to find a partner in a given time as any other sequence. This is the result that would have been predicted from the various gene mapping studies that sug-

Figure 10.16 The kinetics of renaturation of viral and bacterial DNAs. The curves show the renaturation of sheared strands of DNA from two viruses (MS-2 and T4) and a bacterium (*E. coli*). (The formation of double-stranded DNA is plotted against C_0t , which is a term that combines two variables: initial DNA concentration (C_0) and time of incubation (t). A solution containing a high concentration of DNA incubated for a short time will have the same C_0t as one of low concentration incubated for a correspondingly longer time; both will have the same percentage of reannealed DNA.) The genome size, that is, the number of nucleotide base pairs in one copy of total genetic information of the organism, is indicated by the arrows near the upper numerical scale. The shape of each of the renaturation curves is very simple and occurs with a single slope. However, the time over which renaturation occurs is very different and depends on the concentration of complementary fragments, which in turn depends on the size of the genome. The larger the genome, the lower the concentration of complementary fragments in solution, and the greater the time required for renaturation to be complete.

gested the DNA of a chromosome contained one gene after another in a linear array. The renaturation kinetics of viral and bacterial genomes contrast sharply with those obtained on mammalian DNA by Roy Britten and David Kohne of the Carnegie Institution of Washington, D.C. Unlike those of the simpler genomes, the DNA fragments from a mammalian genome reanneal at markedly different rates (Figure 10.17). These differences reflect the fact that the various nucleotide sequences in a preparation of eukaryotic DNA fragments are present at markedly different concentrations. This was the first insight that eukaryotic DNA is not just a simple progression of one gene after another, as in a bacterium or virus, but has a much more complex organization.

When DNA fragments from plants and animals are allowed to reanneal, the curve typically shows three more-or-less distinct steps (Figure 10.17), which correspond to the reannealing of three broad classes of DNA sequences. The three classes reanneal at different rates because they differ as to the number of times their nucleotide sequence is repeated within the population of fragments. The three classes are termed the **highly repeated fraction**, the **moderately repeated fraction**, and the **nonrepeated fraction**.

Figure 10.17 An idealized plot showing the kinetics of renaturation of eukaryotic DNA. When single-stranded DNA is allowed to reanneal, three classes of fragments can usually be distinguished by their frequency of repetition within the genome: a highly repeated DNA fraction, a moderately repeated DNA fraction, and a nonrepeated (single-copy) DNA fraction. (Note: This is an idealized plot: the three classes of sequences are not as clearly separated in an actual renaturation curve.)

Highly Repeated DNA Sequences The highly repeated fraction constitutes anywhere from about 1 to 10 percent of the total DNA. Highly repeated sequences are typically short (a few hundred nucleotides at their longest) and present in clusters in which the given sequence repeats itself over and over again without interruption. A sequence arranged in this end-to-end manner is said to be present *in tandem*. Highly repeated sequences fall into several overlapping categories, including satellite DNAs, minisatellite DNAs, and microsatellite DNAs.

- **Satellite DNAs.** Satellite DNAs consist of short sequences (about five to a few hundred base pairs in length) that form very large clusters, each containing up to several million base pairs of DNA. In many species, the base composition of these DNA segments is sufficiently different from the bulk of the DNA that fragments containing the sequence can be separated into a distinct “satellite” band during density gradient centrifugation (hence the name *satellite* DNA). Satellite DNAs tend to evolve very rapidly, causing the sequences of these genomic elements to vary even between closely related species. The localization of satellite DNA within the centromeres of chromosomes is described on page 403 and in further detail in Section 12.2.
- **Minisatellite DNAs.** Minisatellite sequences range from about 10 to 100 base pairs in length and are found in sizeable clusters containing as many as 3000 repeats. Thus, minisatellite sequences occupy considerably shorter stretches of the genome than do satellite sequences. Minisatellites tend to be unstable, and the number of copies of a particular sequence often increases or decreases from one

generation to the next, most likely as the result of unequal crossing over (see Figure 10.22). Consequently, the length of a particular minisatellite locus is highly variable in the population, even among members of the same family. Because they are so variable (or *polymorphic*) in length, minisatellite sequences form the basis for the technique of *DNA fingerprinting*, which is used to identify individuals in criminal or paternity cases (Figure 10.18).

Figure 10.18 DNA fingerprinting. In this technique, which is used widely to identify an individual from a sample of DNA, the DNA is digested by treatment with specific nucleases (called restriction endonucleases, described in Section 18.12), and the DNA fragments are separated on the basis of length by gel electrophoresis. The location in the gel of DNA fragments containing specific DNA sequences is determined using labeled probes with sequences complementary to those being sought. The DNA fragments that bind these probes have variable lengths from one person to the next because of the presence of variable numbers of short tandem repeats (STRs) in the genome. Forensic labs typically analyze about 13 STR markers that are known to be highly polymorphic. The chance that two individuals will have identical STR profiles is astronomically small. The fingerprint shown in this figure was used in a criminal case in which the defendant was charged with the fatal stabbing of a young woman. The bloodstains on the pants and shirt of the defendant were compared to the known blood standards from the victim and defendant. DNA from the bloodstains on the defendant's clothing did not match his own blood standard, but they did match that of the victim. The lanes contain DNA from the following sources: 1, 2, 3, 9, and 10 are control DNA samples that serve as quality control checks; 4, the defendant's blood; 5, bloodstains from the defendant's pants; 6 and 7, bloodstains from the defendant's shirt; and 8, the victim's blood. With the advent of DNA amplification techniques (i.e., PCR), minuscule samples of DNA can be used for these analyses. (COURTESY OF ORCHID CELLMARK, PRINCETON, NEW JERSEY.)

- **Microsatellite DNAs.** Microsatellites are the shortest sequences (1 to 9 base pairs long) and are typically present in small clusters of about 10 to 40 base pairs in length, which are scattered quite evenly through the genome. DNA replicating enzymes have trouble copying regions of the genome that contain these small, repetitive sequences, which causes these stretches of DNA to change in length through the generations. Because of their variable lengths within the population, microsatellite DNAs have been used to analyze the relationships between different human populations, as illustrated in the following example. It is generally agreed that modern humans arose in Africa. If this is true, then members of different African populations should exhibit greater DNA sequence variation than human populations living on other continents because genomes of African populations have had longer to diverge. The argument for African genesis has received support from numerous studies on human DNA sequences. In one study that analyzed 60 different microsatellite loci, it was found that members of African populations had a significantly greater genetic divergence than Asian or European populations. The vast majority of microsatellite loci occur outside of genes, and changes in their length generally go unnoticed. This is not the case for the microsatellite sequences discussed in the accompanying Human Perspective.

Once it became apparent that eukaryotic genomes contain large numbers of copies of short DNA sequences, researchers sought to learn where these DNA sequences are located in the chromosomes. Are satellite DNA sequences, for example, clustered in particular parts of a chromosome, or scattered uniformly from one end to the other? It was noted above that the discovery of DNA reannealing led to the development of a vast nucleic acid hybridization methodology (discussed at length in Chapter 18). The ability to locate satellite DNA sequences illustrates the analytic power of nucleic acid hybridization.

In the reannealing experiments described on page 400, complementary DNA strands were allowed to bind to one another while colliding randomly in solution. An alternate experimental protocol called *in situ hybridization* was developed in 1969 by Mary Lou Pardue and Joseph Gall of Yale University and was used to determine the location of satellite DNA. The term *in situ* means “in place,” which refers to the fact that the DNA of the chromosomes is kept in place while it is allowed to react with a particular preparation of labeled DNA. In early *in situ* hybridization studies, the DNA to be detected (the probe DNA) was radioactively labeled and was localized by autoradiography. The resolution of the technique has been increased using probes that are labeled with fluorescent dyes and then localized with a fluorescence microscope (as in Figure 10.19). This latter technique is called **fluorescence in situ hybridization (FISH)** and has become so refined that it can be used to map the locations of different sequences along single DNA fibers.

To carry out nucleic acid hybridization, both interactants must be single-stranded. In the experiment depicted in Figure 10.19, the chromosomes from a mitotic cell are spread on a slide, and the DNA is made single-stranded by treating the chromosomes with a hot salt solution that causes the DNA strands to

Figure 10.19 Fluorescence in situ hybridization and the localization of satellite DNA. (a) The steps that are taken in carrying out fluorescence in situ hybridization. In this technique, certain of the nucleotides in the probe DNA are linked covalently to a small organic molecule, usually biotin. Following hybridization, the location of the bound, biotin-labeled DNA can be visualized by treating the preparation with fluorescently labeled avidin, a protein that binds to biotin with very high affinity. Chromosomes in these preparations usually appear red because they have been counterstained with propidium iodide. (b) Localization of α -satellite DNA at the centromere of human chromosomes. The location of the bound, biotin-labeled, satellite DNA is revealed by the yellow fluorescence, which stands out against a background of red, counterstained chromosomes. Fluorescence appears only at the site where each chromosome is constricted, which marks the location of the centromere. (B: FROM HUNTINGTON F. WILLARD, *TRENDS GENET.* 6:414, 1990, WITH PERMISSION FROM ELSEVIER.)

separate and remain apart. During the ensuing hybridization step, the denatured chromosomes are incubated with a solution of biotin-labeled, single-stranded satellite DNA, which binds selectively to complementary strands of immobilized satellite DNA located in the chromosomes. Following the incubation period, the soluble, unhybridized satellite DNA is washed away or digested, and the sites of the bound, labeled DNA fragments are revealed. As shown in Figure 10.19, and described in the accompanying legend, satellite DNA is localized in the centromeric regions of the chromosome (see Figure 12.27). Another example using FISH technology is shown in Figure 10.20.

Moderately Repeated DNA Sequences The moderately repeated fraction of the genomes of plants and animals can vary from about 20 to more than 80 percent of the total DNA, depending on the organism. This fraction includes sequences that are repeated within the genome anywhere from a few times to tens of thousands of times. Included in the moderately repeated DNA fraction are sequences that code for known gene products, either RNAs or proteins, and those that lack a coding function.

1. **Repeated DNA Sequences with Coding Functions.** This fraction of the DNA includes the genes that code for ribosomal RNAs as well as those that code for an important group of chromosomal proteins, the histones. The repeated sequences that code for each of these products are typically identical to one another and located in tandem array. It is essential that the genes encoding ribosomal RNAs be present in multiple numbers because these RNAs are required in large amounts and their synthesis does not benefit from the extra amplification step that occurs for protein-coding genes in which each mRNA acts as a template for the repeated synthesis of a polypeptide. Even though the production of histones does involve an intermediary messenger RNA, so many copies of these proteins are required during early development that several hundred DNA templates must be present.
2. **Repeated DNAs that Lack Coding Functions.** The bulk of the moderately repeated DNA fraction does not encode any type of product. Rather than occurring as clusters of tandem sequences, the members of these families are scattered (i.e., *interspersed*) throughout the genome as individual elements. Most of these repeated sequences can be grouped into two classes that are referred to as SINEs (short *interspersed elements*) or LINEs (*long interspersed elements*). SINEs and LINEs sequences are discussed on page 410.

THE HUMAN PERSPECTIVE

Diseases that Result from Expansion of Trinucleotide Repeats

For decades, biologists believed that genes were always transmitted from generation to generation as stable entities. On rare occasion, a change occurs in the nucleotide sequence of a gene in the germ line, creating a mutation that is subsequently inherited. This is one of the basic tenets of Mendelian genetics. Then in 1991, several laboratories reported a new type of “dynamic mutation” in which the nucleotide sequence of particular genes changed dramatically between parents and offspring. In each case, these mutations affected genes that contained a repeating trinucleotide unit (e.g., CCG or CAG) as part of their sequence. In most members of the population, these particular genes contain a relatively small (but variable) number of repeated trinucleotides, and they are transmitted from one generation to the next without a change in the number of repeats. In contrast, a small fraction of the population possesses a mutant version of the gene that contains a larger number of these repeating units. Unlike the normal version, the mutant alleles are highly unstable, and the number of repeating units tends to increase as the gene passes from parents to offspring. When the number of repeats increases beyond a critical number, the individual inheriting the mutant allele develops a serious disease.

At the present time, more than 20 inherited disorders have been attributed to expansion of trinucleotide repeats. These diseases fall into two basic categories, which we will consider in turn. Type I diseases are all neurodegenerative disorders that result from the expansion of the number of repeats of a CAG trinucleotide within the coding portion of the mutant gene (Figure 1). We can illustrate the nature of these disorders by considering the most prevalent and widely studied of the group, Huntington’s disease (HD). HD is a fatal illness characterized by involuntary, uncoordinated movements; changes in personality, including depression and irritability; and gradual intellectual decline. Symptoms usually begin in the third to fifth decade of life and increase in severity until death.

The normal *HD* gene, which is stably transmitted, contains between 6 and 35 copies of the CAG trinucleotide. The protein encoded by the *HD* gene is called huntingtin, and its precise function remains unclear. CAG is a triplet that encodes the amino acid glutamine. Thus the normal huntingtin polypeptide contains a stretch of 6 to 35 glutamine residues—a polyglutamine tract—as part of its primary structure. We think of polypeptides as having a highly defined primary structure, and most of them do, but huntingtin is normally polymorphic with respect to the length of its polyglutamine tract. The protein appears to function normally as long as the tract length remains below approximately 35 glutamine residues. But if this number is exceeded, the protein takes on new properties, and the person is predisposed to developing HD.

HD exhibits a number of unusual characteristics. Unlike most inherited diseases, HD is a dominant genetic disorder, which means that a person with the mutant allele will develop the disease regardless of whether or not he or she has a normal *HD* allele. In fact, persons who are homozygous for the *HD* allele are no more seriously affected than heterozygotes. This observation indicates that the mutant huntingtin polypeptide causes the disease, not because it fails to carry out a particular function, but because it acquires some type of toxic property, which is referred to as a *gain-of-function* mutation. This interpretation is supported by studies with mice. Mice that are engineered to carry the mutant human *HD* allele (in addition to their own normal alleles) develop a neurodegenerative disease resembling that found in humans. The presence of the one abnormal allele is sufficient to cause disease. Another unusual characteristic of HD and the other CAG disorders is a phenomenon called genetic anticipation, which means that, as the disease is passed from generation to generation, its severity increases and/or it strikes at an increasingly earlier age. This was once a puzzling feature of HD but is now readily explained by the fact that the number of CAG repeats in a mutant allele (and the resulting consequences) often increases dramatically from one generation to the next.

The molecular basis of HD remains unclear, but there is no shortage of theories as to why an expanded glutamine tract may be toxic to brain cells. One feature appears indisputable: when the polyglutamine tract of huntingtin exceeds about 35 residues, the protein (or a fragment cleaved from it) undergoes abnormal folding to produce a misfolded molecule that (1) binds to other mutant

Figure 1 Trinucleotide repeat sequences and human disease. The top line shows a generalized gene that is transcribed into a messenger RNA with several distinct portions, including a 5′ noncoding region called the 5′ UTR (5′ untranslated region), a coding exon that carries the information for the amino acid sequence of the polypeptide, and a 3′ noncoding portion (the 3′ UTR). The introns in the DNA (see Figure 11.29) are not represented in the mature messenger RNA. The general location of the trinucleotide responsible for each of four different diseases (fragile X syndrome, Friedreich’s ataxia, Huntington’s

disease, and myotonic dystrophy) is indicated by the location of each pyramid. The number of repeats responsible for the normal (red), carrier (orange), and disease (yellow) conditions for each disease-causing gene is indicated. Genes responsible for Type I diseases, such as Huntington’s, do not exhibit the intermediate “carrier” state in which an individual possesses an unstable allele but is not affected.

(REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD: J-L MANDEL, NATURE 386:768, 1997; COPYRIGHT 1997.)

huntingtin molecules to form insoluble aggregates, not unlike those seen in the brains of Alzheimer's victims (page 67), and (2) binds to a number of unrelated proteins that do not interact with normal, wild-type huntingtin molecules. Among the proteins bound by mutant huntingtin are several transcription factors, which are proteins involved in the regulation of gene expression. Several of the most important transcription factors present in cells, including TBP (see Figure 11.19) and CBP (see Figure 12.50), contain polyglutamine stretches themselves, which makes them particularly susceptible to aggregation by proteins with mutant, expanded polyglutamine tracts. In fact, the protein aggregates present in degenerating neurons of HD patients contain both of these transcription factors. These results suggest that mutant huntingtin sequesters transcription factors, disrupting the transcription of genes that are required for the health and survival of the affected neurons. This hypothesis has received support from a study in which mice were genetically engineered so that their brain cells lacked the ability to produce certain key transcription factors. These mice exhibited the same type of neurodegeneration as is seen in animals carrying a mutant *HD* gene. Other basic neuronal processes, including axonal transport, mitochondrial permeability and fission, cholesterol synthesis, and protein degradation, are also disrupted by the *HD* mutation and represent possible causes of nerve cell death. It should be noted that a number of HD researchers hold an alternate opinion about the cause of cell death. They argue that it is not the protein aggregates that are toxic, but the soluble mutant protein (or fragments of the mutant protein) itself. In fact, proponents of this view argue that the mutant protein aggregates protect the cell by sequestering the harmful molecules. It is important for practical reasons to distinguish between these possibilities because a number of proposed therapies are aimed at blocking formation of the aggregates, which could actually prove more harmful to a patient.

Type II trinucleotide repeat diseases differ from the Type I diseases in a number of ways. Type II diseases (1) arise from the expansion of a variety of trinucleotides, not only CAG, (2) the trinucleotides involved are present in a part of the gene that does not encode amino acids (Figure 1), (3) the trinucleotides are subject to massive expansion into thousands of repeats, and (4) the diseases affect numerous parts of the body, not only the brain. The best studied Type II disease is fragile X syndrome, so named because the mutant X chromosome is especially susceptible to damage. Fragile X syndrome is characterized by mental retardation as well as a number of physical abnormalities. The disease is caused by a dynamic mutation in a gene called *FMR1* that encodes an RNA-binding protein that regulates the translation of certain mRNAs involved in neuronal development and/or synaptic function. A normal allele of this gene contains anywhere from about 5 to 55 copies of a specific trinucleotide (CGG) that is repeated in a part of the gene that corresponds to the 5' noncoding portion of the messenger RNA (Figure 1). However, once the number of copies rises above about 60, the locus becomes very unstable and the copy number tends to increase rapidly into the thousands. Females with an *FMR1* gene containing 60 to 200 copies of the triplet generally exhibit a normal phenotype but are carriers for the transmission of a highly unstable chromosome to their offspring. If the repeat number in the offspring rises above about 200, the individual is almost always mentally retarded. Unlike an abnormal *HD* allele, which causes disease as the result of a gain of function, an abnormal *FMR1* allele causes disease as the result of a loss of function; *FMR1* alleles containing an expanded CGG number are selectively inactivated so that the gene is not transcribed or translated. Although there is no effective treatment for any of the diseases caused by trinucleotide expansion, the risk of transmitting or possessing a mutant allele can be assessed through genetic screening.

Nonrepeated DNA Sequences As initially predicted by Mendel, classical studies on the inheritance patterns of visible traits led geneticists to conclude that each gene was present in one copy per single (haploid) set of chromosomes. When denatured eukaryotic DNA is allowed to reanneal, a significant fraction of the fragments are very slow to find partners, so slow in fact that they are presumed to be present in a single copy per genome. This fraction comprises the *nonrepeated* (or *single-copy*) DNA sequences, which includes the genes that exhibit Mendelian patterns of inheritance. Because they are present in a single copy in the genome, nonrepeated sequences localize to a particular site on a particular chromosome (Figure 10.20).

Considering the variety of different sequences present, the nonrepeated fraction contains by far the greatest amount of genetic information. Included within the nonrepeated fraction are the DNA sequences that code for virtually all proteins other than histones. Even though these sequences are not present in multiple copies, genes that code for polypeptides are usually members of a family of related genes. This is true for the globins, actins, myosins, collagens, tubulins, integrins, and most other proteins in a eukaryotic cell. Each member of a multigene family is encoded by a different but related sequence. We will look into the origin of these multigene families in the following section.

Now that the human genome has been sequenced and analyzed, we finally have a relatively accurate measure of the

Figure 10.20 Chromosomal localization of a nonrepeated DNA sequence. These mitotic chromosomes were prepared from a dividing mouse cell and incubated with a purified preparation of biotin-labeled DNA encoding one of the nuclear lamin proteins (lamin B₂), which is encoded by a nonrepeated gene. The locations of the bound, labeled DNA appear as bright dots. The lamin gene is present on the homologues of chromosome 10. Each chromosome contains two copies of the gene because the DNA had been replicated prior to the cells entering mitosis. (FROM MONIKA ZEWE ET AL., COURTESY OF WERNER FRANKE, EUR. J. CELL BIOL. 56:349, 1991, WITH PERMISSION FROM ELSEVIER.)

DNA sequences that are responsible for encoding the amino acid sequences of our proteins, and it is remarkably small. If you would have suggested to a geneticist in 1960 that less than 1.5 percent of the human genome encodes the amino acids of our proteins, he or she would have considered the suggestion to be ridiculous. Yet, that is the reality that has emerged from the study of genome sequences. In the following section, we will try to better understand how the remaining 98+ percent of DNA sequences might have evolved.

REVIEW

1. What is a genome? How does the complexity of bacterial genomes differ from that of eukaryotic genomes?
2. What is meant by the term *DNA denaturation*? How does denaturation depend on the GC content of the DNA? How does this variable affect the T_m ?
3. What is a microsatellite DNA sequence? What role do these sequences play in human disease?
4. Which fraction of the genome contains the most information? Why is this true?

10.5 | The Stability of the Genome

Because DNA is the genetic material, we tend to think of it as a conservative molecule whose information content changes slowly over long periods of evolutionary time. In actual fact, the sequence organization of the genome is capable of rapid change, not only from one generation to the next, but within the lifetime of a given individual.

Whole-Genome Duplication (Polyploidization)

As discussed in the first sections of this chapter, peas and fruit flies have pairs of homologous chromosomes in each of their cells. These cells are said to have a **diploid** number of chromosomes. If a person were to compare the number of chromosomes present in the cells of closely related organisms, especially higher plants, they would find that some species have a much greater number of chromosomes than a close relative. Among animals, the widely studied amphibian *Xenopus laevis*, for example, has twice the number of chromosomes as its cousin *X. tropicalis*. These types of discrepancies can be explained by a process known as **polyploidization**, or **whole-genome duplication**. Polyploidization is an event in which offspring are produced that have twice the number of chromosomes in each cell as their diploid parents; the offspring have four homologues of each chromosome rather than two. Polyploidization is thought to occur in either of two ways: two related species mate to form a hybrid organism that contains the combined chromosomes from both parents, or, alternatively, a single-celled embryo undergoes chromosome duplication but the duplicates, rather than being separated into separate cells, are retained in a single cell that develops into a viable embryo. The first mechanism occurs most often in

plants, and the second most often in animals. Polyploidization is particularly common in flowering plants, including numerous crop species (e.g., wheat, bananas, and coffee) depicted in Figure 10.21. When polyploidization occurs in a plant lineage, the chromosome number suddenly doubles and, in most cases, tends to return back toward the original diploid number over an ensuing period of evolution. As a result, different modern plant species are caught at various stages in the evolutionary process of winnowing their gene number. This is the reason that the genomes of different plants tend to have a much greater variation in numbers of genes than that exhibited by different animals (see Figure 10.27).

A “sudden” doubling of the number of chromosomes is a dramatic event, one that gives an organism remarkable evolutionary potential—assuming it can survive the increased number of chromosomes and reproduce. Depending on the circumstances, polyploidization may result in the production of a new species that has a great deal of “extra” genetic information. Several different fates can befall extra copies of a gene; they can be lost by deletion, rendered inactive by deleterious mutations, or, most importantly, they can evolve into new genes that possess new functions. Viewed in this way, extra genetic information is the raw material for evolutionary diversification. In 1971, Susumu Ohno of the City of Hope Cancer Center in Los Angeles put forward the “2R” hypothesis, in which he proposed that the evolution of vertebrates from a much simpler invertebrate ancestor was made possible by two separate rounds of whole-genome duplication during an early evolutionary period. Ohno suggested that the thousands of extra genes that would be generated by genome duplication could be molded by natural selection into new genes that were required to encode the more complex vertebrate body. Over the past three and a half decades, Ohno’s proposal has been hotly debated as geneticists have tried to find evidence that either supports or refutes the notion.

(FROM A. R. LEITCH AND I. J. LEITCH, SCIENCE 320:481, 2008; © 2008, REPRINTED WITH PERMISSION FROM AAAS.)

The problem facing genome analysts is the vast stretch of time that has passed—hundreds of millions of years—since the origin of our earliest vertebrate ancestors. Just as a river or sea slowly wears away the face of the Earth, chromosomal rearrangement and mutation slowly wear away the face of an ancestral genome. Even with the complete sequence of a number of invertebrate and vertebrate genomes in hand, it has still proven a formidable challenge to identify the origin of many of our genes. The strongest evidence for the 2R hypothesis comes from analysis of the amphioxus genome. Amphioxus lacks a backbone, which makes it an invertebrate, but it has a number of features (e.g., a notochord, dorsal tubular nerve cord, and segmental body musculature) that clearly identifies it as a member of the phylum Chordata to which vertebrates belong. The lineages leading to modern vertebrates and amphioxus are thought to have separated about 550 million years ago, yet the two groups share a remarkably similar collection of genes. However, when researchers looked more closely at certain groups of genes, the genomes of vertebrates typically contained four times the number of such genes when compared to the homologous sequences in the amphioxus genome. This finding provides strong support for Ohno's hypothesis of two rounds of whole-genome duplication in the ancestral vertebrate lineage.

Duplication and Modification of DNA Sequences

Polyploidization is an extreme case of genome duplication and occurs only rarely during evolution. In contrast, **gene duplication**, which refers to the duplication of a small portion of a single chromosome, happens with surprisingly high frequency, and its occurrence is readily documented by genome analysis.³ According to one estimate, each gene in the genome

³Actually, three categories of duplication can be distinguished: whole-genome, gene, and segmental duplication. The last category, which refers to the duplication of a large block of chromosomal material (from a few kilobases to hundreds of kilobases in length) is not discussed here, but has a significant impact in genome evolution. Approximately 5 percent of the present human genome consists of segmental duplications that have arisen during the past 35 million years.

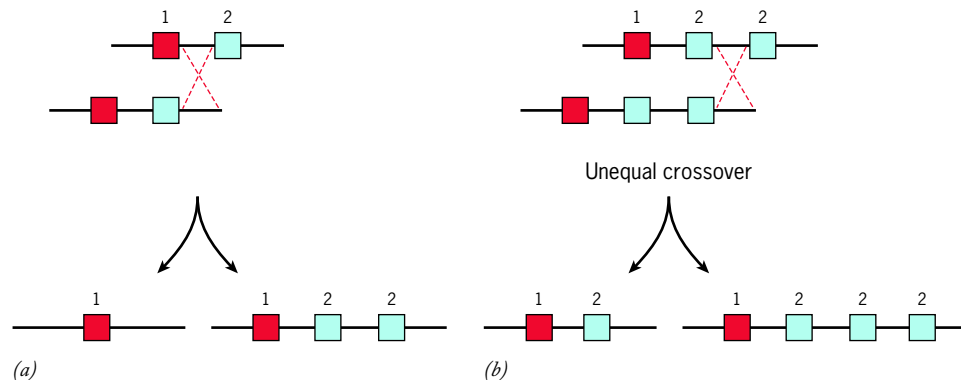

Figure 10.22 Unequal crossing over between duplicated genes provides a mechanism for generating changes in gene number. (a) The initial state shown has two related genes (1 and 2). In a diploid individual, gene 1 on one homologue can align with gene 2 on the other homologue during meiosis. If a crossover occurs during this

has about a 1 percent chance of being duplicated every million years. Duplication of a gene can probably occur by several different mechanisms but is most often thought to be produced by a process of *unequal crossing over*, as depicted in Figure 10.22. Unequal crossing over occurs when a pair of homologous chromosomes comes together during meiosis in such a way that they are not perfectly aligned. As a result of misalignment, genetic exchange between the homologues causes one chromosome to acquire an extra segment of DNA (a duplication) and the other chromosome to lose a DNA segment (a deletion). If the duplication of a particular sequence is repeated in subsequent generations, a cluster of tandemly repeated segments is generated at a localized site within that chromosome (see Figure 10.28).

The vast majority of gene duplicates are either lost during evolution through deletion or rendered nonfunctional by unfavorable mutation. However, in a small percentage of cases, the “extra” copy accumulates favorable mutations and acquires a new function. More often, both copies of the gene undergo mutation so that each evolves a more specialized function than that performed by the original gene. In either case, the two genes will have closely related sequences and encode similar polypeptides, which is to say that they encode different isoforms of a particular protein, such as α - and β -tubulin (page 330). Subsequent duplications of one of the genes can lead to the formation of additional isoforms (e.g., γ -tubulin), and so forth. It becomes apparent from this example that successive gene duplication can generate families of genes that encode polypeptides with related amino acid sequences. The production of a multigene family is illustrated by the evolution of the globin genes.

Evolution of Globin Genes Hemoglobin is a tetramer composed of four globin polypeptides (see Figure 2.38*b*). Examination of globin genes, whether from a mammal or a fish, reveals a characteristic organization. Each of these genes is constructed of three exons and two introns. Exons are parts of genes that code for amino acids in the encoded polypeptide,

misalignment, half the gametes will be missing gene 2 and half will have an extra gene 2. (b) As unequal crossing over continues to occur during meiotic divisions in subsequent generations, a tandemly repeated array of DNA sequences will gradually evolve.

whereas introns do not; they are noncoding intervening sequences. The subject of exons and introns is discussed in detail in Section 11.4 (see Figure 11.24). For the present purposes, we will simply use these gene parts as landmarks of evolution. Examination of genes encoding certain globin-like polypeptides, such as the plant protein leghemoglobin and the muscle protein myoglobin, reveals the presence of four exons and three introns. This is proposed to represent the ancestral

Figure 10.23 A pathway for the evolution of globin genes. Exons are shown in green, introns in brown. The evolutionary steps depicted in the diagram are discussed in the text. The arrangement of α - and β -globin genes on human chromosomes 16 and 11 (shown in blue without their introns in step 7) are the products of several hundred million years of evolution. As discussed in Chapter 2, hemoglobin molecules consist of two pairs of polypeptide chains—one pair is always a member of the α -globin subfamily, and the other pair is always a member of the β -globin subfamily. Specific combinations of α - and β -globins are found at different stages of development. The α - and β -globin chains that are observed in embryonic, fetal, and adult hemoglobins are indicated.

form of the globin gene. It is thought that the modern globin polypeptide arose from the ancestral form as the result of the fusion of two of the globin exons (step 1, Figure 10.23) some 800 million years ago.

A number of primitive fish are known that have only one globin gene (step 2), suggesting that these fish diverged from other vertebrates prior to the first duplication of the globin gene (step 3). Following this duplication approximately 500 million years ago, the two copies diverged by mutation (step 4) to form two distinct globin types, an α type and a β type, located on a single chromosome. This is the present arrangement in the amphibian *Xenopus* and in zebrafish. In subsequent steps, the α and β forms are thought to have become separated from one another by a process of rearrangement that moved them to separate chromosomes (step 5). Each gene then underwent subsequent duplications and divergence (step 6), generating the arrangement of globin genes that exists today in humans (step 7). The evolution of vertebrate globin genes illustrates how gene duplication typically leads to the generation of a family of genes whose individual members have specialized functions (in this case, embryonic, fetal, and adult forms) when compared to the single founding gene.

When the DNA sequences of globin gene clusters were analyzed, researchers found “genes” whose sequences are homologous to those of functional globin genes, but which have accumulated severe mutations that render them nonfunctional. Genes of this type, which are evolutionary relics, are known as **pseudogenes**. Examples of pseudogenes are found in both the human α - and β -globin gene clusters of Figure 10.23. The human genome contains an estimated 19,000 pseudogenes. Although pseudogenes do not encode functional proteins, they can be transcribed into RNAs, which may have regulatory functions. Another point that is evident from examination of the two globin clusters of human chromosomes is how much of the DNA consists of noncoding sequences, either as introns within genes or as spacers between genes. In fact, the globin regions contain a much higher fraction of coding sequences than most other regions of the genome.

“Jumping Genes” and the Dynamic Nature of the Genome

If one looks at repeated sequences that have arisen during the normal course of evolution, one finds that repeats are sometimes present in tandem arrays, sometimes present on two or a few chromosomes (as in the case of the globin genes of Figure 10.23), and sometimes dispersed throughout the genome. If we assume that all members of a family of repeated sequences arose from a single copy, then how can individual members become dispersed among different chromosomes?

The first person to suggest that genetic elements were capable of moving around the genome was Barbara McClintock, a geneticist working with maize (corn) at the Cold Spring Harbor Laboratories in New York. Genetic traits in maize are often revealed as changes in the patterns and markings in leaf and kernel coloration (Figure 10.24). In the late 1940s, McClintock found that certain mutations were very unstable, ap-

Figure 10.24 Visible manifestations of transposition in maize.

Kernels of corn are typically uniform in color. The spots on this kernel result from a mutation in a gene that codes for an enzyme involved in pigment production. Mutations of this type can be very unstable, arising or disappearing during the period in which a single kernel develops. These unstable mutations appear and disappear as the result of the movement of transposable elements into and out of these genes during the period of development. (COURTESY OF VENKATESAN SUNDARESAN, COLD SPRING HARBOR LABORATORY.)

pearing and disappearing from one generation to the next or even during the lifetime of an individual plant. After several years of careful study, she concluded that certain genetic elements were moving from one place in a chromosome to an entirely different site. She called this genetic rearrangement **transposition**, and the mobile genetic elements **transposable elements**. Meanwhile, molecular biologists working with bacteria were finding no evidence of “jumping genes.” In their studies, genes appeared as stable elements situated in a linear array on the chromosome that remained constant from one individual to another and from one generation to the next. McClintock’s findings were largely ignored.

Then, in the late 1960s, several laboratories discovered that certain DNA sequences in bacteria moved on rare occasion from one place in the genome to another. These bacterial transposable elements were called **transposons**. Most transposons encode a protein, or *transposase*, that single-handedly catalyzes the excision of a transposon from a donor DNA site and its subsequent insertion at a target DNA site. This “cut-and-paste” mechanism is mediated by two separate transposase subunits that bind to inverted, repeated sequences at the two ends of the transposon (Figure 10.25, step 1). The two subunits then come together to form an active dimer (step 2) that catalyzes a series of reactions leading to the excision of the transposon (step 3). The transposase–transposon complex then binds to a target DNA (step 4) where the transposase catalyzes the reactions required to integrate the transposon into its new residence (step 5). Integration of the element typically creates a small duplication in the target DNA that flanks the transposed element at the site of insertion. Target site duplications serve as “footprints” to identify sites in the genome that are occupied by transposable elements.

Figure 10.25 Transposition of a bacterial transposon by a “cut-and-paste” mechanism. As discussed in the text, the two ends of this bacterial Tn5 transposon are flanked by repeated sequences (orange segments). The two ends are brought together by the dimerization of a pair of subunits of the transposase (orange spheres). Both strands of the double helix are cleaved at each end, which excises the transposon as part of a complex with the transposase. The transposon–transposase complex is “captured” by a target DNA, and the transposon is inserted in such a way as to produce a small duplication that flanks the transposed element. (Note: Not all DNA transposons move by this mechanism.) (FROM D. R. DAVIES ET AL., SCIENCE 289:77, 2000; COPYRIGHT 2000, REPRINTED WITH PERMISSION FROM AAAS.)

As originally demonstrated by McClintock, eukaryotic genomes contain large numbers of transposable elements. In fact, *at least* 45 percent of the DNA in a human cell nucleus has been derived from transposable elements! The vast majority (>99 percent) of transposable elements are incapable of moving from one place to another; they have either been crippled by mutation or their movement is suppressed by the cell. (Suppression occurs by means of small cellular RNAs [Section 11.5] and DNA methylation [Section 12.4]). However, when transposable elements do change position, they insert widely throughout the target DNA. In fact, many transposable elements can insert themselves within the center of a protein-coding gene. Several examples of such an occurrence have been documented in humans, including a number of cases of hemophilia caused by a mobile genetic element that had “jumped” into the middle of one of the key blood clotting genes. It is estimated that approximately 1 out of 500 disease-causing mutations in humans is the result of the insertion of a transposable element. In addition, the reactivation of transposable elements may contribute to the development of certain cancers.

Figure 10.26 illustrates two major types of eukaryotic transposable elements, DNA transposons and retrotransposons, and their differing mechanism of transposition. As described above for prokaryotes, most eukaryotic DNA transposons are excised from the DNA at the donor site and inserted at a distant target site (Figure 10.26*a*). This “cut-and-paste” mechanism is utilized, for example, by members of the *mariner* family of transposons, which are found throughout the plant and animal kingdoms. **Retrotransposons**, in contrast, operate by means of a “copy-and-paste” mechanism that involves an RNA intermediate (Figure 10.26*b*). The DNA of the transposable element is transcribed, producing an RNA, which is then “reverse transcribed” by an enzyme called **reverse transcriptase**, producing a complementary DNA. The DNA copy is made double-stranded and then integrated into a target DNA site. In most cases, the retrotransposon itself contains the sequence that codes for a reverse transcriptase. Retroviruses, such as the virus responsible for AIDS, use a very similar mechanism to replicate their RNA genome and integrate a DNA copy into a host chromosome.

The Role of Mobile Genetic Elements in Genome Evolution It was noted on page 403 that moderately repeated DNA sequences constitute a significant portion of eu-

karyotic genomes. Unlike the highly repeated fraction of the genome (satellite, minisatellite, and microsatellite DNA), whose sequences reside in tandem and arise by DNA duplication, most of the moderately repeated sequences of the genome are interspersed and arise by transposition of mobile genetic elements. In fact, the two most common families of moderately repeated sequences in human DNA—the *Alu* and L1 families—are retrotransposons. Recall from page 403 that there are two classes of interspersed elements, SINEs and LINEs. *Alu* is an example of the former and L1 is an example of the latter. A full-length, transposable L1 sequence (at least 6000 base pairs in length) encodes a unique protein with two catalytic activities: a reverse transcriptase that makes a DNA copy of the RNA that encoded it and an endonuclease that nicks the target DNA prior to insertion. The human genome is estimated to contain about 500,000 copies of L1, but the vast majority of these are incomplete, immobile elements. Even still, L1 mobility continues to affect human evolution. In one study, for example, that compared the DNA sequences of 25 different people, any two individuals in the group differed in the presence or absence of an L1 element, on average, at 285 sites in their respective genomes.

Even more abundant than L1 are the *Alu* sequences, which are interspersed at more than one million different sites

Figure 10.26 Schematic pathways in the movement of transposable elements. (a) DNA transposons move by a cut-and-paste pathway, whose mechanism is depicted in Figure 10.25. Approximately 3 percent of the human genome consists of DNA transposons, none of which are capable of transposition (i.e., all are relics left in the genome as a result of ancestral activity). (b) Retrotransposons move by a

copy-and-paste pathway. The steps involved in retrotransposition take place both in the nucleus and cytoplasm and require numerous proteins, including those of the host. More than 40 percent of the human genome consists of retrotransposons, only a few of which (e.g., 40–100) are thought to be capable of transposition. More than one mechanism of retrotransposition is known.

throughout the human genome. *Alu* is a family of short, related sequences about 300 base pairs in length. The *Alu* sequence closely resembles that of the small RNA present in the signal recognition particles found in conjunction with membrane-bound ribosomes (page 283). It is presumed that during the course of evolution, this cytoplasmic RNA was copied into a DNA sequence by reverse transcriptase and integrated into the genome. The tremendous amplification of the *Alu* sequence is thought to have occurred by retrotransposition using the reverse transcriptase and endonuclease encoded by L1 sequences.

Given its prevalence in the human genome, one might expect the *Alu* sequence to be repeated in genomes throughout the rest of the animal kingdom, but this is not the case. Comparative genomic studies indicate that the *Alu* sequence first appeared as a transposable element in the genome of primates about 60 million years ago and has been increasing in copy number ever since. The rate of *Alu* transposition has slowed dramatically over the course of primate evolution to its current estimated rate in humans of approximately once in every 200 births. These transposition events generate differences in the locations of *Alu* sequences from one person to another and thus contribute to the genetic diversity in the human population (page 416).

When something new like a transposable element is discovered in an organism, a biologist's first question is usually: What is its function? Many researchers who study transposition believe that transposable elements are primarily "junk." According to this view, a transposable element is a type of genetic parasite that can invade a host genome from the outside world, spread within that genome, and be transmitted to offspring—so long as it doesn't have serious adverse effects on the ability of the host to survive and reproduce. Even if this is the case, it doesn't mean that transposable elements cannot make positive contributions to eukaryotic genomes. Keep in mind that evolution is an opportunistic process—there is no preset path to be followed. Regardless of its origin, once a DNA sequence is present in a genome, it has the *potential* to be "put to use" in some beneficial manner during the course of evolution. For this reason, the portion of the genome formed by transposable elements has been referred to as a "genetic scrap yard." There are several ways that transposable elements appear to have been involved in adaptive evolution:

1. Transposable elements can, on occasion, carry adjacent parts of the host genome with them as they move from one site to another. Theoretically, two unlinked segments of the host genome could be brought together to form a new, composite segment. This may be a primary mechanism in the evolution of proteins that are composed of domains derived from different ancestral genes (as in Figure 2.36).
2. DNA sequences that were originally derived from transposable elements are found as parts of eukaryotic genes as well as parts of the DNA segments that regulate gene expression. For example, several transcription factors, which are the proteins that regulate gene expression, bind to sites in the DNA that arose originally from transposable elements. Even when there is no direct evidence of a function, many transposable elements are very similar in position and sequence to elements in the genomes of distant vertebrate relatives. This type of evolutionary conser-

vation suggests that these sequences carry out some beneficial role in the lives of their hosts (page 413).

3. In some cases, transposable elements themselves appear to have given rise to genes. The enzyme telomerase, which plays a key role in replicating the DNA at the ends of chromosomes (see Figure 12.24c), may be derived from a reverse transcriptase encoded by an ancient retrotransposon. The enzymes involved in the rearrangement of antibody genes (see Figure 17.18) are thought to be derived from a transposase encoded by an ancient DNA transposon. If this is in fact the case, our ability to ward off infectious diseases is a direct consequence of transposition.
4. A number of recent studies have found evidence that mammalian brain cells have a greatly elevated level of L1 retrotransposition compared to that of other tissues. It is hypothesized that these mobile elements, which insert at different sites in the genomes of different nerve cells, contribute to functional differences in the activities of brain cells.

One point is clear: transposition has had a profound impact on the genetic composition of organisms. It is interesting to note that, only a few decades ago, molecular biologists considered the genome to be a stable repository of genetic information. Now it seems remarkable that organisms can maintain themselves from one day to the next in the face of this large-scale disruption by genetic rearrangement. In hindsight, it is not surprising that transposition was first discovered in plants, because transposable elements tend to be much more active in plants than they are in other eukaryotes. For her discovery of transposition, Barbara McClintock was the sole recipient of a Nobel Prize in 1983, at age 81, approximately 35 years after her initial report.

REVIEW

1. Describe the course of evolutionary events that are thought to give rise to multiple-gene families, such as those that encode the globins. How could these events give rise to pseudogenes? How could they give rise to proteins having entirely different functions?
2. Describe two mechanisms by which genetic elements are able to move from one site in the genome to another.
3. Describe the impact that transposable elements have had on the structure of the human genome over the past 50 million years.

10.6 | Sequencing Genomes: The Footprints of Biological Evolution

Determining the nucleotide sequence of all the DNA in a genome is a formidable task. During the 1980s and 1990s, the technology to accomplish this effort gradually improved, as researchers developed new vectors to clone large segments of DNA and increasingly automated procedures to determine the nucleotide sequences of these large fragments (discussed in

Section 18.14). The first complete sequence of a prokaryotic organism was reported in 1995, and the first complete sequence of a eukaryote, the budding yeast *S. cerevisiae*, was published the following year. Over the next few years—as the scientific community awaited the results of work on the human genome—the genomic sequences of numerous prokaryotic and eukaryotic organisms (including a fruit fly, nematode, and flowering plant) were reported. Researchers were able to sequence these genomes with relative speed because they are considerably smaller than the human genome, which contains approximately 3.2 billion base pairs. To put this number into perspective, if each base pair in the DNA were equivalent to a single letter on this page, the information contained in the human genome would produce a book approximately 1 million pages long.

By 2001, the rough draft of the nucleotide sequence of the human genome had been published. The sequence was de-

scribed as “rough” because each segment was sequenced an average of about four times, which is not enough to ensure complete accuracy, and many regions that proved difficult to sequence were excluded. The first attempts to *annotate* the human genomic sequence, that is, to interpret the sequence in terms of the numbers and types of genes it encoded, led to a striking observation concerning gene number. Researchers concluded that the human genome probably contained in the neighborhood of 30,000 protein-coding genes. Up until it had been sequenced, it had been widely assumed that the human genome contained at least 50,000 and maybe as many as 150,000 different genes.

The “finished” version of the human genome sequence was reported in 2004, which meant that (1) each site had been sequenced 7–10 times to ensure a very high degree of accuracy (at least 99.99 percent), and (2) the sequence contained a minimal number of gaps. The gaps that persisted contain regions of the chromosomes—often referred to as “dark matter”—that consist largely of long stretches of highly repeated DNA, especially those in and around the centromeres of each chromosome. Despite exhaustive efforts, these regions have proven impossible to clone, or their sequences have proven impossible to order correctly using current technology.

Despite this remarkable achievement in nucleotide sequencing, the actual number of protein-coding genes in the human genome remains uncertain. Identification of genes using various computer software programs (algorithms) has been plagued with difficulties, and, in fact, the earlier estimate of 30,000 protein-coding human genes has been revised steadily downward. Although it has come as a shock to most biologists, current estimates place the number in the neighborhood of 21,000! This means that humans have roughly the same number of protein-coding genes as a microscopic worm, whose entire body—nervous system and all—consists of approximately 1000 cells (Figure 10.27).⁴

It is evident from this data that it is not possible, as was once thought, to understand the nature of an organism by simply knowing a list of the genes that make up that organism’s genome. If the differences in complexity between organisms cannot be explained by the number of protein-coding genes in their genomes, how can they be explained? We really don’t have a very good answer to that question, but we can list a few possibilities to consider.

1. As will be described in Chapter 12, a single gene can encode a number of related proteins as a result of a process termed *alternative splicing* (see Section 12.5). Several recent studies suggest that over 90 percent of human genes might engage in alternative splicing, so that the actual number of proteins encoded by the human genome is at least several

Figure 10.27 Genome comparisons. Among eukaryotes whose genomes have been sequenced, the number of protein-coding genes (blue bars) varies from about 6,200 in yeast to 57,000 in apples, with vertebrates thought to possess about 20,000. (The high gene number in an apple reflects a relatively recent whole-genome duplication.) It is particularly interesting to note that apparent increases in the complexity of organisms are not reflected in dramatic increases in gene numbers. For example, neither (1) the transition from single-celled eukaryotes, such as *Chlamydomonas*, to the simplest multicellular animals, sponges, nor (2) the transition from invertebrates to vertebrates, is accompanied by major changes in the number of protein-coding genes. Whereas the number of estimated protein-coding genes varies over a modest range among eukaryotes, the amount of DNA in a genome (red bars) varies widely, reaching values of 90 billion base pairs in some salamanders (the actual gene number for these amphibians is unknown).

⁴It can also be seen from Figure 10.27 that there is very little correlation between the number of protein-coding genes and the total amount of DNA in the genome. The puffer fish, for example, which has about the same number of genes as other vertebrates, has a genome that is about one-eighth the size of its human counterpart. The ancestors of puffer fish, like most bony fish, are thought to have had typical vertebrate-sized genomes, which demonstrates that “excess” DNA can be lost in a lineage over evolutionary time. At the other end of the spectrum from the puffer fish, the genome of certain salamanders is roughly 30 times the size of the human genome. The contrasts in genome size among vertebrates reflects a striking difference in the content of noncoding, largely repetitive DNA. The evolutionary significance of these differences is unclear.

times greater than the number of genes it contains. It is likely that greater differences between organisms will emerge when this and other “gene-enhancing” mechanisms are explored further. This expectation is consistent with the observations that vertebrate genes tend to be more complex (i.e., contain more exons) than those of flies and worms and exhibit a higher incidence of alternative splicing.

2. Molecular biologists have devoted an enormous effort to studying the mechanisms that regulate gene expression. Despite this effort, our understanding of these mechanisms is very limited. We have learned, for example, that a large portion of the genome is transcribed into a bewildering array of RNAs, but we have very little information as to what most of these RNAs are doing within the cell. There is a growing belief that many of these RNAs have a gene regulatory function. There is also growing evidence that the number and complexity of these noncoding RNAs can be correlated with the levels of complexity of diverse organisms. In one study, for example, researchers sought to identify the number of microRNAs produced by various organisms. As discussed in the next chapter, microRNAs are one of the best studied regulatory RNAs. Researchers found that sponges expressed about 10 different microRNAs, and sea anemones approximately 40. This compares to approximately 150 identified in worms and fruit flies and at least one thousand in humans. This is not to imply that the number of microRNAs is the primary determinant of morphological complexity. Rather, it suggests that we will have to learn a great deal more about gene regulation if we are going to understand the basis of biological diversity.
3. Over the past decade or so, a new area of biological study (called systems biology) has emerged that focuses on the ways that proteins work together as complex networks rather than as individual actors. A very simple example of a protein network was presented in Figure 2.41. Given that cells produce thousands of different proteins, with varying degrees of interaction, these networks can become very complex and dynamic. A relatively small increase in the number of elements that make up a network, or an increase in the size and complexity of those elements, could dramatically increase the complexity of the network and thus the complexity of the entire organism.

Numerous other factors could be added to this discussion, but the general point is clear: The apparent difference in complexity between different groups of multicellular organisms is less a matter of the amount of genetic information in an organism’s genome than that of the manner in which that information is put to use.

Comparative Genomics: “If It’s Conserved, It Must Be Important”

Consider the following facts: (1) The majority of the genome consists of DNA that resides between the genes, and thus represents intergenic DNA, and (2) each of the roughly 21,000 or so protein-coding human genes consists largely of noncoding portions (intronic DNA). Taken together, these facts indicate that the protein-coding portion of the genome represents a remark-

ably small percentage of the total DNA (estimated at about 1.5 percent). Most of the intergenic and intronic DNA of the genome does not contribute to the survival and reproductive capability of an individual, so there is no selective pressure to maintain its sequence unchanged. As a result, most intergenic and intronic sequences tend to change rapidly as organisms evolve. In other words, these sequences tend not to be conserved. In contrast, those segments of the genome that encode protein sequences or contain regulatory sequences that control gene expression (see Figure 12.45) are subject to natural selection. Natural selection tends to eliminate individuals whose genome contains mutations in these functional elements.⁵ As a result, these sequences tend to be conserved. It follows from these comments that the best way to identify functional sequences is to compare the genomes of different types of organisms.

Despite the fact that humans and mice have not shared a common ancestor for about 75 million years, the two species share similar genes, which tend to be clustered in a remarkably similar pattern. For example, the number and order of human globin genes depicted in Figure 10.23 is basically similar to that found on a comparable segment of DNA in the mouse genome. As a result, it becomes possible to align corresponding regions of the mouse and human genomes. Human chromosome number 12, for example, is composed of a series of segments, in which each segment corresponds roughly to a block of DNA from a mouse chromosome. The number of the mouse chromosome containing each block is indicated.

Even a quick examination of this drawing of a human chromosome reveals the dramatic changes in chromosome structure that occur as evolution generates new species over time. Blocks of genes that are present on the same chromosome in one species can become separated into different chromosomes in a subsequent species. Over time, chromosome numbers can increase or decrease as chromosomes split apart or fuse together. One estimate suggests that approximately 180 breakage and fusion events have taken place in the mouse and human lineages since the time these two present-day mammals last shared a common ancestor. Taken by themselves, changes in the positions of genes have very little effect on the phenotypes of the organisms, but they provide a clear visual footprint of the evolutionary process.

When homologous segments of the mouse and human genome are aligned on the basis of their nucleotide sequences, it is found that approximately 5 percent of DNA sequences are highly conserved between the two species. This is a considerably higher percentage than would have been expected by combining

⁵One can recognize two opposing sides of natural selection. Negative or purifying selection acts to maintain (conserve) sequences with important functions as they are because changes reduce the likelihood that the individual will survive and reproduce. These regions of the genome evolve more slowly than nonfunctional sequences whose change has no effect on the fitness of the individual and are not subject to natural selection (such sequences are said to evolve neutrally). In contrast, positive or Darwinian selection promotes speciation and evolution by selecting for changes in sequence that cause individuals to be better adapted to their environment and thus more likely to survive and reproduce. These regions evolve more rapidly than nonfunctional segments.

the known protein-coding regions and gene regulatory regions (together accounting for roughly 2 percent of the genome). If we adhere to one of the foremost principles of molecular evolution: “if it’s conserved, it must be important,” then these studies are telling us that parts of the genome that were presumed to consist of “useless” sequences actually have important, unidentified functions. Some of these regions undoubtedly encode RNAs that have various regulatory functions (discussed in Section 11.5). Others likely have “chromosomal functions” rather than “genetic functions.” For example, these conserved sequences could be important for chromosome pairing prior to cell division. Whatever the function, these genomic elements are often located at great distances from the closest gene and include some of the most conserved sequences ever discovered, exhibiting virtual identity between human, rat, and mouse genomes.

By comparing stretches of the genome between two distantly related species, such as the human and mouse, one can identify those regions that have been conserved for tens of millions of years. However, this approach won’t identify functional sequences in the human genome that have a more recent evolutionary origin. This could include, for example, genes that are present in humans and absent from mice, or regulatory regions that have changed their sequence over the course of primate evolution to allow them to bind new regulatory proteins. A concerted effort (called the ENCODE Project) is underway to identify all of the functional elements present in the human genome. Unfortunately, we lack the knowledge necessary to recognize many of these functional elements, which obviously confounds the task. One point has become clear from recent studies: a significant proportion of functional DNA sequences are constantly evolving and thus are not highly conserved. In other words, if we restrict our search to conserved sequences, we run the risk of missing many of the most important functional elements in the genome.

The Genetic Basis of “Being Human”

By focusing on conserved sequences, we tend to learn about characteristics that we share with other organisms. If we want to better understand our own unique biological evolution, we have to look more closely at those parts of the genome that distinguish us from other organisms. Chimpanzees are our closest living relative, having shared a common ancestor as recently as 5–7 million years ago. It was thought that a detailed analysis of the differences in DNA sequence and gene organization between chimpanzees and humans might tell us a great deal about the genetic basis for recently evolved features that make us uniquely human, such as our upright walk and advanced use of tools and language. These latter characteristics can be traced to our brain, which has a volume of about 1300 cm³—nearly four times that of a chimpanzee.

The rough draft of the chimpanzee genome was reported in 2005. Overall, the chimpanzee and human genomes differ by roughly 4 percent, which amounts to tens of millions of differences—a level of divergence that is considerably greater than expected from preliminary studies. While some of this divergence is due to single nucleotide changes between the two genomes, most is attributed to larger differences, such as deletions and segmental duplications (see footnote, page 407).

Researchers have been able to identify hundreds of genes in the human lineage that are evolving more quickly than the background (or neutral) rate, presumably in response to natural selection. However, it remains unclear which, if any, of these genes contribute to “making us human.” Some of the fastest evolving genes encode proteins involved in regulation of gene expression (i.e., transcription factors). These are precisely the types of genes that would be expected to generate major phenotypic differences because they can affect the expression of large numbers of other genes. In fact, differences between chimp and human transcription factors are presumably responsible for many of the differences in expression of brain proteins seen in Figure 2.48. This can be illustrated by closer examination of a brain-specific transcription factor called *FOXP2*.

A comparison of the *FOXP2* protein between humans and chimps shows two amino acid differences that have appeared in the human lineage since the time of separation from our last common ancestor. To assess the effects of these amino acid substitutions on *FOXP2* function, human neuronal cells that lacked their own *FOXP2* gene were engineered to express either the chimp or human version of the gene. These two cell populations were then studied in culture to assess the effects of the alternate versions of the transcription factor. It was found that more than 100 target genes were significantly upregulated or downregulated in cells expressing the human *FOXP2* gene when compared to cells expressing the chimp version of the transcription factor. What makes the *FOXP2* gene so interesting is that persons with mutations in the gene suffer from a severe speech and language disorder. Among other deficits, persons with this disorder are unable to perform the fine muscular movements of the lips and tongue that are required to engage in vocal communication. Calculations suggest that the changes in this “speech gene” that distinguish it from the chimp version became “fixed” in the human genome within the past 120,000 to 200,000 years, a time when modern humans are thought to have emerged. (An alteration in DNA sequence is said to be *fixed* if it is now present in virtually all members of the species.) These findings suggest that changes in the *FOXP2* gene may have played an important role in the evolution and development of human speech.

Many other genomic differences between chimps and humans have also been described, including alterations in certain RNA-encoding genes that appear to affect brain development. One of the genes in this latter category, called *HAR1*, stretches for a mere 118 base pairs but contains 18 base substitutions that distinguish it from the corresponding region in the chimp genome. This same region is highly conserved among other vertebrates, so it is only during the evolution of humans that it has experienced such pronounced effects of natural selection. (*HAR* stands for *Human Accelerated Region*). Although the function of *HAR1* is unknown, the fact that it is expressed primarily in the developing fetal brain makes it a gene of interest to researchers trying to unravel the genomic basis of human brain expansion.

Another gene of interest encodes the starch-digesting enzyme amylase that is present in saliva. Chimps have a relatively low-starch diet and have one copy of the *AMY1* gene in their genome (Figure 10.28*a*). During the evolution of humans, there has been an apparent selection for an increased number of copies of the *AMY1* gene, which has resulted in an

increased concentration of the amylase enzyme in human saliva. One might have predicted that an increased amylase level would have been accomplished during evolution by an increase in the level of expression of the single existing *AMY1* gene in the genome, but in this particular case it has resulted from gene duplication. As seen in Figure 10.28b and discussed in the next section, the number of copies of the *AMY1* gene among humans is variable. In fact, the number of copies of this gene tends to be higher in human populations that ingest greater quantities of starch in their diet.

One of the most interesting questions in the area of human evolution concerns possible relationships between modern humans (i. e., *Homo sapiens*) and those of other “human” species (i.e., archaic members of the *Homo* genus that are now extinct). Humans that would be indistinguishable from our

Figure 10.28 Duplication of the amylase gene during human evolution. In the results depicted here, a pair of homologous chromosomes from a chimp (a) or a human (b) have been hybridized to red and green colored probes that bind to different portions of the *AMY1* gene. This gene encodes the starch-digesting enzyme salivary amylase. The number of copies of the *AMY1* gene on each chromosome is revealed by the number of times the fluorescent probes are repeated. The chimp has one copy of the *AMY1* gene on each chromosome (i.e., one copy per genome), whereas humans have a number of copies. The number of copies of the gene varies within the human genome as illustrated here by the fact that one of the two homologous chromosomes from this individual has 4 copies of the gene and the other homologous chromosome has 10 copies. This is an example of a *copy number variation* (page 417). Moreover, the number of copies of the *AMY1* gene in the genomes of a given human population tends to correlate with the amount of starch in the diet of that population. This correlation strongly suggests that the copy number of the *AMY1* gene has been influenced by natural selection. (FROM GEORGE H. PERRY, ET AL., COURTESY OF NATHANIEL J. DOMINY, NATURE GEN. 39:1257, 2007. REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LTD.)

present species, that is, anatomically modern humans, are thought to have first evolved in Africa approximately 200,000 years ago. But *Homo sapiens* are not the only members of the *Homo* genus to have inhabited Earth in the past 200,000 years. In fact, another member of the genus, the Neanderthals (*Homo neanderthalensis*), was a resident of Europe as recently as 35,000 years ago, thousands of years after the arrival of modern humans on the continent. The two species are thought to have shared some of the same regions in the Middle East at an even earlier time period. Given that both of our species inhabited similar areas and were very similar anatomically, paleontologists have wondered whether (1) the two species had interbred or (2) modern humans had simply replaced the Neanderthals without interbreeding. An answer to that question requires detailed information about the differences in DNA sequences between modern humans and Neanderthals.

Beginning in the late 1990s, researchers have developed increasingly sophisticated techniques to isolate and sequence snippets of mitochondrial DNA (mtDNA) from fossil remains of Neanderthals. Mitochondrial DNA is easier to analyze from fossils than is nuclear DNA because each cell contains many copies of the mitochondrial genome and it is much smaller in size. Results of these studies suggested that the Neanderthal mtDNA sequence was sufficiently different from that of modern human mtDNA to conclude that Neanderthals went extinct without contributing genetic material to the modern human mitochondrial genome. In other words, the two species had not interbred and, moreover, had not shared a common ancestor for at least 300,000 years.

By 2010, Svante Pääbo and colleagues at the Max Planck Institute in Germany had assembled a relatively complete sequence of the Neanderthal *nuclear* genome and concluded that modern humans and Neanderthal genomes are 99.84 percent identical. Neanderthals, for example, had the same *FOXP2* allele (discussed above) as do modern humans, which hinted that they too had verbal language skills. Moreover, a detailed comparison of the nuclear genomes from a number of different Neanderthal fossils and those of several present-day humans suggests that approximately 1 to 4 percent of the DNA of modern Europeans and Asians is derived from a Neanderthal source. Many of the genes in the Neanderthal-derived DNA contribute to the immune system’s recognition of pathogens. Acquisition of these genes may have served to protect the newly arrived humans from diseases to which the Neanderthals had previously been exposed. In contrast, the genomes of Africans show no evidence of a contribution by Neanderthals. According to this data, modern humans and Neanderthals interbred at some point in time and space after modern humans had left Africa and before they had spread into Europe and Asia. Other reports suggest that some groups of modern humans have ancient ancestors that may have interbred with other archaic human species besides Neanderthals. These findings have set the stage for some very interesting speculation concerning the human phylogenetic tree. According to some researchers who envision a number of human species sharing the planet over the past 100,000 years or so, our present population can be described as “the last humans standing.”

We have focused in this section on genomic differences between humans and other primates because this is the subject of

the present chapter. It is probably evident from the limited nature of this discussion that researchers have not yet made much progress in identifying the genetic basis of “being human.” Many researchers believe that too much attention in this field has been focused on changes in protein-coding sequences. Instead, they would argue that changes in the regulation of gene expression have played a primary role in human evolution, but it is difficult to ascertain which of these changes have real importance.

Genetic Variation Within the Human Species Population

No one else in the world looks exactly like you because no one else, other than an identical twin, has the same DNA sequence throughout their genome. The human genome that was sequenced by the original Human Genome Project was derived largely from a single human male. Since the completion of that sequence, a great deal of attention has been focused on how DNA sequence varies within the human population. **Genetic polymorphisms** are sites in the genome that vary among different individuals. The term usually refers to a genetic variant that occurs in at least 1 percent of a species population. The concept of genetic polymorphisms began with the discovery in 1900 by an Austrian physician, Karl Landsteiner, that people could have at least three alternate types of blood, A, B, or O. As discussed on page 130, the ABO blood group is a result of members of the population having different alleles of a gene encoding a sugar-transferring enzyme. Now that we are in possession of our own genomic sequence, we are in a position to search for new types of genetic variation that would never have been revealed in the “pregenomic era.”

DNA Sequence Variation The most common type of genetic variability in humans occurs at sites in the genome where single nucleotide differences are found among different members of the population. When present in at least 1 percent of the population, these sites are called **single nucleotide polymorphisms (SNPs)**. The vast majority of SNPs (pronounced “snips”) occur as two alternate alleles, such as A or G. Most SNPs are thought to have arisen by mutation only once during the course of human evolution and are shared by individuals through common descent. Commonly occurring SNPs have been identified by comparing DNA sequences from the genomes of hundreds of different individuals from diverse ethnic populations. On average, two randomly selected human genomes have about 3 million single nucleotide differences between them, or one every thousand base pairs. Although this might appear to be a large number, it means that humans are, on average, 99.9 percent similar to one another with respect to nucleotide sequence, which is probably much greater than most mammalian species. This sequence similarity reflects the fact that we are apparently a young species, in evolutionary terms, and our prehistoric population size was relatively small. Of the 15 million or so SNPs in the genome, it is estimated that approximately 20,000 are found within protein-coding sequences and lead to amino acid replacements within the encoded protein. This corresponds to about one amino acid substitution per gene. It is this body of genetic variation that is thought to be largely responsible for the phenotypic variability observed among humans. The impact of human genome sequence variation on

the practice of medicine is discussed in the accompanying Human Perspective.

Structural Variation As illustrated in Figure 10.29a, segments of the genome can change as the result of duplications, deletions, insertions, inversions (when a piece of DNA exists in a reversed orientation), and other events. These types of changes typically involve segments of DNA ranging from

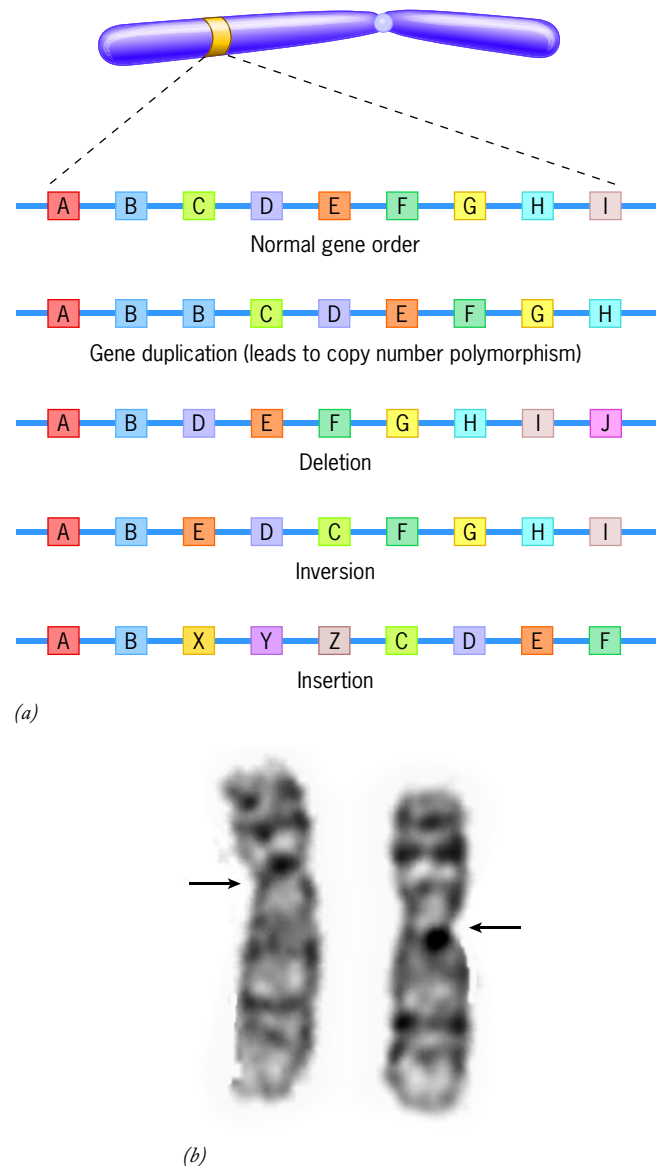

Figure 10.29 Structural variants. (a) Schematic representation of the major types of genomic polymorphisms that involve a significant segment of a chromosome (e.g., thousands of base pairs). Most of these polymorphisms are too small to be detected by microscopic examination of chromosomes but are detected when the number and/or chromosomal location of individual genes are determined. (b) On the left is a normal human chromosome #9, and on the right is a chromosome #9 containing a large inversion that includes the chromosome’s centromere (arrow). This inversion, which is clearly visible microscopically, is present in 1–3 percent of the population. (B: FROM CHARLES LEE, NATURE GEN. 37:661, 2005. REPRINTED BY PERMISSION FROM MACMILLAN PUBLISHERS LIMITED.)

hundreds to millions of base pairs in length. Because of their relatively large size, these types of polymorphisms are called *structural variants*, and we are just beginning to grasp the extent and importance of their presence.

It has been known since the early days of microscopic chromosome analysis that not all healthy people have identical chromosome structures. Figure 10.29*b* shows an example of a common chromosome inversion whose existence has been known for over 30 years. Recent studies have revealed that intermediate-sized structural variants—those that are too small to be seen under the microscope and too large to be readily detected by conventional sequence analysis—are much more common than previously thought. According to one estimate, a typical human genome carries approximately 1000 structural variants, ranging in length from about 500 bases to 1.3 million bases (Mb). Although the estimates vary considerably, it is evident that the fraction of the genome (i.e., total number of base pairs) affected by structural variation is greater than that affected by SNPs. As a result, structural variation has a significant effect on phenotypic variation among humans.

Copy Number Variation As discussed on page 402, the technique of DNA fingerprinting depends on differences in the lengths of minisatellite sequences, which in turn depend on the number of copies of the sequence that are present at particular sites in the chromosomes. This is an example of a *copy number variation* (or *CNV*). Recent findings have revealed that much

larger-sized CNVs (>1 kb) are also common in the human population, affecting approximately 10–15 percent of the genome, including large numbers of protein-coding genes. These larger-sized CNVs are a type of structural variation that results from a duplication or deletion of a DNA segment. Because of such CNVs, many of us carry extra copies of one or more genes that encode important physiological proteins. Extra copies of genes are generally associated with overproduction of a protein, which can disrupt the delicate biochemical balance that exists within a cell. It is found, for example, that a significant number of persons who develop early-onset Alzheimer's disease possess extra copies of the *APP* gene, which encodes the protein thought to be responsible for the disease (page 68). Although the subject has been controversial, there is a growing consensus among researchers that individuals with autism or schizophrenia have a greater-than-normal number of rare CNVs in their genomes. Some of the genes affected by these CNVs are involved in synapse formation and other neurological processes. In some cases, extra copies of a gene can be beneficial, as illustrated by the repeated duplication of the amylase gene (*AMY1*), which has been found in certain human populations that have a high starch content in their diet (Figure 10.28*b*). Figure 10.28*b* also provides an excellent example of a CNV in that it shows the number of *AMY1* genes on both copies of one person's homologous chromosomes. It can be seen that one chromosome contains only 4 copies of the *AMY1* gene, whereas the homologous chromosome contains 10 copies of the gene.

THE HUMAN PERSPECTIVE

Application of Genomic Analyses to Medicine

Over the past several decades, more than a thousand genes have been identified as the cause of rare, heritable diseases. In the vast majority of cases, the gene responsible for the disease being investigated was identified through traditional genetic linkage studies. Such studies begin by locating a number of families whose members exhibit a disproportionately high frequency of a particular disease. The initial challenge is to determine which altered region of the genome is shared by all affected members of the family. Once a region linked to the disease gene is identified, the DNA of that segment can be isolated and the mutant gene pinpointed. This type of genetic approach is well suited for the identification of genes that have very high penetrance, that is, genes whose mutant form virtually guarantees that the individual will be afflicted with the disorder. The mutated gene responsible for Huntington's disease (page 404), for example, exhibits very high penetrance. Furthermore, no other gene defect in the genome causes this disease. Genes that exhibit very high penetrance are said to follow Mendelian inheritance, and more than 3000 such genes have been identified.

Most of the common diseases that afflict our species, such as cancer, heart failure, Alzheimer's disease, diabetes, asthma, depression, and various age-related diseases, have a genetic component, which is to say that they show at least some tendency to run in families. But unlike inherited disorders such as Huntington's disease, there is no single gene that is clearly linked with the condition. Instead, numerous genes are likely to affect the disease risk, with each of them making only a small contribution to the overall likelihood of develop-

ing the disorder. In addition, the development of the disorder is often influenced by nongenetic (i.e., environmental) factors. The likelihood of developing diabetes, for example, is greatly increased in individuals who are seriously overweight, and the likelihood of developing lung cancer is greatly increased by smoking. One of the goals of the medical research community is to identify genes that contribute to the development of these common, but genetically complex, diseases.

Because of their low penetrance, most genes that increase the risk of developing common diseases cannot be identified through family linkage studies.^a Instead, such genes are best identified by analyzing disease occurrence in large populations. To carry out this type of investigation, researchers compare the genotypes of individuals who have the disease in question with individuals of a similar ethnic background who are not afflicted. The goal is to discover an *association* (or correlation) between a particular condition, such as diabetes, and common genetic polymorphisms. The potential value of this approach is illustrated by the discovery in the early 1990s of a strong association between one common allele of the gene encoding the lipoprotein ApoE and the likelihood of developing Alzheimer's

^aNot all genes involved in common diseases have a low penetrance. Alzheimer's disease, for example, occurs with high frequency in persons having certain *APP* alleles (page 68) and breast cancer occurs with high frequency in persons having certain *BRCA* alleles (Section 16.3). But these types of rare, high-penetrance polymorphisms are not major factors in the development of the large majority of cases for either of these diseases.
