Primary prevention of hemorrhagic stroke is the best approach and includes managing hypertension and ameliorating other significant risk factors. Control of hypertension, especially in people older than 55 years of age, reduces the risk of hemorrhagic stroke (Luders, 2007). Additional risk factors are increased age, male gender, and excessive alcohol intake. Stroke risk screenings provide an ideal opportunity to lower hemorrhagic stroke risk by identifying high-risk individuals or groups and educating patients and the community about recognition and prevention.

Complications

Potential complications of hemorrhagic stroke include rebleeding or hematoma expansion; cerebral vasospasm resulting in cerebral ischemia; acute hydrocephalus, which results when free blood obstructs the reabsorption of cerebrospinal fluid (CSF) by the arachnoid villi; and seizures.

Cerebral Hypoxia and Decreased Blood Flow

Immediate complications of a hemorrhagic stroke include cerebral hypoxia, decreased cerebral blood flow, and extension of the area of injury. Providing adequate oxygenation of blood to the brain minimizes cerebral hypoxia. Brain function depends on delivery of oxygen to the tissues. Administering supplemental oxygen and maintaining the hemoglobin and hematocrit at acceptable levels will assist in maintaining tissue oxygenation.

Cerebral blood flow is dependent on the blood pressure, cardiac output, and integrity of cerebral blood vessels. Adequate hydration (IV fluids) must be ensured to reduce blood viscosity and improve cerebral blood flow. Extremes of hypertension or hypotension need to be avoided to prevent changes in cerebral blood flow and the potential for extending the area of injury.

A seizure can also compromise cerebral blood flow, resulting in further injury to the brain. Observing for seizure activity and initiating appropriate treatment are important components of care after a hemorrhagic stroke.

Vasospasm

The development of cerebral vasospasm (narrowing of the lumen of the involved cranial blood vessel) is a serious complication of subarachnoid hemorrhage and is the leading cause of morbidity and mortality in those who survive the initial subarachnoid hemorrhage (Kosty, 2005). The mechanism responsible for vasospasm is not clear, but it is associated with increasing amounts of blood in the subarachnoid cisterns and cerebral fissures, as visualized by CT scan. Monitoring for vasospasm may be performed through the use of bedside transcranial Doppler ultrasonography (TCD) or follow-up cerebral angiography.

Ethics and Related Issues

What Are the Ethical Issues Related to DNR Orders After Severe Stroke?

Situation

An 85-year-old patient is admitted with a large intracerebral hemorrhage, severe neurologic deficits, and a past medical history of coronary artery bypass graft surgery, hypertension, atrial fibrillation, and gout. The patient does not have an advanced directive. The attending physician suggests a do-not-resuscitate (DNR) order to the family.

Dilemma

The principle of autonomy for the patient (including death with dignity) conflicts with the principle of beneficence for the health care providers.

Discussion

1. What arguments would you pose in favor of the DNR order?
2. What arguments would you pose against the DNR order?
3. Does the family have the right to refuse?
4. Is a DNR order an example of "patient abandonment" by health care workers, or an attempt to limit treatment and avoid CPR in a patient with an anticipated poor outcome?

Vasospasm frequently occurs 3 to 14 days after initial hemorrhage, when the clot undergoes lysis (dissolution), and the chance of rebleeding is increased (Hickey, 2009). It leads to increased vascular resistance, which impedes cerebral blood flow and causes brain ischemia and infarction. The signs and symptoms reflect the areas of the brain involved. Vasospasm is often heralded by a worsening headache, a decrease in level of consciousness (confusion, lethargy, and disorientation), or a new focal neurologic deficit (aphasia, hemiparesis).

Management of vasospasm remains difficult and controversial. It is believed that early surgery to clip the aneurysm prevents rebleeding and that removal of blood from the basal cisterns around the major cerebral arteries may prevent vasospasm. Advances in technology have led to the introduction of interventional neuroradiology for the treatment of aneurysms. Endovascular techniques may be used in selected patients to occlude the artery supplying the aneurysm with a balloon, coils, or other techniques to occlude the aneurysm itself. As more studies on these techniques are completed, their use will increase.

Medication may be effective in the treatment of vasospasm. Based on one theory, that vasospasm is caused by an increased influx of calcium into the cell, medication therapy may be used to block or antagonize this action and prevent or reverse the action of vasospasm if already present. The most frequently used calcium channel blocker is nimodipine (Nimotop) (Devlin, 2008). Another therapy for vasospasm, referred to as “triple-H therapy,” is aimed at minimizing the deleterious effects of the associated cerebral ischemia and includes (1) fluid volume expanders (hypervolemia), (2) induced arterial hypertension, and (3) hemodilution (Kosty, 2005).

Increased Intracranial Pressure

An increase in ICP can occur after either an ischemic or a hemorrhagic stroke but almost always follows a subarachnoid hemorrhage, usually because of disturbed circulation of CSF caused by blood in the basal cisterns. Neurologic assessments are performed frequently, and if there is evidence of deterioration from increased ICP (due to cerebral edema, herniation, hydrocephalus, or vasospasm), CSF drainage may be instituted by ventricular catheter drainage. Mannitol may be administered to reduce ICP. When mannitol is used as a long-term measure to control ICP, dehydration and disturbances in electrolyte balance (hyponatremia or hypernatremia; hypokalemia or hyperkalemia) may occur. Mannitol pulls water out of the brain tissue by osmosis and reduces total-body water through diuresis. The patient is monitored for signs of dehydration and for rebound elevation of ICP. Other interventions may include elevating the head of the bed, sedation, and hyperosmolar therapy (discussed in the vasospasm section) (Broderick, Connolly, Feldmann, et al., 2007; Presciutti, 2006).

Hypertension

Hypertension is the most common cause of intracerebral hemorrhage, and its treatment is critical. Specific goals for blood pressure management, which are individualized for each patient, remain controversial. Blood pressure goals may be dependent on the presence of increased ICP.

Clinical trials are currently ongoing to further investigate control of blood pressure in intracerebral hemorrhage (Broderick, et al., 2007). Systolic blood pressure may be lowered to prevent hematoma enlargement. If blood pressure is elevated, antihypertensive therapy (labetalol [Trandate], nifedipine [Cardene], nitroprusside [Nitropress], hydralazine [Apresoline]) may be prescribed. During the administration of antihypertensives, arterial hemodynamic monitoring is important to detect and avoid a precipitous drop in blood pressure, which can produce brain ischemia. Stool softeners are used to prevent straining, which can elevate the blood pressure.

Medical Management

The goals of medical treatment for hemorrhagic stroke are to allow the brain to recover from the initial insult (bleeding), to prevent or minimize the risk of rebleeding, and to prevent or treat complications. Management may consist of bed rest with sedation to prevent agitation and stress, management of vasospasm, and surgical or medical treatment to prevent rebleeding. If the bleeding is caused by anticoagulation with warfarin (Coumadin), the INR may be corrected with fresh-frozen plasma and vitamin K. Because seizures can occur after intracerebral hemorrhage, anti-seizure agents are often administered prophylactically for a brief period of time. Analgesic agents may be prescribed for head and neck pain. The patient is fitted with sequential compression devices or anti-embolism stockings to prevent deep vein thrombosis (DVT). Fever should be treated. Hyperglycemia should also be treated (an IV insulin drip may be required to achieve control) (Broderick, et al., 2007; Presciutti, 2006). After discharge most patients will require antihypertensive medications to decrease their risk of another intracerebral hemorrhage.

Surgical Management

In many cases, a primary intracerebral hemorrhage is not treated surgically. However, if the diameter of the hematoma exceeds 3 cm and the Glasgow Coma Scale score decreases, surgical evacuation is strongly recommended for the patient with a cerebellar hemorrhage (Broderick, et al., 2007). Surgical evacuation is most frequently accomplished via a craniotomy (see Chapter 61).

The patient with an intracranial aneurysm is prepared for surgical intervention as soon as his or her condition is considered stable. Surgical treatment of the patient with an unruptured aneurysm is an option. The goal of surgery is to prevent bleeding in an unruptured aneurysm or further bleeding in an already ruptured aneurysm. This objective is accomplished by isolating the aneurysm from its circulation or by strengthening the arterial wall. An aneurysm may be excluded from the cerebral circulation by means of a ligature or a clip across its neck. If this is not anatomically possible, the aneurysm can be reinforced by wrapping it with some substance to provide support and induce scarring.

Less invasive endovascular treatments are now being used for aneurysms. These procedures are performed by neurosurgeons in neurointerventional radiology facilities. Two procedures include endovascular treatment (occlusion of the parent artery) and aneurysm coiling (obstruction of the aneurysm site with a coil). Although these techniques are

associated with lower risks than intracranial surgery in general, secondary stroke and rupture of the aneurysm are still potential complications.

Postoperative complications include psychological symptoms (disorientation, amnesia, **Korsakoff's syndrome**, personality changes), intraoperative embolization, postoperative internal artery occlusion, fluid and electrolyte disturbances (from dysfunction of the neurohypophyseal system), and gastrointestinal bleeding.

NURSING PROCESS

THE PATIENT WITH A HEMORRHAGIC STROKE

Assessment

A complete neurologic assessment is performed initially and includes evaluation for the following:

- Altered level of consciousness
- Sluggish pupillary reaction
- Motor and sensory dysfunction
- Cranial nerve deficits (extraocular eye movements, facial droop, presence of ptosis)
- Speech difficulties and visual disturbance
- Headache and nuchal rigidity or other neurologic deficits

All patients should be monitored in the intensive care unit after an intracerebral or subarachnoid hemorrhage. Neurologic assessment findings are documented and reported as indicated. The frequency of these assessments varies depending on the patient's condition. Any changes in the patient's condition require reassessment and thorough documentation; changes should be reported immediately.

Alteration in level of consciousness often is the earliest sign of deterioration in a patient with a hemorrhagic stroke. Because nurses have the most frequent contact with patients, they are in the best position to detect subtle changes. Mild drowsiness and slight slurring of speech may be early signs that the level of consciousness is deteriorating.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective tissue perfusion (cerebral) related to bleeding or vasospasm
- Disturbed sensory perception related to medically imposed restrictions (aneurysm precautions)
- Anxiety related to illness and/or medically imposed restrictions (aneurysm precautions)

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include the following:

- Vasospasm
- Seizures
- Hydrocephalus
- Rebleeding
- Hyponatremia

Planning and Goals

The goals for the patient may include improved cerebral tissue perfusion, relief of sensory and perceptual deprivation, relief of anxiety, and the absence of complications.

Nursing Interventions

Optimizing Cerebral Tissue Perfusion

The patient is closely monitored for neurologic deterioration resulting from recurrent bleeding, increasing ICP, or vasospasm. A neurologic flow record is maintained. The blood pressure, pulse, level of consciousness (an indicator of cerebral perfusion), pupillary responses, and motor function are checked hourly. Respiratory status is monitored, because a reduction in oxygen in areas of the brain with impaired autoregulation increases the chances of a cerebral infarction. Any changes are reported immediately.

IMPLEMENTING ANEURYSM PRECAUTIONS. Cerebral aneurysm precautions are implemented for the patient with a diagnosis of aneurysm to provide a nonstimulating environment, prevent increases in ICP, and prevent further bleeding. The patient is placed on immediate and absolute bed rest in a quiet, nonstressful environment, because activity, pain, and anxiety elevate the blood pressure, which increases the risk for bleeding. Visitors, except for family, are restricted.

The head of the bed is elevated 15 to 30 degrees to promote venous drainage and decrease ICP. Some neurologists, however, prefer that the patient remain flat to increase cerebral perfusion.

Any activity that suddenly increases the blood pressure or obstructs venous return is avoided. This includes the Valsalva maneuver, straining, forceful sneezing, pushing oneself up in bed, acute flexion or rotation of the head and neck (which compromises the jugular veins), and cigarette smoking. Any activity requiring exertion is contraindicated. The patient is instructed to exhale through the mouth during voiding or defecation to decrease strain. No enemas are permitted, but stool softeners and mild laxatives are prescribed. Both prevent constipation, which would cause an increase in ICP, as would enemas. Dim lighting is helpful, because photophobia (visual intolerance of light) is common. Coffee and tea, unless decaffeinated, are usually eliminated.

Anti-embolism stockings or sequential compression devices may be prescribed to decrease the incidence of DVT resulting from immobility. The legs are observed for signs and symptoms of DVT (tenderness, redness, swelling, warmth, and edema), and abnormal findings are reported.

The nurse administers all personal care. The patient is fed and bathed to prevent any exertion that might increase the blood pressure. External stimuli are kept to a minimum, including no television, no radio, and no reading. Visitors are restricted in an effort to keep the patient as quiet as possible. This precaution must be individualized based on the patient's condition and response to visitors. A sign indicating this restriction should be placed on the door of the room, and the restrictions should be discussed with both patient and family. The purpose of aneurysm precautions should be thoroughly explained to both the patient (if possible) and family.

Relieving Sensory Deprivation and Anxiety

Sensory stimulation is kept to a minimum for patients on aneurysm precautions. For patients who are awake, alert, and oriented, an explanation of the restrictions helps reduce the patient's sense of isolation. Reality orientation is provided to help maintain orientation.

Keeping the patient well informed of the plan of care provides reassurance and helps minimize anxiety. Appropriate reassurance also helps relieve the patient's fears and anxiety. The family also requires information and support.

Monitoring and Managing Potential Complications

VASOSPASM. The patient is assessed for signs of possible vasospasm: intensified headaches, a decrease in level of responsiveness (confusion, disorientation, lethargy), or evidence of aphasia or partial paralysis. These signs may develop several days after surgery or on the initiation of treatment and must be reported immediately. If vasospasm is diagnosed, calcium channel blockers or fluid volume expanders may be prescribed.

SEIZURES. Seizure precautions are maintained for every patient who may be at risk for seizure activity. Should a seizure occur, maintaining the airway and preventing injury are the primary goals. Medication therapy is initiated at this time, if not already prescribed. The medication of choice for many years has been phenytoin (Dilantin). Its use is being questioned based on the results of research including 527 patients that suggested that phenytoin may increase functional and cognitive disability after subarachnoid hemorrhage (Naidech, Kreiter, Janjua, et al., 2005).

HYDROCEPHALUS. Blood in the subarachnoid space or ventricles impedes the circulation of CSF, resulting in hydrocephalus. A CT scan that indicates dilated ventricles confirms the diagnosis. Hydrocephalus can occur within the first 24 hours (acute) after subarachnoid hemorrhage or several days (subacute) to several weeks (delayed) later. Symptoms vary according to the time of onset and may be nonspecific. Acute hydrocephalus is characterized by sudden onset of stupor or coma and is managed with a ventriculostomy drain to decrease ICP. Symptoms of subacute and delayed hydrocephalus include gradual onset of drowsiness, behavioral changes, and ataxic gait. A ventriculoperitoneal shunt is surgically placed to treat chronic hydrocephalus. Changes in patient responsiveness are reported immediately.

REBLEEDING. The rate of recurrent hemorrhage is approximately 2% after a primary intracerebral hemorrhage. Hypertension is the most serious risk factor, suggesting the importance of appropriate antihypertensive treatment.

Aneurysm rebleeding occurs most frequently during the first 2 weeks after the initial hemorrhage and is considered a major complication. Symptoms of rebleeding include sudden severe headache, nausea, vomiting, decreased level of consciousness, and neurologic deficit. Rebleeding is confirmed by CT scan. Blood pressure is carefully maintained with medications. The most effective preventive treatment is to secure the aneurysm if the patient is a candidate for surgery or endovascular treatment.

HYPONATREMIA. After subarachnoid hemorrhage, hyponatremia is found in up to 30% of patients (Naval, Stevens, Mirski, et al., 2006). Laboratory data must be checked frequently, and hyponatremia (defined as a serum sodium concentration of less than 135 mEq/L) must be identified as early as possible. The patient's primary health care provider needs to be notified of a low serum sodium level that has persisted for 24 hours or longer. The patient is then evaluated for syndrome of inappropriate antidiuretic hormone (SIADH) or cerebral salt-wasting syndrome. (SIADH is described in Chapter 14.) Cerebral salt-wasting syndrome occurs when the kidneys are unable to conserve sodium and volume depletion results. The treatment most often is the use of hypertonic 3% saline.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient and family are provided with information that will enable them to cooperate with the care and restrictions required during the acute phase of hemorrhagic stroke and to prepare them to return home. Patient and family teaching includes information about the causes of hemorrhagic stroke and its possible consequences. In addition, the patient and family are informed about the medical treatments that are implemented, including surgical intervention if warranted, and the importance of interventions taken to prevent and detect complications (ie, aneurysm precautions, close monitoring of the patient). Depending on the presence and severity of neurologic impairment and other complications resulting from the stroke, the patient may be transferred to a rehabilitation unit or center for additional patient and family teaching about strategies to regain self-care ability. Teaching addresses the use of assistive devices or modification of the home environment to help the patient live with the disability. Modifications of the home may be required to provide a safe environment.

CONTINUING CARE. The acute and rehabilitation phase of care focuses on obvious needs, issues, and deficits for the patient with a hemorrhagic stroke. The patient and family are reminded of the importance of following recommendations to prevent further hemorrhagic stroke and keeping follow-up appointments with health care providers for monitoring of risk factors. Referral for home care may be warranted to assess the home environment and the ability of the patient and to ensure that the patient and family are able to manage at home. Home visits provide opportunities to monitor the physical and psychological status of the patient and the ability of the family to cope with any alterations in the patient's status. In addition, the home care nurse reminds the patient and family of the importance of continuing health promotion and screening practices. Chart 62-7 lists teaching points for the patient recovering from a stroke.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Demonstrates intact neurologic status and normal vital signs and respiratory patterns
 - a. Is alert and oriented to time, place, and person

CHART
62-7

HOME CARE CHECKLIST

The Patient Recovering From a Stroke

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Discuss measures to prevent subsequent strokes.	✓	✓
• Identify signs and symptoms of specific complications.	✓	✓
• Identify potential complications and discuss measures to prevent them (blood clots, aspiration, pneumonia, urinary tract infection, fecal impaction, skin breakdown, contracture).	✓	✓
• Identify psychosocial consequences of stroke and appropriate interventions.	✓	✓
• Identify safety measures to prevent falls.	✓	✓
• State names, doses, indications, and side effects of medications.	✓	✓
• Demonstrate adaptive techniques for accomplishing ADLs.	✓	✓
• Demonstrate swallowing techniques (for patients with dysphagia).	✓	✓
• Demonstrate care of enteric feeding tube, if applicable.	✓	✓
• Demonstrate home exercises, use of splints or orthotics, proper positioning, and frequent repositioning.	✓	✓
• Describe procedures for maintaining skin integrity.	✓	✓
• Demonstrate indwelling catheter care, if applicable. Describe a bowel and bladder elimination program as appropriate.	✓	✓
• Identify appropriate recreational or diversional activities, support groups, and community resources.	✓	✓

- b. Demonstrates normal speech patterns and intact cognitive processes
 - c. Demonstrates normal and equal strength, movement, and sensation of all four extremities
 - d. Exhibits normal deep tendon reflexes and pupillary responses
2. Demonstrates normal sensory perceptions
 - a. States rationale for aneurysm precautions
 - b. Exhibits clear thought processes
 3. Exhibits reduced anxiety level
 - a. Is less restless
 - b. Exhibits absence of physiologic indicators of anxiety (eg, has normal vital signs; normal respiratory rate; absence of excessive, fast speech)
 4. Is free of complications
 - a. Exhibits absence of vasospasm
 - b. Exhibits normal vital signs and neuromuscular activity without seizures
 - c. Verbalizes understanding of seizure precautions
 - d. Exhibits normal mental status and normal motor and sensory status
 - e. Reports no visual changes

2 A 58-year-old man is admitted with an ischemic stroke and has left-sided hemiplegia. He is concerned about how to resume sexual relations with his wife and the possibility of not being able to resume sexual intimacy. Identify possible causes of sexual dysfunction after a stroke. What interventions can the nurse implement to address his concerns?

3 A 50-year-old patient with a history of hypertension is expected to be discharged to home today after a 7-day stay for a stroke. She has residual right-sided weakness and a visual field deficit. What teaching would be indicated to prevent another stroke? What resources may be needed to enable her to go home as scheduled?

EBP 4 A patient is admitted to the hospital following a hemorrhagic stroke and is at high risk for vasospasm. What medical and nursing measures should be implemented to prevent vasospasm? Identify the evidence for and the criteria used to evaluate the strength of the evidence for the specific measures identified for prevention of vasospasm.

CRITICAL THINKING EXERCISES

1 A patient had symptoms of an ischemic stroke approximately 1 hour ago and is undergoing a CT scan. What are the time frames, criteria, and dosage for t-PA administration? What nursing assessments and actions would you take? What is your rationale for these assessments and actions?

Management of Patients With Neurologic Trauma

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the mechanisms of injury, clinical signs and symptoms, diagnostic testing, and treatment options for patients with traumatic brain and spinal cord injuries.
- 2 Describe the nursing management of patients with brain injury.
- 3 Use the nursing process as a framework for care of patients with traumatic brain injury.
- 4 Identify the population at risk for spinal cord injury.
- 5 Describe the clinical features and management of the patient with neurogenic shock.
- 6 Discuss the pathophysiology of autonomic dysreflexia and describe the appropriate nursing interventions.
- 7 Use the nursing process as a framework for care of patients with spinal cord injury.

GLOSSARY

- autonomic dysreflexia:** a life-threatening emergency in spinal cord injury patients that causes a hypertensive emergency; also called autonomic hyperreflexia
- brain injury:** an injury to the skull or brain that is severe enough to interfere with normal functioning
- brain injury, closed (blunt):** occurs when the head accelerates and then rapidly decelerates or collides with another object and brain tissue is damaged, but there is no opening through the skull and dura
- brain injury, open:** occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path (penetrating injury), or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain
- complete spinal cord lesion:** a condition that involves total loss of sensation and voluntary muscle control below the lesion
- concussion:** a temporary loss of neurologic function with no apparent structural damage to the brain
- contusion:** bruising of the brain surface
- halo vest:** a lightweight vest with an attached halo that stabilizes the cervical spine
- head injury:** an injury to the scalp, skull, and/or brain
- incomplete spinal cord lesion:** a condition in which there is preservation of the sensory or motor fibers, or both, below the lesion
- neurogenic bladder:** bladder dysfunction that results from a disorder or dysfunction of the nervous system; may result in either urinary retention or bladder overactivity
- paraplegia:** paralysis of the lower extremities with dysfunction of the bowel and bladder from a lesion in the thoracic, lumbar, or sacral region of the spinal cord
- primary injury:** initial damage to the brain that results from the traumatic event
- secondary injury:** an insult to the brain subsequent to the original traumatic event
- spinal cord injury:** an injury to the spinal cord, vertebral column, supporting soft tissue, or intervertebral disks caused by trauma
- tetraplegia (quadriplegia):** paralysis of both arms and legs, with dysfunction of bowel and bladder from a lesion of the cervical segments of the spinal cord
- transection:** severing of the spinal cord itself; transection can be complete (all the way through the cord) or incomplete (partially through)

Trauma involving the central nervous system can be life-threatening. Even if it is not life-threatening, brain and spinal cord injury may result in major physical and psychological dysfunction and can alter the patient's life completely. Neurologic trauma affects the patient, the family, the health care system, and society as a whole because of its major sequelae and the costs of acute and long-term care of patients with trauma to the brain and spinal cord.

Head Injuries

Head injury is a broad classification that includes injury to the scalp, skull, or brain. It is estimated that 1.4 million people sustain a head injury each year in the United States, and approximately 50,000 people die, 235,000 are hospitalized, and 1.1 million are treated and released from an emergency department (Langlois, Rutland-Brown & Thomas, 2006). A head injury may lead to conditions ranging from mild concussion to coma and death; the most serious form is known as a traumatic brain injury (TBI). The most common causes of TBIs are falls (28%), motor vehicle crashes (20%), being struck by objects (19%), and assaults (11%). People at highest risk for TBI are those in the 15- to 19-year age group. Males are twice as likely as females to sustain a TBI. Adults 75 years of age or older have the highest TBI-related hospitalization and death rates, and African Americans also have high mortality rates (Langlois, et al., 2006). An estimated 5.3 million Americans are currently living with a TBI-related disability (National Center for Injury Prevention and Control, 2007). The best approach to head injury is prevention (Chart 63-1).

Pathophysiology

Research suggests that not all brain damage occurs at the moment of impact. Damage to the brain from traumatic injury takes two forms: primary injury and secondary injury. **Primary injury** is the initial damage to the brain that results from the traumatic event. This may include contusions, lacerations, and torn blood vessels due to impact, acceleration/deceleration, or foreign object penetration. **Secondary injury** evolves over the ensuing hours and days after the initial injury and results from inadequate delivery of nutrients and oxygen to the cells (Littlejohns & Bader, 2005).

Physiology ■■■ Pathophysiology

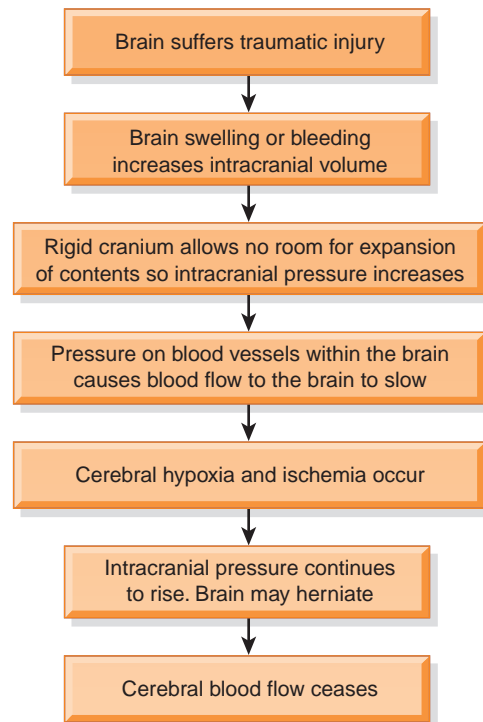

Figure 63-1 Pathophysiology of traumatic brain injury.

The cranial vault contains three main components: brain, blood, and cerebrospinal fluid (CSF). According to the Monro-Kellie doctrine, the cranial vault is a closed system, and if one of the three components increases in volume, at least one of the other two must decrease in volume, or the pressure increases. Any bleeding or swelling within the skull increases the volume of contents within the skull and therefore causes increased intracranial pressure (ICP) (see Chapter 61). If the pressure increases enough, it can cause displacement of the brain through or against the rigid structures of the skull. This causes restriction of blood flow to the brain, decreasing oxygen delivery and waste removal. Cells within the brain become anoxic and cannot metabolize properly, producing ischemia, infarction, irreversible brain damage, and, eventually, brain death (Fig. 63-1).

CHART
63-1

HEALTH PROMOTION

Preventing Head and Spinal Cord Injuries

- Advise drivers to obey traffic laws, and to avoid speeding or driving when under the influence of drugs or alcohol.
- Advise all drivers and passengers to wear seat belts and shoulder harnesses. Children younger than 12 years of age should be restrained in an age/size-appropriate system in the back seat.
- Caution passengers against riding in the back of pickup trucks.
- Advise motorcyclists, scooter riders, bicyclists, skateboarders, and roller skaters to wear helmets.
- Promote educational programs that are directed toward violence and suicide prevention in the community.
- Provide water safety instruction.
- Teach patients steps that can be taken to prevent falls, particularly in the elderly.
- Advise athletes to use protective devices. Recommend that coaches be educated in proper coaching techniques.
- Advise owners of firearms to keep them locked in a secure area where children cannot access them.

Scalp Injury

Isolated scalp trauma is generally classified as a minor injury. Because its many blood vessels constrict poorly, the scalp bleeds profusely when injured. Trauma may result in an abrasion (brush wound), contusion, laceration, or hematoma beneath the layers of tissue of the scalp (subgaleal hematoma). A large avulsion (tearing away) of the scalp may be potentially life-threatening and is a true emergency. Diagnosis of a scalp injury is based on physical examination, inspection, and palpation. Scalp wounds are potential portals of entry for organisms that cause intracranial infections. Therefore, the area is irrigated before the laceration is sutured, to remove foreign material and to reduce the risk for infection. Subgaleal hematomas (hematomas below the outer covering of the skull) usually reabsorb and do not require any specific treatment.

Skull Fractures

A skull fracture is a break in the continuity of the skull caused by forceful trauma. It may occur with or without damage to the brain. Skull fractures can be classified as simple, comminuted, depressed, or basilar. A simple (linear) fracture is a break in the continuity of the bone. A comminuted skull fracture refers to a splintered or multiple fracture line. Depressed skull fractures occur when the bones of the skull are forcefully displaced downward and can vary from a slight depression to bones of the skull being splintered and embedded within brain tissue. A fracture of the base of the skull is called a basilar skull fracture (Fig. 63-2) (Porth & Matfin, 2009). A fracture may be open, indicating a scalp laceration or tear in the dura (eg, from a bullet or an ice pick), or closed, in which case the dura is intact.

Figure 63-2 Basilar fractures allow cerebrospinal fluid to leak from the nose and ears. Adapted from Hickey, J. V. (2009). *The clinical practice of neurological and neurosurgical nursing* (6th ed.). Philadelphia: Lippincott Williams & Wilkins.

Clinical Manifestations

Symptoms, apart from those of the local injury, depend on the severity and the anatomic location of the underlying brain injury. Persistent, localized pain usually suggests that a fracture is present. Fractures of the cranial vault may or may not produce swelling in the region of the fracture; therefore, an x-ray is needed for diagnosis.

Fractures of the base of the skull tend to traverse the paranasal sinus of the frontal bone or the middle ear located in the temporal bone (see Fig. 63-2). Therefore, they frequently produce hemorrhage from the nose, pharynx, or ears, and blood may appear under the conjunctiva. An area of ecchymosis (bruising) may be seen over the mastoid (Battle's sign). Basilar skull fractures are suspected when CSF escapes from the ears (CSF otorrhea) and the nose (CSF rhinorrhea). Drainage of CSF is a serious problem, because meningeal infection can occur if organisms gain access to the cranial contents via the nose, ear, or sinus through a tear in the dura.

Assessment and Diagnostic Findings

X-rays confirm the presence and extent of a skull fracture (Porth & Matfin, 2009). A rapid physical examination and evaluation of neurologic status detects obvious brain injuries, and a computed tomography (CT) scan uses high-speed x-ray scanning to detect less apparent abnormalities. It is a fast, accurate, and safe diagnostic procedure that shows the presence, nature, location, and extent of acute lesions. It is also helpful in the ongoing management of head injury, because it can disclose cerebral edema, contusion, intracerebral or extracerebral hematoma, subarachnoid and intraventricular hemorrhage, and late changes (infarction, hydrocephalus) (Torpy, Lynn & Glass, 2005).

Magnetic resonance imaging (MRI) is used to evaluate patients with head injury when a more accurate picture of the anatomic nature of the injury is warranted and when the patient is stable enough to undergo this longer diagnostic procedure (Torpy, et al., 2005).

Cerebral angiography may also be used to identify supratentorial, extracerebral, and intracerebral hematomas and cerebral contusions. Lateral and anteroposterior views of the skull are obtained.

Gerontologic Considerations

Elderly patients must be assessed carefully (Scheetz, 2005). Older patients with head injuries differ from those who are younger in terms of etiology of injury, higher mortality rates, and poorer functional outcomes (Flanagan, Hibbard & Gordon, 2005). The most common causes of injury in elderly patients are falls and motor vehicle crashes (Thompson & Bourbonniere, 2006). Physiologic changes related to aging may place the older adult at increased risk for injury, alter the type and severity of injury that occurs, or promote the development of complications. Two major factors place older adults at increased risk for hematomas. First, the dura becomes more adherent to the skull with increasing age. Second, many older adults take aspirin and anticoagulants as part of routine management of chronic conditions.

Medical Management

Nondepressed skull fractures generally do not require surgical treatment; however, close observation of the patient is essential. Nursing personnel may observe the patient in the hospital, but if no underlying brain injury is present, the patient may be allowed to return home. If the patient is discharged home, specific instructions must be given to the family (see later discussion of concussion).

Depressed skull fractures usually require surgery with elevation of the skull and débridement, usually within 24 hours of injury. Skull fractures can be a combination of open, compound, closed, or simple. Associated injuries include concurrent scalp laceration, dural tears, and brain injury directly below the fracture from compression of the tissue below the bony injury and from lacerations produced by the bony fragments (Hickey, 2009).

Brain Injury

The most important consideration in any head injury is whether the brain is injured. Even seemingly minor injury can cause significant brain damage secondary to obstructed blood flow and decreased tissue perfusion. The brain cannot store oxygen or glucose to any significant degree. Because the cerebral cells need an uninterrupted blood supply to obtain these nutrients, irreversible brain damage and cell death occur if the blood supply is interrupted for even a few minutes. Clinical manifestations of **brain injury** (injury to the brain that is severe enough to interfere with normal functioning) are listed in Chart 63-2. **Closed (blunt) brain injury** occurs when the head accelerates and then rapidly decelerates or collides with another object (eg, a wall, the dashboard of a car) and brain tissue is damaged but there is no opening through the skull and dura. **Open brain injury** occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path (penetrating injury), or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain.

CHART
63-2

Assessing Traumatic Brain Injury

Be alert for the following signs and symptoms:

- Altered level of consciousness
- Confusion
- Pupillary abnormalities (changes in shape, size, and response to light)
- Altered or absent gag reflex
- Absent corneal reflex
- Sudden onset of neurologic deficits
- Changes in vital signs (altered respiratory pattern, widened pulse pressure, bradycardia, tachycardia, hypothermia, or hyperthermia)
- Vision and hearing impairment
- Sensory dysfunction
- Headache
- Seizures

Types of Brain Injury

Concussion

A **concussion** after head injury is a temporary loss of neurologic function with no apparent structural damage. A concussion (also referred to as a mild TBI) may or may not produce a brief loss of consciousness. The mechanism of injury is usually blunt trauma from an acceleration-deceleration force, a direct blow, or a blast injury (Hoge, McGurk, Thomas, et al., 2008; Martin, Lu, Helmick, et al., 2008). If brain tissue in the frontal lobe is affected, the patient may exhibit bizarre irrational behavior, whereas involvement of the temporal lobe can produce temporary amnesia or disorientation.

There are two types of concussion: mild and classic. A mild concussion may lead to a period of observed or self-reported transient confusion, disorientation, or impaired consciousness. Commonly, there is a memory lapse at the time of injury and a loss of consciousness lasting less than 30 minutes. Other signs and symptoms of neurologic or neuropsychological dysfunction may include seizures, headache, dizziness, irritability, fatigue, or poor concentration (Hickey, 2009).

A classic concussion is an injury that results in a loss of consciousness; characteristically, this usually lasts less than 6 hours. This loss of consciousness is always accompanied by some degree of posttraumatic amnesia. Diagnostic studies may show no apparent structural sign of injury, but the duration of unconsciousness is an indicator of the severity of the concussion.

The patient may be hospitalized overnight for observation or discharged from the hospital in a relatively short time after a concussion. Monitoring includes observing the patient for headache, dizziness, lethargy, irritability, emotional lability, fatigue, poor concentration, decreased attention span, memory difficulties, and intellectual dysfunction that may occur from 1 week to 1 year after the initial injury (Hickey, 2009). The occurrence of these symptoms after injury is referred to as postconcussion syndrome. Recovery may appear complete, but long-term sequelae are possible. Problems at work and at home can result in interpersonal relationship problems or the loss of employment (Bay & McLean, 2007). The family is instructed to observe for the following signs and symptoms and to notify the physician or clinic (or bring the patient to the emergency department) if they occur: difficulty in awakening or speaking, confusion, severe headache, vomiting, and weakness of one side of the body.

Contusion

In cerebral **contusion**, a moderate to severe head injury, the brain is bruised and damaged in a specific area because of severe acceleration-deceleration force or blunt trauma. The impact of the brain against the skull leads to a contusion. Although a contusion may occur in any area of the brain, most are usually located in the anterior portions of the frontal and temporal lobes, around the sylvian fissure, at the orbital areas, and, less commonly, at the parietal and occipital areas.

Contusions are characterized by loss of consciousness associated with stupor and confusion. Other characteristics

can include tissue alteration and neurologic deficit without hematoma formation, alteration in consciousness without localizing signs, and hemorrhage into the tissue that varies in size and is surrounded by edema. The effects of injury (hemorrhage and edema) peak after about 18 to 36 hours. Patient outcome depends on the area and severity of the injury. Temporal lobe contusions carry a greater risk of swelling, rapid deterioration, and brain herniation. Deep contusions are more often associated with hemorrhage and destruction of the reticular activating fibers altering arousal (Hickey, 2009).

Diffuse Axonal Injury

Diffuse axonal injury (DAI) results from widespread shearing and rotational forces that produce damage throughout the brain—to axons in the cerebral hemispheres, corpus callosum, and brain stem. The injured area may be diffuse, with no identifiable focal lesion. DAI is associated with prolonged traumatic coma; it is more serious and is associated with a poorer prognosis than a focal lesion or ischemia (Bay & McLean, 2007).

The patient with DAI in severe head trauma experiences no lucid interval, immediate coma, decorticate and decerebrate posturing (see Fig. 61-1 in Chapter 61), and global cerebral edema. Diagnosis is made by clinical signs in conjunction with a CT or MRI scan. Recovery depends on the severity of the axonal injury.

Intracranial Hemorrhage

Hematomas are collections of blood in the brain that may be epidural (above the dura), subdural (below the dura), or intracerebral (within the brain) (Fig. 63-3). Major symptoms are frequently delayed until the hematoma is large enough to cause distortion of the brain and increased ICP. The signs and symptoms of cerebral ischemia resulting from compression by a hematoma are variable and depend on the speed with which vital areas are affected and the area that is injured (American Association of Neuroscience Nurses [AANN], 2005). In general, a rapidly developing hematoma, even if small, may be fatal, whereas a larger but slowly developing one may allow compensation for increases in ICP.

Epidural Hematoma

After a head injury, blood may collect in the epidural (extradural) space between the skull and the dura mater. This can result from a skull fracture that causes a rupture or laceration of the middle meningeal artery, the artery that runs between the dura and the skull inferior to a thin portion of temporal bone. Hemorrhage from this artery causes rapid pressure on the brain (Vacca, 2007b).

Symptoms are caused by the expanding hematoma. Epidural hematomas are often characterized by a brief loss of consciousness followed by a lucid interval in which the patient is awake and conversant. During this lucid interval, compensation for the expanding hematoma takes place by rapid absorption of CSF and decreased intravascular volume, both of which help maintain a normal ICP. When these mechanisms can no longer compensate, even a small increase in the volume of the blood clot produces a marked elevation in ICP. The patient then becomes increasingly

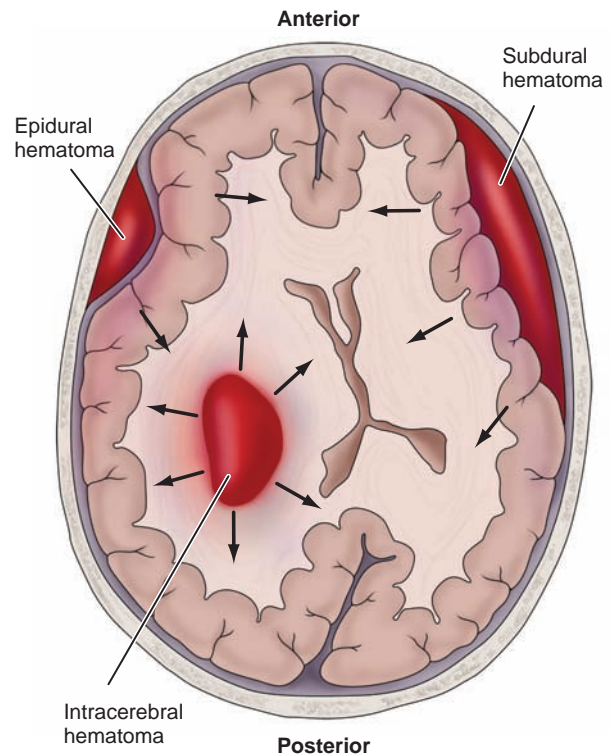

Figure 63-3 Location of epidural, subdural, and intracerebral hematomas.

restless, agitated, and confused as the condition progresses to coma. Then, often suddenly, signs of herniation appear (usually deterioration of consciousness and signs of focal neurologic deficits, such as dilation and fixation of a pupil or paralysis of an extremity), and the patient's condition deteriorates rapidly. The most common type of herniation syndrome associated with an epidural hematoma is uncal herniation (Vacca, 2007b).

An epidural hematoma is considered an extreme emergency; marked neurologic deficit or even respiratory arrest can occur within minutes. Treatment consists of making openings through the skull (burr holes) to decrease ICP emergently, remove the clot, and control the bleeding. A craniotomy may be required to remove the clot and control the bleeding. A drain is usually inserted after creation of burr holes or a craniotomy to prevent reaccumulation of blood.

Subdural Hematoma

A subdural hematoma is a collection of blood between the dura and the brain, a space normally occupied by a thin cushion of fluid. The most common cause of subdural hematoma is trauma, but it can also occur as a result of coagulopathies or rupture of an aneurysm. A subdural hemorrhage is more frequently venous in origin and is caused by the rupture of small vessels that bridge the subdural space (Vacca, 2007c). The subdural hematoma that results may be acute, subacute, or chronic, depending on the size of the involved vessel and the amount of bleeding.

Acute and Subacute Subdural Hematoma. Acute subdural hematomas are associated with major head injury involving

contusion or laceration. Clinical symptoms develop over 24 to 48 hours. Signs and symptoms include changes in the level of consciousness (LOC), pupillary signs, and hemiparesis. There may be minor or even no symptoms with small collections of blood. Coma, increasing blood pressure, decreasing heart rate, and slowing respiratory rate are all signs of a rapidly expanding mass requiring immediate intervention. Subacute subdural hematomas are the result of less severe contusions and head trauma. Clinical manifestations usually appear between 48 hours and 2 weeks after the injury. Signs and symptoms are similar to those of an acute subdural hematoma.

If the patient can be transported rapidly to the hospital, an immediate craniotomy is performed to open the dura, allowing the subdural clot to be evacuated. Successful outcome also depends on the control of ICP and careful monitoring of respiratory function (see the discussion of intracranial surgery in Chapter 61). The mortality rate for patients with acute or subacute subdural hematoma is high because of associated brain damage.

Chronic Subdural Hematoma. Chronic subdural hematomas can develop from seemingly minor head injuries and are seen most frequently in the elderly. The elderly are prone to this type of head injury secondary to brain atrophy, which is a frequent consequence of the aging process. Seemingly minor head trauma may produce enough impact to shift the brain contents abnormally. The time between injury and onset of symptoms can be lengthy (eg, 3 weeks to months), so the actual injury may be forgotten.

A chronic subdural hematoma can resemble other conditions; for example, it may be mistaken for a stroke. The bleeding is less profuse, but compression of the intracranial contents still occurs. The blood within the brain changes in character in 2 to 4 days, becoming thicker and darker. In a few weeks, the clot breaks down and has the color and consistency of motor oil. Eventually, calcification or ossification of the clot takes place. The brain adapts to this foreign body invasion, and the clinical signs and symptoms fluctuate. Symptoms include severe headache, which tends to come and go; alternating focal neurologic signs; personality changes; mental deterioration; and focal seizures. The patient may be labeled neurotic or psychotic if the cause is overlooked.

The treatment of a chronic subdural hematoma consists of surgical evacuation of the clot. The procedure may be carried out through multiple burr holes, or a craniotomy may be performed for a sizable subdural mass that cannot be suctioned or drained through burr holes.

Intracerebral Hemorrhage and Hematoma

Intracerebral hemorrhage is bleeding into the substance of the brain. It is commonly seen in head injuries when force is exerted to the head over a small area (eg, missile injuries, bullet wounds, stab injuries). These hemorrhages within the brain may also result from the following:

- Systemic hypertension, which causes degeneration and rupture of a vessel
- Rupture of a saccular aneurysm
- Vascular anomalies
- Intracranial tumors

- Bleeding disorders such as leukemia, hemophilia, aplastic anemia, and thrombocytopenia
- Complications of anticoagulant therapy

Nontraumatic causes of intracerebral hemorrhage are discussed in Chapter 62.

The onset may be insidious, beginning with the development of neurologic deficits followed by headache. Management includes supportive care, control of ICP, and careful administration of fluids, electrolytes, and antihypertensive medications. Surgical intervention by craniotomy or craniectomy permits removal of the blood clot and control of hemorrhage but may not be possible because of the inaccessible location of the bleeding or the lack of a clearly circumscribed area of blood that can be removed.

Management of Brain Injuries

Assessment and diagnosis of the extent of injury are accomplished by the initial physical and neurologic examinations. CT and MRI scans are the primary neuroimaging diagnostic tools and are useful in evaluating the brain structure. Positron emission tomography (PET) is available in some trauma centers for assessing brain function. A flow chart developed by the Brain Trauma Foundation (2007) for the initial management of brain injury is presented in Figure 63-4.

Any patient with a head injury is presumed to have a cervical spine injury until proven otherwise. The patient is transported from the scene of the injury on a board with the head and neck maintained in alignment with the axis of the body. A cervical collar should be applied and maintained until cervical spine x-rays have been obtained and the absence of cervical spinal cord injury documented.

All therapy is directed toward preserving brain homeostasis and preventing secondary brain injury, which is injury to the brain that occurs after the original traumatic event (Littlejohns & Bader, 2005). Common causes of secondary injury are cerebral edema, hypotension, and respiratory depression that may lead to hypoxemia and electrolyte imbalance. Treatments to prevent secondary injury include stabilization of cardiovascular and respiratory function to maintain adequate cerebral perfusion, control of hemorrhage and hypovolemia, and maintenance of optimal blood gas values.

Treatment of Increased Intracranial Pressure

As the damaged brain swells with edema or as blood collects within the brain, an increase in ICP occurs; this requires aggressive treatment. See Chapter 61 for a discussion of the relationship of ICP to cerebral perfusion pressure (CPP). If the ICP remains elevated, it can decrease the CPP. Initial management is based on the principle of preventing secondary injury and maintaining adequate cerebral oxygenation (see Fig. 63-4).

Surgery is required for evacuation of blood clots, débridement and elevation of depressed fractures of the skull, and suture of severe scalp lacerations. ICP is monitored closely; if increased, it is managed by maintaining adequate oxygenation, elevating the head of the bed, and maintaining normal blood volume. Devices to monitor ICP or drain CSF can be inserted during surgery or at the bedside

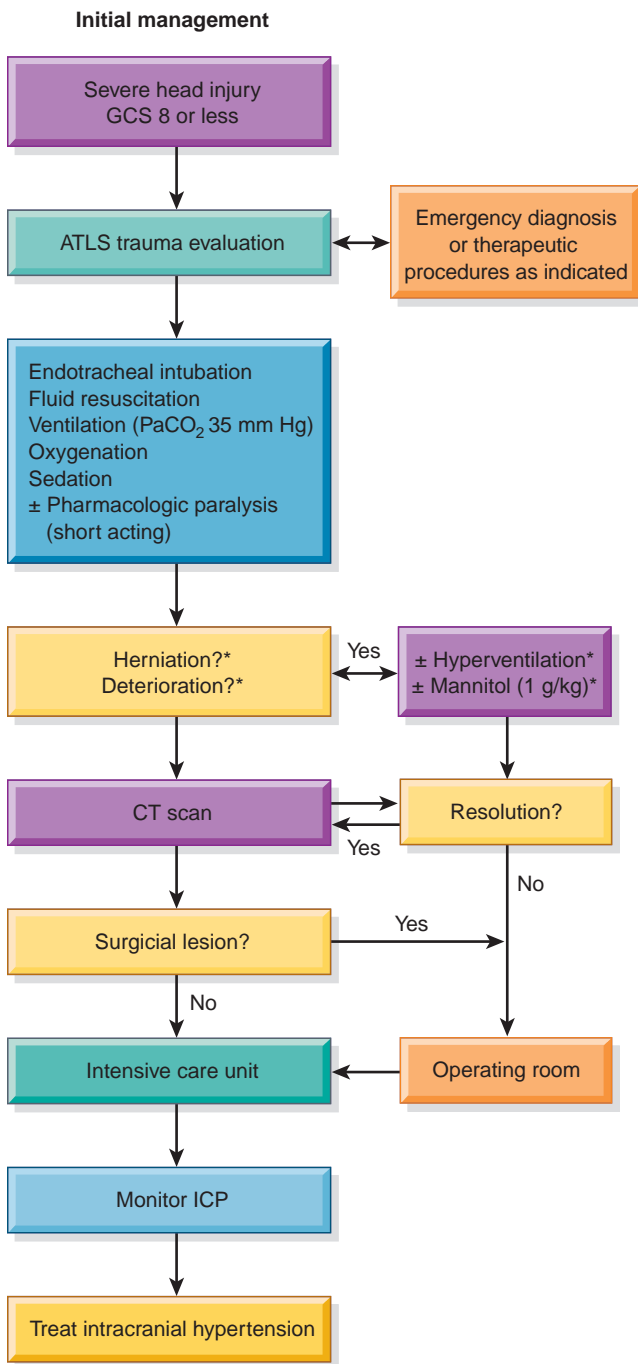

Figure 63-4 Initial management of the patient with traumatic brain injury (treatment option). ATLS, Advanced Trauma Life Support; CT, computed tomography; GCS, Glasgow Coma Score; ICP, intracranial pressure.

using aseptic technique. The patient is cared for in the intensive care unit, where expert nursing care and medical treatment are readily available (AANN, 2005).

Supportive Measures

Treatment also includes ventilatory support, seizure prevention, fluid and electrolyte maintenance, nutritional support,

and management of pain and anxiety. Comatose patients are intubated and mechanically ventilated to ensure adequate oxygenation and protect the airway.

Because seizures can occur after head injury and can cause secondary brain damage from hypoxia, antiseizure agents may be administered. If the patient is very agitated, benzodiazepines may be prescribed to calm the patient without decreasing LOC. These medications do not affect ICP or CPP, making them good choices for the patient with head injury. A nasogastric tube may be inserted, because reduced gastric motility and reverse peristalsis are associated with head injury, making regurgitation and aspiration common in the first few hours.

Brain Death

When a patient has sustained a severe head injury incompatible with life, the patient is a potential organ donor. The nurse may assist in the clinical examination for determination of brain death and in the process of organ procurement. All 50 states recognize the Uniform Determination of Brain Death Act that states death will be determined by accepted medical standards and indicates irreversible loss of all brain function, including the brain stem (Morton, Fontaine, Hudak, et al., 2010). The three cardinal signs of brain death on clinical examination are coma, the absence of brain stem reflexes, and apnea. Adjunctive tests, such as cerebral blood flow studies, electroencephalogram (EEG), transcranial Doppler, and brain stem auditory evoked potential, are often used to confirm brain death (Hickey, 2009). The health care team provides information to the family and assists them with the decision-making process about end-of-life care (Calvin, Kite-Powell & Hickey, 2007). For aspects of neuroscience-related end-of-life care, see Chart 63-3.

NURSING PROCESS

THE PATIENT WITH A TRAUMATIC BRAIN INJURY

Assessment

Depending on the patient's neurologic status, the nurse may elicit information from the patient, from the family, or from witnesses or emergency rescue personnel. Although all usual baseline data may not be collected initially, the immediate health history should include the following questions:

- When did the injury occur?
- What caused the injury? A high-velocity missile? An object striking the head? A fall?
- What was the direction and force of the blow?

A history of unconsciousness or amnesia after a head injury indicates a significant degree of brain damage, and changes that occur minutes to hours after the initial injury can reflect recovery or indicate the development of secondary brain damage. The nurse should determine if there was a loss of consciousness, the duration of the unconscious period, and if the patient could be aroused.

In addition to asking questions that establish the nature of the injury and the patient's condition immediately after

CHART
63-3 **NURSING RESEARCH PROFILE**
Perceptions About End-of-Life Care

Calvin, A. O., Kite-Powell, D. M. & Hickey, J. (2007). The neuroscience ICU nurse's perceptions about end-of-life care. *Journal of Neuroscience Nursing*, 39(3), 143–150.

Purpose

Little is known about palliative or end-of-life care in intensive care units. The purpose of this study was to explore nurses' perceptions of their roles in neuroscience intensive care units, especially their responsibilities in decision making during end-of-life care.

Design

Twelve registered nurses, all employed at the same hospital, volunteered to participate in this qualitative descriptive study. Researchers conducted moderately structured interviews using an interview guide that contained four questions for the first interview. During the second interview, participants were given an opportunity to read and react to a summary of the findings of their first interview. All interviews, which were audiotaped, were private and lasted approximately 1 hour.

Findings

Nurses described three major themes about end-of-life care. The first theme involved providing guidance to the patient and the family members during the end-of-life decision-making process. The second theme was being positioned at the "hub" of the communication process as they became intermediaries between the family members and physicians. The third theme was feeling emotions that covered a wide range from confusion, helplessness, and frustration to feeling emotionally drained, being overcome by very mixed feelings, and feeling privileged.

Nursing Implications

Little research has addressed the perceptions of nurses in neuroscience intensive care units about end-of-life care. This study shows that nurses working in such a unit have unique, central roles in the communication process surrounding the patient's end-of-life care and adds to the limited body of knowledge concerning critical care nurses' experiences with end-of-life care.

the injury, the nurse examines the patient thoroughly. This assessment includes determining the patient's LOC using the Glasgow Coma Scale (GCS) and assessing the patient's response to tactile stimuli (if unconscious), pupillary response to light, corneal and gag reflexes, and motor function. The GCS (Chart 63-4) is based on the three criteria of eye opening, verbal responses, and motor responses to verbal commands or painful stimuli. It is particularly useful for monitoring changes during the acute phase, the first few days after a head injury. It does not take the place of an in-depth neurologic assessment. Additional detailed assess-

ments are made initially and at frequent intervals throughout the acute phase of care (Hickey, 2009). Baseline and ongoing assessments are critical in nursing assessment of the patient with brain injury, whose condition can worsen dramatically and irrevocably if subtle signs are overlooked. More information on assessment is provided in the following sections and in Figure 63-5 and Table 63-1.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective airway clearance and impaired gas exchange related to brain injury
- Ineffective cerebral tissue perfusion related to increased ICP, decreased CPP, and possible seizures
- Deficient fluid volume related to decreased LOC and hormonal dysfunction
- Imbalanced nutrition, less than body requirements, related to increased metabolic demands, fluid restriction, and inadequate intake
- Risk for injury (self-directed and directed at others) related to seizures, disorientation, restlessness, or brain damage
- Risk for imbalanced body temperature related to damaged temperature-regulating mechanisms in the brain
- Risk for impaired skin integrity related to bed rest, hemiparesis, hemiplegia, immobility, or restlessness
- Disturbed thought processes (deficits in intellectual function, communication, memory, information processing) related to brain injury
- Disturbed sleep pattern related to brain injury and frequent neurologic checks
- Interrupted family processes related to unresponsiveness of patient, unpredictability of outcome, prolonged

CHART
63-4 **Assessment for Glasgow Coma Scale**

The Glasgow Coma Scale is a tool for assessing a patient's response to stimuli. Scores range from 3 (deep coma) to 15 (normal).

Eye opening response	Spontaneous	4
	To voice	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Best motor response	Obeys command	6
	Localizes pain	5
	Withdraws	4
	Flexion	3
	Extension	2
	None	1
Total		3 to 15

Figure 63-5 Assessment parameters for the patient with a head injury include (A) eye opening and responsiveness, (B) vital signs, and (C, D) motor response reflected in hand strength or response to painful stimulus. Photo © B. Proud.

recovery period, and the patient's residual physical disability and emotional deficit

- Deficient knowledge about brain injury, recovery, and the rehabilitation process

The nursing diagnoses for the unconscious patient and the patient with increased ICP also apply (see Chapter 61).

Collaborative Problems/Potential Complications

Based on all the assessment data, the major complications include the following:

- Decreased cerebral perfusion
- Cerebral edema and herniation
- Impaired oxygenation and ventilation
- Impaired fluid, electrolyte, and nutritional balance
- Risk of posttraumatic seizures

Planning and Goals

The goals for the patient may include maintenance of a patent airway, adequate CPP, fluid and electrolyte balance, adequate nutritional status, prevention of secondary injury, maintenance of normal body temperature, maintenance of skin integrity, improvement of cognitive function, prevention of sleep deprivation, effective family coping, increased knowledge about the rehabilitation process, and absence of complications.

Nursing Interventions

The nursing interventions for the patient with a head injury are extensive and diverse. They include making nursing assessments, setting priorities for nursing interventions, anticipating needs and complications, and initiating rehabilitation.

Monitoring Neurologic Function

The importance of ongoing assessment and monitoring of the patient with brain injury cannot be overstated. The following parameters are assessed initially and as frequently as the patient's condition requires. As soon as the initial assessment is made, the use of a neurologic flow chart is started and maintained.

LEVEL OF CONSCIOUSNESS. The GCS is used to assess LOC at regular intervals, because changes in the LOC precede all other changes in vital and neurologic signs. The patient's best responses to predetermined stimuli are recorded (see Chart 63-4). Each response is scored (the greater the number, the better the functioning), and the sum of these scores gives an indication of the severity of coma and a prediction of possible outcome. The lowest score is 3 (least responsive); the highest is 15 (most responsive). A GCS between 3 and 8 is generally accepted as indicating a severe head injury (Martin, et al., 2008).

Table 63-1 SUMMARY OF MULTISYSTEM ASSESSMENT MEASURES FOR THE PATIENT WITH TRAUMATIC BRAIN INJURY

System-Specific Considerations	Assessment Data
<p>Neurologic System</p> <ul style="list-style-type: none"> Severe head injury results in unconsciousness and alters many neurologic functions. All body functions must be supported. Increased ICP and herniation syndromes are life-threatening. Measures are instituted to control elevated ICP. 	<ul style="list-style-type: none"> Assessment of neurologic signs Assessment for signs and symptoms of ICP elevation Calculation of cerebral perfusion pressure if ICP monitor is in place Monitoring of antiseizure medication blood levels
<p>Integumentary System (Skin and Mucous Membranes)</p> <ul style="list-style-type: none"> Immobility secondary to injury and unconsciousness contributes to the development of pressure areas and skin breakdown. Intubation causes irritation of the mucous membrane. 	<ul style="list-style-type: none"> Assessment of skin integrity and character of the skin Assessment of oral mucous membrane
<p>Musculoskeletal System</p> <ul style="list-style-type: none"> Immobility contributes to musculoskeletal changes. Decerebrate or decorticate posturing makes proper positioning difficult. 	<ul style="list-style-type: none"> Assessment of range of motion of joints and development of deformities or spasticity
<p>Gastrointestinal System</p> <ul style="list-style-type: none"> Administration of corticosteroids places the patient at high risk for GI hemorrhage. Injury to the GI tract can result in paralytic ileus. Constipation can result from bed rest, NPO status, fluid restriction, and opioids given for pain control. Bowel incontinence is related to the patient's unconscious state or altered mental state. 	<ul style="list-style-type: none"> Assessment of abdomen for bowel sounds and distention Monitoring for decreased hemoglobin
<p>Genitourinary System</p> <ul style="list-style-type: none"> Fluid restriction or use of diuretics can alter the amount of urinary output. Urinary incontinence is related to the patient's unconscious state. 	<ul style="list-style-type: none"> Intake and output record
<p>Metabolic (Nutritional) System</p> <ul style="list-style-type: none"> The patient receives all fluids IV for the first few days until the GI tract is functioning. A nutritional consultation is initiated within the first 24–48 h; parenteral or enteral nutrition may be started. 	<ul style="list-style-type: none"> Assessment of fluid and electrolyte balance Recording of weight, if possible Hematocrit Electrolyte studies
<p>Respiratory System</p> <ul style="list-style-type: none"> Complete or partial airway obstruction will compromise the oxygen supply to the brain. An altered respiratory pattern can result in cerebral hypoxia. A short period of apnea at the moment of impact can result in spotty atelectasis. Systemic disturbances from head injury can cause hypoxemia. Brain injury can alter brain stem respiratory function. Shunting of blood to the lungs as a result of a sympathetic discharge at the time of injury can cause neurogenic pulmonary edema. 	<ul style="list-style-type: none"> Assessment of respiratory function <ul style="list-style-type: none"> Auscultate chest for breath sounds. Note the respiratory pattern if possible (not possible if a ventilator is being used). Note the respiratory rate. Note whether the cough reflex is intact. Arterial blood gas levels Complete blood count Chest x-ray studies Sputum cultures O₂ saturation using pulse oximetry
<p>Cardiovascular System</p> <ul style="list-style-type: none"> The patient may develop cardiac dysrhythmias, tachycardia, or bradycardia. The patient may develop hypotension or hypertension. Because of immobility and unconsciousness, the patient is at high risk for deep vein thromboses and pulmonary emboli. Fluid and electrolyte imbalance can be related to several problems, including alterations in antidiuretic hormone (ADH) secretion, the stress response, or fluid restriction. Specific conditions may occur: <ul style="list-style-type: none"> Diabetes insipidus (DI) Syndrome of inappropriate secretion of ADH (SIADH) Electrolyte imbalance Hyperosmolar nonketotic hyperglycemia 	<ul style="list-style-type: none"> Assessment of vital signs Monitoring for cardiac dysrhythmias Assessment for deep vein thromboses of legs Electrocardiogram Electrolyte studies Blood coagulation studies ¹²⁵I fibrinogen scan of legs Blood glucose level Blood acetone level Blood osmolality Urine specific gravity
<p>Psychological/Emotional Response</p> <ul style="list-style-type: none"> The traumatic head-injured patient is unconscious. The family needs emotional support to deal with the crisis. 	<ul style="list-style-type: none"> Collection of information about the family and the role of the head-injured person within the family Assessment of the family to determine how functional it was before the injury occurred

VITAL SIGNS. Although a change in LOC is the most sensitive neurologic indication of deterioration of the patient's condition, vital signs also are monitored at frequent intervals to assess the intracranial status. Table 63-1 depicts the general assessment parameters for the patient with a head injury.

Signs of increasing ICP include slowing of the heart rate (bradycardia), increasing systolic blood pressure, and widening pulse pressure (Cushing's reflex). As brain compression increases, respirations become rapid, the blood pressure may decrease, and the pulse slows further. This is an ominous development, as is a rapid fluctuation of vital signs (Hickey, 2009). A rapid increase in body temperature is regarded as unfavorable because hyperthermia increases the metabolic demands of the brain and may indicate brain stem damage, a poor prognostic sign. The temperature is maintained at less than 38°C (100.4°F). Tachycardia and arterial hypotension may indicate that bleeding is occurring elsewhere in the body.

MOTOR FUNCTION. Motor function is assessed frequently by observing spontaneous movements, asking the patient to raise and lower the extremities, and comparing the strength and equality of the upper and lower extremities at periodic intervals. To assess upper extremity strength, the nurse instructs the patient to squeeze the examiner's fingers tightly. The nurse assesses lower extremity motor strength by placing the hands on the soles of the patient's feet and asking the patient to push down against the examiner's hands. Examination of the motor system is discussed in Chapter 60 in more detail. The presence or absence of spontaneous movement of each extremity is also noted, and speech and eye signs are assessed.

If the patient does not demonstrate spontaneous movement, responses to painful stimuli are assessed (Hickey, 2009). Motor response to pain is assessed by applying a central stimulus, such as pinching the pectoralis major muscle, to determine the patient's best response. Peripheral stimulation may provide inaccurate assessment data because it may result in a reflex movement rather than a voluntary motor response. Abnormal responses (lack of motor response; extension responses) are associated with a poorer prognosis.

OTHER NEUROLOGIC SIGNS. In addition to the patient's spontaneous eye opening, evaluated with the GCS, the size and equality of the pupils and their reaction to light are assessed. A unilaterally dilated and poorly responding pupil may indicate a developing hematoma, with subsequent pressure on the third cranial nerve due to shifting of the brain. If both pupils become fixed and dilated, this indicates overwhelming injury and intrinsic damage to the upper brain stem and is a poor prognostic sign (Adoni & McNett, 2007).

The patient with a head injury may develop deficits such as anosmia (lack of sense of smell), eye movement abnormalities, aphasia, memory deficits, and posttraumatic seizures or epilepsy. Patients may be left with residual psychological deficits (impulsiveness, emotional lability, or uninhibited, aggressive behaviors) and, as a consequence of the impairment, may lack insight into their emotional responses.

Maintaining the Airway

One of the most important nursing goals in the management of head injury is to establish and maintain an

adequate airway. The brain is extremely sensitive to hypoxia, and a neurologic deficit can worsen if the patient is hypoxic. Therapy is directed toward maintaining optimal oxygenation to preserve cerebral function. An obstructed airway causes carbon dioxide retention and hypoventilation, which can produce cerebral vessel dilation and increased ICP.

Interventions to ensure an adequate exchange of air are discussed in Chapter 61 and include the following:

- Maintaining the unconscious patient in a position that facilitates drainage of oral secretions, with the head of the bed elevated about 30 degrees to decrease intracranial venous pressure (Bader, 2006b)
- Establishing effective suctioning procedures (pulmonary secretions produce coughing and straining, which increase ICP)
- Guarding against aspiration and respiratory insufficiency
- Closely monitoring arterial blood gas values to assess the adequacy of ventilation. The goal is to keep blood gas values within the normal range to ensure adequate cerebral blood flow.
- Monitoring the patient who is receiving mechanical ventilation for pulmonary complications such as acute respiratory distress syndrome (ARDS) and pneumonia (Hickey, 2009)

Monitoring Fluid and Electrolyte Balance

Brain damage can produce metabolic and hormonal dysfunctions. The monitoring of serum electrolyte levels is important, especially in patients receiving osmotic diuretics, those with syndrome of inappropriate antidiuretic hormone (SIADH) secretion, and those with posttraumatic diabetes insipidus.

Serial studies of blood and urine electrolytes and osmolality are carried out because head injuries may be accompanied by disorders of sodium regulation. Hyponatremia is common after head injury due to shifts in extracellular fluid, electrolytes, and volume. Hyperglycemia, for example, can cause an increase in extracellular fluid that lowers sodium. Hypernatremia may also occur as a result of sodium retention that may last several days, followed by sodium diuresis. Increasing lethargy, confusion, and seizures may be the result of electrolyte imbalance.

Endocrine function is evaluated by monitoring serum electrolytes, blood glucose values, and intake and output. Urine is tested regularly for acetone. A record of daily weights is maintained, especially if the patient has hypothalamic involvement and is at risk for the development of diabetes insipidus.

Promoting Adequate Nutrition

Head injury results in metabolic changes that increase calorie consumption and nitrogen excretion. Protein demand increases. Early initiation of nutritional therapy has been shown to improve outcomes in patients with head injury. Patients with brain injury are assumed to be catabolic and nutritional support consultation should be considered as soon as the patient is admitted. Parenteral nutrition via a central line or enteral feedings administered via a nasogastric or nasojejunal feeding tube should be considered (Hickey, 2009). If CSF rhinorrhea occurs, an oral feeding tube should be inserted instead of a nasal tube.

Laboratory values should be monitored closely in patients receiving parenteral nutrition. Elevating the head of the bed and aspirating the enteral tube for evidence of residual feeding before administering additional feedings can help prevent distention, regurgitation, and aspiration. A continuous-drip infusion or pump may be used to regulate the feeding. The principles and technique of enteral feedings are discussed in Chapter 36. Enteral or parenteral feedings are usually continued until the swallowing reflex returns and the patient can meet caloric requirements orally.

Preventing Injury

Often, as the patient emerges from coma, a period of lethargy and stupor is followed by a period of agitation. Each phase is variable and depends on the individual person, the location of the injury, the depth and duration of coma, and the patient's age. Restlessness may be caused by hypoxia, fever, pain, or a full bladder. It may indicate injury to the brain but may also be a sign that the patient is regaining consciousness. (Some restlessness may be beneficial because the lungs and extremities are exercised.) Agitation may also be the result of discomfort from catheters, intravenous (IV) lines, restraints, and repeated neurologic checks. Alternatives to restraints must be used whenever possible.

Strategies to prevent injury include the following:

- The patient is assessed to ensure that oxygenation is adequate and the bladder is not distended. Dressings and casts are checked for constriction.
- Padded side rails are used or the patient's hands are wrapped in mitts to protect the patient from self-injury and dislodging of tubes. Restraints are avoided, because straining against them can increase ICP or cause other injury. Enclosed or floor-level specialty beds may be indicated.
- Opioids are avoided as a means of controlling restlessness, because they depress respiration, constrict the pupils, and alter responsiveness.
- Environmental stimuli are reduced by keeping the room quiet, limiting visitors, speaking calmly, and providing frequent orientation information (eg, explaining where the patient is and what is being done).
- Adequate lighting is provided to prevent visual hallucinations.
- Efforts are made to minimize disruption of the patient's sleep-wake cycles.
- The patient's skin is lubricated with oil or emollient lotion to prevent irritation due to rubbing against the sheet.
- If incontinence occurs, an external sheath catheter may be used on a male patient. Because prolonged use of an indwelling catheter inevitably produces infection, the patient may be placed on an intermittent catheterization schedule.

Maintaining Body Temperature

Fever in the patient with a TBI can be the result of damage to the hypothalamus, cerebral irritation from hemorrhage, or infection. The nurse monitors the patient's temperature every 2 to 4 hours. If the temperature increases, efforts are made to identify the cause and to control it using acetaminophen and cooling blankets to maintain normothermia (Thompson,

Kirkness & Mitchell, 2007). Cooling blankets should be used with caution so as not to induce shivering, which increases ICP. If infection is suspected, potential sites of infection are cultured and antibiotics are prescribed and administered.

Use of mild hypothermia to 34°C to 35°C (94°F to 96°F) has been tested in small randomized controlled trials for at least 12 hours versus normothermia (control) in patients with closed head injury. Early research showed improvement in patient outcomes but needs to be repeated in larger trials. Because hypothermia increases the risk of pneumonia and has other side effects, this treatment is not currently recommended outside of controlled clinical trials (Brain Trauma Foundation, 2007).

Maintaining Skin Integrity

Patients with TBI often require assistance in turning and positioning because of immobility or unconsciousness. Prolonged pressure on the tissues decreases circulation and leads to tissue necrosis. Potential areas of breakdown need to be identified early to avoid the development of pressure ulcers. Specific nursing measures include the following:

- Assessing all body surfaces and documenting skin integrity every 8 hours
- Turning and repositioning the patient every 2 hours
- Providing skin care every 4 hours
- Assisting the patient to get out of bed to a chair three times a day

Improving Cognitive Functioning

Although many patients with head injury survive because of resuscitative and supportive technology, they frequently have significant cognitive sequelae that may not be detected during the acute phase of injury. Cognitive impairment includes memory deficits, decreased ability to focus and sustain attention to a task (distractibility), reduced ability to process information, and slowness in thinking, perceiving, communicating, reading, and writing. Psychiatric, emotional, and relationship problems develop in many patients after head injury. Resulting psychosocial, behavioral, emotional, and cognitive impairments are devastating to the family as well as to the patient (Bay & Bergman, 2006; Jumisko, Lexell & Soderberg, 2005).

These problems require collaboration among many disciplines. A neuropsychologist (specialist in evaluating and treating cognitive problems) plans a program and initiates therapy or counseling to help the patient reach maximal potential. Cognitive rehabilitation activities help the patient to devise new problem-solving strategies. The retraining is carried out over an extended period and may include the use of sensory stimulation and reinforcement, behavior modification, reality orientation, computer training programs, and video games. Assistance from many disciplines is necessary during this phase of recovery. Even if intellectual ability does not improve, social and behavioral abilities may.

The patient recovering from a TBI may experience fluctuations in the level of cognitive function, with orientation, attention, and memory frequently affected. Many types of sensory stimulation programs have been tried, and research on these programs is ongoing (Hickey, 2009). When pushed to a level greater than the impaired cortical functioning allows, the patient may show symptoms of fatigue, anger, and

stress (headache, dizziness). The Rancho Los Amigos Level of Cognitive Function scale is frequently used to assess cognitive function and evaluate ongoing recovery from head injury. Progress through the levels of cognitive function can vary widely for individual patients. Nursing management and a description of each level are included in Table 63-2.

Preventing Sleep Pattern Disturbance

Patients who require frequent monitoring of neurologic status may experience sleep deprivation as they are awakened hourly for assessment of LOC. To allow the patient longer times of uninterrupted sleep and rest, the nurse can group nursing care activities so that the patient is disturbed less frequently. Environmental noise is decreased, and the room lights are dimmed. Back rubs and other measures to increase comfort may promote sleep and rest.

Supporting Family Coping

Having a loved one sustain a TBI produces a great deal of stress in the family. This stress can result from the patient's physical and emotional deficits, the unpredictable outcome, and altered family relationships. Families report difficulties in coping with changes in the patient's temperament, behavior, and personality. Such changes are associated with disruption in family cohesion, loss of leisure pursuits, and loss of work capacity, as well as social isolation of the caretaker. The family may experience marital disruption, anger, grief, guilt, and denial in recurring cycles.

To promote effective coping, the nurse can ask the family how the patient is different now, what has been lost, and what is most difficult about coping with this situation. Helpful interventions include providing family members with accurate and honest information and encouraging them to continue to set well-defined short-term goals. Family counseling helps address the family members' overwhelming feelings of loss and helplessness and gives them guidance for the management of inappropriate behaviors. Support groups help the family members share problems, develop insight, gain information, network, and gain assistance in maintaining realistic expectations and hope.

The Brain Injury Association (see Resources) serves as a clearinghouse for information and resources for patients with head injuries and their families, including specific information on coma, rehabilitation, behavioral consequences of head injury, and family issues. This organization can provide names of facilities and professionals who work with patients with head injuries and can assist families in organizing local support groups.

Many patients with severe head injury die from their injuries, and many of those who survive experience long-term disabilities that prevent them from resuming their previous roles and functions. During the most acute phase of injury, family members need factual information and support from the health care team.

Many patients with severe head injuries that result in brain death are young and otherwise healthy and are therefore considered for organ donation. Family members of patients with such injuries need support during this extremely stressful time and assistance in making decisions to end life support and permit donation of organs. They need to know that the patient who is brain dead and whose respiratory

and cardiovascular systems are maintained through life support is not going to survive and that the severe head injury, not the removal of the patient's organs or the removal of life support, is the cause of the patient's death. Bereavement counselors and members of the organ procurement team are often very helpful to family members in making decisions about organ donation and in helping them cope with stress.

Monitoring and Managing Potential Complications

DECREASED CEREBRAL PERFUSION PRESSURE. Maintenance of adequate CPP is important to prevent serious complications of head injury due to decreased cerebral perfusion. Adequate CPP is greater than 60 mm Hg. If CPP falls below a patient's threshold, a vasodilating cascade occurs, causing the volume of blood to increase inside the brain, causing ICP to increase. A decrease in CPP can impair cerebral perfusion and cause brain hypoxia and ischemia, leading to permanent brain damage. Once the threshold CPP is reached, vasoconstriction of the cerebral blood vessels occurs, causing ICP to decrease (Bader & Arbour, 2005). Therapy (eg, elevation of the head of the bed and increased IV fluids) is directed toward decreasing cerebral edema and increasing venous outflow from the brain. Systemic hypotension, which causes vasoconstriction and a significant decrease in CPP, is treated with increased IV fluids or vasopressors.

CEREBRAL EDEMA AND HERNIATION. The patient with a head injury is at risk for additional complications such as increased ICP and brain stem herniation. Cerebral edema is the most common cause of increased ICP in the patient with a head injury, with the swelling peaking approximately 48 to 72 hours after injury. Bleeding also may increase the volume of contents within the rigid, closed compartment of the skull, causing increased ICP and herniation of the brain stem and resulting in irreversible brain anoxia and brain death (Morton, et al., 2010). Measures to control ICP are discussed in Chapter 61 and listed in Chart 63-5.

IMPAIRED OXYGENATION AND VENTILATION. Impaired oxygen and ventilation may require mechanical ventilatory support. The patient must be monitored for a patent airway, altered breathing patterns, and hypoxemia and pneumonia. Interventions may include endotracheal intubation, mechanical ventilation, and positive end-expiratory pressure. These topics are discussed in further detail in Chapters 25 and 61.

Chart 63-5 • Controlling Intracranial Pressure in Patients With Severe Brain Injury

- Elevate the head of the bed as prescribed.
- Maintain the patient's head and neck in neutral alignment (no twisting or flexing the neck).
- Initiate measures to prevent the Valsalva maneuver (eg, stool softeners).
- Maintain normal body temperature.
- Administer O₂ to maintain PaO₂ >90 mm Hg.
- Maintain fluid balance with normal saline solution.
- Avoid noxious stimuli (eg, excessive suctioning, painful procedures).
- Administer sedation to reduce agitation.
- Maintain cerebral perfusion pressure >70 mm Hg.

Table 63-2 RANCHO LOS AMIGOS SCALE: LEVELS OF COGNITIVE FUNCTION

Cognitive Level	Description	Nursing Management
For levels I–III, the key approach is to <i>provide stimulation</i>.		
I: No response	Completely unresponsive to all stimuli, including painful stimuli	Multiple modalities of sensory input should be used. Examples are listed here, but management should be individualized and expanded based on available materials and patient preferences (determined by obtaining information from the family). <i>Olfactory:</i> perfumes, flowers, shaving lotion <i>Visual:</i> family pictures, card, personal items <i>Auditory:</i> radio, television, tapes of family voices or favorite recordings, talking to patient (nurse, family members). The nurse should tell patient what is going to be done, discuss the environment, provide encouragement. <i>Tactile:</i> touching of skin, rubbing various textures on skin <i>Movement:</i> range-of-motion exercises, turning, repositioning, use of water mattress
II: Generalized response	Nonpurposeful response; responds to pain, but in a nonpurposeful manner	
III: Localized response	Responses more focused: withdraws to pain; turns toward sound; follows moving objects that pass within visual field; pulls on sources of discomfort (eg, tubes, restraints); may follow simple commands but inconsistently and in a delayed manner	
For levels IV–VI, the key approach is to <i>provide structure</i>.		
IV: Confused, agitated response	Alert, hyperactive state in which patient responds to internal confusion/agitation; behavior nonpurposeful in relation to the environment; aggressive, bizarre behavior common	For level IV, which lasts 2–4 weeks, interventions are directed at decreasing agitation, increasing environmental awareness, and promoting safety. <ul style="list-style-type: none"> • Approach patient in a calm manner, and use a soft voice. • Screen patient from environmental stimuli (eg, sounds, sights); provide a quiet, controlled environment. • Remove devices that contribute to agitation (eg, tubes), if possible. • Functional goals cannot be set, because the patient is unable to cooperate.
V: Confused, inappropriate response	When agitation occurs, it is the result of external rather than internal stimuli; focused attention is difficult; memory is severely impaired; responses are fragmented and inappropriate to the situation; there is no carryover of learning from one situation to the other.	For levels V and VI, interventions are directed at decreasing confusion, improving cognitive function, and improving independence in performing ADLs. <ul style="list-style-type: none"> • Provide supervision. • Use repetition and cues to teach ADLs. Focus the patient's attention and help to increase his or her concentration. • Help the patient organize activity. • Clarify misinformation and reorient when confused. • Provide a consistent, predictable schedule (eg, post daily schedule on large poster board).
VI: Confused, appropriate response	Follows simple directions consistently but is inconsistently oriented to time and place; short-term memory worse than long-term memory; can perform some ADLs	
For levels VII–X, the key approach is <i>integration into the community</i>.		
VII: Automatic, appropriate response	Appropriately responsive and oriented within the hospital setting; needs little supervision in ADLs; some carryover of learning; patient has superficial insight into disabilities; has decreased judgment and problem-solving abilities; lacks realistic planning for future	For levels VII–X, interventions are directed at increasing the patient's ability to function with minimal or no supervision in the community. <ul style="list-style-type: none"> • Reduce environmental structure. • Help the patient plan for adapting ADLs for self into the home environment. • Discuss and adapt home living skills (eg, cleaning, cooking) to patient's ability. • Provide stand-by assistance as needed for ADLs and home living skills.
VIII: Purposeful, appropriate	Alert, oriented, intact memory; has realistic goals for the future. Able to complete familiar tasks for 1 h in a distracting environment; overestimates or underestimates abilities, argumentative, easily frustrated, self-centered; uncharacteristically dependent/independent	
IX: Purposeful, appropriate	Independently shifts back and forth between tasks and completes them accurately for at least 2 consecutive hours; uses assistive memory devices to recall schedule and activities; aware of and acknowledges impairments and disabilities when they interfere with task completion; depression may continue; may be easily irritable and have a low frustration tolerance	<ul style="list-style-type: none"> • Provide assistance on request for adapting ADLs and home living skills.
X: Purposeful, appropriate	Able to handle multiple tasks simultaneously in all environments but may require periodic breaks; independently initiates and carries out familiar and unfamiliar tasks but may require more than usual amount of time and/or compensatory strategies to complete them; accurately estimates abilities and independently adjusts to task demands; periodic periods of depression may occur; irritability and low frustration tolerance when sick, fatigued, and/or under stress	<ul style="list-style-type: none"> • Monitor for signs and symptoms of depression. • Help the patient plan, anticipate concerns, and solve problems.

IMPAIRED FLUID, ELECTROLYTE, AND NUTRITIONAL BALANCE. Fluid, electrolyte, and nutritional imbalances are common in the patient with a head injury. Common imbalances include hyponatremia, which is often associated with SIADH (see Chapters 14 and 42), hypokalemia, and hyperglycemia. Modifications in fluid intake with tube feedings or IV fluids, including hypertonic saline, may be necessary to treat these imbalances (Hickey, 2009). Insulin administration may be prescribed to treat hyperglycemia.

Undernutrition is also a common problem in response to the increased metabolic needs associated with severe head injury. Decisions about early feeding should be individualized; options include IV hyperalimentation or placement of a feeding tube (jejunal or gastric). Caloric expenditure can increase up to 120% to 140% with TBI, requiring close monitoring of nutritional status. Feeding tubes should be placed 3 to 7 days after neurologic injury to replace energy and nitrogen losses, prevent increased mortality, and improve outcomes (Hickey, 2009).

POSTTRAUMATIC SEIZURES. Patients with head injury are at an increased risk for posttraumatic seizures. Posttraumatic seizures are classified as immediate (within 24 hours after injury), early (within 1 to 7 days after injury), or late (more than 7 days after injury) (Hickey, 2009). Seizure prophylaxis is the practice of administering antiseizure medications to patients with head injury to prevent seizures. It is important to prevent posttraumatic seizures, especially in the immediate and early phases of recovery, because seizures may increase ICP and decrease oxygenation. However, many antiseizure medications impair cognitive performance and can prolong the duration of rehabilitation. Therefore, it is important to weigh the overall benefit of these medications against their side effects. Research evidence supports the use of prophylactic antiseizure agents to prevent immediate and early seizures after head injury, but not for prevention of late seizures (Barker, 2008). The nursing management of seizures is addressed in Chapter 61.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Teaching early in the course of head injury often focuses on reinforcing informa-

tion given to the family about the patient's condition and prognosis. As the patient's status and expected outcome change over time, family teaching may focus on interpretation and explanation of changes in the patient's physical and psychological responses.

If the patient's physical status allows discharge to home, the patient and family are instructed about limitations that can be expected and complications that may occur. The nurse explains to the patient and family, verbally and in writing, how to monitor for complications that merit contacting the neurosurgeon. Depending on the patient's prognosis and physical and cognitive status, the patient may be included in teaching about self-care management strategies.

If the patient is at risk for late posttraumatic seizures, antiseizure medications may be prescribed at discharge. The patient and family require instruction about the side effects of these medications and the importance of continuing to take them as prescribed.

CONTINUING CARE. The rehabilitation phase of care for the patient with a TBI begins at hospital admission. Admission to the rehabilitation unit is a milestone in a patient's recovery and requires intense work by the patient to complete the daily schedule of therapies. The goals of rehabilitation are to maximize the patient's ability to return to his or her highest level of functioning and to his or her home and the community, address concerns before discharge for a smooth transition to home or rehabilitation, and promote independence with adaptation to deficits (Hickey, 2009). The patient is encouraged to continue the rehabilitation program after discharge, because improvement in status may continue 3 or more years after injury. Changes in the patient with a TBI and the effects of long-term rehabilitation on the family and their coping abilities need ongoing assessment. Continued teaching and support of the patient and family are essential as their needs and the patient's status change. Teaching points to address with the family of the patient who is about to return home are described in Chart 63-6.

Depending on his or her status, the patient is encouraged to return to normal activities gradually. Referral to support

CHART
63-6

HOME CARE CHECKLIST

The Patient With a Traumatic Brain Injury

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Explain the need for monitoring for changes in neurologic status and for complications.	✓	✓
• Identify changes in neurologic status and signs and symptoms of complications that should be reported to the neurosurgeon or nurse.		✓
• Demonstrate safe techniques to assist patient with self-care, hygiene, and ambulation.		✓
• Demonstrate safe technique for eating, feeding patient, or assisting patient with eating.	✓	✓
• Explain rationale for taking medications as prescribed.	✓	✓
• Identify need for close monitoring of behavior due to changes in cognitive functioning.		✓
• Describe household modifications needed to ensure safe environment for the patient.		✓
• Describe strategies for reinforcing positive behaviors.		✓
• State importance of continuing follow-up by health care team.	✓	✓

groups and to the Brain Injury Association may be warranted.

During the acute and rehabilitation phases of care, the focus of teaching is on obvious needs, issues, deficits, and complications. Complications after TBI include infections (eg, pneumonia, urinary tract infection [UTI], septicemia, wound infection, osteomyelitis, meningitis, ventriculitis, brain abscess) and heterotrophic ossification (painful bone overgrowth in weight-bearing joints).

The nurse needs to remind the patient and family of the need for continuing health promotion and screening practices after the initial phase of care. Patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Attains or maintains effective airway clearance, ventilation, and brain oxygenation
 - a. Achieves normal blood gas values and has normal breath sounds on auscultation
 - b. Mobilizes and clears secretions
2. Achieves satisfactory fluid and electrolyte balance
 - a. Demonstrates serum electrolytes within normal range
 - b. Has no clinical signs of dehydration or overhydration
3. Attains adequate nutritional status
 - a. Has less than 50 mL of aspirate in stomach before each tube feeding
 - b. Is free of gastric distention and vomiting
 - c. Shows minimal weight loss
4. Avoids injury
 - a. Shows lessening agitation and restlessness
 - b. Is oriented to time, place, and person
5. Maintains normal body temperature
 - a. Absence of fever
 - b. Absence of hypothermia
6. Demonstrates intact skin integrity
 - a. Exhibits no redness or breaks in skin integrity
 - b. Exhibits no pressure ulcers
7. Shows improvement in cognitive function and improved memory
8. Demonstrates normal sleep–wake cycle
9. Demonstrates absence of complications
 - a. Exhibits normal vital signs and body temperature, and increasing orientation to time, place, and person
 - b. Demonstrates normal or reduced ICP
10. Experiences no posttraumatic seizures
 - a. Takes antiseizure medications as prescribed
 - b. Identifies side effects/adverse effects of antiseizure medications
11. Family demonstrates adaptive family processes
 - a. Joins support group
 - b. Shares feelings with appropriate health care personnel
 - c. Makes end-of-life decisions, if needed
12. Participates in rehabilitation process as indicated for patient and family members
 - a. Takes active role in identifying rehabilitation goals and participating in recommended patient care activities
 - b. Prepares for discharge

Spinal Cord Injury

Spinal cord injury (SCI) is a major health disorder. Almost 200,000 people in the United States live each day with a disability from SCI, and an estimated 11,000 new injuries occur each year (Hickey, 2009). SCI is primarily an injury of young adult males and 50% of those injured are between 16 and 30 years of age. Patients over the age of 60 years account for 10% of SCIs, and this figure has steadily risen over the past 25 years (Dawodu, 2007).

Motor vehicle crashes account for 48% of reported cases of SCI, with falls (23%), violence primarily from gunshot wounds (14%), recreational sporting activities (9%), and other events accounting for the remaining injuries. **Paraplegia** (paralysis of the lower body) and **tetraplegia** (formerly quadriplegia—paralysis of all four extremities) can occur, with incomplete tetraplegia (formerly quadriplegia) the largest category, followed by complete paraplegia, complete tetraplegia, and paraplegia.

The predominant risk factors for SCI include young age, male gender, and alcohol and drug use. The frequency with which these risk factors are associated with SCI serves to emphasize the importance of primary prevention. The same interventions suggested earlier in this chapter for head injury prevention serve to decrease the incidence of SCI as well (see Chart 63-1).

Most (80%) people who live with SCIs are men. The approximate ethnic distribution is 62% Caucasian, 22% African American, 13% Hispanic, and 3% other racial or ethnic groups (Dawodu, 2007). Life expectancy continues to increase for people with SCI because of improved health care but remains slightly lower than for those without SCI. The major causes of death are pneumonia, pulmonary emboli (PE), and septicemia (Dawodu, 2007; Hickey, 2009).

Pathophysiology

Damage in SCI ranges from transient concussion (from which the patient fully recovers), to contusion, laceration, and compression of the spinal cord substance (either alone or in combination), to complete **transection** (severing) of the spinal cord (which renders the patient paralyzed below the level of the injury). The vertebrae most frequently involved are the 5th, 6th, and 7th cervical vertebrae (C5 to C7), the 12th thoracic vertebra (T12), and the 1st lumbar vertebra (L1). These vertebrae are most susceptible because there is a greater range of mobility in the vertebral column in these areas (Sherwood, Crago, Spiro, et al., 2007).

SCIs can be separated into two categories: primary injuries and secondary injuries. Primary injuries are the result of the initial insult or trauma and are usually permanent. Secondary injuries are usually the result of a contusion or

tear injury, in which the nerve fibers begin to swell and disintegrate. A secondary chain of events produces ischemia, hypoxia, edema, and hemorrhagic lesions, which in turn result in destruction of myelin and axons. The secondary injury is of primary concern for critical care nurses. Experts believe secondary injury is the principal cause of spinal cord degeneration at the level of injury and that it is reversible during the first 4 to 6 hours after injury. Methods of early treatment are essential to prevent partial damage from becoming total and permanent (Sherwood, et al., 2007).

Clinical Manifestations

Manifestations of SCI depend on the type and level of injury (Chart 63-7). The type of injury refers to the extent of injury to the spinal cord itself. **Incomplete spinal cord lesions** (the sensory or motor fibers, or both, are preserved below the lesion) are classified according to the area of spinal cord damage: central, lateral, anterior, or peripheral. The American Spinal Injury Association (ASIA) provides classification of SCI according to the degree of sensory and motor function present after injury (Chart 63-8). “Neurologic level” refers to the lowest level at which sensory and motor functions are normal. Below the neurologic level, there is total sensory and motor paralysis, loss of bladder and bowel control (usually with urinary retention and bladder distention), loss of sweating and vasomotor tone, and marked reduction of blood pressure from loss of peripheral vascular resistance. A **complete spinal cord lesion** (total loss of sensation and voluntary muscle control below the lesion) can result in paraplegia or tetraplegia.

If conscious, the patient usually complains of acute pain in the back or neck, which may radiate along the involved nerve. However, absence of pain does not rule out spinal injury, and a careful assessment of the spine should be conducted if there has been a significant force and mechanism of injury (ie, concomitant head injury). Often the patient speaks of fear that the neck or back is broken.

Respiratory dysfunction is related to the level of injury. The muscles contributing to respiration are the abdominals and intercostals (T1 to T11) and the diaphragm (C4). In high cervical cord injury, acute respiratory failure is the leading cause of death. Functional abilities by level of injury are described in Table 63-3.

Assessment and Diagnostic Findings

A detailed neurologic examination is performed. Diagnostic x-rays (lateral cervical spine x-rays) and CT scanning are usually performed initially. An MRI scan may be ordered as a further workup if a ligamentous injury is suspected, because significant spinal cord damage may exist even in the absence of bony injury (Hickey, 2009). If an MRI scan is contraindicated, a myelogram may be used to visualize the spinal axis. An assessment is made for other injuries, because spinal trauma often is accompanied by concomitant injuries, commonly to the head and chest. Continuous electrocardiographic monitoring may be indicated if a spinal cord injury is suspected, because bradycardia (slow heart rate) and asystole (cardiac standstill) are common in patients with acute spinal cord injuries.

Emergency Management

The immediate management at the scene of the injury is critical, because improper handling of the patient can cause further damage and loss of neurologic function. Any patient who is involved in a motor vehicle crash, a diving or contact sports injury, a fall, or any direct trauma to the head and neck must be considered to have SCI until such an injury is ruled out. Initial care must include a rapid assessment, immobilization, extrication, and stabilization or control of life-threatening injuries, and transportation to the most appropriate medical facility. Immediate transportation to a trauma center with the capacity to manage major neurologic trauma is then necessary (Hickey, 2009).

At the scene of the injury, the patient must be immobilized on a spinal (back) board, with the head and neck maintained in a neutral position, to prevent an incomplete injury from becoming complete. One member of the team must assume control of the patient’s head to prevent flexion, rotation, or extension; this is done by placing the hands on both sides of the patient’s head at about ear level to limit movement and maintain alignment while a spinal board or cervical immobilizing device is applied. If possible, at least four people should slide the patient carefully onto a board for transfer to the hospital. Any twisting movement may irreversibly damage the spinal cord by causing a bony fragment of the vertebra to cut into, crush, or sever the cord completely.

The standard of care is that the patient is referred to a regional spinal injury or trauma center because of the multidisciplinary personnel and support services required to counteract the destructive changes that occur in the first 24 hours after injury. However, no randomized controlled trials have been conducted to confirm that referral results in better outcomes for the patient with SCI (Jones & Bagnall, 2008). During treatment in the emergency and x-ray departments, the patient is kept on the transfer board. The patient must always be maintained in an extended position. No part of the body should be twisted or turned, and the patient is not allowed to sit up. Once the extent of the injury has been determined, the patient may be placed on a rotating specialty bed (Fig. 63-6) or in a cervical collar (Fig. 63-7). Later, if SCI and bone instability have been ruled out, the patient may be moved to a conventional bed or the collar may be removed without harm. If a specialty bed is needed but not available, the patient should be placed in a cervical collar and on a firm mattress.

Medical Management (Acute Phase)

The goals of management are to prevent secondary injury, to observe for symptoms of progressive neurologic deficits, and to prevent complications. The patient is resuscitated as necessary, and oxygenation and cardiovascular stability are maintained. SCI is a devastating event; new treatment methods and medications are continually being investigated for the acute and chronic phases of care (Fehlings & Baptiste, 2005).

Pharmacologic Therapy

Administration of high-dose IV corticosteroids or methylprednisolone sodium succinate in the first 24 or 48 hours is

Chart 63-7 • Effects of Spinal Cord Injuries

Central Cord Syndrome

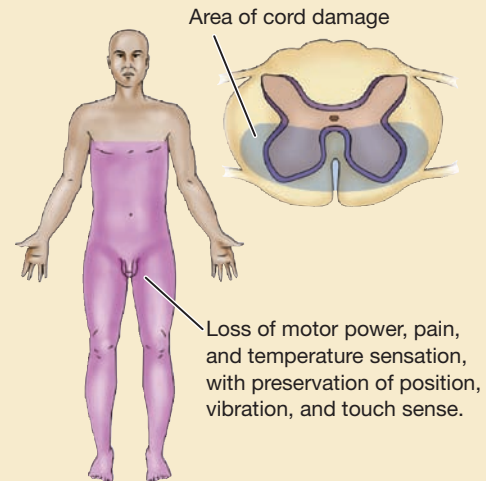

- Characteristics: Motor deficits (in the upper extremities compared to the lower extremities; sensory loss varies but is more pronounced in the upper extremities); bowel/bladder dysfunction is variable, or function may be completely preserved.
- Cause: Injury or edema of the central cord, usually of the cervical area. May be caused by hyperextension injuries.

Central Cord Syndrome

Anterior Cord Syndrome

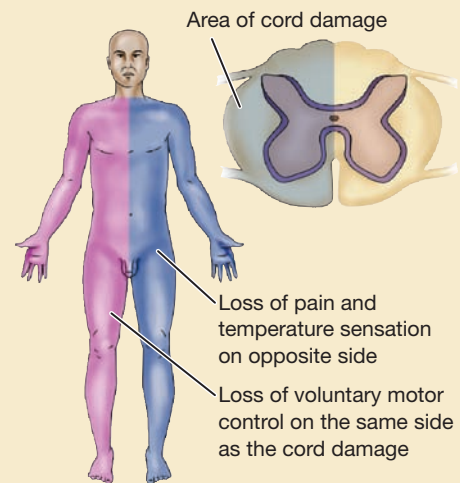

- Characteristics: Loss of pain, temperature, and motor function is noted below the level of the lesion; light touch, position, and vibration sensation remain intact.
- Cause: The syndrome may be caused by acute disk herniation or hyperflexion injuries associated with fracture-dislocation of vertebra. It also may occur as a result of injury to the anterior spinal artery, which supplies the anterior two thirds of the spinal cord.

Anterior Cord Syndrome

Brown-Séquard Syndrome (Lateral Cord Syndrome)

- Characteristics: Ipsilateral paralysis or paresis is noted, together with ipsilateral loss of touch, pressure, and vibration and contralateral loss of pain and temperature.
- Cause: The lesion is caused by a transverse hemisection of the cord (half of the cord is transected from north to south), usually as a result of a knife or missile injury, fracture-dislocation of a unilateral articular process, or possibly an acute ruptured disk.

Brown-Séquard Syndrome

Chart 63-8 • ASIA Impairment Scale

- A = Complete:** No motor or sensory function is preserved in the sacral segments S4–S5.
- B = Incomplete:** Sensory but not motor function is preserved below the neurologic level, and includes the sacral segments S4–S5.
- C = Incomplete:** Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade less than 3.
- D = Incomplete:** Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade of 3 or greater.
- E = Normal:** Motor and sensory function are normal.

controversial. Despite the ongoing controversy surrounding the practice, the use of IV high-dose methylprednisolone is accepted as standard therapy for SCI in many countries and remains an established clinical practice in most trauma centers in the United States (Hickey, 2009).

Respiratory Therapy

Oxygen is administered to maintain a high partial pressure of oxygen (PaO_2), because hypoxemia can create or worsen a neurologic deficit of the spinal cord. If endotracheal intubation is necessary, extreme care is taken to avoid flexing or extending the patient's neck, which can result in extension of a cervical injury.

In high cervical spine injuries, spinal cord innervation to the phrenic nerve, which stimulates the diaphragm, is lost. Diaphragmatic pacing (electrical stimulation of the phrenic nerve) attempts to stimulate the diaphragm to help the patient breathe (Sole, Klein & Moseley, 2009). Intramuscular diaphragmatic pacing is currently in the clinical trial phase for the patient with a high cervical injury. This is implanted via laparoscopic surgery, usually after the acute phase.

Skeletal Fracture Reduction and Traction

Management of SCI requires immobilization and reduction of dislocations (restoration of normal position) and stabilization of the vertebral column.

Cervical fractures are reduced, and the cervical spine is aligned with some form of skeletal traction, such as skeletal tongs or calipers, or with use of the halo device (Sole, et al., 2009). A variety of skeletal tongs are available, all of which involve fixation in the skull in some manner. The Gardner-Wells tongs require no predrilled holes in the skull. Crutchfield and Vinke tongs are inserted through holes made in the skull with a special drill under local anesthesia.

Traction is applied to the skeletal traction device by weights, the amount depending on the size of the patient and the degree of fracture displacement. The traction force is exerted along the longitudinal axis of the vertebral bodies, with the patient's neck in a neutral position. The traction is then gradually increased by adding more weights. As the amount of traction is increased, the spaces between the intervertebral disks widen and the vertebrae are given a chance to slip back into position. Reduction usually occurs after correct alignment has been restored. Once reduction is

Table 63-3 FUNCTIONAL ABILITIES BY LEVEL OF CORD INJURY

Injury Level	Segmental Sensorimotor Function	Dressing, Eating	Elimination	Mobility*
C1	Little or no sensation or control of head and neck; no diaphragm control; requires continuous ventilation	Dependent	Dependent	Limited. Voice or sip-n-puff controlled electric wheelchair
C2 to C3	Head and neck sensation; some neck control; independent of mechanical ventilation for short periods	Dependent	Dependent	Same as for C1
C4	Good head and neck sensation and motor control; some shoulder elevation; diaphragm movement	Dependent, may be able to eat with adaptive sling	Dependent	Limited to voice, mouth, head, chin, or shoulder-controlled electric wheelchair
C5	Full head and neck control; shoulder strength; elbow flexion	Independent with assistance	Maximal assistance	Electric or modified manual wheelchair, needs transfer assistance
C6	Fully innervated shoulder; wrist extension or dorsiflexion	Independent or with minimal assistance	Independent or with minimal assistance	Independent in transfers and wheelchair
C7 to C8	Full elbow extension; wrist plantar flexion; some finger control	Independent	Independent	Independent; manual wheelchair
T1 to T5	Full hand and finger control; use of intercostal and thoracic muscles	Independent	Independent	Independent; manual wheelchair
T6 to T10	Abdominal muscle control, partial to good balance with trunk muscles	Independent	Independent	Independent; manual wheelchair
T11 to L5	Hip flexors, hip abductors (L1–L3); knee extension (L2–L4); knee flexion and ankle dorsiflexion (L4–L5)	Independent	Independent	Short distance to full ambulation with assistance
S1 to S5	Full leg, foot, and ankle control; innervation of perineal muscles for bowel, bladder, and sexual function (S2–S4)	Independent	Normal to impaired bowel and bladder function	Ambulate independently with or without assistance

* Assistance refers to adaptive equipment, setup, or physical assistance.

achieved, as verified by cervical spine x-rays and neurologic examination, the weights are gradually removed until the amount of weight needed to maintain the alignment is identified. The weights should hang freely so as not to interfere with the traction. Traction is sometimes supplemented with manual manipulation of the neck by a surgeon to help achieve realignment of the vertebral bodies.

A halo device may be used initially with traction, or may be applied after removal of the tongs. It consists of a stainless steel halo ring that is fixed to the skull by four pins. The ring is attached to a removable halo vest, a device that

Figure 63-7 Cervical collar. Courtesy of Aspen Medical Products, Irvine, CA.

Figure 63-8 Halo and vest for cervical and thoracic injuries. Courtesy of Acromed Corp., Cleveland, OH.

suspends the weight of the unit circumferentially around the chest. A metal frame connects the ring to the chest. Halo devices provide immobilization of the cervical spine while allowing early ambulation (Fig. 63-8).

Thoracic and lumbar injuries are usually treated with surgical intervention followed by immobilization with a fitted brace. Traction is not indicated either before or after surgery, due to the relative stability of the spine in these regions.

NURSING ALERT

The patient's vital organ functions and body defenses must be supported and maintained until spinal and neurogenic shock abates and the neurologic system has recovered from the traumatic insult; this can take up to 4 months (Hickey, 2009).

Surgical Management

Surgery is indicated in any of the following situations:

- Compression of the cord is evident.
- The injury results in a fragmented or unstable vertebral body.
- The injury involves a wound that penetrates the cord.
- Bony fragments are in the spinal canal.
- The patient's neurologic status is deteriorating.

Research indicates that early surgical stabilization improves the clinical outcome of patients compared to surgery

performed later during the clinical course. The goals of surgical treatment are to preserve neurologic function by removing pressure from the spinal cord and to provide stability (Sherwood, et al., 2007).

Management of Acute Complications of Spinal Cord Injury

Spinal and Neurogenic Shock

The spinal shock associated with SCI reflects a sudden depression of reflex activity in the spinal cord (areflexia) below the level of injury. The muscles innervated by the part of the spinal cord segment below the level of the lesion are without sensation, paralyzed, and flaccid, and the reflexes are absent. In particular, the reflexes that initiate bladder and bowel function are affected. Bowel distention and paralytic ileus can be caused by depression of the reflexes and are treated with intestinal decompression by insertion of a nasogastric tube (Dawodu, 2007).

Neurogenic shock develops as a result of the loss of autonomic nervous system function below the level of the lesion (Dawodu, 2007). The vital organs are affected, causing decreases in blood pressure, heart rate, and cardiac output, as well as venous pooling in the extremities and peripheral vasodilation. In addition, the patient does not perspire in the paralyzed portions of the body, because sympathetic activity is blocked; therefore, close observation is required for early detection of an abrupt onset of fever. Further discussion of neurogenic shock can be found in Chapter 15.

With injuries to the cervical and upper thoracic spinal cord, innervation to the major accessory muscles of respiration is lost and respiratory problems develop. These include decreased vital capacity, retention of secretions, increased partial pressure of arterial carbon dioxide (PaCO_2) levels and decreased oxygen levels, respiratory failure, and pulmonary edema.

Deep Vein Thrombosis

Deep vein thrombosis (DVT) is a potential complication of immobility and is common in patients with SCI. Patients who develop DVT are at risk for PE, a life-threatening complication. Manifestations of PE include pleuritic chest pain, anxiety, shortness of breath, and abnormal blood gas values (increased PaCO_2 and decreased PaO_2). Low-dose anticoagulation therapy usually is initiated to prevent DVT and PE, along with the use of anti-embolism stockings or pneumatic compression devices. In some cases, permanent indwelling filters (see Chapter 23) may be placed prophylactically in the vena cava to prevent emboli (dislodged clots) from migrating to the lungs and causing a PE (Hickey, 2009).

NURSING ALERT

The calves or thighs should never be massaged because of the danger of dislodging an undetected thromboemboli.

Other Complications

In addition to respiratory complications (respiratory failure, pneumonia) and **autonomic dysreflexia** (characterized by pounding headache, profuse sweating, nasal congestion,

piloerection [“goose bumps”], bradycardia, and hypertension), other complications that may occur include pressure ulcers and infection (urinary, respiratory, and local infection at the skeletal traction pin sites) (Vacca, 2007a).

NURSING PROCESS

THE PATIENT WITH ACUTE SPINAL CORD INJURY

Assessment

The patient’s breathing pattern and the strength of the cough are assessed, and the lungs are auscultated, because paralysis of abdominal and respiratory muscles diminishes coughing and makes clearing of bronchial and pharyngeal secretions difficult. Reduced excursion of the chest also results.

The patient is monitored closely for any changes in motor or sensory function and for symptoms of progressive neurologic damage. In the early stages of SCI, determining whether the cord has been severed may not be possible, because signs and symptoms of cord edema are indistinguishable from those of cord transection. Edema of the spinal cord may occur with any severe cord injury and may further compromise spinal cord function.

Motor and sensory functions are assessed through careful neurologic examination. These findings are recorded on a flow sheet so that changes in the baseline neurologic status can be monitored closely and accurately. The ASIA classification is commonly used to describe level of function for patients with SCI (see Chart 63-8). Chart 63-7 gives examples of the effects of altered spinal cord function. At the minimum:

- Motor ability is tested by asking the patient to spread the fingers, squeeze the examiner’s hand, and move the toes or turn the feet.
- Sensation is evaluated by gently pinching the skin or touching it lightly with an object such as a tongue blade, starting at shoulder level and working down both sides of the extremities. The patient should have both eyes closed so that the examination reveals true findings, not what the patient hopes to feel. The patient is asked where the sensation is felt.
- Any decrease in neurologic function is reported immediately.

The patient is also assessed for spinal shock, a complete loss of all reflex, motor, sensory, and autonomic activity below the level of the lesion that causes bladder paralysis and distention. The lower abdomen is palpated for signs of urinary retention and overdistention of the bladder. Further assessment is made for gastric dilation and paralytic ileus caused by an atonic bowel, a result of autonomic disruption.

Temperature is monitored, because the patient may have periods of hyperthermia as a result of alteration in temperature control due to autonomic disruption.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient’s major nursing diagnoses may include the following:

- Ineffective breathing patterns related to weakness or paralysis of abdominal and intercostal muscles and inability to clear secretions
- Ineffective airway clearance related to weakness of intercostal muscles
- Impaired bed and physical mobility related to motor and sensory impairments
- Disturbed sensory perception related to motor and sensory impairment
- Risk for impaired skin integrity related to immobility and sensory loss
- Impaired urinary elimination related to inability to void spontaneously
- Constipation related to presence of atonic bowel as a result of autonomic disruption
- Acute pain and discomfort related to treatment and prolonged immobility

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include:

- DVT
- Orthostatic hypotension
- Autonomic dysreflexia

Planning and Goals

The goals for the patient may include improved breathing pattern and airway clearance, improved mobility, improved sensory and perceptual awareness, maintenance of skin integrity, relief of urinary retention, improved bowel function, promotion of comfort, and absence of complications.

Nursing Interventions

Promoting Adequate Breathing and Airway Clearance

Possible impending respiratory failure is detected by observing the patient, measuring vital capacity, monitoring oxygen saturation through pulse oximetry, and monitoring arterial blood gases. Early and vigorous attention to clearing bronchial and pharyngeal secretions can prevent retention of secretions and atelectasis. Suctioning may be indicated, but it should be used with caution to avoid stimulating the vagus nerve and producing bradycardia and cardiac arrest.

If the patient cannot cough effectively because of decreased inspiratory volume and inability to generate sufficient expiratory pressure, chest physical therapy and assisted coughing may be indicated. Specific breathing exercises are supervised by the nurse to increase the strength and endurance of the inspiratory muscles, particularly the diaphragm. Assisted coughing promotes clearing of secretions from the upper respiratory tract and is similar to the use of abdominal thrusts to clear an airway (see Chapter 25). Proper humidification and hydration are important to prevent secretions from becoming thick and difficult to remove even with coughing. The patient is assessed for signs of respiratory infection (eg, cough, fever, dyspnea).

Ascending edema of the spinal cord in the acute phase may cause respiratory difficulty that requires immediate intervention. Therefore, the patient's respiratory status must be monitored closely.

Improving Mobility

Proper body alignment is maintained at all times. The patient is repositioned frequently and is assisted out of bed as soon as the spinal column is stabilized. The feet are prone to footdrop; therefore, various types of splints are used to prevent footdrop. When used, the splints are removed and reapplied every 2 hours. Trochanter rolls, applied from the crest of the ilium to the mid thigh of both legs, help prevent external rotation of the hip joints.

Patients with lesions above the midthoracic level have loss of sympathetic control of peripheral vasoconstrictor activity, leading to hypotension. These patients may tolerate changes in position poorly and require monitoring of blood pressure when positions are changed. If not on a rotating specialty bed, the patient should not be turned unless the spine is stable and the physician has indicated that it is safe to do so.

Contractures can develop rapidly with immobility and muscle paralysis. A joint that is immobilized too long becomes fixed as a result of contractures of the tendon and joint capsule. Atrophy of the extremities results from disuse. Contractures and other complications may be prevented by range-of-motion exercises that help preserve joint motion and stimulate circulation. Passive range-of-motion exercises should be implemented as soon as possible after injury. Toes, metatarsals, ankles, knees, and hips should be put through a full range of motion at least four, and ideally five, times daily.

For most patients who have a cervical fracture without neurologic deficit, reduction in traction followed by rigid immobilization for 6 to 8 weeks restores skeletal integrity. These patients are allowed to move gradually to an erect position. A neck brace or molded collar is applied when the patient is mobilized after traction is removed (see Fig. 63-7).

Promoting Adaptation to Sensory and Perceptual Alterations

The nurse assists the patient to compensate for sensory and perceptual alterations that occur with SCI. The intact senses above the level of the injury are stimulated through touch, aromas, flavorful food and beverages, conversation, and music. Additional strategies include the following:

- Providing prism glasses to enable the patient to see from the supine position
- Encouraging use of hearing aids, if indicated, to enable the patient to hear conversations and environmental sounds
- Providing emotional support to the patient
- Teaching the patient strategies to compensate for or cope with sensory deficits

Maintaining Skin Integrity

Pressure ulcers are a significant complication of SCI. The most common sites are over the ischial tuberosity, the greater trochanter, the sacrum, and the occiput (back of head). In the acute care setting, during the initial phase of hospitalization, it may be necessary to delay rehabilitation in 20% to 30% of patients because of pressure ulcers. Pressure ulcers may begin within hours of an acute SCI where pressure is continuous and where the peripheral circulation

is inadequate as a result of spinal shock and a recumbent position. It is important to move the patient from the backboard as soon as possible and inspect the skin. In addition, patients who wear cervical collars for prolonged periods may develop breakdown from the pressure of the collar under the chin, on the shoulders, and at the occiput. In addition, pressure ulcers can add substantially to the personal and economic costs of living with a SCI. The prevalence of this complication ranges from 17% for people 2 months after injury to 33% for those living with an SCI.

The most effective approach to addressing this costly complication of SCI is prevention (King, Porter & Vertiz, 2008). The patient's position is changed at least every 2 hours. Turning not only assists in the prevention of pressure ulcers but also prevents pooling of blood and edema in the dependent areas. Careful inspection of the skin is made each time the patient is turned. The skin over the pressure points is assessed for redness or breaks; the perineum is checked for soilage, and the catheter is observed for adequate drainage. The patient's general body alignment and comfort are assessed. Special attention should be given to pressure areas in contact with the transfer board.

In addition, the patient's skin should be kept clean by washing with a mild soap, rinsing well, and blotting dry. Pressure-sensitive areas should be kept well lubricated and soft with hand cream or lotion. The patient is educated about the danger of pressure ulcers and is encouraged to take control and make decisions about appropriate skin care (King, et al., 2008). See Chapter 11 for other aspects of the prevention of pressure ulcers.

Maintaining Urinary Elimination

Immediately after SCI, the urinary bladder becomes atonic and cannot contract by reflex activity. Urinary retention is the immediate result. Because the patient has no sensation of bladder distention, overstretching of the bladder and detrusor muscle may occur, delaying the return of bladder function.

Intermittent catheterization is carried out to avoid overdistention of the bladder and UTI. If this is not feasible, an indwelling catheter is inserted temporarily. At an early stage, family members are shown how to carry out intermittent catheterization and are encouraged to participate in this facet of care, because they will be involved in long-term follow-up and must be able to recognize complications so that treatment can be instituted.

The patient is taught to record fluid intake, voiding pattern, amounts of residual urine after catheterization, characteristics of urine, and any unusual sensations that may occur. The management of a **neurogenic bladder** (bladder dysfunction that results from a disorder or dysfunction of the nervous system) is discussed in detail in Chapter 11.

Improving Bowel Function

Immediately after SCI, a paralytic ileus usually develops as a result of neurogenic paralysis of the bowel; therefore, a nasogastric tube is often required to relieve distention and to prevent vomiting and aspiration.

Bowel activity usually returns within the first week. As soon as bowel sounds are heard on auscultation, the patient

is given a high-calorie, high-protein, high-fiber diet, with the amount of food gradually increased. The nurse administers prescribed stool softeners to counteract the effects of immobility and analgesic agents. A bowel program is instituted as early as possible.

Providing Comfort Measures: The Patient in Halo Traction

A patient who has had pins, tongs, or calipers placed for cervical stabilization may have a slight headache or discomfort for several days after the pins are inserted. Patients initially may be bothered by the rather startling appearance of these devices, but usually they readily adapt to it because the device provides comfort for the unstable neck (see Fig. 63-8). The patient may complain of being caged in and of noise created by any object coming in contact with the steel frame of a halo device, but he or she can be reassured that adaptation will occur.

The areas around the four pin sites of a halo device are cleaned daily and observed for redness, drainage, and pain. The pins are observed for loosening, which may contribute to infection. If one of the pins becomes detached, the head is stabilized in a neutral position by one person while another notifies the neurosurgeon. A torque screwdriver should be readily available in case the screws on the frame need tightening.

The skin under the halo vest is inspected for excessive perspiration, redness, and skin blistering, especially on the bony prominences. The vest is opened at the sides to allow the torso to be washed. The liner of the vest should not become wet, because dampness causes skin excoriation. Powder is not used inside the vest, because it may contribute to the development of pressure ulcers. The liner should be changed periodically to promote hygiene and good skin care. If the patient is to be discharged with the vest, detailed instructions must be given to the family, with time allowed for them to demonstrate the necessary skills of halo vest care (Chart 63-9).

Monitoring and Managing Potential Complications

THROMBOPHLEBITIS. Thrombophlebitis is a relatively common complication in patients after SCI. The patient must be assessed for symptoms of thrombophlebitis and PE. Chest pain, shortness of breath, and changes in arterial blood gas values must be reported promptly to the physician. The circumferences of the thighs and calves are measured and recorded daily; further diagnostic studies are performed if a significant increase is noted. Patients remain at high risk for thrombophlebitis for several months after the initial injury. Patients with paraplegia or tetraplegia are at increased risk for the rest of their lives. Immobilization and the associated venous stasis, as well as varying degrees of autonomic disruption, contribute to the high risk and susceptibility for DVT (Hickey, 2009).

Anticoagulation is initiated once head injury and other systemic injuries have been ruled out. Low-dose fractionated or unfractionated heparin may be followed by long-term oral anticoagulation (ie, warfarin) or subcutaneous fractionated heparin injections. Additional measures such as range-of-motion exercises, anti-embolism stockings, and adequate hydration are important preventive measures.

The Patient With a Halo Vest

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe the rationale for use of the halo vest.	✓	✓
• Demonstrate assessment of frame, traction, tongs, and pins.		✓
• Describe emergency measures if respiratory or other complications develop while patient is in halo vest or if frame becomes dislodged.		✓
• Demonstrate pin care using correct technique.		✓
• Identify signs and symptoms of infection.	✓	✓
• Assess the skin for reddened or irritated areas and breakdown.		✓
• Demonstrate care of skin.		✓
• Explain the reasons for and the method for changing the vest liner.	✓	✓
• Demonstrate safe techniques to assist patient with self-care, hygiene, and ambulation.		✓
• Identify signs and symptoms of complications (DVT, respiratory impairment, urinary tract infection).		✓

Pneumatic compression devices may also be used to reduce venous pooling and promote venous return. It is also important to avoid external pressure on the lower extremities that may result from flexion of the knees while the patient is in bed.

ORTHOSTATIC HYPOTENSION. For the first 2 weeks after SCI, the blood pressure tends to be unstable and quite low. It gradually returns to preinjury levels, but periodic episodes of severe orthostatic hypotension frequently interfere with efforts to mobilize the patient. Interruption in the reflex arcs that normally produce vasoconstriction in the upright position, coupled with vasodilation and pooling in abdominal and lower extremity vessels, can result in blood pressure readings of 40 mm Hg systolic and 0 mm Hg diastolic. Orthostatic hypotension is a particularly common problem for patients with lesions above T7. In some patients with tetraplegia, even slight elevations of the head can result in dramatic decreases in blood pressure.

A number of techniques can be used to reduce the frequency of hypotensive episodes. Close monitoring of vital signs before and during position changes is essential. Vasopressor medication can be used to treat the profound vasodilation. Anti-embolism stockings should be applied to improve venous return from the lower extremities. Abdominal binders may also be used to encourage venous return and provide diaphragmatic support when the patient is upright. Activity should be planned in advance, and adequate time should be allowed for a slow progression of position changes from recumbent to sitting and upright. Tilt tables frequently are helpful in assisting patients to make this transition.

AUTONOMIC DYSREFLEXIA. Autonomic dysreflexia (autonomic hyperreflexia) is an acute emergency that occurs as a result of exaggerated autonomic responses to stimuli that are harmless in normal people. It occurs only after spinal shock has resolved. This syndrome is characterized by a severe, pounding headache with paroxysmal hypertension, profuse diaphoresis (most often of the forehead), nausea, nasal congestion, and bradycardia. It occurs among patients

with cord lesions above T6 (the sympathetic visceral outflow level) after spinal shock has subsided. The sudden increase in blood pressure may cause a rupture of one or more cerebral blood vessels or lead to increased ICP. A number of stimuli may trigger this reflex: distended bladder (the most common cause); distention or contraction of the visceral organs, especially the bowel (from constipation, impaction); or stimulation of the skin (tactile, pain, thermal stimuli, pressure ulcer). Because this is an emergency situation, the objectives are to remove the triggering stimulus and to avoid the possibly serious complications.

The following measures are carried out:

- The patient is placed immediately in a sitting position to lower blood pressure.
- Rapid assessment is performed to identify and alleviate the cause.
- The bladder is emptied immediately via a urinary catheter. If an indwelling catheter is not patent, it is irrigated or replaced with another catheter.
- The rectum is examined for a fecal mass. If one is present, a topical anesthetic agent is inserted 10 to 15 minutes before the mass is removed, because visceral distention or contraction can cause autonomic dysreflexia.
- The skin is examined for any areas of pressure, irritation, or broken skin.
- Any other stimulus that could be the triggering event, such as an object next to the skin or a draft of cold air, must be removed.
- If these measures do not relieve the hypertension and excruciating headache, a ganglionic blocking agent (hydralazine hydrochloride [Apresoline]) is prescribed and administered slowly by the IV route.
- The medical record or chart is labeled with a clearly visible note about the risk of autonomic dysreflexia.
- The patient is instructed about prevention and management measures.
- Any patient with a lesion above the T6 segment is informed that such an episode is possible and may occur even many years after the initial injury.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. In most cases, patients with SCI (ie, patients with tetraplegia or paraplegia) need long-term rehabilitation. The process begins during hospitalization, as acute symptoms begin to subside or come under better control and the overall deficits and long-term effects of the injury become clear. The goals begin to shift from merely surviving the injury to learning strategies necessary to cope with the alterations that the injury imposes on activities of daily living (ADLs). The emphasis shifts from ensuring that the patient is stable and free of complications to specific assessment and planning designed to meet the patient's rehabilitation needs. Patient teaching may initially focus on the injury and its effects on mobility, dressing, and bowel, bladder, and sexual function. As the patient and family acknowledge the consequences of the injury and the resulting disability, the focus of teaching broadens to address issues necessary for carrying out the tasks of daily living and taking charge of their lives (Kinder, 2005). Teaching begins in the acute phase and continues throughout rehabilitation and throughout the patient's life as changes occur, the patient ages, and problems arise (Capoor & Stein, 2005).

Caring for the patient with SCI at home may at first seem a daunting task to the family. They will require dedicated nursing support to gradually assume full care of the patient. Although maintaining function and preventing complications will remain important, goals regarding self-care and preparation for discharge will assist in a smooth transition to rehabilitation and eventually to the community.

CONTINUING CARE. The goal of the rehabilitation process is independence. The nurse becomes a support to both the patient and the family, assisting them to assume responsibility for increasing aspects of patient care and management. Care for the patient with SCI involves members of all the health care disciplines, which may include nursing, medicine, rehabilitation, respiratory therapy, physical and occupational therapy, case management, and social services. The nurse often serves as coordinator of the management team and as a liaison with rehabilitation centers and home care agencies. The patient and family often require assistance in dealing with the psychological impact of the injury and its consequences; referral to a psychiatric clinical nurse specialist or other mental health care professional often is helpful.

The nurse should reassure female patients with SCI that pregnancy is not contraindicated and fertility is relatively unaffected, but that pregnant women with acute or chronic SCI pose unique management challenges. The normal physiologic changes of pregnancy may predispose women with SCI to many potentially life-threatening complications, including autonomic dysreflexia, pyelonephritis, respiratory insufficiency, thrombophlebitis, PE, and unattended delivery. Preconception assessment and counseling are strongly recommended to ensure that the woman is in optimal health and to increase the likelihood of an uneventful pregnancy and healthy outcomes (Smeltzer, 2007; Smeltzer & Wetzel-Effinger, 2009).

As more patients survive acute SCI, they face the changes associated with aging with a disability. Therefore, teaching in the home and community focuses on health promotion and

addresses the need to minimize risk factors (eg, smoking, alcohol and drug abuse, obesity). Routine health screening and preventive services are needed for the older adult with SCI (Barker, 2008). Home care nurses and others who have contact with patients with SCI are in a position to teach patients about healthy lifestyles, remind them of the need for health screenings, and make referrals as appropriate. Assisting patients to identify accessible health care providers, clinical facilities, and imaging centers may increase the likelihood that they will participate in health screening.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Demonstrates improvement in gas exchange and clearance of secretions, as evidenced by normal breath sounds on auscultation
 - a. Breathes easily without shortness of breath
 - b. Performs hourly deep-breathing exercises, coughs effectively, and clears pulmonary secretions
 - c. Is free of respiratory infection (ie, has normal temperature, respiratory rate, and pulse; normal breath sounds; absence of purulent sputum)
2. Moves within limits of the dysfunction and demonstrates completion of exercises within functional limitations
3. Demonstrates adaptation to sensory and perceptual alterations
 - a. Uses assistive devices (eg, prism glasses, hearing aids, computers) as indicated
 - b. Describes sensory and perceptual alterations as a consequence of injury
4. Demonstrates optimal skin integrity
 - a. Exhibits normal skin turgor; skin is free of red- dened areas or breaks
 - b. Participates in skin care and monitoring proce- dures within functional limitations
5. Regains urinary bladder function
 - a. Exhibits no signs of UTI (ie, has normal tempera- ture; voids clear, dilute urine)
 - b. Has adequate fluid intake
 - c. Participates in bladder training program within functional limitations
6. Regains bowel function
 - a. Reports regular pattern of bowel movement
 - b. Consumes adequate dietary fiber and oral fluids
 - c. Participates in bowel training program within functional limitations
7. Reports absence of pain and discomfort
8. Is free of complications
 - a. Demonstrates no signs of thrombophlebitis, DVT, or PE
 - b. Maintains blood pressure within normal limits
 - c. Reports no lightheadedness with position changes
 - d. Exhibits no manifestations of autonomic dysre- flexia (ie, absence of headache, diaphoresis, nasal congestion, bradycardia, or diaphoresis)

Medical Management of Long-Term Complications of Spinal Cord Injury

The patient faces a lifetime of disability, requiring ongoing follow-up and care. The expertise of a number of health professionals, including physicians (specifically a physiatrist), rehabilitation nurses, occupational therapists, physical therapists, psychologists, social workers, rehabilitation engineers, and vocational counselors, is necessary at different times as the need arises.

As people with SCI age, they have the same medical problems as other people. In addition, they face the threat of complications associated with their disability (Hickey, 2009). Usually, patients are encouraged to attend a spine clinic when complications and other issues arise. Lifetime care includes assessment of the urinary tract at prescribed intervals, because there is the likelihood of continuing alteration in detrusor and sphincter function, and the patient is prone to UTI.

Long-term problems and complications of SCI include premature aging, disuse syndrome, autonomic dysreflexia (discussed earlier), bladder and kidney infections, spasticity, and depression (Capoor & Stein, 2005). Pressure ulcers with potential complications of sepsis, osteomyelitis, and fistulas occur in about 10% of patients. Spasticity may be particularly disabling. Heterotopic ossification (overgrowth of bone) in the hips, knees, shoulders, and elbows occurs in many patients after SCI. Both of these complications are painful and can produce a loss of range of motion (Hickey, 2009). Management includes observing for and addressing any alteration in physiologic status and psychological outlook, as well as the prevention and treatment of long-term complications. The nursing role involves emphasizing the need for vigilance in self-assessment and care.

NURSING PROCESS

THE PATIENT WITH TETRAPLEGIA OR PARAPLEGIA

Assessment

Assessment focuses on the patient's general condition, complications, and how the patient is managing at that particular point in time. A head-to-toe assessment and review of systems should be part of the database, with emphasis on the areas that are prone to problems in this population. A thorough inspection of all areas of the skin for redness or breakdown is critical. The nurse reviews the established bowel and bladder program with the patient, because the program must continue uninterrupted. Patients with tetraplegia or paraplegia have varying degrees of loss of motor power, deep and superficial sensation, vasomotor control, bladder and bowel control, and sexual function. They are faced with potential complications related to immobility, skin breakdown and pressure ulcers, recurring UTIs, and contractures. Knowledge about these particular issues can further guide the assessment in any setting. Nurses in all settings, including home care, must be aware of these potential complications in the lifetime management of these patients.

An understanding of the emotional and psychological responses to tetraplegia or paraplegia is achieved by observing the responses and behaviors of the patient and family and by listening to their concerns. Documenting these assessments and reviewing the plan with the entire team on a regular basis provide insight into how both the patient and the family are coping with the changes in lifestyle and body functioning. Additional information frequently can be gathered from the social worker or psychiatric/mental health worker.

It takes time for the patient and family to comprehend the magnitude of the disability. They may go through stages of grief, including shock, disbelief, denial, anger, depression, and acceptance. During the acute phase of the injury, denial can be a protective mechanism to shield the patient from the overwhelming reality of what has happened. As the patient realizes the permanent nature of paraplegia or tetraplegia, the grieving process may be prolonged and all-encompassing because of the recognition that long-held plans and expectations are interrupted or permanently altered. A period of depression often follows as the patient experiences a loss of self-esteem in areas of self-identity, sexual functioning, and social and emotional roles. Exploration and assessment of these issues can assist in developing a meaningful plan of care.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses of the patient with tetraplegia or paraplegia may include the following:

- Impaired bed and physical mobility related to loss of motor function
- Risk for disuse syndrome
- Risk for impaired skin integrity related to permanent sensory loss and immobility
- Impaired urinary elimination related to level of injury
- Constipation related to effects of spinal cord disruption
- Sexual dysfunction related to neurologic dysfunction
- Ineffective coping related to impact of disability on daily living
- Deficient knowledge about requirements for long-term management

Collaborative Problems/Potential Complications

Based on all the assessment data, potential complications of tetraplegia or paraplegia that may develop include:

- Spasticity
- Infection and sepsis

Planning and Goals

The goals for the patient may include attainment of some form of mobility; maintenance of healthy, intact skin; achievement of bladder management without infection; achievement of bowel control; achievement of sexual expression; strengthening of coping mechanisms; and absence of complications.

Nursing Interventions

The patient requires extensive rehabilitation, which is less difficult if appropriate nursing management has been

carried out during the acute phase of the injury or illness. Nursing care is one of the key factors determining the success of the rehabilitation program. The main objective is for the patient to live as independently as possible in the home and community.

Increasing Mobility

EXERCISE PROGRAMS. The unaffected parts of the body are built up to optimal strength to promote maximal self-care. The muscles of the hands, arms, shoulders, chest, spine, abdomen, and neck must be strengthened in the patient with paraplegia, because he or she must bear full weight on these muscles to ambulate. The triceps and the latissimus dorsi are important muscles used in crutch walking. The muscles of the abdomen and the back also are necessary for balance and for maintaining the upright position.

To strengthen these muscles, the patient can do push-ups when in a prone position and sit-ups when in a sitting position. Extending the arms while holding weights (traction weights can be used) also develops muscle strength. Squeezing rubber balls or crumpling newspaper promotes hand strength.

With encouragement from all members of the rehabilitation team, the patient with paraplegia can develop the increased exercise tolerance needed for gait training and ambulation activities. The importance of maintaining cardiovascular fitness is stressed to the patient. Alternative exercises to increase the heart rate to target levels must be designed within the patient's abilities.

MOBILIZATION. After the spine is stable enough to allow the patient to assume an upright posture, mobilization activities are initiated. A brace or vest may be used, depending on the level of the lesion. A patient whose paralysis is a result of complete transection of the cord can begin weight bearing early, because no further damage can be incurred. The sooner muscles are used, the less chance there is of disuse atrophy. The earlier the patient is brought to a standing position, the less opportunity there is for osteoporotic changes to take place in the long bones. Weight bearing also reduces the possibility of renal calculi and enhances many other metabolic processes.

Braces and crutches enable some patients with paraplegia to ambulate for short distances. Ambulation using crutches requires a high expenditure of energy. Motorized wheelchairs and specially equipped vans can provide greater independence and mobility for patients with high-level SCI or other lesions. Every effort should be made to encourage the patient to be as mobile and active as possible.

Preventing Disuse Syndrome

Patients are at high risk for development of contractures as a result of disuse syndrome due to the musculoskeletal system changes (atrophy) brought about by the loss of motor and sensory functions below the level of injury. Range-of-motion exercises must be provided at least four times a day, and care is taken to stretch the Achilles tendon with exercises. The patient is repositioned frequently and is maintained in proper body alignment whether in bed or in a wheelchair.

Contractures can complicate day-to-day care, increasing the difficulty of positioning and decreasing mobility. A number of surgical procedures have been tried with varying degrees of success. These techniques are used if more conservative approaches fail, but the best treatment is prevention.

Promoting Skin Integrity

Because these patients spend a great portion of their lives in wheelchairs, pressure ulcers are an ever-present threat. Contributing factors are permanent sensory loss over pressure areas; immobility, which makes relief of pressure difficult; trauma from bumps (against the wheelchair, toilet, furniture, and so forth) that cause unnoticed abrasions and wounds; loss of protective function of the skin from excoriation and maceration due to excessive perspiration and possible incontinence; and poor general health (anemia, edema, malnutrition), leading to poor tissue perfusion. The prevention and management of pressure ulcers are discussed in detail in Chapter 11.

The person with tetraplegia or paraplegia must take responsibility for monitoring (or directing monitoring) of his or her skin status. This involves relieving pressure and not remaining in any position for longer than 2 hours, in addition to ensuring that the skin receives meticulous attention and cleansing. The patient is taught that ulcers develop over bony prominences that are exposed to unrelieved pressure in the lying and sitting positions. The most vulnerable areas are identified. The patient with paraplegia is instructed to use mirrors, if possible, to inspect these areas morning and night, observing for redness, slight edema, or any abrasions. While in bed, the patient should turn at 2-hour intervals and then inspect the skin again for redness that does not fade on pressure. The bottom sheet should be checked for wetness and for creases. The patient with tetraplegia or paraplegia who cannot perform these activities is encouraged to direct others to check these areas and prevent ulcers from developing.

The patient is taught to relieve pressure while in the wheelchair by doing push-ups, leaning from side to side to relieve ischial pressure, and tilting forward while leaning on a table. The caregiver for the patient with tetraplegia will need to perform these activities if the patient cannot do so independently. A wheelchair cushion is prescribed to meet individual needs, which may change in time with changes in posture, weight, and skin tolerance. A referral can be made to a rehabilitation engineer, who can measure pressure levels while the patient is sitting and then tailor the cushion and other necessary aids and assistive devices to the patient's needs.

The diet for the patient with tetraplegia or paraplegia should be high in protein, vitamins, and calories to ensure minimal wasting of muscle and the maintenance of healthy skin, and high in fluids to maintain well-functioning kidneys. Excessive weight gain and obesity should be avoided, because they further limit mobility.

Improving Bladder Management

The effect of the spinal cord lesion on the bladder depends on the level of injury, the degree of cord damage, and the length of time after injury. A patient with tetraplegia or

paraplegia usually has either a reflex or a nonreflex bladder (see Chapter 11). Both bladder types increase the risk of UTI.

The nurse emphasizes the importance of maintaining an adequate flow of urine by encouraging a fluid intake of about 2.5 L daily. The patient should empty the bladder frequently so that there is minimal residual urine and should pay attention to personal hygiene, because infection of the bladder and kidneys almost always occurs by the ascending route. The perineum must be kept clean and dry, and attention must be given to the perianal skin after defecation. Underwear should be cotton (which is more absorbent) and should be changed at least once a day.

If an external catheter (condom catheter) is used, the sheath is removed nightly; the penis is cleansed to remove urine and is dried carefully, because warm urine on the periurethral skin promotes the growth of bacteria. Attention also is given to the collection bag. The nurse emphasizes the importance of monitoring for signs of UTI: cloudy, foul-smelling urine or hematuria (blood in the urine); fever; or chills.

The female patient who cannot achieve reflex bladder control or self-catheterization may need to wear pads or waterproof undergarments. Surgical intervention may be indicated in some patients to create a urinary diversion.

Establishing Bowel Control

The objective of a bowel training program is to establish bowel evacuation through reflex conditioning, a technique described in Chapter 11. If the SCI occurs above the sacral segments or nerve roots and there is reflex activity, the anal sphincter may be massaged (digital stimulation) to stimulate defecation. If the cord lesion involves the sacral segment or nerve roots, anal massage is not performed, because the anus may be relaxed and lack tone. Massage is also contraindicated if there is spasticity of the anal sphincter. The anal sphincter is massaged by inserting a gloved finger (which has been adequately lubricated) 2.5 to 3.7 cm (1 to 1.5 inches) into the rectum and moving it in a circular motion or from side to side. It soon becomes apparent which area triggers the defecation response. This procedure should be performed at regular time intervals (usually every 48 hours), after a meal, and at a time that will be convenient for the patient at home. The patient also is taught the symptoms of impaction (frequent loose stools; constipation) and is cautioned to watch for hemorrhoids. A diet with sufficient fluids and fiber is essential to developing a successful bowel training program, avoiding constipation, and decreasing the risk of autonomic dysreflexia.

Counseling on Sexual Expression

Many patients with tetraplegia and paraplegia can have some form of meaningful sexual relationship, although modifications are necessary. The patient and partner benefit from counseling about the range of sexual expression possible, special techniques and positions, exploration of body sensations offering sensual feelings, and urinary and bowel hygiene as related to sexual activity. For men with erectile failure, penile prostheses enable them to have and sustain an erection, and impotence drugs may be helpful. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis), for example, are oral smooth muscle relaxants that

cause blood to flow into the penis, resulting in an erection (see Chapter 49).

Sexual education and counseling services are included in the rehabilitation services at spinal centers. Small-group meetings in which patients can share their feelings, receive information, and discuss sexual concerns and practical aspects are helpful in producing effective attitudes and adjustments.

Enhancing Coping Mechanisms

The impact of the disability and loss becomes marked when the patient returns home. Each time something new enters the patient's life (eg, a new relationship, going to work), the patient is reminded anew of his or her limitations. Grief reactions and depression are common.

To work through this depression, the patient must have some hope for relief in the future. The nurse can encourage the patient to feel confident in his or her ability to achieve self-care and relative independence. The role of the nurse ranges from caretaker during the acute phase to teacher, counselor, and facilitator as the patient gains mobility and independence.

The patient's disability affects not only the patient but also the entire family. In many cases, family therapy is helpful in working through issues as they arise. Adjustment to the disability leads to the development of realistic goals for the future, making the best of the abilities that are left intact and reinvesting in other activities and relationships. Rejection of the disability causes self-destructive neglect and noncompliance with the therapeutic program, which leads to more frustration and depression. Crises for which interventions may be sought include social, psychological, marital, sexual, and psychiatric problems. The family usually requires counseling, social services, and other support systems to help them cope with the changes in their lifestyle and socioeconomic status.

A major goal of nursing management is to help the patient overcome his or her sense of futility and to encourage the patient in the emotional adjustment that must be made before he or she is willing to venture into the outside world. However, an excessively sympathetic attitude on the part of the nurse may cause the patient to develop an overdependence that defeats the purpose of the entire rehabilitation program. The patient is taught and assisted when necessary, but the nurse should avoid performing activities that the patient can do independently with a little effort. This approach to care more than repays itself in the satisfaction of seeing a completely demoralized and helpless patient become independent and find meaning in a newly emerging lifestyle.

Monitoring and Managing Potential Complications

SPASTICITY. Muscle spasticity is one of the most problematic complications of tetraplegia and paraplegia. These incapacitating flexor or extensor spasms, which occur below the level of the spinal cord lesion, interfere with both the rehabilitation process and ADLs. Spasticity results from an imbalance between the facilitatory and inhibitory effects on neurons that exist normally. The area of the cord distal to the site of injury or lesion becomes disconnected from the higher inhibitory centers located in the brain, so facilitatory impulses, which originate from muscles, skin, and ligaments, predominate.

Spasticity is defined as a condition of increased muscle tone in a muscle that is weak. Initial resistance to stretching is quickly followed by sudden relaxation. The stimulus that precipitates spasm can be obvious, such as movement or a position change, or subtle, such as a slight jarring of the wheelchair. Most patients with tetraplegia or paraplegia have some degree of spasticity. With SCI, the onset of spasticity usually occurs from a few weeks to 6 months after the injury. The same muscles that are flaccid during the period of spinal shock develop spasticity during recovery. The intensity of spasticity tends to peak approximately 2 years after the injury, after which the spasms tend to regress.

Management of spasticity is based on the severity of symptoms and the degree of incapacitation. The antispasmodic medication baclofen (Lioresal) is one of the most commonly used agents because it is available in an oral and an intrathecal form. Other medications such as diazepam (Valium) and dantrolene (Dantrium) are also effective in controlling spasm (Saulino & Jacobs, 2006). All of the antispasmodic medications cause drowsiness, weakness, and vertigo in some patients. Passive range-of-motion exercises and frequent turning and repositioning are helpful, because stiffness tends to increase spasticity. These activities also are essential in the prevention of contractures, pressure ulcers, and bowel and bladder dysfunction.

INFECTION AND SEPSIS. Patients with tetraplegia and paraplegia are at increased risk for infection and sepsis from a variety of sources: urinary tract, respiratory tract, and pressure ulcers. Sepsis remains a major cause of complications and death in these patients. Prevention of infection and sepsis is essential through maintenance of skin integrity, complete emptying of the bladder at regular intervals, and prevention of urinary and fecal incontinence. The risk for respiratory infection can be decreased by avoiding contact with people who have symptoms of respiratory infection, performing coughing and deep-breathing exercises to prevent pooling of respiratory secretions, receiving yearly influenza vaccines, and giving up smoking. A high-protein diet is important in maintaining an adequate immune system, as is avoiding factors that may reduce immune system function, such as excessive stress, drug abuse, and excessive alcohol intake.

If infection occurs, the patient requires thorough assessment and prompt treatment. Antibiotic therapy and adequate hydration, in addition to local measures (depending on the site of infection), are initiated immediately.

UTIs are minimized or prevented by aseptic technique in catheter management, adequate hydration, bladder training program, and prevention of overdistention of the bladder and urinary stasis.

Skin breakdown and infection are prevented by maintenance of a turning schedule; frequent back care; regular assessment of all skin areas; regular cleaning and lubrication of the skin; passive range-of-motion exercise to prevent contractures; pressure relief over broken skin areas, bony prominences, and heels; and wrinkle-free bed linen.

Pulmonary infections are managed and prevented by frequent coughing, turning, and deep-breathing exercises and chest physiotherapy; aggressive respiratory care and suctioning of the airway if a tracheostomy is present; assisted coughing as needed; and adequate hydration.

Infections of any kind can be life-threatening. Aggressive nursing interventions are key to prevention, detection, and early management.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patients with tetraplegia or paraplegia are at risk for complications for the rest of their lives. Therefore, a major aspect of nursing care is teaching the patient and family about these complications and about strategies to minimize risks. UTIs, contractures, infected pressure ulcers, and sepsis may necessitate hospitalization. Other late complications that may occur include lower extremity edema, joint contractures, respiratory dysfunction, and pain. To avoid these and other complications, the patient and a family member are taught skin care, catheter care, range-of-motion exercises, breathing exercises, and other care techniques. Teaching is initiated as soon as possible and extends into the rehabilitation or long-term care facility and home. In all aspects of care, it is important for the nurse and patient to set mutual goals and discuss the tasks the patient is capable of doing independently and which tasks the patient needs assistance to complete. (See Chapter 11 for a more detailed discussion of rehabilitation.)

CONTINUING CARE. Referral for home care is often appropriate for assessment of the home setting, patient teaching, and evaluation of the patient's physical and emotional status. During visits by the home care nurse, teaching about strategies to prevent or minimize potential complications is reinforced. The home environment is assessed for adequacy for care and for safety. Environmental modifications are made, and specialized equipment is obtained, ideally before the patient goes home.

The home care nurse also assesses the patient's and the family's adherence to recommendations and their use of coping strategies. The use of inappropriate coping strategies (eg, drug and alcohol use) is assessed, and referrals to counseling are made for the patient and family. Appropriate and effective coping strategies are reinforced. The nurse reviews previous teaching and determines the need for further physical or psychological assistance. The patient's self-esteem and body image may be very poor at this time. Because people with high levels of social support often report feelings of well-being despite major physical disability, it is beneficial for the nurse to assess and promote further development of the support system and effective coping strategies for each patient.

The patient requires continuing, lifelong follow-up by the physician, physical therapist, and other rehabilitation team members, because the neurologic deficit is usually permanent and new deficits, complications, and secondary conditions can develop. These require prompt attention before they take their toll in additional physical impairment, time, morale, and financial costs. The local counselor for the Office of Vocational Rehabilitation works with the patient with respect to job placement or additional educational or vocational training.

The nurse is in a good position to remind patients and family members of the need for continuing health promotion and screening practices. Referral to accessible health care providers and imaging centers is important in health

promotion and health screening. Chapter 10 has more information on chronic illness and disability.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Attains some form of mobility
2. Contractures do not develop
3. Maintains healthy, intact skin
4. Achieves bladder control, absence of UTI
5. Achieves bowel control
6. Reports sexual satisfaction
7. Shows improved adaptation to environment and others
8. Exhibits reduction in spasticity
 - a. Reports understanding of the precipitating factors
 - b. Uses measures to reduce spasticity
9. Describes long-term management required
10. Exhibits absence of complications

CRITICAL THINKING EXERCISES

1 A 75-year-old man is brought to the emergency department by his family, who report that he fell approximately 2 weeks ago in the bathroom. The patient does not recall the event. His family states that he is sleeping more than usual and seems forgetful. The patient is prescribed warfarin (Coumadin) daily. What type of injury has he most likely sustained? What type of medical treatment might he undergo? What discharge instructions are warranted for this patient's family or caregiver?

2 A 19-year-old man with a spinal cord injury at the T6 level complains of a severe headache. He is diaphoretic and flushed above the level of injury. His blood pressure is 230/110 mm Hg. What do you suspect is happening? What are the possible causes of his condition, and how would you intervene? What is included in your teaching plan for the patient and family before discharge?

EBP 3 A 56-year-old man who is married and the father of two children was involved in a motor vehicle crash 2 days ago, and he sustained a C4 fracture with spinal cord injury. As a result, he has tetraplegia and is on a mechanical ventilator in a neurologic intensive care unit. What recommendations would you make for the care of this patient to prevent secondary injury? What is the evidence base for these recommendations? Identify the criteria used to evaluate the strength of the evidence for these practices.

Management of Patients With Neurologic Infections, Autoimmune Disorders, and Neuropathies

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Differentiate among the infectious disorders of the nervous system according to causes, manifestations, medical care, and nursing management.
- 2 Describe the pathophysiology, clinical manifestations, and medical and nursing management of multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome.
- 3 Use the nursing process as a framework for care of patients with multiple sclerosis and Guillain-Barré syndrome.
- 4 Describe disorders of the cranial nerves, their manifestations, and indicated nursing interventions.
- 5 Develop a plan of nursing care for the patient with a cranial nerve disorder.

GLOSSARY

- ataxia:** impaired coordination of movements
- bulbar paralysis:** immobility of muscles innervated by cranial nerves with their cell bodies in the lower portion of the brain stem
- diplopia:** double vision, or the awareness of two images of the same object occurring in one or both eyes
- dyskinesia:** impaired ability to execute voluntary movements
- dysphagia:** difficulty swallowing, causing the patient to be at risk for aspiration
- dysphonia:** voice impairment or altered voice production
- neuropathy:** general term indicating a disorder of the nervous system
- paresthesia:** a sensation of numbness or tingling or a “pins and needles” sensation
- prion:** a particle smaller than a virus that is resistant to standard sterilization procedures
- spasticity:** muscular hypertonicity with increased resistance to stretch often associated with weakness, increased deep tendon reflexes, and diminished superficial reflexes
- spongiform:** having the appearance or quality of a sponge

The diverse group of neurologic disorders that make up infectious and autoimmune disorders and cranial and peripheral neuropathies presents unique challenges for nursing care. The nurse who cares for patients with these disorders must have a clear understanding of the pathologic processes and the clinical outcomes. Some of the issues nurses must help patients and families confront include adaptation to the effects of the disease, potential changes in family dynamics, and, possibly, end-of-life issues.

INFECTIOUS NEUROLOGIC DISORDERS

The infectious disorders of the nervous system include meningitis, brain abscesses, various types of encephalitis, and Creutzfeldt-Jakob and variant Creutzfeldt-Jakob disease. The clinical manifestations, assessment, and diagnostic findings as well as the medical and nursing management are related to the specific infectious process.

Meningitis

Meningitis is an inflammation of the lining around the brain and spinal cord caused by bacteria or viruses (Iggulden, 2006). Meningitis can be the primary reason a patient is hospitalized or can develop during hospitalization and is classified as septic or aseptic. Septic meningitis is caused by bacteria. In aseptic meningitis, the cause is viral or secondary to lymphoma, leukemia, or human immunodeficiency virus (HIV). The bacteria *Streptococcus pneumoniae* and *Neisseria meningitidis* are responsible for 80% of cases of meningitis in adults (van de Beek, de Gans, Tunkel,

et al., 2006). *Haemophilus influenzae* was once a common cause of meningitis in children, but, because of vaccination, infection with this organism is now rare in developed countries (Mazzoni, Pearson & Rowland, 2006).

Outbreaks of *N. meningitidis* infection are most likely to occur in dense community groups, such as college campuses and military installations. Although infections occur year round, the peak incidence is in the winter and early spring. Factors that increase the risk of bacterial meningitis include tobacco use and viral upper respiratory infection, because they increase the amount of droplet production. Otitis media and mastoiditis increase the risk of bacterial meningitis, because the bacteria can cross the epithelial membrane and enter the subarachnoid space. People with immune system deficiencies are also at greater risk for development of bacterial meningitis.

Pathophysiology

Meningeal infections generally originate in one of two ways: through the bloodstream as a consequence of other infections or by direct spread, such as might occur after a traumatic injury to the facial bones or secondary to invasive procedures.

N. meningitidis concentrates in the nasopharynx and is transmitted by secretion or aerosol contamination. Bacterial or meningococcal meningitis also occurs as an opportunistic infection in patients with acquired immunodeficiency syndrome (AIDS) and as a complication of Lyme disease (Chart 64-1).

Once the causative organism enters the bloodstream, it crosses the blood-brain barrier and proliferates in the cerebrospinal fluid (CSF). The host immune response stimulates the release of cell wall fragments and lipopolysaccharides, facilitating inflammation of the subarachnoid and pia mater. Because the cranial vault contains little room for

Chart 64-1 • Meningitis in Specific Populations

Meningitis can occur as a complication of other diseases and is an opportunistic infection seen with greater frequency in patients who are immunocompromised.

Meningitis in Patients with Acquired Immunodeficiency Syndrome (AIDS)

- Aseptic, cryptococcal, and tuberculous forms of meningitis have been reported in patients with AIDS.
- Acute and chronic forms of aseptic meningitis may occur with AIDS; both are accompanied by headache, but signs of meningeal irritation usually occur with the acute form.
- Aseptic meningitis may be accompanied by cranial nerve palsies. The meningitis is thought to be related to direct infection of the central nervous system by human immunodeficiency virus (HIV) because it can be isolated from the cerebrospinal fluid (CSF).
- Cryptococcal meningitis is the most common fungal infection of the central nervous system in patients with AIDS. Patients may experience headache, nausea, vomiting, seizures, confusion, and lethargy. Treatment consists of IV administration of amphotericin B followed by fluconazole. Maintenance therapy with fluconazole may be necessary to prevent relapse.

- Some immunosuppressed patients develop few if any symptoms because of blunted inflammatory responses; others develop atypical features.

Meningitis in Patients with Lyme Disease

- Lyme disease is a multisystem inflammatory process caused by the tick-transmitted spirochete *Borrelia burgdorferi*.
- Neurologic abnormalities are seen in later stages (stages 2 or 3). Stage 2 occurs with the start of a characteristic rash or 1 to 6 months after the rash has disappeared.
- Neurologic abnormalities include aseptic meningitis, chronic lymphocytic meningitis, and encephalitis.
- Cranial nerve inflammation, including Bell's palsy and other peripheral neuropathies, is common.
- Stage 3 (the chronic form of the disease) begins years after the initial tick infection and is characterized by arthritis, skin lesions, and neurologic abnormalities.
- Most patients with stage 2 and 3 Lyme disease are treated with IV antibiotics, usually ceftriaxone or penicillin G.
- Meningeal and systemic symptoms begin to improve within days, although other symptoms, such as headache, may persist for weeks.

expansion, the inflammation may cause increased intracranial pressure (ICP). CSF circulates through the subarachnoid space, where inflammatory cellular materials from the affected meningeal tissue enter and accumulate.

The prognosis for bacterial meningitis depends on the causative organism, the severity of the infection and illness, and the timeliness of treatment. Acute fulminant presentation may include adrenal damage, circulatory collapse, and widespread hemorrhages (Waterhouse-Friderichsen syndrome). This syndrome is the result of endothelial damage and vascular necrosis caused by the bacteria. Complications include visual impairment, deafness, seizures, paralysis, hydrocephalus, and septic shock.

Clinical Manifestations

Headache and fever are frequently the initial symptoms. Fever tends to remain high throughout the course of the illness. The headache is usually either steady or throbbing and very severe as a result of meningeal irritation (Bickley, 2007). Meningeal irritation results in a number of other well-recognized signs common to all types of meningitis:

- Neck mobility: A stiff and painful neck (nuchal rigidity) can be an early sign and any attempts at flexion of the head are difficult because of spasms in the muscles of the neck. Normally the neck is supple, and the patient can easily bend the head and neck forward.
- Positive Kernig's sign: When the patient is lying with the thigh flexed on the abdomen, the leg cannot be completely extended (Fig. 64-1).
- Positive Brudzinski's sign: When the patient's neck is flexed (after ruling out cervical trauma or injury), flexion of the knees and hips is produced; when the lower extremity of one side is passively flexed, a similar movement is seen in the opposite extremity (see Fig. 64-1). Brudzinski's sign is a more sensitive indicator of meningeal irritation than Kernig's sign.
- Photophobia (extreme sensitivity to light): This finding is common, although the cause is unclear.

A rash can be a striking feature of *N. meningitidis* infection, occurring in about half of patients with this type of meningitis. Skin lesions develop, ranging from a petechial rash with purpuric lesions to large areas of ecchymosis.

Disorientation and memory impairment are common early in the course of the illness. The changes depend on the severity of the infection as well as the individual response to the physiologic processes. Behavioral manifestations are also common. As the illness progresses, lethargy, unresponsiveness, and coma may develop.

Seizures can occur and are the result of areas of irritability in the brain. ICP increases secondary to diffuse brain swelling or hydrocephalus (van de Beek, et al., 2006). The initial signs of increased ICP include decreased level of consciousness and focal motor deficits. If ICP is not controlled, the uncus of the temporal lobe may herniate through the tentorium, causing pressure on the brain stem. Brain stem herniation is a life-threatening event that causes cranial nerve dysfunction and depresses the centers of vital functions, such as the medulla. See Chapter 61 for discussion of the patient with a change in level of consciousness (LOC) or increased ICP.

An acute fulminant infection occurs in about 10% of patients with meningococcal meningitis, producing signs of overwhelming septicemia: an abrupt onset of high fever, extensive purpuric lesions (over the face and extremities), shock, and signs of disseminated intravascular coagulation (DIC). Death may occur within a few hours after onset of the infection.

Assessment and Diagnostic Findings

If the clinical presentation suggests meningitis, diagnostic testing is conducted to identify the causative organism. A computed tomography (CT) scan or magnetic resonance imaging (MRI) scan is used to detect a shift in brain contents (which may lead to herniation) prior to a lumbar puncture. Bacterial culture and Gram staining of CSF and blood are key diagnostic tests. CSF studies demonstrate low glucose, high protein levels, and high white blood cell count (Mazzoni, et al., 2006). Gram staining allows for rapid identification of the causative bacteria and initiation of appropriate antibiotic therapy (van de Beek, et al., 2006).

Researchers have developed a bedside risk score for use in adults with bacterial meningitis. Risks for an unfavorable outcome include older age, a heart rate of greater than 120 bpm, low Glasgow Coma score, cranial nerve palsies, and a positive Gram stain 1 hour after presentation to the hospital (Weisfelt, van de Beek, Spanjaard, et al., 2007).

Prevention

The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) (2008) recommends that the meningococcal conjugated vaccine be given to adolescents entering high school and to college freshmen living in dormitories. Freshmen living in dormitories have a three times greater risk of developing meningococcal meningitis as compared with the general population and students living off campus. Most states mandate education addressing meningococcal meningitis

Figure 64-1 Testing for meningeal irritation. **A**, Kernig's sign. **B**, Brudzinski's sign.

and the availability of vaccination so that families can make informed decisions.

People in close contact with patients with meningococcal meningitis should be treated with antimicrobial chemoprophylaxis using rifampin (Rifadin), ciprofloxacin hydrochloride (Cipro), or ceftriaxone sodium (Rocephin). Therapy should be started within 24 hours after exposure because a delay in the initiation of therapy limits the effectiveness of the prophylaxis. Vaccination should also be considered as an adjunct to antibiotic chemoprophylaxis for anyone living with a person who develops meningococcal infection. Vaccination against *H. influenzae* and *S. pneumoniae* should be encouraged for children and at-risk adults (Matthews, Miller & Mott, 2007).

Medical Management

Successful outcomes depend on the early administration of an antibiotic that crosses the blood–brain barrier into the subarachnoid space in sufficient concentration to halt the multiplication of bacteria. Vancomycin hydrochloride in combination with one of the cephalosporins (eg, ceftriaxone sodium, cefotaxime sodium) is administered intravenously (IV) (van de Beek, et al., 2006).

Dexamethasone (Decadron) has been shown to be beneficial as adjunct therapy in the treatment of acute bacterial meningitis and in pneumococcal meningitis if it is administered 15 to 20 minutes before the first dose of antibiotic and every 6 hours for the next 4 days. Studies indicate that dexamethasone improves the outcome in adults and does not increase the risk of gastrointestinal bleeding (van de Beek, et al., 2006).

Dehydration and shock are treated with fluid volume expanders. Seizures, which may occur early in the course of the disease, are controlled with phenytoin (Dilantin). Increased ICP is treated as necessary (see Chapter 61).

Nursing Management

The patient with meningitis is critically ill; therefore, many of the nursing interventions are collaborative with the physician, respiratory therapist, and other members of the health care team. The patient's safety and well-being depend on sound nursing judgment.

Neurologic status and vital signs are continually assessed. Pulse oximetry and arterial blood gas values are used to quickly identify the need for respiratory support if increasing ICP compromises the brain stem. Insertion of a cuffed endotracheal tube (or tracheotomy) and mechanical ventilation may be necessary to maintain adequate tissue oxygenation.

Blood pressure (usually monitored using an arterial line) is assessed for incipient shock, which precedes cardiac or respiratory failure. Rapid IV fluid replacement may be prescribed, but care is taken to prevent fluid overload. Fever also increases the workload of the heart and cerebral metabolism. ICP will increase in response to increased cerebral metabolic demands. Therefore, measures are taken to reduce body temperature as quickly as possible.

Other important components of nursing care include the following measures:

- Protecting the patient from injury secondary to seizure activity or altered LOC

- Monitoring daily body weight; serum electrolytes; and urine volume, specific gravity, and osmolality, especially if syndrome of inappropriate antidiuretic hormone (SIADH) is suspected
- Preventing complications associated with immobility, such as pressure ulcers and pneumonia
- Instituting infection control precautions until 24 hours after initiation of antibiotic therapy (oral and nasal discharge is considered infectious)

Any sudden, critical illness can be devastating to the family. Because the patient's condition is often critical and the prognosis guarded, the family needs to be informed about the patient's condition. Periodic family visits are essential to facilitate coping of the patient and family. An important aspect of the nurse's role is to support the family and assist them in identifying others who can be supportive to them during the crisis.

Brain Abscess

Brain abscesses account for less than 2% of space-occupying brain lesions in the United States and are more common in males during the first two decades of life (Mazzoni, et al., 2006). Brain abscesses are rare in immunocompetent people; they are more frequently diagnosed in people who are immunosuppressed as a result of an underlying disease or use of immunosuppressive medications.

Pathophysiology

A brain abscess is a collection of infectious material within the tissue of the brain. Bacteria are the most common causative organisms. The most common predisposing conditions for abscesses among immunocompetent adults are otitis media and rhinosinusitis. An abscess can result from intracranial surgery, penetrating head injury, or tongue piercing. Organisms causing brain abscess may reach the brain by hematologic spread from the lungs, gums, tongue, or heart, or from a wound or intra-abdominal infection (Mazzoni, et al., 2006). Brain abscesses in immunocompromised people may result from various pathogens. To prevent brain abscess, otitis media, mastoiditis, rhinosinusitis, dental infections, and systemic infections should be treated promptly.

Clinical Manifestations

The clinical manifestations of a brain abscess result from alterations in intracranial dynamics (edema, brain shift), infection, or the location of the abscess (Chart 64-2).

Headache, usually worse in the morning, is the most prevailing symptom. Fever, vomiting, and focal neurologic deficits occur as well. Focal deficits such as weakness and decreasing vision reflect the area of brain that is involved. As the abscess expands, symptoms of increased ICP such as decreasing LOC and seizures are observed.

Assessment and Diagnostic Findings

Neuroimaging studies such as MRI or CT scanning identify the size and location of the abscess. The MRI or CT scans reveal a ring around a hypodense area (Mazzoni, et al., 2006). Aspiration of the abscess, guided by CT or MRI, is

CHART
64-2

Assessing for Brain Abscesses

Be alert for the following signs and symptoms:

Frontal Lobe

Hemiparesis
Aphasia (expressive)
Seizures
Frontal headache

Temporal Lobe

Localized headache
Changes in vision
Facial weakness
Aphasia

Cerebellar Abscess

Occipital headache
Ataxia (inability to coordinate movements)
Nystagmus (rhythmic, involuntary movements of the eye)

the best method to culture and identify the infectious organism. Blood cultures are obtained if the abscess is believed to arise from a distant source. Chest x-ray is performed to rule out predisposing lung infections and an electroencephalogram (EEG) may help localize the lesion (Hickey, 2009).

Medical Management

Treatment is aimed at controlling increased ICP, draining the abscess, and providing antimicrobial therapy directed at the abscess and the primary source of infection. Large IV doses of antibiotics are administered to penetrate the blood-brain barrier and reach the abscess. The choice of the specific antibiotic medication is based on culture and sensitivity testing and directed at the causative organism. A stereotactic CT-guided aspiration may be used to drain the abscess and identify the causative organism. Corticosteroids may be prescribed to help reduce the inflammatory cerebral edema if the patient shows evidence of an increasing neurologic deficit. Antiseizure medications (phenytoin, phenobarbital) may be prescribed to prevent or treat seizures.

Nursing Management

Nursing care focuses on continuing to assess the neurologic status, administering medications, assessing the response to treatment, and providing supportive care.

Ongoing neurologic assessment alerts the nurse to changes in ICP, which may indicate a need for more aggressive intervention. The nurse also assesses and documents the responses to medications. Blood laboratory test results, specifically blood glucose and serum potassium levels, need to be closely monitored when corticosteroids are prescribed. Administration of insulin or electrolyte replacement may be required to return these values to normal or acceptable levels.

Patient safety is another key nursing responsibility. Injury may result from decreased LOC or falls related to motor weakness or seizures (Hughes, 2008).

The patient with a brain abscess is very ill, and neurologic deficits, such as hemiparesis, seizures, visual deficits, and cranial nerve palsies, may remain after treatment. Seizures are common sequelae. The nurse must assess the family's ability to express distress at the patient's condition, cope with the patient's illness and deficits, and obtain support.

Herpes Simplex Virus Encephalitis

Encephalitis is an acute inflammatory process of the brain tissue. Herpes simplex virus (HSV) is the most common cause of acute encephalitis in the United States (Mazzoni, et al., 2006). There are two herpes simplex viruses: HSV-1 and HSV-2. HSV-1 typically affects children and adults. HSV-2 most commonly affects neonates and is discussed in pediatric textbooks.

Pathophysiology

The pathology of encephalitis involves local necrotizing hemorrhage that becomes more generalized, followed by edema. There is also progressive deterioration of nerve cell bodies (Porth & Matfin, 2009).

Clinical Manifestations

The initial symptoms of HSV-1 encephalitis include fever, headache, and confusion. Focal neurologic symptoms reflect the areas of cerebral inflammation and necrosis and include fever, headache, behavioral changes, focal seizures, dysphasia, hemiparesis, and altered LOC (Porth & Matfin, 2009).

Assessment and Diagnostic Findings

Neuroimaging studies, such as EEG, and CSF examination are used to diagnose HSV encephalitis. MRI is the neuroimaging study of choice for detection of early changes caused by HSV-1; the study shows edema in the temporal lobe. The EEG shows diffuse slowing or focal changes in the temporal lobe in about 80% of patients (Mazzoni, et al., 2006). Lumbar puncture often reveals a high opening pressure and low glucose and high protein levels in CSF samples. Viral cultures are almost always negative. The polymerase chain reaction (PCR) is the standard test for early diagnosis of HSV-1 encephalitis. PCR identifies the DNA bands of HSV-1 in the CSF. The validity of PCR is very high between the 3rd and 10th days after symptom onset.

Medical Management

Acyclovir (Zovirax) or ganciclovir (Cytovene), antiviral agents, are the medications of choice in the treatment of HSV (Matthews, et al., 2007). Early administration of antiviral agents (usually well tolerated) improves the prognosis associated with HSV-1 encephalitis. The mode of action is inhibition of viral DNA replication. To prevent relapse, treatment should continue for up to 3 weeks. Slow IV administration over 1 hour prevents crystallization of the medication in the urine. The usual dose of acyclovir is decreased if the patient has a history of renal insufficiency. Studies are in progress to determine the effectiveness of an oral agent, valacyclovir hydrochloride (Valtrex), in the treatment of HSV-1 encephalitis.

Nursing Management

Assessment of neurologic function is key to monitoring the progression of disease. Comfort measures to reduce headache include dimming the lights, limiting noise and visitors, grouping nursing interventions, and administering analgesic agents (Matthews, et al., 2007). Opioid analgesic medications may mask neurologic symptoms; therefore, they are used cautiously. Seizures and altered LOC require care directed at injury prevention and safety. Nursing care addressing patient and family anxieties is ongoing throughout the illness. Monitoring of blood chemistry test results and urinary output alert the nurse to the presence of renal complications related to antiviral therapy.

Arthropod-Borne Virus Encephalitis

Arthropod vectors transmit several types of viruses that cause encephalitis. The primary vector in North America is the mosquito. In cases of West Nile virus, humans are the secondary host; birds are the primary host. Arbovirus infection (transmitted by arthropod vectors) occurs in specific geographic areas during the summer and fall. In the United States, West Nile and St. Louis are the most common types of arboviral encephalitis; both are members of the Japanese encephalitis serogroup. West Nile virus develops in 1 out of 150 cases of encephalitis (Matthews, et al., 2007; Mazzoni, et al., 2006).

Pathophysiology

Viral replication occurs at the site of the mosquito bite. The host immune response attempts to control viral replication. If the immune response is inadequate, viremia will ensue. The virus gains access to the central nervous system (CNS) via the cerebral capillaries, resulting in encephalitis. It spreads from neuron to neuron, predominantly affecting the cortical gray matter, the brain stem, and the thalamus. Meningeal exudates compound the clinical presentation by irritating the meninges and increasing ICP.

Clinical Manifestations

St. Louis and West Nile encephalitis most commonly affect adults. Climate, an environment conducive to arthropod proliferation, and human behavior contribute to the occurrence of St. Louis and West Nile encephalitis. An arboviral encephalitis begins with early flulike symptoms, but specific neurologic manifestations depend on the viral type. A unique clinical feature of St. Louis encephalitis is SIADH with hyponatremia. Signs and symptoms specific to West Nile encephalitis include a maculopapular or morbilliform rash on the neck, trunk, and arms; enlarged lymph nodes and legs; and flaccid paralysis (Matthews, et al., 2007). Both West Nile and St. Louis encephalitis can result in parkinsonianlike movements, reflecting inflammation of the basal ganglia. Seizures, a poor prognostic indicator, are present in both types of encephalitis but are more common in the St. Louis type.

Assessment and Diagnostic Findings

After a brief febrile prodrome, neurologic symptoms reflect the area of the brain that is involved. Neuroimaging and CSF evaluation are useful in the diagnosis of arboviral

encephalitis. The MRI scan demonstrates inflammation of the basal ganglia in cases of St. Louis encephalitis and inflammation in the periventricular area in cases of West Nile encephalitis. Immunoglobulin M antibodies to West Nile virus are observed in serum and CSF. Serum cultures are not useful, because the viremia is brief. PCR evaluation of CSF may demonstrate viral ribonucleic acid (RNA).

Medical Management

No specific medication for arboviral encephalitis includes controlling the seizures and the increased ICP. Interferon may be useful in treating St. Louis encephalitis. Ribavirin and interferon alpha-2b show some effect against West Nile virus but have not been evaluated in controlled studies (Tunkel, Glaser, Block, et al., 2008). Neuropsychiatric complications, such as emotional outbursts and other behavior changes, occur frequently.

Nursing Management

If the patient is very ill, hospitalization may be required. The nurse carefully assesses neurologic status and identifies improvement or deterioration in the patient's condition. Injury prevention is key in light of the potential for falls or seizures. Arboviral encephalitis may result in death or lifelong residual health issues such as neurologic deficits and seizures (Mazzoni, et al., 2006). The family will need support and teaching to cope with these outcomes.

Public education addressing the prevention of arboviral encephalitis is a key nursing role. Clothing that provides coverage and insect repellents containing 25% to 30% diethyltoluamide (DEET) should be used on exposed clothing and skin in high-risk areas to decrease mosquito and tick bites. Screens should be in good repair in the home, and standing water should be removed. Blood donation centers screen all blood for West Nile virus. Cases of West Nile virus must be reported to the CDC.

Fungal Encephalitis

Fungal infections of the CNS occur rarely in healthy people. The presentation of fungal encephalitis is related to geographic area or to an immune system that is compromised due to disease or immunosuppressive medication. Causes of fungal infections include *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Aspergillus fumigatus*, *Candida*, and *Coccidioides immitis* (Mazzoni, et al., 2006). *C. immitis* is found mainly in California, Arizona, New Mexico, and Texas. *B. dermatitidis* exists in the southeastern United States and in the Ohio, St. Lawrence, and Mississippi River basins. It is a risk for coal miners, construction workers, and farmers. *C. neoformans* is associated with exposure to bird droppings and may be seen in bird handlers.

Pathophysiology

The fungal spores enter the body via inhalation. They initially infect the lungs, causing vague respiratory symptoms or pneumonitis. The fungi may enter the bloodstream, causing a fungemia. If the fungemia overwhelms the person's immune system, the fungus may spread to the CNS. The

fungal invasion may cause meningitis, encephalitis, brain abscess, granuloma, or arterial thrombus (Mazzoni, et al., 2006).

Clinical Manifestations

The common symptoms of fungal encephalitis include fever, malaise, headache, meningeal signs, and change in LOC or cranial nerve dysfunction. Symptoms of increased ICP related to hydrocephalus often occur. *C. neoformans* and *C. immitis* are associated with specific skin lesions. *H. capsulatum* is associated with seizures, and *A. fumigatus* may cause ischemic or hemorrhagic strokes.

Assessment and Diagnostic Findings

A history of immunosuppression associated with AIDS or use of immunosuppressive medications may indicate fungal disease of the brain. Occupational and travel history may point to a fungal cause of CNS infection. Infections caused by *H. capsulatum* and *C. immitis* will demonstrate fungal antibodies in serologic tests. The CSF usually demonstrates elevated white cell and protein levels; glucose levels are decreased. *C. neoformans* is easily identified in CSF fungal cultures. *Candida* may be cultured from the blood or CSF. To identify *B. dermatitidis*, cisternal or ventricular cultures of CSF may need to be obtained. *A. fumigatus* is difficult to isolate in CSF and is diagnosed by lung biopsy. Neuroimaging is used to identify CNS changes related to fungal infection. MRI is the study of choice; it demonstrates areas of hemorrhage, abscess, or enhanced meninges indicating inflammation.

Medical Management

Medical management is directed at the causative fungus and the neurologic consequences of the infection. Seizures are controlled by standard antiseizure medications. Increased ICP is controlled by repeated lumbar punctures or shunting of CSF.

Antifungal agents are administered for a specific period to cure the infection in patients with competent immune systems. Patients with compromised immune systems receive antifungal therapy until the infection is controlled, after which they receive a maintenance dose of the medication for an indefinite period. Although the dose and duration of treatment depend on the causative fungi, amphotericin B is the standard antifungal agent used in treatment. Dosing depends on the causative organism, and it is usually administered by IV. The most common adverse reactions are fever, nausea and vomiting, anemia, uremia, and hypokalemia (Mazzoni, et al., 2006). Renal insufficiency is a serious reaction to amphotericin B that can occur. Fluconazole (Diflucan) or flucytosine (Ancobon) may be administered orally in conjunction with amphotericin B as maintenance therapy. Potential side effects of fluconazole include nausea, vomiting, and a transient increase in liver enzymes. The most common adverse reaction to flucytosine is bone marrow suppression. Therefore, patients receiving flucytosine should have leukocyte and platelet counts monitored regularly.

Nursing Management

The ICP will increase if hydrocephalus develops and the inflammatory response progresses. Nursing assessment aimed at early identification of increased ICP is necessary to ensure

early control and management. (See Chapter 61 for management of the patient with increased ICP.) Administering nonopioid analgesic agents, limiting environmental stimuli, and positioning may optimize patient comfort. Administering diphenhydramine (Benadryl) and acetaminophen (Tylenol) approximately 30 minutes before giving amphotericin B may prevent flulike side effects. If renal insufficiency develops, the dose may need to be reduced. Increasing levels of serum creatinine and blood urea nitrogen (BUN) may alert the nurse to the development of renal insufficiency and the need to address the patient's renal status.

Providing support assists the patient and family to cope with the illness. Workup of the patient for immunodeficiency diseases such as AIDS may put additional stress on the family. The nurse may need to mobilize community support systems for the patient and family, because the recovery may be long.

Creutzfeldt-Jakob and Variant Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) and variant Creutzfeldt-Jakob disease (vCJD) belong to a group of degenerative, infectious neurologic disorders called transmissible spongiform encephalopathies (TSE). CJD is very rare and has no identifiable cause. vCJD is the human variation of bovine spongiform encephalopathy (BSE); it results from the ingestion by humans of prions in infected beef. TSEs are caused by **prions**, proteinaceous particles that are smaller than a virus and are resistant to standard methods of sterilization. Although CJD and vCJD have distinct clinical features, one characteristic they share is a lack of CNS inflammation. CJD may lie dormant for decades before causing neurologic degeneration. The incubation period of vCJD seems to be shorter (less than 10 years). It is not known whether an increased number of cases will appear in the future. In both diseases, the symptoms are progressive, there is no definitive treatment, and the outcome is fatal.

About 150 cases of vCJD have been reported, almost all in the United Kingdom (Mazzoni, et al., 2006). The risk of vCJD in the United States is thought to be low, because cattle are fed primarily with soy-derived feed as opposed to feed containing animal parts.

Pathophysiology

The prion is a unique pathogen because it lacks nucleic acid, which enables the organism to withstand conventional means of sterilization. How the prion replicates in the absence of nucleic acid is unknown (Glatzel, Stoek, Seeger, et al., 2005). In both CJD and vCJD, the prion crosses the blood-brain barrier and is deposited in brain tissue and causes degeneration of brain tissue. Cell death occurs, and spongy vacuoles are produced in the brain (**spongiform** changes). The spongiform vacuoles are surrounded by amyloid plaque.

Ninety percent of the cases of CJD appear sporadically; the incidence is 1 case per 1 million people. Although it is not transmittable by typical human contact, 5% of cases of sporadic CJD result from contaminated neurosurgical instruments, cadaver-derived growth factor, or corneal

transplants. Ten percent of cases appear to be familial (Ward, Everington, Cousens, et al., 2007).

In 1996 the first case of vCJD was described. The mode of transmission was linked to the ingestion of beef contaminated with neurologic tissue. In 1998, additional concerns were raised about the safety of the blood supply in the United Kingdom. The prion exists in lymphoid tissue and blood in both vCJD and CJD. Both prion diseases are believed to be blood-borne. No method is available to screen blood for infectivity. The American Red Cross will not accept blood from anyone who has traveled to Europe in the past 6 months.

Clinical Manifestations

CJD and vCJD have several clinically distinct features. Psychiatric symptoms occur early in vCJD, whereas they are a late symptom in CJD. The mean age at onset of vCJD is 27 years, whereas the mean age for CJD onset is 50 years. The presenting symptoms of vCJD include affective symptoms (ie, behavioral changes), sensory disturbance, and limb pain. Muscle spasms and rigidity, dysarthria, incoordination, cognitive impairment, and sleep disturbances follow. Patients with sporadic CJD present with mental deterioration, ataxia, and visual disturbance. Memory loss, involuntary movement, paralysis, and mutism occur as the disease progresses. After clinical presentation, people with vCJD survive an average of 22 months; those with CJD survive for about 6 months (Mazzoni, et al., 2006).

Assessment and Diagnostic Findings

Historically, brain biopsy was used to diagnose CJD. The three diagnostic tests currently used in suspicious clinical presentations to support the diagnosis of CJD are immunologic assessment, electroencephalography, and MRI scanning. Immunologic assessment of CSF detects a protein kinase inhibitor called 14-3-3. The presence of this inhibitor indicates neuronal cell death, which is not specific to CJD but does support the diagnosis. The EEG reveals a characteristic pattern over the duration of the disease. After initial slowing, the EEG shows periodic activity. Later in the course of the disease, the EEG shows burst-suppressions characterized by periodic spikes alternating with slow periods. The MRI scan demonstrates symmetric or unilateral hyperintense signals arising from the basal ganglia.

Patients with vCJD do not demonstrate EEG or CSF changes, and the MRI scan shows bilateral hyperintensity of the posterior thalamus. The prion associated with vCJD has been shown to accumulate in the tonsils and other lymphoreticular tissues; therefore, tonsillar biopsy may be used in the diagnosis of vCJD.

Medical Management

After the onset of specific neurologic symptoms, progression of disease occurs quickly. There is no effective treatment for CJD or vCJD. The care of the patient is supportive and palliative. Goals of care include prevention of injury related to immobility and dementia, promotion of patient comfort, and provision of support and education for the family.

Nursing Management

The nursing care of patients is primarily supportive and palliative. Psychological and emotional support of the patient and family throughout the course of the illness is needed.

Care extends to providing for a dignified death and supporting the family through the processes of grief and loss. Hospice services are appropriate either at home or at an inpatient facility. See Chapter 17 for an in-depth discussion of end-of-life issues.

Prevention of disease transmission is an important part of nursing care. Although patient isolation is not necessary, use of standard precautions is important. Institutional protocols are followed for blood and body fluid exposure and decontamination of equipment. In the operating room, it is recommended that disposable instruments be used and then incinerated, because conventional methods of sterilization do not destroy the prion. The World Health Organization has guidelines that outline the stringent sterilization methods that must be used to destroy prions on surfaces.

AUTOIMMUNE PROCESSES

Autoimmune nervous system disorders include multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome.

Multiple Sclerosis

Multiple sclerosis (MS) is an immune-mediated, progressive demyelinating disease of the CNS. Demyelination refers to the destruction of myelin, the fatty and protein material that surrounds certain nerve fibers in the brain and spinal cord; it results in impaired transmission of nerve impulses (Fig. 64-2). MS may occur at any age but typically manifests in young adults between the ages of 20 and 40 years; it affects women more frequently than men (Porth & Matfin, 2009).

The cause of MS is an area of ongoing research (Costello & Sipe, 2008). Autoimmune activity results in demyelination, but the sensitized antigen has not been identified. Multiple factors play a role in the initiation of the immune process. Geographic prevalence is highest in Europe, New Zealand, southern Australia, the northern United States, and southern Canada (Olek, 2005). Researchers believe that some environmental exposure at a young age may play a role in the development of MS later in life.

Genetic predisposition is indicated by the presence of a specific cluster (haplotype) of human leukocyte antigens (HLAs) on the cell wall. Its presence may increase susceptibility to factors, such as viruses, that trigger the autoimmune response activated in MS. A specific virus capable of initiating the autoimmune response has not been identified. It is believed that deoxyribonucleic acid (DNA) on the virus mimics the amino acid sequence of myelin, resulting in an immune system cross-reaction in the presence of a defective immune system.

Pathophysiology

Sensitized T and B lymphocytes cross the blood-brain barrier; their function is to check the CNS for antigens and then leave. In MS, sensitized T cells remain in the CNS and promote the infiltration of other agents that damage the immune system. The immune system attack leads to inflammation that destroys myelin (which normally insulates the

Figure 64-2 The process of demyelination. **A** and **B** depict a normal nerve cell and axon with myelin. **C** and **D** show the slow disintegration of myelin, resulting in a disruption in axon function.

axon and speeds the conduction of impulses along the axon) and the oligodendroglial cells that produce myelin in the CNS.

Demyelination interrupts the flow of nerve impulses and results in a variety of manifestations, depending on the nerves affected. Plaques appear on demyelinated axons, further interrupting the transmission of impulses. Demyelinated axons are scattered irregularly throughout the CNS (Fig. 64-3). The areas most frequently affected are the optic nerves, chiasm, and tracts; the cerebrum; the brain stem and cerebellum; and the spinal cord. The axons themselves begin to degenerate, resulting in permanent and irreversible damage (Costello & Sipe, 2008; Porth & Matfin, 2009).

Clinical Manifestations

The course of MS may assume many different patterns (Fig. 64-4) (Lublin & Reingold, 1996). In some patients, the disease follows a benign course, and symptoms are so mild that the patient does not seek health care or treatment. Between 80% and 85% of patients with MS have a relapsing-remitting (RR) course. With each relapse, recovery is usually complete; however, residual deficits may occur and accumulate over time, contributing to functional decline. Fifty percent of those with the RR course of MS progress to a secondary progressive course, in which disease progression occurs with or without relapses. Ten percent of patients have a primary progressive course, in which disabling symptoms steadily increase, with rare plateaus and temporary improvement. Primary progressive MS may result in quadriplegia, cognitive dysfunction,

Figure 64-3 Multiple sclerosis. **A**, A computed tomography scan of brain demonstrates an area of demyelination in the periventricular white matter of the right frontal lobe. The plaque is perpendicular to the lateral ventricle, a typical finding in multiple sclerosis. **B**, A magnetic resonance image of the spinal cord in the same patient highlights another typical finding: a flame-shaped area of demyelination within the midcervical region of the spinal cord. Courtesy of the Danbury Hospital Department of Radiology.

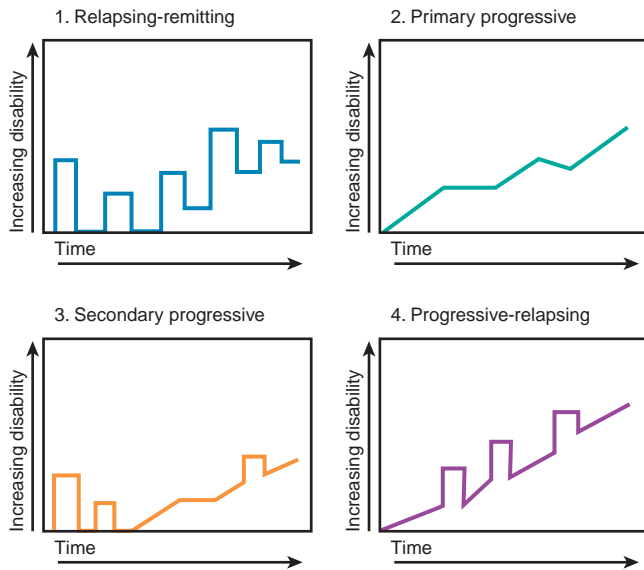

Figure 64-4 Types and courses of multiple sclerosis (MS). **1**, Relapsing-remitting (RR) MS is characterized by clearly acute attacks with full recovery or with sequelae and residual deficit upon recovery. Periods between disease relapses are characterized by lack of disease progression. **2**, Primary progressive (PP) MS is characterized by disease showing progression of disability from onset, without plateaus and temporary minor improvements. **3**, Secondary progressive (SP) MS begins with an initial RR course, followed by progression of variable rate, which may also include occasional relapses and minor remissions. **4**, Progressive-relapsing (PR) MS shows progression from onset but with clear acute relapses with or without recovery. From Lublin, F. D. & Reingold, S. C. (1996). Defining the clinical course of multiple sclerosis: Results of an international survey. *Neurology*, 46(64), 907–911. Used with permission from Lippincott Williams & Wilkins.

visual loss, and brain stem syndromes. The least common presentation (about 5% of cases) is the progressive relapsing course. It is characterized by relapses with continuous disabling progression between exacerbations (Mazzoni, et al., 2006).

The signs and symptoms of MS are varied and multiple, reflecting the location of the lesion (plaque) or combination of lesions. The primary symptoms most commonly reported are fatigue, depression, weakness, numbness, difficulty in coordination, loss of balance, and pain (Johnson, 2008; Newland, 2008). Visual disturbances due to lesions in the optic nerves or their connections may include blurring of vision, **diplopia** (double vision), patchy blindness (scotoma), and total blindness.

Fatigue affects most people with MS and is often the most disabling symptom. Heat, depression, anemia, deconditioning, and medication may contribute to fatigue. Avoiding hot temperatures, effective treatment of depression and anemia, and occupational and physical therapies may help control fatigue. Additional strategies include a balance of rest and activities, good nutrition, and a healthy lifestyle including avoidance of alcohol and cigarette smoking (Iggulden, 2006; Johnson, 2008).

Pain is another common symptom of MS that can contribute to social isolation. Lesions on the sensory pathways cause pain. Additional sensory manifestations include

paresthesias, dysesthesias, and proprioception loss (Stern, 2005). Many people with MS need daily analgesic medications. In some cases, pain is managed with opioids, anti-seizure medications, or antidepressants. Rarely, surgery may be needed to interrupt pain pathways.

Among perimenopausal women, those with MS are more likely to have pain related to osteoporosis. In addition to estrogen loss, immobility and corticosteroid therapy play a role in the development of osteoporosis among women with MS. Bone mineral density testing is recommended for this high-risk group (Smeltzer, Zimmerman & Capriotti, 2005). Diagnosis and treatment of osteoporosis are discussed in Chapter 68.

Spasticity (muscle hypertonicity) of the extremities and loss of the abdominal reflexes result from involvement of the main motor pathways (pyramidal tracts) of the spinal cord. Cognitive and psychosocial problems may reflect frontal or parietal lobe involvement. Some degree of cognitive change (eg, memory loss, decreased concentration) occurs in about half of patients, but severe cognitive changes with dementia (progressive organic mental disorder) are rare.

Involvement of the cerebellum or basal ganglia can produce **ataxia** (impaired coordination of movements) and tremor. Loss of the control connections between the cortex and the basal ganglia may occur and cause emotional lability and euphoria. Bladder, bowel, and sexual dysfunctions are common.

Secondary complications of MS include urinary tract infections, constipation, pressure ulcers, contracture deformities, dependent pedal edema, pneumonia, reactive depression, and osteoporosis. Emotional, social, marital, economic, and vocational problems may also occur.

Exacerbations and remissions are characteristic of MS. During exacerbations, new symptoms appear and existing ones worsen; during remissions, symptoms decrease or disappear. Relapses may be associated with emotional and physical stress.

Gerontologic Considerations

The life expectancy for patients with MS is not dramatically different from that of patients without MS; those diagnosed with secondary progressive disease live an average of 35 years after onset (Mazzoni, et al., 2006). Patients with MS who are elderly have specific physical and psychosocial challenges. They may have chronic health problems, for which they may be taking additional medications that could interact with medications prescribed for MS. The absorption, distribution, metabolism, and excretion of medications are altered in the elderly as a result of age-related changes in renal and liver functions. Therefore, elderly patients must be monitored closely for adverse and toxic effects of MS medications and for osteoporosis (particularly with frequent corticosteroid use that may be needed to treat exacerbations). The cost of medications may lead to poor adherence to the prescribed regimen in elderly patients on fixed incomes.

Elderly patients with MS are particularly concerned about increasing disability, family burden, marital concern, and the possible future need for nursing home care. Immobility

resulting in fewer social opportunities contributes to loneliness and depression. Along with functional loss, spasticity, pain and bladder dysfunction, impaired sleep, and an increased need for assistance with self-care contribute to the physical challenges experienced by the elderly patient with MS (Stern, 2005).

Assessment and Diagnostic Findings

The diagnosis of MS is based on the presence of multiple plaques in the CNS observed with MRI (Mazzoni, et al., 2006). Electrophoresis of CSF identifies the presence of oligoclonal banding (several bands of immunoglobulin G bonded together, indicating an immune system abnormality). Evoked potential studies can help define the extent of the disease process and monitor changes. Underlying bladder dysfunction is diagnosed by urodynamic studies. Neuropsychological testing may be indicated to assess cognitive impairment. A sexual history helps identify changes in sexual function.

Medical Management

No cure exists for MS. An individual treatment program is indicated to relieve the patient's symptoms and provide continuing support, particularly for patients with cognitive changes, who may need more structure and support. The goals of treatment are to delay the progression of the disease, manage chronic symptoms, and treat acute exacerbations. Many patients with MS have a stable disease course and require only intermittent treatment, whereas others experience steady progression of their disease. Symptoms requiring intervention include spasticity, fatigue, bladder dysfunction, and ataxia. Management strategies target the various motor and sensory symptoms and effects of immobility that can occur.

Pharmacologic Therapy

Medications prescribed for MS include those for disease modification and those for symptom management. The disease-modifying therapies available to treat MS include immunomodulating therapies and immunosuppressive agents (Ross, Hackbarth, Rohl, et al., 2008).

Disease-Modifying Therapies

The disease-modifying medications reduce the frequency of relapse, the duration of relapse, and the number and size of plaques observed on MRI. All of the medications require injection.

Interferon beta-1a (Rebif) and interferon beta-1b (Betaseron) are administered subcutaneously. Another preparation of interferon beta-1a, Avonex, is administered intramuscularly once a week. Side effects of all the interferon-beta medications include flulike symptoms that can be managed with acetaminophen and ibuprofen and resolve after a few months. Additional side effects include potential liver damage, fetal abnormalities, and depression. For optimal control of disability, disease-modifying medications should be started early in the course of the disease (Ross, et al., 2008).

Glatiramer acetate (Copaxone) reduces the rate of relapse in the RR course of MS. It decreases the number of plaques noted on MRI and increases the time between relapses. Copaxone is administered subcutaneously daily. It

acts by increasing the antigen-specific suppressor T cells. Side effects are minimal and manageable (Miller & Jezewski, 2006). Copaxone is an option for those with an RR course; however, it may take 6 months for evidence of an immune response to appear.

IV methylprednisolone, the key agent in treating acute relapse in the RR course, shortens the duration of relapse. It exerts anti-inflammatory effects by acting on T cells and cytokines. One gram is administered IV daily for 3 days, followed by an oral taper of prednisone. Side effects include mood swings, weight gain, and electrolyte imbalances (Mazzoni, et al., 2006).

The medication mitoxantrone (Novantrone) is administered via IV infusion every 3 months. Novantrone can reduce the frequency of clinical relapses in patients with secondary-progressive or worsening relapsing-remitting MS. Patients must be very closely monitored for side effects, especially cardiac toxicity.

Symptom Management

Medications are also prescribed for management of specific symptoms. Baclofen (Lioresal), a gamma-aminobutyric acid (GABA) agonist, is the medication of choice for treating spasticity. It can be administered orally or by intrathecal injection for severe spasticity (Ridley & Rawlings, 2006). Benzodiazepines (Valium), tizanidine (Zanaflex), and dantrolene (Dantrium) may also be used to treat spasticity. Patients with disabling spasms and contractures may require nerve blocks or surgical intervention. Fatigue that interferes with activities of daily living (ADLs) may be treated with amantadine (Symmetrel), pemoline (Cylert), or fluoxetine (Prozac). Ataxia is a chronic problem most resistant to treatment. Medications used to treat ataxia include beta-adrenergic blockers (Inderal), antiseizure agents (Neurontin), and benzodiazepines (Klonopin).

Bladder and bowel problems are often among the most difficult ones for patients, and a variety of medications (anticholinergic agents, alpha-adrenergic blockers, antispasmodic agents) may be prescribed. Nonpharmacologic strategies also assist in establishing effective bowel and bladder elimination (see later discussion).

Urinary tract infection is often superimposed on the underlying neurologic dysfunction. Ascorbic acid (vitamin C) may be prescribed to acidify the urine, making bacterial growth less likely. Antibiotics are prescribed when appropriate.

NURSING PROCESS

THE PATIENT WITH MULTIPLE SCLEROSIS

Assessments

Nursing assessment addresses neurologic deficits, secondary complications, and the impact of the disease on the patient and family. The patient's mobility and balance are observed to determine whether there is risk of falling. Assessment of function is carried out both when the patient is well rested and when fatigued. The patient is assessed for weakness, spasticity, visual impairment, incontinence, and

disorders of swallowing and speech. Additional areas of assessment include how MS has affected the patient's lifestyle, how the patient is coping, and what the patient would like to improve.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Impaired bed and physical mobility related to weakness, muscle paresis, spasticity
- Risk for injury related to sensory and visual impairment
- Impaired urinary and bowel elimination (urgency, frequency, incontinence, constipation) related to nervous system dysfunction
- Impaired verbal communication and risk for aspiration related to cranial nerve involvement
- Disturbed thought processes (loss of memory, dementia, euphoria) related to cerebral dysfunction
- Ineffective individual coping related to uncertainty of course of MS
- Impaired home maintenance management related to physical, psychological, and social limits imposed by MS
- Potential for sexual dysfunction related to lesions or psychological reaction

Planning and Goals

The major goals for the patient may include promotion of physical mobility, avoidance of injury, achievement of bladder and bowel continence, promotion of speech and swallowing mechanisms, improvement of cognitive function, development of coping strengths, improved home maintenance management, and adaptation to sexual dysfunction.

Nursing Interventions

An individualized program of physical therapy, rehabilitation, and education is combined with emotional support. An educational plan of care is developed to enable the person with MS to deal with the physiologic, social, and psychological problems that accompany chronic disease. Research shows that depression, pain, fatigue, and walking difficulty all decrease physical activity (Motl, Snook & Schapiro, 2007). Assisting patients with management of these symptoms may help increase the level of physical activity and overall sense of well-being. (Chart 64-3).

Promoting Physical Mobility

Relaxation and coordination exercises promote muscle efficiency. Progressive resistive exercises are used to strengthen weak muscles, because diminishing muscle strength is often significant in MS.

EXERCISES. Walking improves the gait, particularly the problem of loss of position sense of the legs and feet. If certain muscle groups are irreversibly affected, other muscles can be trained to compensate. Instruction in the use of assistive devices may be needed to ensure their safe and correct use.

MINIMIZING SPASTICITY AND CONTRACTURES. Muscle spasticity is common and, in its later stages, is characterized by severe adductor spasm of the hips with flexor spasm of the hips and knees. Without relief, fibrous contractures of these joints occur. Warm packs may be beneficial, but hot baths should be avoided because of risk of burn injury secondary to sensory loss and increasing symptoms that may occur with elevation of the body temperature.

CHART
64-3

NURSING RESEARCH PROFILE

Physical Activity in People With Multiple Sclerosis

Motl, R. W., Snook, E. M. & Schapiro, R. T. (2007). Symptoms and physical activity behavior in individuals with multiple sclerosis. *Research in Nursing & Health*, 31(5), 466–475.

Purpose

Physical activity is a unique challenge for people with multiple sclerosis (MS). This study examined the relationships among overall and specific symptoms, such as difficulty walking and other physical activity issues in people with MS.

Design

In this cross-sectional descriptive study, 133 people (104 women and 78 men) with MS completed questionnaires measuring overall and specific symptoms (ie, depression, pain, and fatigue), difficulty walking, and physical activity. The purpose was to examine the relationships between overall and specific symptoms, difficulty walking, and physical activity. Participants in the study were recruited from local MS support groups over a 6-month time period.

Findings

The descriptive findings of the study showed that those with MS who have more intense overall symptoms had more difficulty walking and lower levels of physical activity. The path analysis suggested that higher levels of physical symptoms were directly and indirectly related to lower levels of physical activity. Another important finding was that the indirect pathway involved difficulty walking.

Nursing Implications

People with MS who have intense overall symptoms have a reduction in physical activity in comparison to those with MS and less intense overall symptoms. This study found that the reduction in physical activity can be partly explained by walking difficulty. The authors suggest that nursing interventions to promote physical activity in people with MS might need to include adaptive activities that do not require a lot of walking.

Daily exercises for muscle stretching are prescribed to minimize joint contractures. Special attention is given to the hamstrings, gastrocnemius muscles, hip adductors, biceps, and wrist and finger flexors. Muscle spasticity is common and interferes with normal function. A stretch–hold–relax routine is helpful for relaxing and treating muscle spasticity. Swimming and stationary bicycling are useful, and progressive weight bearing can relieve spasticity in the legs. The patient should not be hurried in any of these activities, because this often increases spasticity.

ACTIVITY AND REST. The patient is encouraged to work and exercise to a point just short of fatigue. Very strenuous physical exercise is not advisable, because it raises the body temperature and may aggravate symptoms. The patient is advised to take frequent short rest periods, preferably lying down. Extreme fatigue may contribute to the exacerbation of symptoms.

MINIMIZING EFFECTS OF IMMOBILITY. Because of the decrease in physical activity that often occurs with MS, complications associated with immobility, including pressure ulcers, expiratory muscle weakness, and accumulation of bronchial secretions, need to be considered and steps taken to prevent them. Measures to prevent such complications include assessing and maintaining skin integrity and having the patient perform coughing and deep-breathing exercises.

Preventing Injury

If motor dysfunction causes problems of incoordination and clumsiness, or if ataxia is apparent, the patient is at risk for falling. To overcome this disability, the patient is taught to walk with feet apart to widen the base of support and to increase walking stability. If loss of position sense occurs, the patient is taught to watch the feet while walking. Gait training may require assistive devices (walker, cane, braces, crutches, parallel bars) and instruction about their use by a physical therapist. If the gait remains inefficient, a wheelchair or motorized scooter may be the solution. The occupational therapist is a valuable resource person in suggesting and securing aids to promote independence. If incoordination is a problem and tremor of the upper extremities occurs when voluntary movement is attempted (intention tremor), weighted bracelets or wrist cuffs are helpful. The patient is trained in transfer and activities of daily living (ADLs).

Because sensory loss may occur in addition to motor loss, pressure ulcers are a continuing threat to skin integrity. The need to use a wheelchair continuously increases the risk. See Chapter 11 for a discussion of the prevention and treatment of pressure ulcers.

Enhancing Bladder and Bowel Control

Generally, bladder symptoms fall into the following categories: (1) inability to store urine (hyperreflexic, uninhibited); (2) inability to empty the bladder (hyporeflexic, hypotonic); and (3) a mixture of both types. The patient with urinary frequency, urgency, or incontinence requires special support. The sensation of the need to void must be heeded immediately, so the bedpan or urinal should be readily available. A voiding time schedule is set up (every 1.5 to 2 hours initially, with gradual lengthening of the interval).

The patient is instructed to drink a measured amount of fluid every 2 hours and then attempt to void 30 minutes after drinking. Use of a timer or wristwatch with an alarm may be helpful for the patient who does not have enough sensation to signal the need to empty the bladder. The nurse encourages the patient to take the prescribed medications to treat bladder spasticity, because this allows greater independence. Intermittent self-catheterization (see Chapter 11) has been successful in maintaining bladder control in patients with MS. If a female patient has permanent urinary incontinence, urinary diversion procedures may be considered. The male patient may wear a condom appliance for urine collection.

Bowel problems include constipation, fecal impaction, and incontinence. Adequate fluids, dietary fiber, and a bowel-training program are frequently effective in solving these problems. See Chapter 11 for a discussion of promoting bowel continence.

Enhancing Communication and Managing Swallowing Difficulties

If the cranial nerves that control the mechanisms of speech and swallowing are affected, dysarthrias (defects of articulation) marked by slurring, low volume of speech, and difficulties in phonation may occur. **Dysphagia** (difficulty swallowing) may also occur. A speech therapist evaluates speech and swallowing and instructs the patient, family, and health team members about strategies to compensate for speech and swallowing problems. The nurse reinforces this instruction and encourages the patient and family to adhere to the plan. Impaired swallowing increases the patient's risk of aspiration; therefore, strategies are needed to reduce that risk. Such strategies include having suction apparatus available, careful feeding, and proper positioning for eating.

Improving Sensory and Cognitive Function

Measures may be taken if visual defects or changes in cognitive status occur.

VISION. The cranial nerves affecting vision may be affected by MS. An eye patch or a covered eyeglass lens may be used to block the visual impulses of one eye if the patient has diplopia (double vision). Prism glasses may be helpful for patients who are confined to bed and have difficulty reading in the supine position. People who are unable to read regular-print materials are eligible for the free "talking book" services of the Library of Congress or may obtain large-print or audio books from local libraries.

COGNITION AND EMOTIONAL RESPONSES. Cognitive impairment and emotional lability occur early in MS in some patients and may impose numerous stresses on the patient and family. Some patients with MS are forgetful and easily distracted and may exhibit emotional lability.

Patients adapt to illness in a variety of ways, including denial, depression, withdrawal, and hostility. Emotional support assists patients and their families to adapt to the changes and uncertainties associated with MS and to cope with the disruption in their lives. The family should be made aware of the nature and degree of cognitive impairment. Patients with MS have identified that the support of family and friends is a primary need (Koopman, Benbow &

Vandervoort, 2006). The patient is assisted to set meaningful and realistic goals, to remain as active as possible, and to maintain interests and activities. Hobbies may help the patient's morale and provide satisfying interests if the disease progresses to the stage in which formerly enjoyed activities can no longer be pursued. The environment is kept structured, and lists and other memory aids are used to help the patient with cognitive changes maintain a daily routine. The occupational therapist can be helpful in formulating a structured daily routine.

STRENGTHENING COPING MECHANISMS. The diagnosis of MS is always distressing to the patient and family. They need to know that no two patients with MS have identical symptoms or courses of illness. Although some patients do experience significant disability early, others have a near-normal lifespan with minimal disability. Some families, however, face overwhelming frustrations and problems. MS affects people who are often in a productive stage of life and concerned about career and family responsibilities. Family conflict, disintegration, separation, and divorce are not uncommon. Often, very young family members assume the responsibility of caring for a parent with MS. Nursing interventions in this area include alleviating stress and making appropriate referrals for counseling and support to minimize the adverse effects of dealing with chronic illness.

The nurse, mindful of these complex problems, initiates home care and coordinates a network of services, including social services, speech therapy, physical therapy, and home-maker services. To strengthen the patient's coping skills, as much information as possible is provided. Patients need an updated list of available assistive devices, services, and resources.

Coping through problem solving involves helping the patient define the problem and develop alternatives for its management. Careful planning and maintaining flexibility and a hopeful attitude are useful for psychological and physical adaptation.

Improving Home Management

MS can affect every facet of daily living. Certain abilities are often impossible to regain after they are lost. Physical function may vary from day to day. Modifications that allow independence in home management should be implemented (eg, assistive eating devices, raised toilet seat, bathing aids, telephone modifications, long-handled comb, tongs, modified clothing). Exposure to heat increases fatigue and muscle weakness, so air conditioning is recommended in at least one room. Exposure to extreme cold may increase spasticity.

Promoting Sexual Functioning

Patients with MS and their partners face problems that interfere with sexual activity, both as a direct consequence of nerve damage and also from psychological reactions to the disease. Easy fatigability, conflicts arising from dependency and depression, emotional lability, and loss of self-esteem compound the problem. Erectile and ejaculatory disorders in men and orgasmic dysfunction and adductor spasms of the thigh muscles in women can make sexual intercourse difficult or impossible. Bladder and bowel incontinence and urinary tract infections add to the difficulties.

Collaboration between the patient, family, and health care provider is essential for supporting intimacy (Moore, 2007). A sexual counselor can help bring into focus the patient's or partner's sexual resources and suggest relevant information and supportive therapy. Sharing and communicating feelings, planning for sexual activity (to minimize the effects of fatigue), and exploring alternative methods of sexual expression may open up a wide range of sexual enjoyment and experiences.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. As the disease progresses, the patient and family need to learn new strategies to maintain optimal independence. Teaching of new self-care techniques may be initiated in the hospital or clinic setting and reinforced in the home. Self-care education may address the use of assistive devices, self-catheterization, and administration of medications that affect the course of the disease or treat complications. A teaching plan that addresses intramuscular or subcutaneous administration of medications is developed for the patient and his or her family (Cox & Stone, 2006). One research study showed that use of a local anesthetic cream reduced pain and fear associated with intramuscular medication administration in 18 patients with MS (Buhse, 2006). Exercises that enable the patient to continue some form of activity or that maintain or improve swallowing, speech, or respiratory function may be taught to the patient and family (Chart 64-4).

CONTINUING CARE. After discharge, the home care nurse often provides teaching and reinforcement of new interventions in the patient's home. Nurses in the home setting assess for changes in the patient's physical and emotional status, provide physical care to the patient if required, coordinate outpatient services and resources, and encourage health promotion, appropriate health screenings, and adaptation. If changes in the disease or its course are noted, the home care nurse encourages the patient to contact the primary care provider, because treatment of an acute exacerbation or new problem may be indicated. Continuing health care and follow-up are recommended.

The patient with MS is encouraged to contact the local chapter of the National Multiple Sclerosis Society for services, publications, and contact with others who have MS (see Resources). Local chapters also provide direct services to patients. Through group participation, the patient has an opportunity to meet others with similar problems, share experiences, and learn self-help methods in a social environment.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Improves physical mobility
 - a. Participates in gait-training and rehabilitation program
 - b. Establishes a balanced program of rest and exercise
 - c. Uses assistive devices correctly and safely
2. Is free of injury
 - a. Uses visual cues to compensate for decreased sense of touch or position
 - b. Asks for assistance when necessary

CHART
64-4  **HOME CARE CHECKLIST**
The Patient With Multiple Sclerosis (MS)

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State how to access the local chapter of the National MS Society and available resources.	✓	✓
• Discuss the clinical course of MS.	✓	✓
• Identify strategies to manage symptoms (pain, cognitive responses, dysphagia, tremors, visual disturbances).	✓	✓
• State how to prevent complications (pressure ulcers, pneumonia, depression).	✓	✓
• Identify coping strategies.	✓	✓
• Identify ways to minimize fatigue.	✓	✓
• Explain how to prevent injury.	✓	✓
• State ways to adapt to sexual dysfunction.	✓	✓
• Discuss ways to control bowel and bladder function.	✓	✓
• Name benefits of exercise and physical activity.	✓	✓
• Identify ways to minimize immobility and spasticity.	✓	✓
• Describe medication regimen and potential adverse effects.	✓	✓
• Demonstrate correct techniques of administering injectable medications, if prescribed.	✓	✓

3. Attains or maintains control of bladder and bowel patterns
 - a. Monitors self for urine retention and employs intermittent self-catheterization technique, if indicated
 - b. Identifies the signs and symptoms of urinary tract infection
 - c. Maintains adequate fluid and fiber intake
4. Participates in strategies to improve speech and swallowing
 - a. Practices exercises recommended by speech therapist
 - b. Maintains adequate nutritional intake without aspiration
5. Compensates for altered thought processes
 - a. Uses lists and other aids to compensate for memory losses
 - b. Discusses problems with trusted advisor or friend
 - c. Substitutes new activities for those that are no longer possible
6. Demonstrates effective coping strategies
 - a. Maintains sense of control
 - b. Modifies lifestyle to fit goals and limitations
 - c. Verbalizes desire to pursue goals and developmental tasks of adulthood
7. Adheres to plan for home maintenance management
 - a. Uses appropriate techniques to maintain independence
 - b. Engages in health promotion activities and health screenings as appropriate
8. Adapts to changes in sexual function
 - a. Is able to discuss problem with partner and appropriate health professional
 - b. Identifies alternative means of sexual expression

Myasthenia Gravis

Myasthenia gravis, an autoimmune disorder affecting the myoneural junction, is characterized by varying degrees of weakness of the voluntary muscles. Approximately 60,000 people have myasthenia gravis in the United States. Women are affected more frequently than men, and they tend to develop the disease at an earlier age (20 to 40 years of age, versus 60 to 70 years for men) (Mazzoni, et al., 2006).

Pathophysiology

Normally, a chemical impulse precipitates the release of acetylcholine from vesicles on the nerve terminal at the myoneural junction. The acetylcholine attaches to receptor sites on the motor endplate and stimulates muscle contraction. Continuous binding of acetylcholine to the receptor site is required for muscular contraction to be sustained.

In myasthenia gravis, antibodies directed at the acetylcholine receptor sites impair transmission of impulses across the myoneural junction. Therefore, fewer receptors are available for stimulation, resulting in voluntary muscle weakness that escalates with continued activity (Fig. 64-5). These antibodies are found in 80% to 90% of people with myasthenia gravis (Hickey, 2009). Eighty percent of people with myasthenia gravis have either thymic hyperplasia or a thymic tumor, and the thymus gland is believed to be the site of antibody production. In patients who are antibody negative, researchers believe that the offending antibody is directed at a portion of the receptor site rather than the whole complex.

Clinical Manifestations

The initial manifestation of myasthenia gravis in two thirds of patients involves the ocular muscles. Diplopia (double

Figure 64-5 Myasthenia gravis. **A**, Normal acetylcholine (ACh) receptor site. **B**, ACh receptor site in myasthenia gravis.

vision) and ptosis (drooping of the eyelids) are common (Allen, 2006). Many patients also experience weakness of the muscles of the face and throat (bulbar symptoms) and generalized weakness. Weakness of the facial muscles results in a bland facial expression. Laryngeal involvement produces **dysphonia** (voice impairment) and increases the risk of choking and aspiration. Generalized weakness affects all the extremities and the intercostal muscles, resulting in decreasing vital capacity and respiratory failure. Myasthenia gravis is purely a motor disorder with no effect on sensation or coordination.

Assessment and Diagnostic Findings

An acetylcholinesterase inhibitor test is used to diagnose myasthenia gravis. The acetylcholinesterase inhibitor stops the breakdown of acetylcholine, thereby increasing availability at the neuromuscular junction. Edrophonium chloride (Tensilon), a fast-acting acetylcholinesterase inhibitor, is administered IV to diagnose myasthenia gravis. Thirty seconds after injection, facial muscle weakness and ptosis should resolve for about 5 minutes (Hickey, 2009). Immediate improvement in muscle strength after administration of this agent represents a positive test and usually confirms the diagnosis. Atropine should be available to control the side effects of edrophonium, which include bradycardia, sweating, and cramping.

The presence of acetylcholine receptor antibodies is identified in the serum (Mazzoni, et al., 2006). Repetitive muscle stimulation demonstrates a decrease in successive action potentials. The thymus gland, a site of acetylcholine receptor antibody production, may be enlarged in myasthenia gravis, and may be identified by MRI scan. A single-fiber electromyography (EMG) detects a delay or failure of neuromuscular transmission and is about 99% sensitive in confirming the diagnosis of myasthenia gravis (Hickey, 2009; Karpoff & Labus, 2008).

Medical Management

Management of myasthenia gravis is directed at improving function and reducing and removing circulating antibodies. Therapeutic modalities include administration of anticholinesterase medications and immunosuppressive therapy, plasmapheresis, and thymectomy. There is no cure for

myasthenia gravis; treatments do not stop the production of the acetylcholine receptor antibodies.

Pharmacologic Therapy

Pyridostigmine bromide (Mestinon), an anticholinesterase medication, is the first line of therapy. It provides symptomatic relief by inhibiting the breakdown of acetylcholine and increasing the relative concentration of available acetylcholine at the neuromuscular junction. The dosage is gradually increased to a daily maximum and is administered in divided doses (usually four times a day). Adverse effects of anticholinesterase medications include fasciculations, abdominal pain, diarrhea, and increased oropharyngeal secretions (Allen, 2006). Pyridostigmine tends to have fewer side effects than other anticholinesterase medications (Chart 64-5).

If pyridostigmine bromide does not improve muscle strength and control fatigue, the next agents used are the immunomodulating drugs. The goal of immunosuppressive therapy is to reduce production of the antibody. Corticosteroids suppress the patient's immune response, decreasing the amount of antibody production, and this correlates with clinical improvement. An initial dose of prednisone is given daily; as symptoms improve, the medication is tapered and a maintenance dose may be given indefinitely (Mazzoni, et al., 2006). As the corticosteroid medications take effect the dosage of anticholinesterase medication can usually be lowered. Cytotoxic medications are used to treat myasthenia gravis if there is inadequate response to steroids. Azathioprine (Imuran) inhibits T lymphocytes and reduces acetylcholine receptor antibody levels. Therapeutic effects may not be evident for 3 to 12 months. Leukopenia and hepatotoxicity are serious adverse effects, so monthly evaluation of liver enzymes and white blood cell count is necessary.

Intravenous immune globulin (IVIG) is also used to treat exacerbations, and, in selected patients, it is used on a long-term adjunctive basis. IVIG treatment is easy to administer and involves the administration of pooled human gamma-globulin, and improvement occurs in a few days (Hickey, 2009).

A number of medications are contraindicated for patients with myasthenia gravis because they exacerbate the symptoms. The physician and the patient should weigh risks and benefits before any new medications are prescribed,

including antibiotics, cardiovascular medications, anti-seizure and psychotropic medications, morphine, quinine and related agents, beta-blockers, and nonprescription medications (Allen, 2006). Procaine (Novocain) should be avoided, and the patient's dentist is informed of the diagnosis of myasthenia gravis.

Plasmapheresis

Plasmapheresis (plasma exchange) is a technique used to treat exacerbations. The patient's plasma and plasma components are removed through a centrally placed large-bore double-lumen catheter. The blood cells and antibody-containing plasma are separated, after which the cells and a plasma substitute are reinfused. Plasma exchange produces a temporary reduction in the level of circulating antibodies. The typical course of plasmapheresis consists of daily or alternate-day treatment, and the number of treatments is determined by the patient's response. Plasma exchange improves symptoms in 75% of patients; however, improvement lasts only a few weeks after treatment is completed (Hickey, 2009).

Surgical Management

Thymectomy (surgical removal of the thymus gland) can produce antigen-specific immunosuppression and result in clinical improvement. The procedure results in either partial or complete remission. A course of preoperative plasmapheresis decreases the time needed for postoperative mechanical ventilation. The entire gland must be removed for optimal clinical outcomes; therefore, surgeons prefer the transsternal surgical approach. After surgery, the patient is monitored in an intensive care unit, with special attention to respiratory function. The patient is weaned from mechanical ventilation after thorough respiratory assessment. After the thymus gland is removed, it may take up to 3 years

for the patient to benefit from the procedure, because of the long life of circulating T cells (Allen, 2006).

Complications**Respiratory Failure**

A myasthenic crisis is an exacerbation of the disease process characterized by severe generalized muscle weakness and respiratory and bulbar weakness that may result in respiratory failure. Crisis may result from disease exacerbation or a specific precipitating event. The most common precipitator is respiratory infection; others include medication change, surgery, pregnancy, and medications that exacerbate myasthenia. A cholinergic crisis caused by overmedication with cholinesterase inhibitors is rare; atropine sulfate should be on hand to treat bradycardia or respiratory distress (Hickey, 2009).

Neuromuscular respiratory failure is the critical complication in myasthenic and cholinergic crises. Respiratory muscle and bulbar weakness combine to cause respiratory compromise. Weak respiratory muscles do not support inhalation. An inadequate cough and an impaired gag reflex, caused by bulbar weakness, result in poor airway clearance. A downward trend of two respiratory function tests, the negative inspiratory force and vital capacity, is the first clinical sign of respiratory compromise.

Endotracheal intubation and mechanical ventilation may be needed (see Chapter 25). Noninvasive positive-pressure ventilation uses an external device that provides respiratory support without endotracheal intubation. Cholinesterase inhibitors are stopped when respiratory failure occurs and gradually restarted after the patient demonstrates improvement with a course of plasmapheresis or IVIG. Nutritional support may be needed if the patient is intubated for a long period.

Nursing Management

Because myasthenia gravis is a chronic disease and most patients are seen on an outpatient basis, much of the nursing care focuses on patient and family teaching. Educational topics for outpatient self-care include medication management, energy conservation, strategies to help with ocular manifestations, and prevention and management of complications.

Medication management is a crucial component of ongoing care. Understanding the actions of the medications and taking them on schedule is emphasized, as are the consequences of delaying medication and the signs and symptoms of myasthenic and cholinergic crises. The patient can determine the best times for daily dosing by keeping a diary to determine fluctuation of symptoms and to learn when the medication is wearing off. The medication schedule can then be manipulated to maximize strength throughout the day.

NURSING ALERT

Maintenance of stable blood levels of anticholinesterase medications is imperative to stabilize muscle strength. Therefore, the anticholinesterase medications must be administered on time. Any delay in administration of medications may exacerbate muscle weakness and make it impossible for the patient to take medications orally.

The patient is also taught strategies to conserve energy. To do this, the nurse helps the patient identify the optimal times for rest throughout the day. If the patient lives in a two-story home, the nurse can suggest that frequently used items (eg, hygiene products, cleaning products, snacks) be kept on each floor to minimize travel between floors. The patient is encouraged to apply for a handicapped license plate to minimize walking from parking spaces, and to schedule activities to coincide with peak energy and strength levels.

To minimize the risk of aspiration, mealtimes should coincide with the peak effects of anticholinesterase medication. In addition, rest before meals is encouraged to reduce muscle fatigue. The patient is advised to sit upright during meals, with the neck slightly flexed to facilitate swallowing. Soft foods in gravy or sauces can be swallowed more easily; if choking occurs frequently, the nurse can suggest puréed food with a puddinglike consistency. Suction should be available at home, with the patient and family instructed in its use. Supplemental feedings may be necessary in some patients to ensure adequate nutrition (Randell, Byars, Williams, et al., 2008).

Impaired vision results from ptosis of one or both eyelids, decreased eye movement, or double vision. To prevent corneal damage when the eyelids do not close completely, the patient is instructed to tape the eyes closed for short intervals and to regularly instill artificial tears. Patients who wear eyeglasses can have “crutches” attached to help lift the eyelids. Patching of one eye can help with double vision.

The patient is reminded of the importance of maintaining health promotion practices and of following health care

screening recommendations. Factors that exacerbate symptoms and potentially cause crisis should be noted and avoided: emotional stress, infections (particularly respiratory infections), vigorous physical activity, some medications, and high environmental temperature. The Myasthenia Gravis Foundation of America provides support groups, services, and educational materials for patients, families, and health care providers (see Resources).

Myasthenic Crisis

Respiratory distress and varying degrees of dysphagia (difficulty swallowing), dysarthria (difficulty speaking), eyelid ptosis, diplopia, and prominent muscle weakness are symptoms of myasthenic crisis. The patient is placed in an intensive care unit for constant monitoring because of associated intense and sudden fluctuations in clinical condition.

Providing ventilatory assistance takes precedence in the immediate management of the patient with myasthenic crisis. Ongoing assessment for respiratory failure is essential. The nurse assesses the respiratory rate, depth, and breath sounds and monitors pulmonary function parameters (vital capacity and negative inspiratory force) to detect pulmonary problems before respiratory dysfunction progresses. Blood is drawn for arterial blood gas analysis. Endotracheal intubation and mechanical ventilation may be needed (see Chapter 25).

If the abdominal, intercostal, and pharyngeal muscles are severely weak, the patient cannot cough, take deep breaths, or clear secretions. Chest physical therapy, including postural drainage to mobilize secretions and suctioning to remove secretions, may have to be performed frequently. (Postural drainage should not be performed for 30 minutes after feeding.)

Assessment strategies and supportive measures include the following:

- Arterial blood gases, serum electrolytes, input and output, and daily weight are monitored.
- If the patient cannot swallow, nasogastric tube feedings may be prescribed.
- Sedatives and tranquilizers are avoided, because they aggravate hypoxia and hypercapnia and can cause respiratory and cardiac depression.

Guillain-Barré Syndrome

Guillain-Barré syndrome is an autoimmune attack on the peripheral nerve myelin. The result is acute, rapid segmental demyelination of peripheral nerves and some cranial nerves, producing ascending weakness with **dyskinesia** (inability to execute voluntary movements), hyporeflexia, and **paresthesias** (numbness). An antecedent event (most often a viral infection) precipitates clinical presentation (Palmieri, 2005). *Campylobacter jejuni*, cytomegalovirus, Epstein-Barr virus, *Mycoplasma pneumoniae*, *H. influenzae*, and HIV are the most common infectious agents that are associated with the development of Guillain-Barré syndrome.

The annual incidence of Guillain-Barré syndrome is 1 to 2 cases per 100,000, and it is more frequent in males between 16 and 25 years of age and between 45 and 60 years of age (Palmieri, 2005). Results of studies on recovery rates

differ, but most indicate that 60% to 75% of patients recover completely. Residual deficits of varying degree occur in 20% to 25% of patients. Residual deficits are most likely in patients with rapid disease progression, those who require mechanical ventilation, and those 60 years of age or older. Death occurs in 5% of cases, resulting from respiratory failure, autonomic dysfunction, sepsis, or pulmonary emboli (Mazzoni, et al., 2006).

Pathophysiology

Myelin is a complex substance that covers nerves, providing insulation and speeding the conduction of impulses from the cell body to the dendrites. The cell that produces myelin in the peripheral nervous system is the Schwann cell. In Guillain-Barré syndrome, the Schwann cell is spared, allowing for remyelination in the recovery phase of the disease.

Guillain-Barré syndrome is the result of a cell-mediated and humoral immune attack on peripheral nerve myelin proteins that causes inflammatory demyelination. The best-accepted theory of cause is molecular mimicry, in which an infectious organism contains an amino acid that mimics the peripheral nerve myelin protein. The immune system cannot distinguish between the two proteins and attacks and destroys peripheral nerve myelin. The exact location of the immune attack within the peripheral nervous system is the ganglioside GM1b. With the autoimmune attack, there is an influx of macrophages and other immune-mediated agents that attack myelin and cause inflammation and destruction, interruption of nerve conduction, and axonal loss (Ho, Thakur, Gorson, et al., 2008; Palmieri, 2005).

Clinical Manifestations

Guillain-Barré syndrome typically begins with muscle weakness and diminished reflexes of the lower extremities. Hyporeflexia and weakness may progress to tetraplegia. Demyelination of the nerves that innervate the diaphragm and intercostal muscles results in neuromuscular respiratory failure. Sensory symptoms include paresthesias of the hands and feet and pain related to the demyelination of sensory fibers.

The antecedent event usually occurs 2 weeks before symptoms begin. Weakness usually begins in the legs and progresses upward. Maximum weakness, the plateau, varies in length but usually includes neuromuscular respiratory failure and bulbar weakness. The duration of the symptoms is variable; complete functional recovery may take up to 2 years. Any residual symptoms are permanent and reflect axonal damage from demyelination.

Cranial nerve demyelination can result in a variety of clinical manifestations. Optic nerve demyelination may result in blindness. Bulbar muscle weakness related to demyelination of the glossopharyngeal and vagus nerves results in the inability to swallow or clear secretions. Vagus nerve demyelination results in autonomic dysfunction, manifested by instability of the cardiovascular system. The presentation is variable and may include tachycardia, bradycardia, hypertension, or orthostatic hypotension. The symptoms of autonomic dysfunction occur and resolve rapidly. Guillain-Barré syndrome does not affect cognitive function or LOC.

Although the classic clinical features include areflexia and ascending weakness, variation in presentation occurs. There may be a sensory presentation, with progressive sensory symptoms; an atypical axonal destruction; or the Miller-Fisher variant, which includes paralysis of the ocular muscles, ataxia, and areflexia (Iggulden, 2006).

Assessment and Diagnostic Findings

The patient presents with symmetric weakness, diminished reflexes, and upward progression of motor weakness. A history of a viral illness in the previous few weeks suggests the diagnosis. Changes in vital capacity and negative inspiratory force are assessed to identify impending neuromuscular respiratory failure. Serum laboratory tests are not useful in the diagnosis. However, elevated protein levels are detected in CSF evaluation, without an increase in other cells. Evoked potential studies demonstrate a progressive loss of nerve conduction velocity.

Medical Management

Because of the possibility of rapid progression and neuromuscular respiratory failure, Guillain-Barré syndrome is a medical emergency, requiring management in an intensive care unit. After baseline values are identified, assessment of changes in muscle strength and respiratory function alert the clinician to the physical and respiratory needs of the patient. Respiratory therapy or mechanical ventilation may be necessary to support pulmonary function and adequate oxygenation. Some clinicians recommend elective intubation before the onset of extreme respiratory muscle fatigue. Emergent intubation may result in autonomic dysfunction (Mazzoni, et al., 2006). Mechanical ventilation may be required for an extended period. The patient is weaned from mechanical ventilation after the respiratory muscles can again support spontaneous respiration and maintain adequate tissue oxygenation.

Other interventions are aimed at preventing the complications of immobility. These may include the use of anticoagulant agents and anti-embolism stockings or sequential compression boots to prevent thrombosis and pulmonary emboli.

Plasmapheresis and IVIG are used to directly affect the peripheral nerve myelin antibody level (Mazzoni, et al., 2006). Both therapies decrease circulating antibody levels and reduce the amount of time the patient is immobilized and dependent on mechanical ventilation. Studies indicate that IVIG and plasmapheresis are equally effective in treating Guillain-Barré syndrome; however, IVIG is the therapy of choice because it is associated with fewer side effects. The cardiovascular risks posed by autonomic dysfunction require continuous electrocardiographic (ECG) monitoring. Tachycardia and hypertension are treated with short-acting medications such as alpha-adrenergic blocking agents. The use of short-acting agents is important, because autonomic dysfunction is very labile. Hypotension is managed by increasing the amount of IV fluid administered.

NURSING PROCESS

THE PATIENT WITH GUILLAIN-BARRÉ SYNDROME

Assessment

Ongoing assessment for disease progression is critical. The patient is monitored for life-threatening complications (respiratory failure, cardiac dysrhythmias, deep vein thrombosis [DVT]), so that appropriate interventions can be initiated. Because of the threat to the patient in this sudden, potentially life-threatening disease, the nurse must assess the patient's and family's ability to cope and their use of coping strategies.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective breathing pattern and impaired gas exchange related to rapidly progressive weakness and impending respiratory failure
- Impaired bed and physical mobility related to paralysis
- Imbalanced nutrition, less than body requirements, related to inability to swallow
- Impaired verbal communication related to cranial nerve dysfunction
- Fear and anxiety related to loss of control and paralysis

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include the following:

- Respiratory failure
- Autonomic dysfunction

Planning and Goals

The major goals for the patient may include improved respiratory function, increased mobility, improved nutritional status, effective communication, decreased fear and anxiety, and absence of complications.

Nursing Interventions

Maintaining Respiratory Function

Respiratory function can be maximized with incentive spirometry and chest physiotherapy. Monitoring for changes in vital capacity and negative inspiratory force is key to early intervention for neuromuscular respiratory failure. Mechanical ventilation is required if the vital capacity falls, making spontaneous breathing impossible and tissue oxygenation inadequate.

The potential need for mechanical ventilation should be discussed with the patient and family on admission to provide time for psychological preparation and decision making. Intubation and mechanical ventilation result in less anxiety if they are initiated on a nonemergency basis to a well-informed patient. The patient may require mechanical ventilation for a long period. Nursing management of the patient requiring mechanical ventilation is discussed in Chapter 25.

Bulbar weakness that impairs the ability to swallow and clear secretions is another factor in the development of res-

piratory failure in the patient with Guillain-Barré syndrome. Suctioning may be needed to maintain a clear airway.

The nurse assesses the blood pressure and heart rate frequently to identify autonomic dysfunction, so that interventions can be initiated quickly if needed. Medications are administered or a temporary pacemaker is placed for clinically significant bradycardia.

Enhancing Physical Mobility

Nursing interventions to enhance physical mobility and prevent the complications of immobility are key to the function and survival of patients. The paralyzed extremities are supported in functional positions, and passive range-of-motion exercises are performed at least twice daily. DVT and pulmonary embolism are threats to the paralyzed patient. Nursing interventions are aimed at preventing DVT. Range-of-motion exercises, position changes, anticoagulation, the use of anti-embolism stockings or sequential compression boots, and adequate hydration decrease the risk of DVT.

Padding may be placed over bony prominences, such as the elbows and heels, to reduce the risk of pressure ulcers (Iggulden, 2006). The need for consistent position changes every 2 hours cannot be overemphasized. The nurse evaluates laboratory test results that may indicate malnutrition or dehydration, both of which increase the risk of pressure ulcers. The nurse collaborates with the physician and dietitian to develop a plan to meet the patient's nutritional and hydration needs.

Providing Adequate Nutrition

Paralytic ileus may result from insufficient parasympathetic activity. In this event, the nurse administers IV fluids and parenteral nutrition as a supplement and monitors for the return of bowel sounds. If the patient cannot swallow because of **bulbar paralysis** (immobility of muscles), a gastrostomy tube may be placed to administer nutrients. The nurse carefully assesses the return of the gag reflex and bowel sounds before resuming oral nutrition.

Improving Communication

Because of paralysis, the patient cannot talk, laugh, or cry and therefore has no method for communicating needs or expressing emotion. Establishing some form of communication with picture cards or an eye blink system provides a means of communication. Collaboration with the speech therapist may be helpful in developing a communication mechanism that is most effective for a specific patient.

Decreasing Fear and Anxiety

The patient and family are faced with a sudden, potentially life-threatening disease, and anxiety and fear are constant themes for them. The impact of disease on the family depends on the patient's role within the family. Referral to a support group may provide information and support to the patient and family.

The family may feel helpless in caring for the patient. Mechanical ventilation and monitoring devices may frighten and intimidate them. Family members often want to participate in physical care; with instruction and support by the nurse, they should be allowed and encouraged to do so.

In addition to fear, the patient may experience isolation, loneliness, and lack of control. Nursing interventions that increase the patient's sense of control include providing

information about the condition, emphasizing a positive appraisal of coping resources, and teaching relaxation exercises and distraction techniques. The positive attitude and atmosphere of the multidisciplinary team are important to promote a sense of well-being.

Diversional activities are encouraged to decrease loneliness and isolation. Encouraging visitors, engaging visitors or volunteers to read to the patient, listening to music or books on tape, and watching television are ways to alleviate the patient’s sense of isolation.

Monitoring and Managing Potential Complications

Thorough assessment of respiratory function at regular and frequent intervals is essential, because respiratory insufficiency and subsequent failure due to weakness or paralysis of the intercostal muscles and diaphragm may develop quickly. Respiratory failure is the major cause of mortality. In addition to the respiratory rate and the quality of respirations, vital capacity is monitored frequently and at regular intervals, so that respiratory insufficiency can be anticipated. Decreasing vital capacity with associated muscle weakness indicates impending respiratory failure. Signs and symptoms include breathlessness while speaking, shallow and irregular breathing, use of accessory muscles, tachycardia, weak cough, and changes in respiratory pattern.

Other complications include cardiac dysrhythmias, which necessitate ECG monitoring; transient hypertension; orthostatic hypotension; DVT; pulmonary embolism; urinary retention; and other threats to any immobilized and paralyzed patient. These require monitoring and attention to prevent them and prompt treatment if indicated.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patients with Guillain-Barré syndrome and their families are usually frightened by the

sudden onset of life-threatening symptoms and their severity. Therefore, teaching the patient and family about the disorder and its generally favorable prognosis is important (Chart 64-6).

During the acute phase of the illness, the patient and family are instructed about strategies they can implement to minimize the effects of immobility and other complications. As function begins to return, family members and other home care providers are instructed about care of the patient and their role in the rehabilitation process. Preparation for discharge is an interdisciplinary effort requiring family or caregiver education by all team members, including the nurse, physician, occupational and physical therapists, speech therapist, and respiratory therapist.

CONTINUING CARE. Most patients with Guillain-Barré syndrome experience complete recovery. Patients who have experienced total or prolonged paralysis require intensive rehabilitation; the extent depends on the patient’s needs. Approaches include a comprehensive inpatient program if deficits are significant, an outpatient program if the patient can travel by car, or a home program of physical and occupational therapy. The recovery phase may be long and requires patience as well as involvement on the part of the patient and family.

During acute care, the focus is on immediate issues and deficits. The nurse needs to remind or instruct patients and family members of the need for continuing health promotion and screening practices after this initial phase of care.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Maintains effective respirations and airway clearance
 - a. Has normal breath sounds on auscultation
 - b. Demonstrates gradual improvement in respiratory function

 CHART 64-6 HOME CARE CHECKLIST The Patient With Guillain-Barré Syndrome		
At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe the disease process of Guillain-Barré syndrome.	✓	✓
• Manage respiratory needs: tracheostomy care, suctioning.		✓
• Demonstrate proper body mechanics regarding lifting and transfers.		✓
• Practice gait training and strength endurance.	✓	✓
• Perform range-of-motion exercises.	✓	✓
• Perform activities of daily living and manage self-care: <ul style="list-style-type: none"> • Nutrition • Bowel and bladder management • Skin care • Adaptive equipment for bathing, hygiene, grooming, dressing 	✓ ✓ ✓ ✓	✓ ✓ ✓ ✓
• Operate and explain function of medical equipment and mobility aids: walkers, wheelchairs, bedside commodes, tub transfer benches, adaptive devices.	✓	✓
• Use coping mechanisms and diversional activities appropriately.	✓	✓
• Implement safety measures in the home.	✓	✓
• Know how to contact and use community resources and the Guillain-Barré Syndrome Foundation International.	✓	✓

2. Shows increasing mobility
 - a. Regains use of extremities
 - b. Participates in rehabilitation program
 - c. Demonstrates no contractures and minimal muscle atrophy
3. Receives adequate nutrition and hydration
 - a. Consumes diet adequate to meet nutritional needs
 - b. Swallows without aspiration
4. Demonstrates recovery of speech
 - a. Communicates needs through alternative strategies
 - b. Practices exercises recommended by the speech therapist
5. Shows lessening fear and anxiety
6. Has absence of complications
 - a. Breathes spontaneously
 - b. Has vital capacity within normal range
 - c. Exhibits normal arterial blood gases and pulse oximetry

CRANIAL NERVE DISORDERS

Because the brain stem and cranial nerves involve vital motor, sensory, and autonomic functions of the body, these nerves may be affected by conditions arising primarily within these structures or in secondary extension from adjacent disease processes. The cranial nerves are examined separately and in sequence (see Chapter 60). Some cranial nerve deficits can be detected by observing the patient's face, eye movements, speech, and swallowing. EMG is used to investigate motor and sensory dysfunction. An MRI scan is used to obtain images of the cranial nerves and brain stem. An overview of disorders that may affect each of the cranial nerves, including clinical manifestations and nursing interventions, is presented in Table 64-1. The following discussion centers on the most common disorders of the cranial nerves: trigeminal neuralgia, a condition affecting the fifth cranial nerve, and Bell's palsy, caused by involvement of the seventh cranial nerve.

Trigeminal Neuralgia (Tic Douloureux)

Trigeminal neuralgia is a condition of the fifth cranial nerve that is characterized by paroxysms of pain in the area innervated by any of the three branches, but most commonly the second and third branches of the trigeminal nerve (Mazzoni, et al., 2006) (Fig. 64-6). The pain ends as abruptly as it starts and is described as a unilateral shooting and stabbing sensation. The unilateral nature of the pain is an important feature. Associated involuntary contraction of the facial muscles can cause sudden closing of the eye or twitching of the mouth, hence the former name *tic douloureux* (painful twitch). Although the cause is not certain, vascular compression and pressure are suggested causes. As the brain changes with age, a loop of a cerebral artery or vein may compress the nerve root entry point, and this can be identified on MRI scan (Gronseth, Cruccu, Alksne, et al., 2008).

Trigeminal neuralgia occurs most often before 35 years of age and is more common in women and in people with MS compared to the general population (Gronseth, et al., 2008; Mazzoni, et al., 2006). Pain-free intervals may be measured in terms of minutes, hours, days, or longer. With advancing years, the painful episodes tend to become more frequent and agonizing. The patient lives in constant fear of attacks.

Paroxysms can occur with any stimulation of the terminals of the affected nerve branches, such as washing the face, shaving, brushing the teeth, eating, and drinking. A draft of cold air or direct pressure against the nerve trunk may also cause pain. Certain areas are called trigger points because the slightest touch immediately starts a paroxysm or episode. To avoid stimulating these areas, patients with trigeminal neuralgia try not to touch or wash their faces, shave, chew, or do anything else that might cause an attack. These behaviors are a clue to the diagnosis.

Medical Management

Pharmacologic Therapy

Antiseizure agents, such as carbamazepine (Tegretol), relieve pain in most patients with trigeminal neuralgia by reducing the transmission of impulses at certain nerve terminals. Carbamazepine is taken with meals. Serum levels must be monitored to avoid toxicity in patients who require high doses to control the pain. Side effects include nausea, dizziness, drowsiness, and aplastic anemia. The patient is monitored for bone marrow depression during long-term therapy. Gabapentin (Neurontin) and baclofen (Lioresal) are also used for pain control. If pain control is still not achieved, phenytoin (Dilantin) may be used as adjunctive therapy.

Surgical Management

If pharmacologic management fails to relieve pain, a number of surgical options are available. Although these procedures may relieve facial pain for a few years, recurrence and complication rates are high (Hickey, 2009). The choice of procedure depends on the patient's preference and health status.

Microvascular Decompression of the Trigeminal Nerve

An intracranial approach is used to relieve the contact between the cerebral vessel and the trigeminal nerve root entry. With the aid of an operating microscope, the artery loop is lifted from the nerve to relieve the pressure, and a small prosthetic device is inserted to prevent recurrence of impingement on the nerve. The postoperative management is the same as for other intracranial surgeries (see Chapter 61).

Radiofrequency Thermal Coagulation

Percutaneous radiofrequency produces a thermal lesion on the trigeminal nerve. Although immediate pain relief is experienced, dysesthesia of the face and loss of the corneal reflex may occur. Use of stereotactic MRI for identification of the trigeminal nerve followed by gamma knife radiosurgery is being used at some medical centers.

Percutaneous Balloon Microcompression

Percutaneous balloon microcompression disrupts large myelinated fibers in all three branches of the trigeminal nerve. After its placement, the balloon is filled with a

Table 64-1 DISORDERS OF CRANIAL NERVES

Disorder	Clinical Manifestations	Nursing Interventions
Olfactory Nerve—I Head trauma Intracranial tumor Intracranial surgery	Unilateral or bilateral anosmia (temporary or persistent) Diminished taste for food	Assess sense of smell. Assess for cerebrospinal fluid rhinorrhea if patient has sustained head trauma.
Optic Nerve—II Optic neuritis Increased intracranial pressure Pituitary tumor	Lesions of optic tract producing homonymous hemianopsia	Assess visual acuity. Restructure environment to prevent injuries. Teach patient to accommodate for visual loss.
Oculomotor Nerve—III Trochlear Nerve—IV Abducens Nerve—VI Vascular Brain stem ischemia Hemorrhage and infarction Neoplasm Trauma Infection	Dilation of pupil with loss of light reflex on one side Impairment of ocular movement Diplopia Gaze palsies Ptosis of eyelid	Assess extraocular movement and for nonreactive pupil.
Trigeminal Nerve—V Trigeminal neuralgia Head trauma Cerebellopontine lesion Sinus tract tumor and metastatic disease Compression of trigeminal root by tumor	Pain in face Diminished or loss of corneal reflex Chewing dysfunction	Assess for pain and triggering mechanisms for pain. Assess for difficulty in chewing. Discuss trigger zones and pain precipitants with patient. Protect cornea from abrasion. Ensure good oral hygiene. Educate patient about medication regimen.
Facial Nerve—VII Bell's palsy Facial nerve tumor Intracranial lesion Herpes zoster	Facial dysfunction; weakness and paralysis Hemifacial spasm Diminished or absent taste Pain	Recognize facial paralysis as emergency; refer for treatment as soon as possible. Teach protective care for eyes. Select easily chewed foods; patient should eat and drink from unaffected side of mouth. Emphasize importance of oral hygiene. Provide emotional support for changed appearance of face.
Vestibulocochlear Nerve—VIII Tumors and acoustic neuroma Vascular compression of nerve Ménière's syndrome	Tinnitus Vertigo Hearing difficulties	Assess pattern of vertigo. Provide for safety measures to prevent falls. Ensure that patient can maintain balance before ambulating. Caution patient to change positions slowly. Assist with ambulation. Encourage use of assistive devices.
Glossopharyngeal Nerve—IX Glossopharyngeal neuralgia from neurovascular compression of cranial nerves IX and X Trauma Inflammatory conditions Tumor Vertebral artery aneurysms	Pain at base of tongue Difficulty in swallowing Loss of gag reflex Palatal, pharyngeal, and laryngeal paralysis	Assess for paroxysmal pain in throat, decreased or absent swallowing, and gag and cough reflexes. Monitor for dysphagia, aspiration, and nasal dysarthric speech. Position patient upright for eating or tube feeding.
Vagus Nerve—X Spastic palsy of larynx; bulbar paralysis; high vagal paralysis Guillain-Barré syndrome Vagal body tumors Nerve paralysis from malignancy, surgical trauma such as carotid endarterectomy	Voice changes (temporary or permanent hoarseness) Vocal paralysis Dysphagia	Assess for airway obstruction/provide airway management. Prevent aspiration. Support patient having voice reconstruction procedures.
Spinal Accessory Nerve—XI Spinal cord disorder Amyotrophic lateral sclerosis Trauma Guillain-Barré syndrome	Drooping of affected shoulder with limited shoulder movement Weakness or paralysis of head rotation, flexion, extension; shoulder elevation	Support patient undergoing diagnostic tests.
Hypoglossal Nerve—XII Medullary lesions Amyotrophic lateral sclerosis Polio and motor system disease, which may destroy hypoglossal nuclei Multiple sclerosis Trauma	Abnormal movements of tongue Weakness or paralysis of tongue muscles Difficulty in talking, chewing, and swallowing	Observe swallowing ability. Observe speech pattern. Be aware of swallowing or vocal difficulties. Prepare for alternate feeding methods (tube feeding) to maintain nutrition.

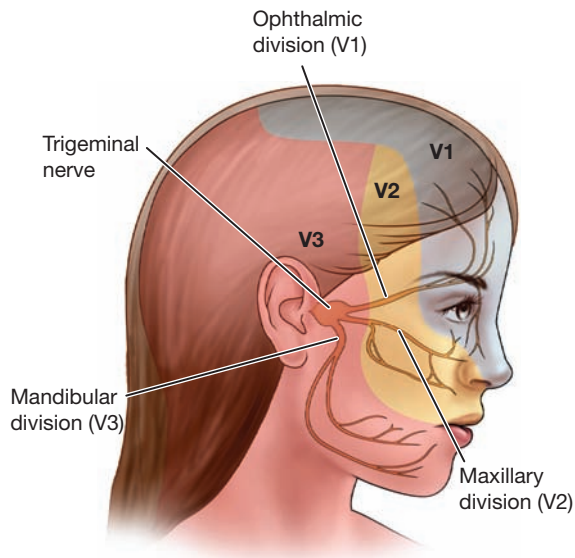

Figure 64-6 Distribution of trigeminal nerve branches.

contrast material for fluoroscopic identification. The balloon compresses the nerve root for 1 minute and provides microvascular decompression.

Nursing Management

Preventing Pain

Preoperative management of a patient with trigeminal neuralgia occurs mostly on an outpatient basis and includes recognizing factors that may aggravate excruciating facial pain, such as food that is too hot or too cold or jarring of the patient's bed or chair. Even washing the face, combing the hair, or brushing the teeth may produce acute pain. The nurse can assist the patient in preventing or reducing this pain by providing instructions about preventive strategies. Providing cotton pads and room temperature water for washing the face, instructing the patient to rinse with mouthwash after eating if tooth brushing causes pain, and performing personal hygiene during pain-free intervals are all effective strategies. The patient is instructed to take food and fluids at room temperature, to chew on the unaffected side, and to ingest soft foods. The nurse recognizes that anxiety, depression, and insomnia often accompany chronic painful conditions and uses appropriate interventions and referrals. See Chapter 13 for management of patients with chronic pain.

Providing Postoperative Care

Postoperative neurologic assessments are conducted to evaluate the patient for facial motor and sensory deficits in each of the three branches of the trigeminal nerve. If the surgery results in sensory deficits to the affected side of the face, the patient is instructed not to rub the eye because the pain of a resulting injury will not be detected. The eye is assessed for irritation or redness. Artificial tears may be prescribed to prevent dryness in the affected eye. The patient is cautioned not to chew on the affected side until numbness has diminished. The patient is observed carefully for any difficulty in eating or swallowing foods of different consistencies.

Bell's Palsy

Bell's palsy (facial paralysis) is caused by unilateral inflammation of the seventh cranial nerve, which results in weakness or paralysis of the facial muscles on the affected side (Fig. 64-7). Although the cause is unknown, theories about causes include vascular ischemia, viral disease (herpes simplex, herpes zoster), autoimmune disease, or a combination of all of these factors. Most adults with Bell's palsy are younger than 45 years of age (Carlson & Pfadt, 2005).

Bell's palsy may be a type of pressure paralysis. The inflamed, edematous nerve becomes compressed to the point of damage, or its blood supply is occluded, producing ischemic necrosis of the nerve. The face is distorted from paralysis of the facial muscles; increased lacrimation (tearing); and painful sensations in the face, behind the ear, and in the eye. The patient may experience speech difficulties and may be unable to eat on the affected side because of weakness or paralysis of the facial muscles. Most patients recover completely, and Bell's palsy rarely recurs (Carlson & Pfadt, 2005).

Medical Management

The objectives of treatment are to maintain the muscle tone of the face and to prevent or minimize denervation. The patient should be reassured that no stroke has occurred and that spontaneous recovery occurs within 3 to 5 weeks in most patients.

Corticosteroid therapy (prednisone) may be prescribed to reduce inflammation and edema; this reduces vascular compression and permits restoration of blood circulation to the nerve. Early administration of corticosteroid therapy appears to diminish the severity of the disease, relieve the pain, and prevent or minimize denervation (Carlson & Pfadt, 2005).

Figure 64-7 Distribution of the facial nerve.

Facial pain is controlled with analgesic agents. Heat may be applied to the involved side of the face to promote comfort and blood flow through the muscles. Electrical stimulation may be applied to the face to prevent muscle atrophy. Although most patients recover with conservative treatment, surgical exploration of the facial nerve may be indicated if a tumor is suspected, for surgical decompression of the facial nerve, or for surgical treatment of a paralyzed face.

Nursing Management

While the paralysis lasts, nursing care involves protection of the eye from injury. Frequently, the eye does not close completely and the blink reflex is diminished, so the eye is vulnerable to injury from dust and foreign particles. Corneal irritation and ulceration may occur. Distortion of the lower lid alters the proper drainage of tears. To prevent injury, the eye should be covered with a protective shield at night. The eye patch may abrade the cornea, however, because there is some difficulty in keeping the partially paralyzed eyelids closed. Moisturizing eye drops during the day and eye ointment at bedtime may help prevent injury (Carlson & Pfadt, 2005). The patient can be taught to close the paralyzed eyelid manually before going to sleep. Wrap-around sunglasses or goggles may be worn during the day to decrease normal evaporation from the eye.

After the sensitivity of the nerve to touch decreases and the patient can tolerate touching the face, the nurse can suggest massaging the face several times daily, using a gentle upward motion, to maintain muscle tone. Facial exercises, such as wrinkling the forehead, blowing out the cheeks, and whistling, may be performed with the aid of a mirror to prevent muscle atrophy. Exposure of the face to cold and drafts is avoided.

DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM

Peripheral Neuropathies

A peripheral **neuropathy** (disorder of the nervous system) is a disorder affecting the peripheral motor and sensory nerves. Peripheral nerves connect the spinal cord and brain to all other organs. They transmit motor impulses from the brain and relay sensory impulses to the brain. Peripheral neuropathies are characterized by bilateral and symmetric disturbance of function, usually beginning in the feet and hands. The most common cause of peripheral neuropathy is diabetes with poor glycemic control (Tesfaye, Chaturvedi, Simon, et al., 2005). The major symptoms of peripheral nerve disorders are loss of sensation, muscle atrophy, weakness, diminished reflexes, pain, and paresthesia (numbness, tingling) of the extremities.

Peripheral nerve disorders are diagnosed by history, physical examination, and electrodiagnostic studies such as electroencephalography. The diagnosis of peripheral neuropathy in the geriatric population is challenging because many symptoms, such as decreased reflexes, can be associated with the normal aging process (Miller, 2009).

No specific treatment exists for peripheral neuropathy. Elimination or control of the cause may slow progression.

Patients with peripheral neuropathy are at risk for falls, thermal injuries, and skin breakdown. The plan of care includes inspection of the lower extremities for skin breakdown. Assistive devices such as a walker or cane may decrease the risk of falls. Bath water temperature is checked to avoid thermal injury. Footwear should be accurately sized. Driving may be limited or eliminated, thereby disrupting the patient's sense of independence.

Mononeuropathy

Mononeuropathy is limited to a single peripheral nerve and its branches. It arises when the trunk of the nerve is compressed or entrapped (as in carpal tunnel syndrome), traumatized (as when bruised by a blow), overstretched (as in joint dislocation), punctured by a needle used to inject a drug or damaged by the drugs thus injected, or inflamed because an adjacent infectious process extends to the nerve trunk. Mononeuropathy is frequently seen in patients with diabetes.

Pain is seldom a major symptom of mononeuropathy when the condition is due to trauma, but in patients with complicating inflammatory conditions such as arthritis, pain is prominent. Pain is increased with all body movements that tend to stretch, strain, or cause pressure on the injured nerve and sudden jarring of the body (eg, from coughing or sneezing). The skin in the areas supplied by nerves that are injured or diseased may become reddened and glossy, the subcutaneous tissue may become edematous, and the nails and hair in this area are altered. Chemical injuries to a nerve trunk, such as those caused by drugs injected into or near it, are often permanent.

The objective of treatment of mononeuropathy is to remove the cause, if possible (eg, freeing the compressed nerve). Local corticosteroid injections may reduce inflammation and the pressure on the nerve. Aspirin or codeine may be used to relieve pain.

Nursing care involves protection of the affected limb or area from injury, as well as appropriate patient teaching about mononeuropathy and its treatment.

CRITICAL THINKING EXERCISES

1 A 19-year-old college student is admitted with suspected meningitis. Identify two assessment parameters that indicate meningitis. What interventions would be included in your plan of care to protect the patient from injury? The patient's family has many questions about the disease and their risk of contracting meningitis. Develop a teaching plan that would describe meningitis and prophylactic therapy for the patient's family and close contacts.

2 Your patient has been prescribed a new medication for the treatment of MS that requires self-injection. She reports that she has a fear of self-injection. Identify additional assessment parameters that need to be used. Develop a teaching plan for self-injection. What resources may be needed to enable her to be successful?

EBP 3 Your 40-year-old patient is being investigated for trigeminal neuralgia. What is the current evidence base for diagnostic evaluation and treatment of trigeminal neuralgia? Identify the criteria used to evaluate the strength of the evidence for diagnostic evaluation and treatment of trigeminal neuralgia. How would you use this information in developing a nursing plan of care for this patient?

Management of Patients With Oncologic or Degenerative Neurologic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify the pathophysiologic processes responsible for oncologic disorders.
- 2 Describe brain and spinal cord tumors: their classification, clinical manifestations, diagnosis, and medical and nursing management.
- 3 Use the nursing process as a framework for care of patients with cerebral metastases or inoperable brain tumors.
- 4 Identify the pathophysiologic processes responsible for various degenerative neurologic disorders.
- 5 Use the nursing process as a framework for care of patients with Parkinson's disease.
- 6 Identify resources for patients and families with oncologic and degenerative neurologic disorders.
- 7 Use the nursing process as a framework for care of patients following a cervical discectomy.

GLOSSARY

- akathisia:** restlessness, urgent need to move around, and agitation
- bradykinesia:** very slow voluntary movements and speech
- chorea:** rapid, jerky, involuntary, purposeless movements of the extremities or facial muscles, including facial grimacing
- dementia:** a progressive organic mental disorder characterized by personality changes, confusion, disorientation, and deterioration of intellect associated with impaired memory and judgment
- dyskinesia:** impaired ability to execute voluntary movements
- dysphonia:** abnormal voice quality caused by weakness and incoordination of muscles responsible for speech
- micrographia:** small and often illegible handwriting
- neurodegenerative:** a disease, process, or condition that leads to deterioration of normal cells or function of the nervous system
- papilledema:** edema of the optic nerve
- paresthesia:** a sensation of numbness, tingling, or a "pins and needles" sensation
- radiculopathy:** disease of a spinal nerve root, often resulting in pain and extreme sensitivity to touch
- sciatica:** inflammation of the sciatic nerve, resulting in pain and tenderness along the nerve through the thigh and leg
- spondylosis:** ankylosis or stiffening of the cervical or lumbar vertebrae

The occurrence of oncologic or degenerative disease processes in the neurologic system produces a unique set of nursing challenges. Oncologic disorders include brain and spinal cord tumors. Degenerative neurologic disorders include Parkinson's disease, Huntington disease, Alzheimer's disease, amyotrophic lateral sclerosis, muscular dystrophies, and degenerative disk disease. Postpolio syndrome is thought to be degenerative in nature and is included in this chapter.

ONCOLOGIC DISORDERS OF THE BRAIN AND SPINAL CORD

Oncologic disorders of the brain and spinal cord include several types of neoplasms, each with its own biology, prognosis, and treatment options. Because of the unique anatomy and physiology of the central nervous system (CNS), this collection of neoplasms is challenging to diagnose and treat.

Primary Brain Tumors

A brain tumor is a localized intracranial lesion that occupies space within the skull. A tumor usually grows as a spherical mass, but it also can grow diffusely and infiltrate tissue. The effects of neoplasms are caused by the compression and infiltration of tissue. A variety of physiologic changes result, causing any or all of the following pathophysiologic events:

- Increased intracranial pressure (ICP) and cerebral edema
- Seizure activity and focal neurologic signs
- Hydrocephalus
- Altered pituitary function

Primary brain tumors originate from cells and structures within the brain. Secondary, or metastatic, brain tumors develop from structures outside the brain and occur in 10% to 20% of patients with cancer. Brain tumors rarely metastasize outside the CNS (Arzbaeher, 2007). Metastatic lesions to the brain can occur from the lung, breast, lower gastrointestinal tract, pancreas, kidney, and skin (melanomas).

The cause of primary brain tumors is unknown. The strongest risk factor is exposure to ionizing radiation. Both glial and meningeal neoplasms have been linked to irradiation of the cranium, with a latency period of 10 to 20 years after exposure (American Brain Tumor Association [ABTA], 2007). Many additional risk factors have been investigated, but only rare genetic mutations, familial tendencies for astrocytoma, and epilepsy and seizures show strong evidence of an association. In the case of epilepsy and seizures, the relationship is unlikely to be causal (Pollock, 2006).

An estimated 21,810 new cases of malignant brain and other nervous system tumors are projected for the year 2008 (Jemal, Siegel, Ward, et al., 2008). Secondary tumors or metastases to the brain from a systemic primary cancer are even more common than new cases of malignant brain and other nervous system tumors. The highest incidence of brain tumors in adults occurs in the fifth, sixth, and seventh

decades. In adults, most brain tumors originate from glial cells (cells that make up the structure and support system of the brain and spinal cord) and are supratentorial (located above the covering of the cerebellum). Neoplastic lesions in the brain ultimately cause death by impairing vital functions, such as respiration, or by increasing ICP. Between 1990 and 2004, death rates for brain and other nervous system tumors declined in both men and women. The rates decreased by 12.6% for men and by 14.4% for women.

Types of Primary Brain Tumors

Brain tumors may be classified into several groups: those arising from the coverings of the brain (eg, dural meningioma), those developing in or on the cranial nerves (eg, acoustic neuroma), those originating within brain tissue (eg, glioma), and metastatic lesions originating elsewhere in the body. Tumors of the pituitary and pineal glands and of cerebral blood vessels are also types of brain tumors. Relevant clinical considerations include the location and the histologic character of the tumor. Tumors may be benign or malignant. A benign tumor, such as a colloid cyst, can occur in a vital area and can grow large enough to have serious effects (Richards & Ballard, 2008). See Chart 65-1 for the classification of brain tumors.

Gliomas

Glial tumors, the most common type of intracerebral brain neoplasm, are divided into many categories (Wen & Kesari, 2008). Astrocytomas are the most common type of glioma and are graded from I to IV, indicating the degree of malignancy (Arzbaeher, 2007). The grade is based on cellular density, cell mitosis, and appearance. Usually, these tumors spread by infiltrating into the surrounding neural connective tissue and therefore cannot be totally removed without causing considerable damage to vital structures.

Oligodendrogial tumors represent 20% of gliomas and are categorized as low grade or high grade (anaplastic) (ABTA, 2007). The histologic distinction between astrocy-

Chart 65-1 • Classification of Brain Tumors in Adults

I. Intracerebral Tumors

- A. Gliomas—infiltrate any portion of the brain; most common type of brain tumor
1. Astrocytomas (grades I and II)
 2. Glioblastoma multiforme (astrocytoma grades III and IV)
 3. Oligodendrocytoma (low and high grades)
 4. Ependymoma (grades I to IV)
 5. Medulloblastoma

II. Tumors Arising From Supporting Structures

- A. Meningiomas
- B. Neuromas (acoustic neuroma, schwannoma)
- C. Pituitary adenomas

III. Developmental Tumors

- A. Angiomas
- B. Dermoid, epidermoid, teroma, craniopharyngioma

IV. Metastatic Lesions

tomas and oligodendrogliomas is difficult to make but important, because oligodendrogliomas are more sensitive than astrocytomas to chemotherapy.

Meningiomas

Meningiomas, which represent 15% of all primary brain tumors, are common benign encapsulated tumors of arachnoid cells on the meninges (Pollock, 2006). They are slow growing and occur most often in middle-aged adults (more often in women). Meningiomas most often occur in areas proximal to the venous sinuses. Manifestations depend on the area involved and are the result of compression rather than invasion of brain tissue. Preferred treatment for symptomatic lesions is surgery with complete removal or partial dissection.

Acoustic Neuromas

An acoustic neuroma is a tumor of the eighth cranial nerve, the cranial nerve most responsible for hearing and balance. It usually arises just within the internal auditory meatus, where it frequently expands before filling the cerebellopontine recess. An acoustic neuroma may grow slowly and attain considerable size before it is correctly diagnosed. The patient usually experiences loss of hearing, tinnitus, and episodes of vertigo and staggering gait. As the tumor becomes larger, painful sensations of the face may occur on the same side, as a result of the tumor's compression of the fifth cranial nerve. Many acoustic neuromas are benign and can be managed conservatively. Many that continue to grow can be surgically removed and have a good prognosis (see Chapter 59) (Pollock, 2006). Some acoustic neuromas may be suitable for stereotactic radiotherapy rather than open craniotomy. Stereotactic radiotherapy is discussed later in this chapter.

Pituitary Adenomas

Pituitary tumors represent about 10% to 15% of all brain tumors and cause symptoms as a result of pressure on adjacent structures or hormonal changes such as hyperfunction or hypofunction of the pituitary (Pollock, 2006).

Pressure Effects of Pituitary Adenomas

Pressure from a pituitary adenoma may be exerted on the optic nerves, optic chiasm, or optic tracts or on the hypothalamus or the third ventricle if the tumor invades the cavernous sinuses or expands into the sphenoid bone. These pressure effects produce headache, visual dysfunction, hypothalamic disorders (disorders of sleep, appetite, temperature, and emotions), increased ICP, and enlargement and erosion of the sella turcica.

Hormonal Effects of Pituitary Adenomas

Functioning pituitary tumors can produce one or more hormones normally produced by the anterior pituitary. There are prolactin-secreting pituitary adenomas (prolactinomas), growth hormone-secreting pituitary adenomas that produce acromegaly in adults, and adrenocorticotrophic hormone (ACTH)-producing pituitary adenomas that result in Cushing's disease (Gordon, 2007). Adenomas that secrete thyroid-stimulating hormone or follicle-stimulating hormone and luteinizing hormone occur infrequently, whereas

adenomas that produce both growth hormone and prolactin are relatively common.

The female patient whose pituitary gland is secreting excessive quantities of prolactin presents with amenorrhea or galactorrhea (excessive or spontaneous flow of milk). Male patients with prolactinomas may present with impotence and hypogonadism. Acromegaly, caused by excess growth hormone, produces enlargement of the hands and feet, distortion of the facial features, and pressure on peripheral nerves (entrapment syndromes). The clinical features of Cushing's disease, a condition associated with prolonged overproduction of cortisol, occur with excessive production of ACTH. Manifestations include a form of obesity with redistribution of fat to the facial, supraclavicular, and abdominal areas; hypertension; purple striae and ecchymoses; osteoporosis; elevated blood glucose levels; and emotional disorders. Endocrine disorders resulting from these tumors are discussed in Chapter 42.

Angiomas

Brain angiomas (masses composed largely of abnormal blood vessels) are found either in or on the surface of the brain. They occur in the cerebellum in 83% of cases. Some persist throughout life without causing symptoms; others cause symptoms of a brain tumor. Occasionally, the diagnosis is suggested by the presence of another angioma somewhere in the head or by a bruit (an abnormal sound) that is audible over the skull. Because the walls of the blood vessels in angiomas are thin, these patients are at risk for hemorrhagic stroke. In fact, cerebral hemorrhage in people younger than 40 years of age should suggest the possibility of an angioma.

Gerontologic Considerations

The most frequent tumor types in the elderly are anaplastic astrocytoma, glioblastoma multiforme, and cerebral metastases from other sites. The incidence of primary brain tumors and the likelihood of malignancy increase with age. Intracranial tumors can produce personality changes, confusion, speech dysfunction, or disturbances of gait. In elderly patients, early signs and symptoms of intracranial tumors can be easily overlooked or incorrectly attributed to cognitive and neurologic changes associated with normal aging. Neurologic signs and symptoms in the elderly must be carefully evaluated, because 10% of brain metastases occur in patients with a history of prior cancer. Researchers are investigating patterns of care and clinical outcomes of elderly patients with primary brain tumors (Barnholtz-Sloan, Williams, Maldonado, et al., 2008).

Clinical Manifestations

Brain tumors can produce both focal or generalized neurologic signs and symptoms. Generalized symptoms reflect increased ICP, and the most common focal or specific signs and symptoms result from tumors that interfere with functions in specific brain regions. Figure 65-1 indicates common tumor sites in the brain.

Increased Intracranial Pressure

As discussed in Chapter 61, the skull is a rigid compartment containing essential noncompressible contents: brain matter,

Figure 65-1 Common brain tumor sites.

intravascular blood, and cerebrospinal fluid (CSF). According to the modified Monro-Kellie hypothesis, if any one of these skull components increases in volume, ICP increases unless one of the other components decreases in volume. Consequently, any change in volume occupied by the brain (as occurs with disorders such as brain tumor or cerebral edema) produces signs and symptoms of increased ICP.

Symptoms of increased ICP result from a gradual compression of the brain by the enlarging tumor. The effect is a disruption of the equilibrium that exists between the brain, the CSF, and the cerebral blood. As the tumor grows, compensatory adjustments may occur through compression of intracranial veins, reduction of CSF volume (by increased absorption or decreased production), a modest decrease in cerebral blood flow, or reduction of intracellular and extracellular brain tissue mass. When these compensatory mechanisms fail, the patient develops signs and symptoms of increased ICP, most often including headache, nausea with or without vomiting, and **papilledema** (edema of the optic disk) (Rowland, 2005). Personality changes and a variety of focal deficits, including motor, sensory, and cranial nerve dysfunction, are common.

Headache

Headache, although not always present, is most common in the early morning and is made worse by coughing, straining, or sudden movement. It is thought to be caused by the tumor's invading, compressing, or distorting the pain-sensitive structures or by edema that accompanies the tumor.

Headaches are usually described as deep or expanding or as dull but unrelenting. Frontal tumors usually produce a bilateral frontal headache; pituitary gland tumors produce pain radiating between the two temples (bitemporal); in cerebellar tumors, the headache may be located in the suboccipital region at the back of the head.

Vomiting

Vomiting, seldom related to food intake, is usually the result of irritation of the vagal centers in the medulla. Forceful vomiting is described as projectile vomiting.

Visual Disturbances

Papilledema is present in 70% to 75% of patients and is associated with visual disturbances such as decreased visual acuity, diplopia (double vision), and visual field deficits (Rowland, 2005).

Localized Symptoms

Common focal or localized symptoms are hemiparesis, seizures, and mental status changes (Rowland, 2005). When specific regions of the brain are affected, additional local signs and symptoms occur, such as sensory and motor abnormalities, visual alterations, alterations in cognition, and language disturbances (eg, aphasia). The progression of the signs and symptoms is important, because it indicates tumor growth and expansion. For example, a rapidly developing hemiparesis is more typical of a highly malignant glioma than of a low-grade tumor.

Although some tumors are not easily localized because they lie in so-called silent areas of the brain (ie, areas in which functions are not definitely determined), many tumors can be localized by correlating the signs and symptoms to specific areas in the brain, as follows:

- A motor cortex tumor produces seizurelike movements localized on one side of the body, called jacksonian seizures.
- An occipital lobe tumor produces visual manifestations: contralateral homonymous hemianopsia (visual loss in half of the visual field on the opposite side of the tumor) and visual hallucinations.
- A cerebellar tumor causes dizziness, an ataxic or staggering gait with a tendency to fall toward the side of the lesion, marked muscle incoordination, and nystagmus (involuntary rhythmic eye movements), usually in the horizontal direction.
- A frontal lobe tumor frequently produces personality disorders, changes in emotional state and behavior, and an apathetic mental attitude. The patient often becomes extremely untidy and careless and may use obscene language.
- A cerebellopontine angle tumor usually originates in the sheath of the acoustic nerve and gives rise to a characteristic sequence of symptoms. Tinnitus and vertigo appear first, soon followed by progressive nerve deafness (eighth cranial nerve dysfunction). Numbness and tingling of the face and tongue occur (due to involvement of the fifth cranial nerve). Later, weakness or paralysis of the face develops (seventh cranial nerve involvement). Finally, because the enlarging tumor presses on the cerebellum, abnormalities in motor function may be present.

Assessment and Diagnostic Findings

The history of the illness and the manner and time frame in which the symptoms evolved are key components in the diagnosis of brain tumors. A neurologic examination indicates the areas of the CNS that are involved. To assist in the precise localization of the lesion, a battery of tests is performed. Computed tomography (CT) scans, enhanced by a contrast agent, can give specific information concerning the number, size, and density of the lesions and the extent of secondary cerebral edema. CT scans can provide information about the ventricular system. A magnetic resonance imaging (MRI) scan is the most helpful diagnostic tool for detecting brain tumors, particularly smaller lesions, and tumors in the brain stem and pituitary regions, where bone is thick (Fig. 65-2). In a few instances, the appearance of a brain tumor on an MRI scan is so characteristic that a biopsy is unnecessary, especially when the tumor is located in a part of the brain that is difficult to biopsy (Rowland, 2005).

Positron emission tomography (PET) is used to supplement MRI scanning in centers where it is available. On PET scans, low-grade tumors are associated with hypometabolism and high-grade tumors show hypermetabolism. This information can be useful in making treatment decisions (ABTA, 2007). Computer-assisted stereotactic (three-dimensional) biopsy is used to diagnose deep-seated brain tumors and to provide a basis for treatment and prognosis.

Figure 65-2 Low-grade glioma. Magnetic resonance image of the brain shows an abnormal density in the right temporal lobe. Courtesy of the Hospital of the University of Pennsylvania, Nuclear Medicine Section, Philadelphia, PA.

Cerebral angiography provides visualization of cerebral blood vessels and can localize most cerebral tumors.

An electroencephalogram (EEG) can detect an abnormal brain wave in regions occupied by tumor; it is used to evaluate temporal lobe seizures and to assist in ruling out other disorders. Cytologic studies of the CSF may be performed to detect malignant cells, because CNS tumors can shed cells into the CSF.

Medical Management

A variety of medical treatment modalities, including chemotherapy and external-beam radiation therapy, are used alone or in combination with surgical resection (Wen & Kesari, 2008). Radiation therapy, the cornerstone of treatment for many brain tumors, decreases the incidence of recurrence of incompletely resected tumors. Brachytherapy (the surgical implantation of radiation sources to deliver high doses at a short distance) has had promising results for primary malignancies. It is usually used as an adjunct to conventional radiation therapy or as a rescue measure for recurrent disease.

Intravenous (IV) autologous bone marrow transplantation is used in some patients who will receive chemotherapy or radiation therapy, because it can “rescue” the patient from the bone marrow toxicity associated with high doses of chemotherapy and radiation. A fraction of the patient’s bone marrow is aspirated, usually from the iliac crest, and stored. The patient receives large doses of chemotherapy or radiation therapy to destroy large numbers of malignant cells. The marrow is then reinfused by IV after treatment is completed.

Gene transfer therapy uses retroviral vectors to carry genes to the tumor, reprogramming the tumor tissue for susceptibility to treatment. This approach is being tested (ABTA, 2007).

Surgical Management

The objective of surgical management is to remove or destroy the entire tumor without increasing the neurologic deficit (paralysis, blindness) or to relieve symptoms by partial removal (decompression). A variety of treatment modalities may be used; the specific approach depends on the type of tumor, its location, and its accessibility. In many patients, combinations of these modalities are used. Most pituitary adenomas are treated by transsphenoidal microsurgical removal (see Chapter 61), and the remainder of tumors that cannot be removed completely are treated by radiation (Pollock, 2006). An untreated brain tumor ultimately leads to death, either from increasing ICP or from the damage the tumor causes to brain tissue.

Conventional surgical approaches require a craniotomy (incision into the skull). See Chapter 61 for a discussion of care of the patient who has undergone a craniotomy. This approach is used in patients with meningiomas, acoustic neuromas, cystic astrocytomas of the cerebellum, colloid cysts of the third ventricle, congenital tumors such as dermoid cyst, and some of the granulomas. With improved imaging techniques and the availability of the operating microscope and microsurgical instrumentation, even large tumors can be removed through a relatively small craniotomy. For patients with malignant glioma, complete removal of the tumor and cure are not possible, but the rationale for resection includes relief of ICP, removal of any necrotic tissue, and reduction in the bulk of the tumor, which theoretically leaves behind fewer cells to become resistant to radiation or chemotherapy.

Stereotactic approaches involve the use of a three-dimensional frame that allows very precise localization of the tumor; a stereotactic frame and multiple imaging studies (x-rays, CT scans) are used to localize the tumor and verify its position (Fig. 65-3). New brain-mapping technology helps determine how close diseased areas of the brain are to structures essential for normal brain function. Lasers or radiation can be delivered with stereotactic approaches. Radioisotopes such as iodine 131 (^{131}I) can also be implanted directly into the tumor (brachytherapy) while minimizing effects on surrounding brain tissue.

Stereotactic procedures may be performed using a linear accelerator or gamma knife to perform radiosurgery. These procedures allow treatment of deep, inaccessible tumors, often in a single session. Precise localization of the tumor is accomplished by the stereotactic approach and by minute measurements and precise positioning of the patient. Multiple narrow beams then deliver a very high dose of radiation. An advantage of this method is that no surgical incision is needed; a disadvantage is the lag time between treatment and the desired result (Pollock, 2006; Swinson & Friedman, 2008).

Nursing Management

The patient with a brain tumor may be at increased risk for aspiration as a result of cranial nerve dysfunction. Preoperatively, the gag reflex and ability to swallow are evaluated. In

Figure 65-3 **A**, Using stereotactic or “brain-mapping” guided approach, a 3-D computer image fuses the computed tomography image and magnetic resonance image to pinpoint the exact location of the brain tumor. This low-grade astrocytoma is localized adjacent to the brain stem, is nonoperable, and is treated with radiation. Note the optic chiasm and optic nerves. **B**, Computerized image of the prescribed radiation dose.

patients with diminished gag response, care includes teaching the patient to direct food and fluids toward the unaffected side, having the patient sit upright to eat, offering a semisoft diet, and having suction readily available. The effects of increased ICP caused by the tumor mass are reviewed in Chapter 61. The nurse performs neurologic checks, monitors vital signs, maintains a neurologic flow chart, spaces nursing interventions to prevent rapid increase in ICP, and reorients the patient when necessary to person, time, and place. Patients with changes in cognition caused by their lesion require frequent reorientation and the use of orienting devices (eg, personal possessions, photographs, lists, a

clock), supervision of and assistance with self-care, and ongoing monitoring and intervention for prevention of injury. Patients with seizures are carefully monitored and protected from injury. Motor function is checked at intervals, because specific motor deficits may occur, depending on the tumor's location. Sensory disturbances are assessed. Speech is evaluated. Eye movement and pupillary size and reaction may be affected by cranial nerve involvement.

The psychosocial effects on family caregivers of a family member who has a primary malignant brain tumor may be significant (Schmer, Ward-Smith, Latham, et al., 2008) (Chart 65-2).

The nursing process for patients undergoing neurosurgery is discussed in Chapter 61. The patient's functional abilities should be reassessed postoperatively, because changes can occur.

Cerebral Metastases

A significant number of patients with cancer experience neurologic deficits caused by metastasis to the brain. Although metastatic lesions to the brain are the most common intracerebral tumor, their exact incidence is unknown (Raizer & Abrey, 2007). This high rate of occurrence is clinically important as more patients with all forms of cancer live longer because of improved therapies. Neurologic signs and symptoms include headache, gait disturbances, visual impairment, personality changes, altered mentation (memory loss and confusion), focal weakness, paralysis, aphasia, and seizures. These signs and symptoms can be devastating to both patient and family.

Medical Management

The treatment of metastatic brain cancer is palliative and involves eliminating or reducing serious symptoms. Even when palliation is the goal, distressing signs and symptoms can be relieved, thereby improving the quality of life for both patient and family. Patients with intracerebral metastases who are not treated have a steady downhill course with a limited survival time, whereas those who are treated may survive for slightly longer periods. The median survival time for patients with no treatment for brain metastases is 1 month; with corticosteroid treatment alone it is 2 months; radiation therapy extends the median survival time to 3 to 6 months.

The therapeutic approach includes radiation therapy (the foundation of treatment), surgery (usually for a single intracranial metastasis), and chemotherapy; more often, some combination of these treatments is the optimal method. Gamma knife radiosurgery is considered if three or fewer lesions are present.

Pharmacologic Therapy

Corticosteroids are useful in relieving headache and alterations in level of consciousness. Corticosteroids such as dexamethasone (Decadron) and prednisone are thought to reduce inflammation and edema around tumors (Karch, 2008). Other medications used include osmotic diuretics (eg, mannitol [Osmitrol]) to decrease the fluid content of the brain, which leads to a decrease in ICP. Antiseizure agents (eg, phenytoin [Dilantin]) are used to prevent and treat seizures (Rowland, 2005). The pharmacologic management of pituitary tumors is complex and usually carried

CHART

NURSING RESEARCH PROFILE

The Caregiver Perspective When a Family Member Has a Malignant Brain Tumor

Schmer, C., Ward-Smith, P., Latham, S., et al. (2008). When a family member has a malignant brain tumor: The caregiver perspective. *Journal of Neuroscience Nursing*, 40(2), 78–84.

Purpose

There have been no significant advances in the treatment of malignant brain tumors over the past 25 years, and care is performed primarily by family members. The purpose of this study was to explore the perspective of the caregiver for a patient receiving chemotherapy for initial treatment of a malignant brain tumor.

Design

This was a phenomenologic study that used interviews to explore caregiver perspectives. Ten family members (seven spouses, two daughters, and one son-in-law) provided data. Semi-structured interviews took place with the caregiver while the patient was receiving chemotherapy within the first 6 months of treatment for a primary malignant brain tumor. Data analysis was conducted using Colaizzi's method, a qualitative data analysis technique, to identify themes.

Findings

Data analysis uncovered three main themes. The first was that the diagnosis of a brain tumor is a shock; all participants used the work *shock* when explaining their feelings on hearing the diagnosis. The second was that immediate family role changes occur; diagnosis of a primary malignant brain tumor and subsequent treatment resulted in immediate family role changes for both the patient and caregiver. The final theme was that there are psychosocial effects for the caregiver, his or her family, and the person with the brain tumor. Participants did not perceive caring for the family member as a burden.

Nursing Implications

Little research has focused on the experience and changing roles of family members immediately after diagnosis or during the initial treatment phase of a terminal illness. This research provides beginning knowledge for health care professionals about the experience of a family caregiver of a patient with a primary brain tumor. During the first 6 months of treatment, there was a low physical need burden but significant psychosocial effects. Nurses working with patients and families should be prepared to address these psychosocial effects (eg, family role changes).

out on an outpatient basis (Gordon, 2007). Venous thromboembolic events, such as deep vein thrombosis (DVT) and pulmonary embolism (PE), occur in about 15% of patients and are associated with significant morbidity. Anticoagulants usually are not prescribed because of the risk of CNS hemorrhage; however, prophylactic therapy with low-molecular-weight heparin is under investigation.

Chemotherapy plays a small role in managing brain metastasis because of poor penetration across the blood-brain barrier. Drug penetration and sensitivity of brain cells are two factors that determine the responsiveness of metastatic brain tumors to chemotherapy. Research is being directed at multidrug regimens and drug resistance (ABTA, 2007). Encouraging results have been seen with chemotherapeutic agents such as carmustine (BCNU), lomustine (CCNU), and PCV (a triple-drug combination of procarbazine hydrochloride, lomustine, and vincristine). Promising results have been seen with the use of topotecan (Hy-camtin), another chemotherapy agent.

Pain is managed by means of a stepped progression in the doses and type of analgesic agents needed for relief. If the patient has severe pain, morphine can be infused into the epidural or subarachnoid space through a spinal needle and a catheter placed as near as possible to the spinal segment where the pain is projected. Small doses of morphine are administered at prescribed intervals (see Chapter 13).

NURSING PROCESS

THE PATIENT WITH CEREBRAL METASTASES OR INCURABLE BRAIN TUMOR

Assessment

The nursing assessment includes a baseline neurologic examination and focuses on how the patient is functioning, moving, and walking; adapting to weakness or paralysis and to loss of vision and speech; and dealing with seizures. Assessment addresses symptoms that cause distress to the patient and affect the quality of life, including pain, respiratory problems, bowel and bladder disorders, sleep disturbances, and impairment of skin integrity, fluid balance, and temperature regulation (Arzbaecher, 2007). Tumor invasion, compression, or obstruction may cause these disorders.

Nutritional status is assessed, because cachexia (weak and emaciated condition) is common in patients with metastases. The nurse explores changes associated with poor nutritional status (anorexia, pain, weight loss, altered metabolism, muscle weakness, malabsorption, and diarrhea) and asks the patient about altered taste sensations that may be secondary to dysphagia, weakness, and depression and about distortions and impaired sense of smell (anosmia).

The nurse takes a dietary history to assess food intake, intolerance, and preferences. Calculation of body mass index can confirm the loss of subcutaneous fat and lean body mass (see Chapter 5). Biochemical measurements are reviewed to assess the degree of malnutrition, impaired cellular immunity, and electrolyte balance (see Appendix

A for normal laboratory values). A dietitian assists in determining the caloric needs of the patient.

The nurse works with other members of the health care team to assess the impact of the illness on the family in terms of home care, altered relationships, financial problems, time pressures, and family problems. This information is important in helping family members cope with the diagnosis and the changes associated with it.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Self-care deficit (feeding, bathing, and toileting) related to loss or impairment of motor and sensory function and decreased cognitive abilities
- Imbalanced nutrition, less than body requirements, related to cachexia due to treatment and tumor effects, decreased nutritional intake, and malabsorption
- Anxiety related to fear of dying, uncertainty, change in appearance, or altered lifestyle
- Interrupted family processes related to anticipatory grief and the burdens imposed by the care of the person with a terminal illness

Other nursing diagnoses of the patient with cerebral metastases may include acute pain related to tumor compression; impaired gas exchange related to dyspnea; constipation related to decreased fluid and dietary intake and medications; impaired urinary elimination related to reduced fluid intake, vomiting, and side effects of medications; sleep pattern disturbances related to discomfort and fear of dying; impairment of skin integrity related to cachexia, poor tissue perfusion, and decreased mobility; deficient fluid volume related to fever, vomiting, and low fluid intake; and ineffective thermoregulation related to hypothalamic involvement, fever, and chills. See Chapter 16 for assessment and nursing interventions for the patient with cancer.

Planning and Goals

The goals for the patient may include compensating for self-care deficits, improving nutrition, reducing anxiety, enhancing family coping skills, and absence of complications.

Nursing Interventions

Compensating for Self-Care Deficits

The patient may have difficulty participating in goal setting as the tumor metastasizes and affects cognitive function. The nurse should encourage the family to keep the patient as independent as possible for as long as possible. Increasing assistance with self-care activities is required. Because the patient with cerebral metastasis and the family live with uncertainty, they are encouraged to plan for each day and to make the most of each day. The tasks and challenges are to assist the patient to find useful coping mechanisms, adaptations, and compensations for solving problems that arise. This helps patients maintain some sense of control. An individualized exercise program helps maintain strength, endurance, and range of motion. Eventually, referral for home or hospice care may be necessary (see Chapter 17).

Improving Nutrition

Patients with nausea, vomiting, diarrhea, breathlessness, and pain are rarely interested in eating. These symptoms are managed or controlled through assessment, planning, and care. The nurse teaches the family how to position the patient for comfort during meals. Meals are planned for times when the patient is rested and in less distress from pain or the effects of treatment.

The patient needs to be clean, comfortable, and free of pain for meals, in an environment that is as attractive as possible. Oral hygiene before meals helps to improve appetite. Offensive sights, sounds, and odors are eliminated. Creative strategies may be required to make food more palatable, provide enough fluids, and increase opportunities for socialization during meals. The family may be asked to keep a daily weight chart and to record the quantity of food eaten to determine the daily calorie count. Dietary supplements, if acceptable to the patient, can be provided to meet increased caloric needs. If the patient is not interested in most usual foods, those foods preferred by the patient should be offered. When the patient shows marked deterioration as a result of tumor growth and effects, some other form of nutritional support (eg, tube feeding, parenteral nutrition) may be indicated if consistent with the patient's end-of-life preferences (Dudek, 2006). Nursing interventions include assessing the patency of the central and IV lines or feeding tube, monitoring the insertion site for infection, checking the infusion rate, monitoring intake and output, and changing the IV tubing and dressing. Family members are instructed in these techniques if they will be providing care at home. Parenteral nutrition can be provided at home if indicated.

The patient's quality of life may guide the selection, initiation, maintenance, and discontinuation of nutritional support. The nurse and family should not place too much emphasis on eating or on discussions about food, because the patient may not desire aggressive nutritional intervention. The subsequent course of action must be congruent with the wishes and choices of the patient and family.

Relieving Anxiety

Patients with cerebral metastases may be restless, with changing moods that may include intense depression, euphoria, paranoia, and severe anxiety. The response of patients to terminal illness reflects their pattern of reaction to other crisis situations. Serious illness imposes additional strains that often bring other unresolved problems to light. The patient's own coping strategies can help deal with anxious and depressed feelings. Health care providers need to be sensitive to the patient's concerns and fears.

Patients need the opportunity to exercise some control over their situation. A sense of mastery can be gained as they learn to understand the disease and its treatment and how to deal with their feelings. The presence of family, friends, a spiritual advisor, and health professionals may be supportive. Support groups such as the Brain Tumor Support Group may provide a feeling of support and strength.

Spending time with patients allows them time to talk and to communicate their fears and concerns. Open communication and acknowledgment of fears are often therapeutic. Touch is also a form of communication. These patients need

reassurance that continuing care will be provided and that they will not be abandoned. The situation becomes more endurable when others share in the experience of dying. If a patient's emotional reactions are very intense or prolonged, additional help from a spiritual advisor, social worker, or mental health professional may be indicated.

Enhancing Family Processes

The family needs to be reassured that their loved one is receiving optimal care and that attention will be paid to the patient's changing symptoms and concerns. When the patient can no longer carry out self-care, the family and additional support systems (social worker, home health aide, home care nurse, hospice nurse) may be needed. End-of-life care is provided with respect, and reassurance is provided by communicating the plan of care to the family (Fields, 2007).

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient and family often have major responsibility for care at home. Therefore, teaching includes pain management strategies, prevention of complications related to treatment strategies, and methods to ensure adequate fluid and food intake (Chart 65-3). Teaching needs of the patient and family regarding care priorities are likely to change as the disease progresses. The nurse should assess the changing needs of the patient and the family and inform them about resources and services early, to assist them in dealing with changes in the patient's condition.

CONTINUING CARE. Home care nursing and hospice services are valuable resources that should be made available to the patient and the family early in the course of a terminal illness. Anticipating needs before they occur can assist in smooth initiation of services. Home care needs and interventions focus on four major areas: palliation of symptoms and pain control, assistance in self-care, control of treatment complications, and administration of specific forms of treatment, such as parenteral nutrition. The home care nurse assesses pain management, respiratory status, complications of the disorder and its treatment, and the patient's cognitive and emotional status. Additionally, the nurse assesses the family's ability to perform necessary care and notifies the physician about changing needs or complications if indicated.

The patient and family who elect to care for the patient at home as the disease progresses benefit from the care and support provided through hospice and palliative care services (Fields, 2007). Steps to initiate hospice care, including discussion of hospice care as an option, should not be postponed until death is imminent. Exploration of hospice care as an option should be initiated at a time when hospice services can provide support and care to the patient and family consistent with their end-of-life decisions and can assist in allowing death with dignity. End-of-life care is further described in Chapter 17.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Engages in self-care activities as long as possible
 - a. Uses assistive devices or accepts assistance as needed

- b. Schedules periodic rest periods to permit maximal participation in self-care
2. Maintains as optimal a nutritional status as possible
 - a. Eats and accepts food within limits of condition and preferences
 - b. Accepts alternative methods of providing nutrition if indicated
3. Reports being less anxious
 - a. Is less restless and is sleeping better
 - b. Verbalizes concerns and fears about death
 - c. Participates in activities of personal importance as long as feasible
4. Family members seek help as needed
 - a. Demonstrate ability to bathe, feed, and care for the patient and participate in pain management and prevention of complications
 - b. Express feelings and concerns to appropriate health professionals
 - c. Discuss and seek hospice care as an option

Spinal Cord Tumors

Tumors within the spine are classified according to their anatomic relation to the spinal cord. They include intramedullary lesions (within the spinal cord), extramedullary-intradural lesions (within or under the spinal dura), and extramedullary-extradural lesions (outside the dural membrane). Tumors that occur within the spinal cord or exert pressure on it cause symptoms ranging from localized or shooting pains and weakness and loss of reflexes above the tumor level to progressive loss of motor function and paralysis. Usually, sharp pain occurs in the area inner-

vated by the spinal roots that arise from the cord in the region of the tumor. In addition, increasing sensory deficits develop below the level of the lesion.

Assessment and Diagnostic Findings

Neurologic examination and diagnostic studies are used to make the diagnosis. Neurologic examination includes assessment of pain, loss of reflexes, loss of sensation or motor function, and the presence of weakness and paralysis. Additional assessment findings usually include pain duration for longer than 1 month and an elevated erythrocyte sedimentation rate. Helpful diagnostic studies include x-rays, radionuclide bone scans, CT scans, MRI scans, and biopsy. The MRI scan is the most commonly used and the most sensitive diagnostic tool, and it is particularly helpful in detecting epidural spinal cord compression and metastases (Rowland, 2005).

Medical Management

Treatment of specific intraspinal tumors depends on the type and location of the tumor and the presenting symptoms and physical status of the patient. Surgical intervention is the primary treatment for most spinal cord tumors. Other treatment modalities include partial removal of the tumor, decompression of the spinal cord, chemotherapy, and radiation therapy, particularly for intramedullary tumors and metastatic lesions (Rowland, 2005).

Epidural spinal cord compression occurs in 5% to 7% of patients who die of cancer and is considered a neurologic emergency. For the patient with epidural spinal cord compression resulting from metastatic cancer (most commonly from breast, prostate, or lung), high-dose dexamethasone (Decadron) combined with radiation therapy is effective in relieving pain (Held-Warmkessel, 2005). See Chapter 16 for a discussion of care of the patient with spinal cord

compression. Palliative care may be an option for the medical management of some patients.

Surgical Management

Tumor removal is desirable but not always possible. The goal is to remove as much tumor as possible while sparing uninvolved portions of the spinal cord. Microsurgical techniques have improved the prognosis for patients with intramedullary tumors. Prognosis is related to the degree of neurologic impairment at the time of surgery, the speed with which symptoms occurred, and the origin of the tumor. Patients with extensive neurologic deficits before surgery usually do not make significant functional recovery even after successful tumor removal.

Nursing Management

Providing Preoperative Care

The objectives of preoperative care include recognition of neurologic changes through ongoing assessments, pain control, and management of altered activities of daily living (ADLs) resulting from sensory and motor deficits and bowel and bladder dysfunction. The nurse assesses for weakness, muscle wasting, spasticity, sensory changes, bowel and bladder dysfunction, and potential respiratory problems, especially if a cervical tumor is present. The patient is also evaluated for coagulation deficiencies. A history of aspirin intake is obtained and reported, because the use of aspirin may impede hemostasis postoperatively. Breathing exercises are taught and demonstrated preoperatively. Postoperative pain management strategies are discussed with the patient before surgery.

Assessing the Patient After Surgery

The patient is monitored for deterioration in neurologic status. A sudden onset of neurologic deficit is an ominous sign and may be due to vertebral collapse associated with spinal cord infarction. Frequent neurologic checks are carried out, with emphasis on movement, strength, and sensation of the upper and lower extremities. Assessment of sensory function involves pinching the skin of the arms, legs, and trunk to determine if there is loss of feeling and, if so, at what level. Vital signs are monitored at regular intervals.

Managing Pain

The prescribed pain medication should be administered in adequate amounts and at appropriate intervals to relieve pain and prevent its recurrence. Pain is the hallmark of spinal metastasis. Patients with sensory root involvement or vertebral collapse may suffer excruciating pain, which requires effective pain management (Hickey, 2009).

The bed is usually kept flat initially. The nurse turns the patient as a unit, keeping shoulders and hips aligned and the back straight. The side-lying position is usually the most comfortable, because this position imposes the least pressure on the surgical site. Placement of a pillow between the knees of the patient in a side-lying position helps to prevent extreme knee flexion.

Monitoring and Managing Potential Complications

If the tumor was in the cervical area, respiratory compromise due to postoperative edema may occur. The nurse monitors

the patient for asymmetric chest movement, abdominal breathing, and abnormal breath sounds. For a high cervical lesion, the endotracheal tube remains in place until adequate respiratory function is ensured. The patient is encouraged to perform deep-breathing and coughing exercises.

The area over the bladder is palpated or a bladder scan is performed to assess for urinary retention. The nurse also monitors for incontinence, because urinary dysfunction usually implies significant decompensation of spinal cord function. An intake and output record is maintained. Additionally, the abdomen is auscultated for bowel sounds.

Staining of the dressing may indicate leakage of CSF from the surgical site, which may lead to serious infection or to an inflammatory reaction in the surrounding tissues that can cause severe pain in the postoperative period.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

In preparation for discharge, the patient is assessed for the ability to function independently in the home and for the availability of resources such as family members to assist in caregiving. Patients with residual sensory involvement are cautioned about the dangers of extremes in temperature. They should be alerted to the dangers of heating devices (eg, hot water bottles, heating pads, space heaters). The patient is taught to check skin integrity daily. Patients with impaired motor function related to motor weakness or paralysis may require training in ADLs and safe use of assistive devices, such as a cane, walker, or wheelchair.

The patient and family members are instructed about pain management strategies, bowel and bladder management, and assessment for signs and symptoms that should be reported promptly.

Continuing Care

Referral for inpatient or outpatient rehabilitation may be warranted to improve self-care abilities. A home care referral may be indicated and provides the home care nurse with the opportunity to assess the patient's physical and psychological status and the patient's and family's ability to adhere to recommended management strategies. During the home visit, the nurse determines whether changes in neurologic function have occurred. The patient's respiratory status and nutritional status are assessed. The adequacy of pain management is assessed, and modifications are made to ensure adequate pain relief. The need for hospice services or placement in an extended-care facility is discussed with the patient and family if warranted, and the patient is asked about preferences for end-of-life care. Additionally, social workers may be consulted to assist the patient and family members in identifying support groups and agencies that can provide help in coping with the disease process.

DEGENERATIVE DISORDERS

Disorders of the central and peripheral nervous system that are **neurodegenerative** (leading to deterioration of normal cells or function of the nervous system) are characterized by the slow onset of signs and symptoms. Patients are managed

at home for as long as possible and are admitted to the acute care setting for exacerbations, treatments, and surgical interventions as needed.

Parkinson's Disease

Parkinson's disease is a slowly progressing neurologic movement disorder that eventually leads to disability. It is the fourth most common neurodegenerative disease, and 50,000 new cases are reported each year in the United States (Chen & Fernandez, 2007; Thomure, 2006). The disease affects men more often than women. Symptoms usually first appear in the fifth decade of life; however, cases have been diagnosed as early as 30 years of age.

The degenerative or idiopathic form of Parkinson's disease is the most common; there is also a secondary form with a known or suspected cause. Although the cause of most cases is unknown, research suggests several causative factors, including genetics, atherosclerosis, excessive accumulation of oxygen free radicals, viral infections, head trauma, chronic use of antipsychotic medications, and some environmental exposures.

Pathophysiology

Parkinson's disease is associated with decreased levels of dopamine resulting from destruction of pigmented neuronal cells in the substantia nigra in the basal ganglia region of the brain (Fig. 65-4). Fibers or neuronal pathways project from the substantia nigra to the corpus striatum, where neurotransmitters are key to the control of complex body movements. Through the neurotransmitters acetylcholine (excitatory) and dopamine (inhibitory), striatal neurons relay messages to the higher motor centers that control and refine motor movements. The loss of dopamine stores in this area of the brain results in more excitatory neurotransmitters than inhibitory neurotransmitters, leading to an imbalance that affects voluntary movement.

Clinical symptoms do not appear until 60% of the pigmented neurons are lost and the striatal dopamine level is decreased by 80%. Cellular degeneration impairs the extrapyramidal tracts that control semiautomatic functions and coordinated movements; motor cells of the motor cortex and the pyramidal tracts are not affected. Researchers are working on uncovering the exact mechanism of neurodegeneration; current theories suggest that it results from oxidative stress in a portion of the neuron known as Lewy bodies, protein aggregation, or a combination of the two mechanisms (Barker & Barasi, 2008).

Clinical Manifestations

Parkinson's disease has a gradual onset, and symptoms progress slowly over a chronic, prolonged course. The cardinal signs are tremor, rigidity, **bradykinesia** (abnormally slow movements), and postural instability (Chen & Fernandez, 2007; Thomure, 2006).

Tremor

Although symptoms are variable, a slow, unilateral resting tremor is present in the majority of patients at the time of diagnosis (Chen & Fernandez, 2007). Resting tremor

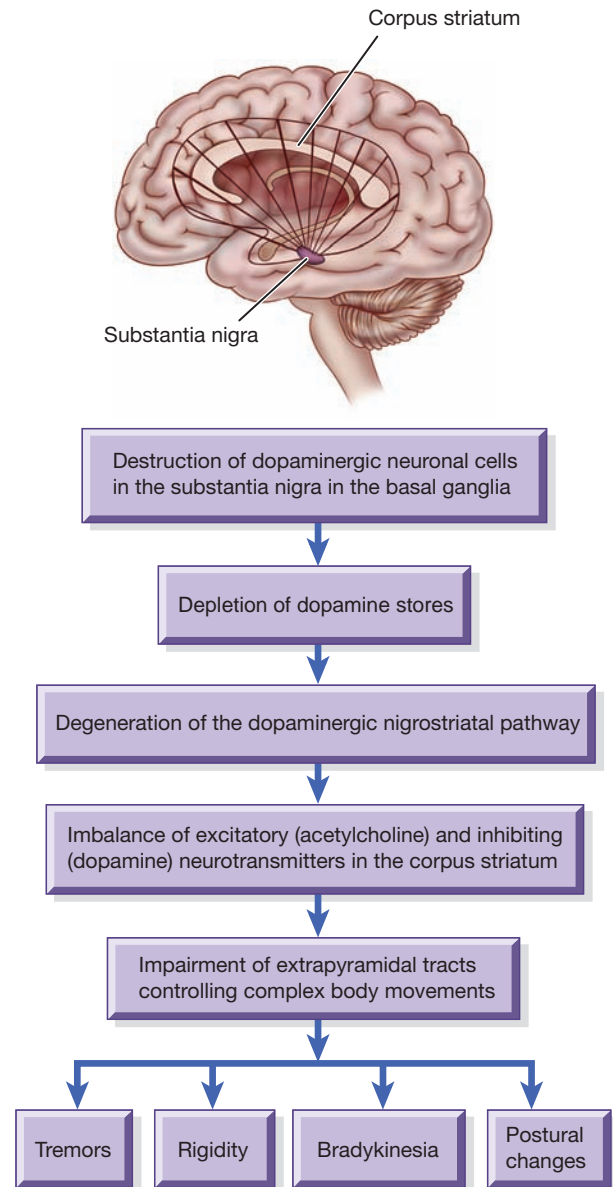

Figure 65-4 Pathophysiology of Parkinson's disease. The nuclei in the substantia nigra project fibers to the corpus striatum. The nerve fibers carry dopamine to the corpus striatum. The loss of dopamine nerve cells from the brain's substantia nigra is thought to be responsible for the symptoms of parkinsonism.

characteristically disappears with purposeful movement but is evident when the extremities are motionless. The tremor may manifest as a rhythmic, slow turning motion (pronation–supination) of the forearm and the hand and a motion of the thumb against the fingers as if rolling a pill between the fingers. Tremor is present while the patient is at rest; it increases when the patient is walking, concentrating, or feeling anxious.

Rigidity

Resistance to passive limb movement characterizes muscle rigidity. Passive movement of an extremity may cause the limb to move in jerky increments, referred to as lead-pipe or cog-wheel movements (Chen & Fernandez, 2007).

Involuntary stiffness of the passive extremity increases when another extremity is engaged in voluntary active movement. Stiffness of the arms, legs, face, and posture are common. Early in the disease, the patient may complain of shoulder pain due to rigidity.

Bradykinesia

One of the most common features of Parkinson's disease is bradykinesia, which refers to the overall slowing of active movement (Chen & Fernandez, 2007; Thomure, 2006). Patients may also take longer to complete activities and have difficulty initiating movement, such as rising from a sitting position or turning in bed.

Postural Instability

The patient commonly develops postural and gait problems. A loss of postural reflexes occurs, and the patient stands with the head bent forward and walks with a propulsive gait. The posture is caused by the forward flexion of the neck, hips, knees, and elbows. The patient may walk faster and faster, trying to move the feet forward under the body's center of gravity (shuffling gait). Difficulty in pivoting causes loss of balance (either forward or backward). Gait impairment and postural instability place the patient at increased risk for falls (Sadowski, Jones, Gordon, et al., 2007).

Other Manifestations

The effect of Parkinson's disease on the basal ganglia often produces autonomic symptoms that include excessive and uncontrolled sweating, paroxysmal flushing, orthostatic hypotension, gastric and urinary retention, constipation, and sexual dysfunction (Miller, 2009). Psychiatric changes include depression, **dementia** (progressive mental deterioration), delirium, and hallucinations. Depression is common; whether it is a reaction to the disorder or is related to a biochemical abnormality is uncertain. Mental changes may appear in the form of cognitive, perceptual, and memory deficits, although intellect is not usually affected. A number of psychiatric manifestations (personality changes, psychosis, dementia, and acute confusion) are common in elderly patients with Parkinson's disease. Dementia affects up to 75% of patients over the course of the disease (Weintraub & Hurtig, 2007). In addition, auditory and visual hallucinations have been reported in up to 40% of people with Parkinson's disease and may be associated with depression, dementia, lack of sleep, or adverse effects of medications.

Hypokinesia (abnormally diminished movement) is also common and may appear after the tremor. The freezing phenomenon refers to a transient inability to perform active movement and is thought to be an extreme form of bradykinesia. Additionally, the patient tends to shuffle and exhibits a decreased arm swing. As dexterity declines, **micrographia** (small handwriting) develops. The face becomes increasingly masklike and expressionless, and the frequency of blinking decreases. **Dysphonia** (soft, slurred, low-pitched, and less audible speech) may occur as a result of weakness and incoordination of the muscles responsible for speech. In many cases, the patient develops dysphagia, begins to drool, and is at risk for choking and aspiration.

Complications associated with Parkinson's disease are common and are typically related to disorders of movement.

As the disease progresses, patients are at risk for respiratory and urinary tract infection, skin breakdown, and injury from falls. The adverse effects of medications used to treat the symptoms are associated with numerous complications such as dyskinesia or orthostatic hypotension (Karch, 2008).

Assessment and Diagnostic Findings

Although laboratory tests and imaging studies are not helpful to the clinician in diagnosing Parkinson's disease, ongoing research with PET and single photon emission computed tomography (SPECT) scanning has been helpful in understanding the disease and advancing treatment. Currently, the disease is diagnosed clinically from the patient's history and the presence of two of the four cardinal manifestations: tremor, rigidity, bradykinesia, and postural changes.

Early diagnosis can be difficult because patients rarely are able to pinpoint when the symptoms started. Often, a family member notices a change such as stooped posture, a stiff arm, a slight limp, tremor, or slow, small handwriting. The medical history, presenting symptoms, neurologic examination, and response to pharmacologic management are carefully evaluated when making the diagnosis (Thomure, 2006).

Medical Management

Treatment is directed at controlling symptoms and maintaining functional independence, because no medical or surgical approaches in current use prevent disease progression. Care is individualized for each patient based on presenting symptoms and social, occupational, and emotional needs. Pharmacologic management is the mainstay of treatment, although advances in research have led to increased surgical options. Patients are usually cared for at home and are admitted to the hospital only for complications or to initiate new treatments.

Pharmacologic Therapy

Antiparkinsonian medications act by (1) increasing striatal dopaminergic activity; (2) reducing the excessive influence of excitatory cholinergic neurons on the extrapyramidal tract, thereby restoring a balance between dopaminergic and cholinergic activities; or (3) acting on neurotransmitter pathways other than the dopaminergic pathway.

Levodopa (Larodopa) is the most effective agent and the mainstay of treatment. Levodopa is converted to dopamine in the basal ganglia, producing symptom relief. Levodopa is available in three forms: immediate-release, orally disintegrating, and sustained-release tablets (Halkias, Haq, Huang, et al., 2007). The beneficial effects of levodopa are most pronounced in the first few years of treatment. Benefits begin to wane and adverse effects become more severe over time. Confusion, hallucinations, depression, and sleep alterations are associated with prolonged use.

Within 5 to 10 years, most patients develop a response to the medication characterized by **dyskinesia** (abnormal involuntary movements), including facial grimacing, rhythmic jerking movements of the hands, head bobbing, chewing and smacking movements, and involuntary movements of the trunk and extremities. The patient may experience an

on-off syndrome in which sudden periods of near immobility (“off effect”) are followed by a sudden return of effectiveness of the medication (“on effect”). Various adjunctive therapies are used to minimize dyskinesias (Chen & Fernandez, 2007). Another potential complication of long-term dopaminergic medication use is neuroleptic malignant syndrome, which is characterized by severe rigidity, stupor, and hyperthermia (Ward, 2005). Additional medications used to treat Parkinson’s disease are described in Table 65-1.

Surgical Management

The limitations of levodopa therapy, improvements in stereotactic surgery, and new approaches in transplantation have renewed interest in the surgical treatment of Parkinson’s disease. In patients with disabling tremor, rigidity, or severe levodopa-induced dyskinesia, surgery may be considered. Although surgery provides symptom relief in selected patients, it has not been shown to alter the course of the disease or to produce permanent improvement.

Stereotactic Procedures

Thalamotomy and pallidotomy are effective in relieving many of the symptoms of Parkinson’s disease (Rowland, 2005). Patients eligible for these procedures are those who have had an inadequate response to medical therapy; they must meet strict criteria to be eligible. Candidates eligible for these procedures are patients with idiopathic Parkinson’s disease who are taking maximum doses of antiparkinsonian medications. Patients with dementia and atypical Parkinson’s disease are usually not considered for stereotactic procedures. Parkinson’s disease rating scales and specific neurologic tests are used to identify eligible patients.

The intent of thalamotomy and pallidotomy is to interrupt the nerve pathways and thereby alleviate tremor or rigidity. During thalamotomy, a stereotactic electrical stimulator destroys part of the ventrolateral portion of the thalamus in an attempt to reduce tremor; the most common complications are ataxia and hemiparesis. Pallidotomy involves destruction of part of the ventral aspect of the medial globus

Table 65-1 SUMMARY OF MEDICATIONS USED TO TREAT PARKINSON’S DISEASE

Medications	Indications and Therapeutic Effects	Common Side Effects
Anticholinergic Agents Trihexyphenidyl hydrochloride (Apo-Trihex) Benztropine mesylate (Cogentin)	Control of tremor and rigidity Counteract the action of acetylcholine	Blurred vision, flushing, rash, constipation, urinary retention, and acute confusional states Contraindicated in patients with narrow-angle glaucoma
Antiviral Agents Amantadine hydrochloride (Symmetrel)	Reduce rigidity, tremor, bradykinesia, and postural changes in early Parkinson’s disease	Psychiatric disturbances (mood changes, confusion, depression, hallucinations), lower extremity edema, nausea, epigastric distress, urinary retention, headache, and visual impairment
Dopamine Agonists Bromocriptine mesylate (Parlodel) Pergolide (Permax)	Early Parkinson’s disease as well as secondary drug therapy after carbidopa or levodopa loses effectiveness	Nausea, vomiting, diarrhea, lightheadedness, hypotension, impotence, and psychiatric effects
Nonergot Derivatives Ropinirole hydrochloride (Requip) Pramipexole (Mirapex)	Early stages of Parkinson’s disease	May cause drowsiness or dizziness
Monoamine Oxidase Inhibitors Selegiline (Eldepryl) Rasagiline (Azilect)	Inhibit dopamine breakdown	Can cause hypertensive crisis
Catechol-O-Methyltransferase Inhibitors Entacapone (Comtan) Tolcapone (Tasmar)	Increase the duration of action of carbidopa or levodopa Reduce motor fluctuations in patients with advanced Parkinson’s disease	
Antidepressants Tricyclic Antidepressants Amitriptyline hydrochloride (Elavil)	Anticholinergic and antidepressant	Hypertension, insomnia, dry mouth
Serotonin Reuptake Inhibitors Fluoxetine hydrochloride (Prozac) Bupropion hydrochloride (Wellbutrin)	Antidepressant	Clinical worsening and suicide risk
Antihistamines Diphenhydramine hydrochloride (Benadryl) Orphenadrine citrate (Banflex) Phenindamine hydrochloride (Neo-Synephrine)	May reduce tremors	Anticholinergic and sedative effects

Figure 65-5 A stereotactic frame is applied to a patient's head in preparation for pallidotomy. The frame immobilizes the head.

pallidus through electrical stimulation in patients with advanced disease. The procedure is effective in reducing rigidity, bradykinesia, and dyskinesia, thus improving motor function and ADLs in the immediate postoperative course. Potential complications include hemiparesis and stroke, as well as cognitive, speech, swallowing, and visual changes.

A CT scan, x-ray, MRI scan, or angiogram is used to localize the appropriate surgical site in the brain. Then the patient's head is positioned in a stereotactic frame (Fig. 65-5). After the surgeon makes an incision in the skin and a burr hole, an electrode is passed through to the target area in the thalamus or globus pallidum. The desired response of the patient to the electrical stimulation (ie, a decrease in rigidity) is the basis for the selection of the area of the brain to be destroyed. Stereotactic procedures are completed on one side of the brain at a time. If rigidity or tremor is bilateral, a 6-month interval is suggested between procedures.

Neural Transplantation

Ongoing research is exploring transplantation of porcine neuronal cells, human fetal cells, and stem cells (Rowland, 2005). Legal, ethical, and political concerns surrounding the use of fetal brain cells and stem cells have limited the implementation of these procedures.

Deep Brain Stimulation

Pacemakerlike brain implants are used to relieve tremors (Rowland, 2005). The stimulation can be bilateral or unilateral; bilateral stimulation of the subthalamic nucleus is thought to be of greater benefit to patients than results achieved with thalamotomy, pallidotomy, or fetal nigral transplantation. In deep brain stimulation, an electrode is placed in the thalamus and connected to a pulse generator that is implanted in a subcutaneous subclavicular or abdominal pouch. The battery-powered pulse generator sends high-frequency electrical impulses through a wire placed under the skin to a lead anchored to the skull (Fig. 65-6). The electrode blocks nerve pathways in the brain that cause tremors. These devices are not without complications that can result from both the surgical procedure needed for implantation and the device itself (eg, lead leakage) (Stewart, Desaloms & Sanghera, 2005).

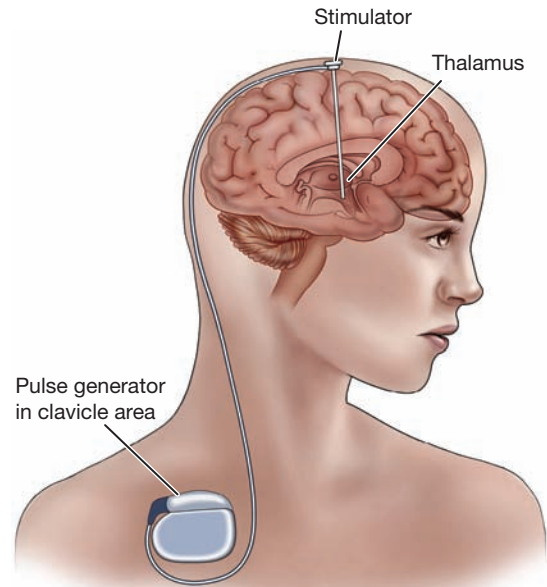

Figure 65-6 Deep brain stimulation is provided by a pulse generator surgically implanted in a pouch beneath the clavicle. The generator sends high-frequency electrical impulses to the thalamus, thereby blocking the nerve pathways associated with tremors in Parkinson's disease.

NURSING PROCESS

THE PATIENT WITH PARKINSON'S DISEASE

Assessment

Assessment focuses on how the disease has affected the patient's ADLs and functional abilities. The patient is observed for degree of disability and functional changes that occur throughout the day, such as responses to medication. Almost every patient with a movement disorder has some functional alteration and may have some type of behavioral dysfunction. The following questions may be useful to assess alterations:

- Do you have leg or arm stiffness?
- Have you experienced any irregular jerking of your arms or legs?
- Have you ever been "frozen" or rooted to the spot and unable to move?
- Does your mouth water excessively? Have you (or others) noticed yourself grimacing or making faces or chewing movements?
- What specific activities do you have difficulty doing?

During this assessment, the nurse observes the patient for quality of speech, loss of facial expression, swallowing deficits (drooling, poor head control, coughing), tremors, slowness of movement, weakness, forward posture, rigidity, evidence of mental slowness, and confusion. Parkinson's disease symptoms, as well as side effects of medications, put these patients at high risk for falls; therefore, a fall risk assessment should be conducted (Sadowski, et al., 2007).

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Impaired physical mobility related to muscle rigidity and motor weakness
- Self-care deficits (feeding, dressing, hygiene, and toileting) related to tremor and motor disturbance
- Constipation related to medication and reduced activity
- Imbalanced nutrition, less than body requirements, related to tremor, slowness in eating, difficulty in chewing and swallowing
- Impaired verbal communication related to decreased speech volume, slowness of speech, inability to move facial muscles
- Ineffective coping related to depression and dysfunction due to disease progression

Other nursing diagnoses may include sleep pattern disturbances, deficient knowledge, risk for injury, risk for activity intolerance, disturbed thought processes, and compromised family coping.

Planning and Goals

The goals for the patient may include improving functional mobility, maintaining independence in ADLs, achieving adequate bowel elimination, attaining and maintaining acceptable nutritional status, achieving effective communication, and developing positive coping mechanisms.

Nursing Interventions

Improving Mobility

A progressive program of daily exercise will increase muscle strength, improve coordination and dexterity, reduce muscular rigidity, and prevent contractures that occur when muscles are not used. Walking, riding a stationary bicycle, swimming, and gardening are all exercises that help maintain joint mobility. Stretching (stretch–hold–relax) and range-of-motion exercises promote joint flexibility. Postural exercises are important to counter the tendency of the head and neck to be drawn forward and down. A physical therapist may be helpful in developing an individualized exercise program and can provide instruction to the patient and caregiver on exercising safely. Faithful adherence to an exercise and walking program helps delay the progress of the disease. Warm baths and massage, in addition to passive and active exercises, help relax muscles and relieve painful muscle spasms that accompany rigidity.

Balance may be adversely affected because of the rigidity of the arms (arm swinging is necessary in normal walking). Special walking techniques must be learned to offset the shuffling gait and the tendency to lean forward. The patient is taught to concentrate on walking erect, to watch the horizon, and to use a wide-based gait (ie, walking with the feet separated). A conscious effort must be made to swing the arms, raise the feet while walking, and use a heel–toe placement of the feet with long strides. The patient is advised to practice walking to marching music or to the sound of a ticking metronome, because this provides sensory rein-

forcement. Performing breathing exercises while walking helps move the rib cage and aerate parts of the lungs. Frequent rest periods aid in preventing frustration and fatigue.

Enhancing Self-Care Activities

Encouraging, teaching, and supporting the patient during ADLs promote self-care (Stewart, et al., 2005). See Chapter 11 for rehabilitation techniques.

Environmental modifications are necessary to compensate for functional disabilities. Patients may have severe mobility problems that make normal activities impossible. Adaptive or assistive devices may be useful. A hospital bed at home with bedside rails, an overbed frame with a trapeze, or a rope tied to the foot of the bed can provide assistance in pulling up without help. An occupational therapist can evaluate the patient's needs in the home, make recommendations regarding adaptive devices, and teach the patient and caregiver how to improvise.

Improving Bowel Elimination

The patient may have severe problems with constipation. Among the factors causing constipation are weakness of the muscles used in defecation, lack of exercise, inadequate fluid intake, and decreased autonomic nervous system activity. The medications used for the treatment of the disease also inhibit normal intestinal secretions. A regular bowel routine may be established by encouraging the patient to follow a regular time pattern, consciously increase fluid intake, and eat foods with moderate fiber content. Laxatives should be avoided. Psyllium (Metamucil), for example, decreases constipation but carries the risk of bowel obstruction (Karch, 2008). A raised toilet seat is useful, because the patient has difficulty in moving from a standing to a sitting position.

Improving Nutrition

Patients may have difficulty maintaining their weight. Eating becomes a very slow process, requiring concentration due to a dry mouth from medications and difficulty chewing and swallowing. These patients are at risk for aspiration because of impaired swallowing and the accumulation of saliva. They may be unaware that they are aspirating; subsequently, bronchopneumonia may develop.

Monitoring weight on a weekly basis indicates whether caloric intake is adequate. Supplemental feedings increase caloric intake. As the disease progresses, a nasogastric tube or percutaneous endoscopic gastroscopy may be necessary to maintain adequate nutrition. A dietitian can be consulted regarding nutritional needs.

Enhancing Swallowing

Swallowing difficulties and choking are common in Parkinson's disease (Chen & Fernandez, 2007). These can lead to problems with poor head control, tongue tremor, hesitancy in initiating swallowing, difficulty in shaping food into a bolus, and disturbances in pharyngeal motility. To offset these problems, the patient should sit in an upright position during mealtime. A semisolid diet with thick liquids is easier to swallow than solids; thin liquids should be avoided. Thinking through the swallowing sequence is helpful. The patient is taught to place the food on the tongue, close the lips and

teeth, lift the tongue up and then back, and swallow. The patient is encouraged to chew first on one side of the mouth and then on the other. To control the buildup of saliva, the patient is reminded to hold the head upright and make a conscious effort to swallow. Massaging the facial and neck muscles before meals may be beneficial.

Encouraging the Use of Assistive Devices

An electric warming tray keeps food hot and allows the patient to rest during the prolonged time that it may take to eat. Special utensils also assist at mealtime. A plate that is stabilized, a nonspill cup, and eating utensils with built-up handles are useful self-help devices. The occupational therapist can assist in identifying appropriate adaptive devices.

Improving Communication

Speech disorders are present in most patients with Parkinson's disease. The low-pitched, monotonous, soft speech of patients requires that they make a conscious effort to speak slowly, with deliberate attention to what they are saying. The patient is reminded to face the listener, exaggerate the pronunciation of words, speak in short sentences, and take a few deep breaths before speaking. A speech therapist may be helpful in designing speech improvement exercises and assisting the family and health care personnel to develop and use a method of communication that meets the patient's needs. A small electronic amplifier is helpful if the patient has difficulty being heard.

Supporting Coping Abilities

Support can be given by encouraging the patient and pointing out that activities will be maintained through active participation. A combination of physiotherapy, psychotherapy, medication therapy, and support group participation may help reduce the depression that often occurs. Patients with Parkinson's disease can become withdrawn. It is best if patients are active participants in their therapeutic program, including social and recreational events. A planned program of activity throughout the day prevents too much daytime sleeping as well as disinterest and apathy.

Patients often feel embarrassed, apathetic, inadequate, bored, and lonely. In part, these feelings may result from physical slowness and the great effort that even small tasks require. The patient is assisted and encouraged to set achievable goals (eg, improvement of mobility). Every effort should be made to encourage patients to carry out the tasks involved in meeting their own daily needs and to remain independent. Doing things for the patient merely to save time undermines the basic goal of improving coping abilities and promoting a positive self-concept.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patient and family education is important in the management of Parkinson's disease. Teaching needs depend on the severity of symptoms and the stage of the disease. Care must be taken not to overwhelm the patient and family with too much information early in the disease process. The patient's and family's need for information is ongoing as adaptations become necessary. The education plan should include a clear explanation of the disease and the goal of assisting the patient to re-

main functionally independent as long as possible. Every effort is made to explain the nature of the disease and its management to offset disabling anxieties and fears. The patient and family must be taught about the effects and side effects of medications and about the importance of reporting side effects to the physician (Chart 65-4).

CONTINUING CARE. In the early stages, the patient can be managed well at home. Family members often serve as caregivers, with home care or community services available to assist in meeting health care needs as the disease progresses. The family caregiver may be under considerable stress from living with and caring for a person with a significant disability. Providing information about treatment and care prevents many unnecessary problems. The caregiver is included in the plan and may be advised to learn stress reduction techniques, to include others in the caregiving process, to obtain periodic relief from responsibilities, and to have a yearly health assessment. Allowing family members to express feelings of frustration, anger, and guilt is often helpful to them.

The patient should be evaluated in the home for adaptation and safety needs and compliance with the plan of care. In the advanced stages, patients usually enter long-term care facilities if family support is absent. Periodically, admission to an acute care facility may be necessary for changes in medical management or treatment of complications. Nurses provide support, education, and monitoring of patients over the course of the illness.

The nurse involved in home and continuing care needs to remind the patient and family members of the importance of addressing health promotion needs such as screening for hypertension and stroke risk assessments in this predominantly elderly population. Patients are taught about the importance of these activities and are referred to appropriate health care providers. Informational booklets and a newsletter for patient education are published by the National Parkinson's Foundation, Inc., and the American Parkinson's Disease Association (see Resources).

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Strives toward improved mobility
 - a. Participates in exercise program daily
 - b. Walks with wide base of support; exaggerates arm swinging when walking
 - c. Takes medications as prescribed
2. Progresses toward self-care
 - a. Allows time for self-care activities
 - b. Uses self-help devices
3. Maintains bowel function
 - a. Consumes adequate fluid
 - b. Increases dietary intake of fiber
 - c. Reports regular pattern of bowel function
4. Attains improved nutritional status
 - a. Swallows without aspiration
 - b. Takes time while eating
5. Achieves a method of communication
 - a. Communicates needs
 - b. Practices speech exercises

CHART

HOME CARE CHECKLIST

The Patient With Parkinson's Disease

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Define Parkinson's disease and discuss its long-term effects.	✓	✓
• Identify the medication regimen and name adverse effects, and precautions.	✓	✓
• Discuss the risk for injury; prevent falls; implement adaptive measures in the home.	✓	✓
• Describe nutritional needs, dietary restrictions, dysphagia management, and ways to prevent aspiration.	✓	✓
• Manage constipation: fluid intake, bowel routine.	✓	✓
• Manage urinary problems: functional incontinence, retention (indwelling urinary catheter care, suprapubic catheter care).	✓	✓
• Explain effects of immobility and define preventive care: skin breakdown (frequent turning, pressure release, skin care), pneumonia (deep breathing, movement), contractures (range-of-motion exercises).	✓	✓
• Define benefits of daily exercise program.	✓	✓
• Walk and balance safely.	✓	
• Demonstrate speech and communication skills: speech exercises, communication techniques, breathing exercises.	✓	
• Name signs and symptoms of infection (urinary and respiratory) and state when health care provider should be notified.	✓	✓
• Describe strategies to promote self-care activities and independence.	✓	✓
• Identify resources: American Parkinson's Disease Association, National Parkinson's Disease Foundation, and local support groups.	✓	✓

6. Copes with effects of Parkinson's disease
 - a. Sets realistic goals
 - b. Demonstrates persistence in meaningful activities
 - c. Verbalizes feelings to appropriate person

Huntington Disease

Huntington disease is a chronic, progressive, hereditary disease of the nervous system that results in progressive involuntary choreiform movement and dementia. The disease affects approximately 1 in 10,000 men or women of all races at midlife. It is transmitted as an autosomal dominant genetic disorder; therefore, each child of a parent with Huntington disease has a 50% risk of inheriting the disorder (Skirton, 2005).

A genetic marker for Huntington disease has been identified. Researchers can identify people who will develop this disease. However, genetic testing offers no hope of cure or even specific prediction of the timing of disease onset. Even though the gene was mapped in 1983 and presymptomatic testing has been offered since 1986, many patients choose not to be tested. For most people, the benefits of testing are unclear because of ethical issues and concerns about confidentiality. Genetic counseling is crucial after testing, and patients and their families may require long-term psychological counseling and emotional, financial, and legal

support. People of childbearing age with a family history of Huntington disease often seek information about their risk of disease transmission.

Pathophysiology

The basic pathology involves premature death of cells in the striatum (caudate and putamen) of the basal ganglia, the region deep within the brain that is involved in the control of movement. Cells also are lost in the cortex, the region of the brain associated with thinking, memory, perception, and judgment, and in the cerebellum, the area that coordinates voluntary muscle activity. Why the protein destroys only certain brain cells is unknown, but several theories have been proposed to explain the phenomenon (Barker & Barasi, 2008; Skirton, 2005). One possible theory is that a building block for protein called glutamine abnormally collects in the cell nucleus, causing cell death (Walker, 2007).

Clinical Manifestations

The most prominent clinical features of the disease are **chorea** (abnormal involuntary movements), intellectual decline, and, often, emotional disturbance (Bickley, 2007; Walker, 2007). As the disease progresses, a constant writhing, twisting, uncontrollable movement may involve the entire body. These motions are devoid of purpose or rhythm, although patients may try to turn them into purposeful movement. All of the body musculature is involved. Facial movements produce tics and grimaces. Speech becomes slurred, hesitant, often explosive, and eventually

unintelligible. Chewing and swallowing are difficult, and there is a constant danger of choking and aspiration. Chorea movements persist during sleep but are diminished.

As with speech, the gait becomes disorganized to the point that ambulation eventually is impossible. Although independent ambulation should be encouraged for as long as possible, a wheelchair usually becomes necessary. Eventually, the patient is confined to bed when the chorea interferes with walking, sitting, and all other activities. Bladder and bowel control is lost. Cognitive function is usually affected, with dementia usually occurring. Initially, the patient is aware that the disease is responsible for the myriad dysfunctions that are occurring. The mental and emotional changes that occur may be more devastating to the patient and family than the abnormal movements. Personality changes may result in nervous, irritable, or impatient behaviors. In the early stages, patients are particularly subject to uncontrollable fits of anger; profound, often suicidal depression; apathy; anxiety; psychosis; or euphoria. Judgment and memory are impaired, and dementia eventually ensues. Hallucinations, delusions, and paranoid thinking may precede the appearance of disjointed movements. Emotional and cognitive symptoms often become less acute as the disease progresses (Walker, 2007).

Onset usually occurs between 35 and 45 years of age, although about 10% of patients are children. The disease progresses slowly. Despite a ravenous appetite, patients usually become emaciated and exhausted. Patients succumb in 10 to 20 years to heart failure, pneumonia, or infection, or as a result of a fall or choking.

Assessment and Diagnostic Findings

The diagnosis is made based on the clinical presentation of characteristic symptoms, a positive family history, the known presence of a genetic marker, and exclusion of other causes.

Management

Although no treatment halts or reverses the underlying process, medications may reduce chorea. Thiothixene hydrochloride (Navane) and haloperidol decanoate (Haldol), which predominantly block dopamine receptors, improve the chorea in many patients. Motor signs must be assessed and evaluated on an ongoing basis so that optimal therapeutic drug levels can be reached. **Akathisia** (motor restlessness) in the overmedicated patient is dangerous because it may be mistaken for the restless fidgeting of the illness and consequently may be overlooked. In certain types of the disease, hypokinetic motor impairment resembles Parkinson's disease. In patients who present with rigidity, some temporary benefit may be obtained from antiparkinson medications, such as levodopa (Larodopa).

Patients who have emotional disturbances, particularly depression, may be helped by antidepressant medications. The threat of suicide is present particularly early in the course of the disease (Walker, 2007). Psychotic symptoms usually respond to antipsychotic medications. Psychotherapy aimed at allaying anxiety and reducing stress may be beneficial. Nurses must look beyond the disease to focus on the patient's needs and capabilities (Chart 65-5). Chart 65-6 explores an ethical issue related to end-of-life care for a patient with Huntington disease.

Several new treatments, such as fetal tissue transplantation and the use of growth factor delivered to the basal ganglia region of the brain, are under investigation (Barker & Barasi, 2008; Skirton, 2005).

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The needs of the patient and family for education depend on the nature and severity of the physical, cognitive, and psychological changes experienced by the patient. The patient and family members are taught about the medications prescribed and about signs indicating a need for change in medication or dosage. The teaching plan addresses strategies to manage symptoms such as chorea, swallowing problems, limitations in ambulation, and loss of bowel and bladder function. Consultation with a speech therapist may be indicated to assist in identifying alternative communication strategies if speech is affected.

Continuing Care

A program combining medical, nursing, psychological, social, occupational, speech, and physical rehabilitation services and palliative care is needed to help the patient and family cope with this severely disabling illness (Olson & Cristian, 2005). Huntington disease exacts enormous emotional, physical, social, and financial tolls on every member of the patient's family. The family needs supportive care as they adjust to the impact of the illness (Skirton, 2005; Walker, 2007). Regular follow-up visits help allay the fear of abandonment.

Home care assistance, day care centers, respite care, and eventually skilled long-term care can assist the patient and family in coping with the constant strain of the illness. Although the relentless progression of the disease cannot be halted, families can benefit from supportive care.

Voluntary organizations can be major aids to families and have been largely responsible for bringing the illness to national attention. The Huntington's Disease Foundation of America helps patients and families by providing information, referrals, family and public education, and support for research.

Alzheimer's Disease

Alzheimer's disease, or senile dementia of the Alzheimer's type, is a chronic, progressive, and degenerative brain disorder that is accompanied by profound effects on memory, cognition, and ability for self-care. Approximately 4.5 million people in the United States are affected (Ganzer, 2007). Alzheimer's disease is one of the most feared disorders of modern times because of its catastrophic consequences for the patient, family, and caregivers, who are faced with many crucial end-of-life decisions. Chapter 12 discusses the manifestations, management, and nursing care of the patient with Alzheimer's disease.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a disease of unknown cause in which there is a loss of motor neurons (nerve cells controlling muscles) in the anterior horns of

Chart 65-5 • Care of the Patient With Huntington Disease

Nursing Diagnosis: Risk for injury from falls and possible skin breakdown (pressure ulcers, abrasions), resulting from constant movement

Nursing Interventions

- Pad the sides and head of the bed; ensure that the patient can see over the sides of bed.
- Use padded heel and elbow protectors.
- Keep the skin meticulously clean.
- Apply emollient cleansing agent and skin lotion as needed.
- Use soft sheets and bedding.
- Have patient wear football padding or other forms of padding.
- Encourage ambulation with assistance to maintain muscle tone.
- Secure the patient (only if necessary) in bed or chair with padded protective devices, making sure that they are loosened frequently.

Nursing Diagnosis: Imbalanced nutrition, less than body requirements, due to inadequate intake and dehydration resulting from swallowing or chewing disorders and danger of choking or aspirating food

Nursing Interventions

- Administer phenothiazines as prescribed before meals (appears to calm some patients).
- Talk to the patient before mealtime to promote relaxation; use mealtime for social interaction. Provide undivided attention and help the patient enjoy the mealtime experience.
- Use a warming tray to keep food warm.
- Learn the position that is best for *this* patient. Keep patient as close to upright as possible while feeding. Stabilize patient's head gently with one hand while feeding.
- Show the food and explain what the foods are (eg, whether hot or cold).
- Encircle the patient with one arm and get as close as possible to provide stability and support while feeding. Use pillows and wedges for additional support.
- Do not interpret stiffness, turning away, or sudden turning of the head as rejection; these are uncontrollable choreiform movements.
- For feeding, use a long-handled spoon (iced-tea spoon). Place spoon on middle of tongue and exert slight pressure.
- Place bite-sized food between patient's teeth. Serve stews, casseroles, and thick liquids.
- Disregard messiness and treat the person with dignity.

Wait for the patient to chew and swallow before introducing another spoonful. Make sure that bite-sized food is small. Give between-meal feedings. Constant movement expends more calories. Patients often have voracious appetites, particularly for sweets.

Use blenderized meals if patient cannot chew; do not repeatedly give the same strained baby foods; gradually introduce increased textures and consistencies to the diet. For swallowing difficulties:

- Apply gentle deep pressure around the patient's mouth.
- Rub fingers in circles on the patient's cheeks and then down each side of the patient's throat.

Develop skill in Heimlich maneuver (to be used in the event of choking).

Nursing Diagnosis: Anxiety and impaired communication from excessive grimacing and unintelligible speech

Nursing Interventions

- Read to the patient.
- Employ biofeedback and relaxation therapy to reduce stress.
- Consult with speech therapist to help maintain and prolong communication abilities.
- Try to devise a communication system, perhaps using cards with words or pictures of familiar objects, before verbal communication becomes too difficult. Patients can indicate correct card by hitting it with hand, grunting, or blinking the eyes.
- Learn how this particular patient expresses needs and wants—particularly nonverbal messages (widening of eyes, responses).
- Patients can understand even if unable to speak. Do not isolate patients by ceasing to communicate with them.

Nursing Diagnosis: Disturbed thought processes and impaired social interaction

Nursing Interventions

- Reorient the patient after awakening.
- Have clock, calendar, and wall posters in view to assist in orientation.
- Use every opportunity for one-to-one contact.
- Use music for relaxation.
- Have the patient wear a medical identification bracelet.
- Keep the patient in the social mainstream.
- Recruit and train volunteers for social interaction. Role-model appropriate and creative interactions.
- Do not abandon a patient because the disease is eventually terminal. Patients are *living* until the end.

the spinal cord and the motor nuclei of the lower brain stem. It is often referred to as Lou Gehrig's disease after the famous baseball player who suffered from the disease. As motor neuron cells die, the muscle fibers that they supply undergo atrophic changes. Neuronal degeneration may occur in both the upper and lower motor neuron systems (see Chapter 60). The leading theory held by researchers is that overexcitation of nerve cells by the neurotransmitter glutamate results in cell injury and neuronal degeneration. Possible causes of ALS include autoimmune disease, free radical damage, and oxidative stress. In 5% to 10% of cases the cause is transmission of an autosomal dominant trait for familial ALS (Runge & Patterson, 2006; Tiwari, Xu &

Hayward, 2005). Several risk factors have been identified, but the exact cause is still unknown (Gal, Strom, Kilty, et al., 2007; Tiwari, et al., 2005).

Clinical Manifestations

Clinical manifestations depend on the location of the affected motor neurons, because specific neurons activate specific muscle fibers. The chief symptoms are fatigue, progressive muscle weakness, cramps, fasciculations (twitching), and incoordination. Loss of motor neurons in the anterior horns of the spinal cord results in progressive weakness and atrophy of the muscles of the arms, trunk, or legs. Spasticity usually is present, and the deep tendon stretch reflexes

Ethics and Related Issues

What Constitutes Assisted Suicide?

Situation

A 65-year-old man is admitted to the hospital with Huntington disease. He is in respiratory distress and near death and he is unable to communicate his wishes. The family state that they want no heroic measures, and the physician writes a “do not resuscitate” order on the chart.

Dilemma

The principle of beneficence and the nurse’s duty to provide care conflict with the principle of respect for the person and the patient’s right to death with dignity.

Discussion

1. Is the “do not resuscitate” order an act of assisted suicide?
2. Is it active or passive euthanasia? What is the nurse’s role in caring for the patient if this action conflicts with his or her personal beliefs?
3. If no other nurse is available to provide care, does the nurse on duty have the right to refuse to provide care? Is this patient abandonment?

become brisk and overactive. Usually, the function of the anal and bladder sphincters remains intact, because the spinal nerves that control muscles of the rectum and urinary bladder are not affected.

In about 25% of patients, weakness starts in the muscles supplied by the cranial nerves, and difficulty in talking, swallowing, and ultimately breathing occurs. When the patient ingests liquids, soft palate and upper esophageal weakness causes the liquid to be regurgitated through the nose. Weakness of the posterior tongue and palate impairs the ability to laugh, cough, or even blow the nose. If bulbar muscles are impaired, speaking and swallowing are progressively difficult, and aspiration becomes a risk. The voice assumes a nasal sound, and articulation becomes so disrupted that speech is unintelligible. Some emotional lability may be present. It was traditionally believed that ALS spared cognitive function, but it is now recognized that some patients experience cognitive impairment.

The prognosis generally is based on the area of CNS involvement and the speed with which the disease progresses. Eventually, respiratory function is compromised. Death usually occurs as a result of infection, respiratory failure, or aspiration.

Assessment and Diagnostic Findings

ALS is diagnosed on the basis of the signs and symptoms, because no clinical or laboratory tests are specific for this disease. Electromyography and muscle biopsy studies of the affected muscles indicate reduction in the number of functioning motor units. An MRI scan may show high signal intensity in the corticospinal tracts; this differentiates ALS from a multifocal motor neuropathy. Neuropsychological testing can assist in assessment and diagnosis (Phukan, Pender & Hardiman, 2007).

Management

No specific therapy exists for ALS. The main focus of medical and nursing management is on interventions to maintain or improve function, well-being, and quality of life. The average survival time is 3 to 5 years with death due, most commonly, to respiratory insufficiency (Tiware, et al., 2005).

The medication riluzole (Rilutek), a glutamate antagonist, is the only medication with U.S. Food and Drug Administration approval for treatment of ALS (Hickey, 2009). The action of riluzole is not clear, but its pharmacologic properties suggest that it may have a neuroprotective effect in the early stages of ALS. Symptomatic treatment and rehabilitative measures are used to support the patient and improve the quality of life. Baclofen (Lioresal), dantrolene sodium (Dantrium), or diazepam (Valium) may be useful for patients troubled by spasticity, which causes pain and interferes with self-care. Research evaluating the effect of ceftriaxone sodium (Rocephin) found that it slows the course of the disease in animals, but it has not yet been tested in humans (Brown, 2005).

Most patients with ALS are managed at home and in the community, with hospitalization for acute problems. The most common reasons for hospitalization are dehydration and malnutrition, pneumonia, and respiratory failure; recognizing these problems at an early stage in the illness allows for the development of preventive strategies. End-of-life issues include pain, dyspnea, and delirium (Olson & Cristian, 2005).

Mechanical ventilation (using negative-pressure ventilators) is an option if alveolar hypoventilation develops. Noninvasive positive-pressure ventilation is also an option. The use of noninvasive positive-pressure ventilation is particularly helpful at night and postpones the decision about whether to undergo a tracheotomy for long-term mechanical ventilation.

A patient experiencing aspiration and swallowing may require enteral feeding. A percutaneous endoscopic gastrostomy tube is inserted before the forced vital capacity drops below 50% of the predicted value. The tube can be safely placed in patients who are using noninvasive positive-pressure ventilation for ventilatory support (Hickey, 2009).

Decisions about life support measures are made by the patient and family and should be based on a thorough understanding of the disease, the prognosis, and the implications of initiating such therapy. Patients are encouraged to complete an advance directive or “living will” to preserve their autonomy in decision making. See Chapter 17 for additional discussion of end-of-life care.

The Amyotrophic Lateral Sclerosis Association has broad programs of research funding, patient and clinical services, patient information and support, and medical and public information. The *ALS Association Quarterly Newsletter* is a source of practical information (see Resources).

Muscular Dystrophies

The muscular dystrophies are a group of incurable muscle disorders characterized by progressive weakening and wasting of the skeletal or voluntary muscles. Most of these diseases are inherited. Duchenne muscular dystrophy, the most common type, occurs in 1 of every 3500 male births

(Rowland, 2005). The pathologic features include degeneration and loss of muscle fibers, variation in muscle fiber size, phagocytosis and regeneration, and replacement of muscle tissue by connective tissue. The common characteristics of these diseases include varying degrees of muscle wasting and weakness and abnormal elevation in serum levels of muscle enzymes (Barker & Barasi, 2008). Differences among these diseases center on the genetic pattern of inheritance, the muscles involved, the age at onset, and the rate of disease progression. The unique needs of these patients, who in the past did not live to adulthood, must be addressed as they live longer because of better supportive care.

Medical Management

Treatment of the muscular dystrophies focuses on supportive care and prevention of complications in the absence of a cure or specific pharmacologic interventions (Rowland, 2005). The goal of supportive management is to keep the patient active and functioning as normally as possible and to minimize functional deterioration. An individualized therapeutic exercise program is prescribed to prevent muscle tightness, contractures, and disuse atrophy. Night splints and stretching exercises are used to delay contractures of the joints, especially the ankles, knees, and hips. Braces may compensate for muscle weakness.

Spinal deformity is a severe problem. Weakness of trunk muscles and spinal collapse occur almost routinely in patients with severe neuromuscular disease. To help prevent spinal deformity, the patient is fitted with an orthotic jacket to improve sitting stability and reduce trunk deformity. This measure also supports cardiovascular status. In time, spinal fusion is performed to maintain spinal stability. Other procedures may be carried out to correct deformities.

Compromised pulmonary function may result either from progression of the disease or from deformity of the thorax secondary to severe scoliosis. Upper respiratory infections and fractures from falls must be vigorously treated in a way that minimizes immobilization because joint contractures become worse when the patient's activities are more restricted than usual.

Other difficulties may be manifested in relation to the underlying disease. Weakness of the facial muscles makes it difficult to attend to dental hygiene and to speak clearly. Gastrointestinal tract problems may include gastric dilation, rectal prolapse, and fecal impaction. Finally, cardiomyopathy appears to be a common complication in all forms of muscular dystrophy (Rowland, 2005).

Genetic counseling is advised for parents and siblings of the patient because of the genetic nature of this disease. The Muscular Dystrophy Association works to combat neuromuscular disease through research, programs of patient services and clinical care, and professional and public education (see Resources).

Nursing Management

The goals of the patient and the nurse are to maintain function at optimal levels and to enhance the quality of life. Therefore, the patient's physical requirements, which are considerable, are addressed without losing sight of emotional and developmental needs. The patient and family are actively involved in decision making, including end-of-life decisions.

During hospitalization for treatment of complications, the knowledge and expertise of the patient and family members responsible for caregiving in the home are assessed. Because the patient and family caregivers often have developed caregiving strategies that work effectively for them, these strategies need to be acknowledged and accepted, and provisions must be made to ensure that they are maintained during hospitalization.

Families of adolescents and young adults with muscular dystrophy need assistance to shift the focus of care from pediatric to adult care and to understand the usual disease course. Nursing goals include assisting the adolescent to make the transition to adult values and expectations while providing age-appropriate ongoing care. The nurse may need to help build the confidence of an older adolescent or adult patient by encouraging him or her to pursue job training to become economically independent. Other nursing interventions might include guidance in accessing adult health care and finding appropriate programs in sex education.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The management goals are addressed in special rehabilitation programs or in the patient's home and community. Therefore, the patient and family require information and instruction about the disorder, its anticipated course, and care and management strategies that will optimize the patient's growth and development and physical and psychological status. Members of a variety of health-related disciplines are involved in patient and family teaching; recommendations are communicated to all members of the health care team so that they may work toward common goals (Rowland, 2005).

Continuing Care

Both the neuromuscular disease and the associated deformities may progress in adolescence and adulthood. Self-help and assistive devices can aid in maintaining maximum independence. These devices, recommended by physical and occupational therapists, often become necessary as more muscle groups are affected.

The family is taught to monitor the patient for respiratory problems, because respiratory infection and cardiac failure are the most common causes of death (Rowland, 2005). As respiratory difficulties develop, patients and their families need information regarding respiratory support. Options currently exist that can provide ventilatory support (eg, negative-pressure devices, positive-pressure ventilators) while allowing mobility. Patients can remain relatively independent in a wheelchair, for example, while being maintained on a ventilator at home for many years.

The patient is encouraged to continue with range-of-motion exercises to prevent contractures, which are particularly disabling. Practical adaptations must be made, however, to cope with the effects of chronic neuromuscular disability. The patient at various stages of the disease may require a manual or an electric wheelchair, gait aids, upper and lower extremity and spinal orthoses, seating systems, bathroom equipment, lifts, ramps, and additional assistive devices, all of which require a team approach. The home

care nurse assesses how the patient and family are managing, makes referrals, and coordinates the activities of the physical therapist, occupational therapist, and social services.

The patient is greatly concerned about issues surrounding the threat of increasing disability and dependence on others, accompanied by a significant deterioration in health-related quality of life. The patient is faced with a progressive loss of function, leading eventually to death. Feelings of helplessness and powerlessness are common. Each functional loss is accompanied by grief and mourning. The patient and family are assessed for depression, anger, or denial. The patient and family are assisted and encouraged to address decisions about end-of-life options before their need arises.

A psychiatric nurse clinician or other mental health professional may assist the patient to cope and adapt to the disease. By understanding and addressing the physical and psychological needs of the patient and family, the nurse provides a hopeful, supportive, and nurturing environment.

Degenerative Disk Disease

Low back pain is the second most common neurologic disorder in the United States. It is estimated that there were more than 450,000 lumbar spinal surgeries for herniated disks, stenosis, and degenerative changes in 2003 in the United States (Agency for Healthcare Research and Quality, 2008). There are significant economic costs to patients, their families, and society. Acute low back pain lasts less than 3 months, whereas chronic or degenerative disease has a duration of 3 months or longer. Most back problems are related to disk disease.

Pathophysiology

The intervertebral disk is a cartilaginous plate that forms a cushion between the vertebral bodies (Fig. 65-7A). This tough, fibrous material is incorporated in a capsule. A ball-like cushion in the center of the disk is called the nucleus

pulposus. In herniation of the intervertebral disk (ruptured disk), the nucleus of the disk protrudes into the annulus (the fibrous ring around the disk), with subsequent nerve compression. Protrusion or rupture of the nucleus pulposus usually is preceded by degenerative changes that occur with aging. Loss of protein polysaccharides in the disk decreases the water content of the nucleus pulposus. The development of radiating cracks in the annulus weakens resistance to nucleus herniation. After trauma (falls and repeated minor stresses such as lifting incorrectly), the cartilage may be injured.

For most patients, the immediate symptoms of trauma are short-lived, and those resulting from injury to the disk do not appear for months or years. Then, with degeneration in the disk, the capsule pushes back into the spinal canal, or it may rupture and allow the nucleus pulposus to be pushed back against the dural sac or against a spinal nerve as it emerges from the spinal column (see Fig. 65-7B). This sequence produces pain due to **radiculopathy** (pressure in the area of distribution of the involved nerve endings). Continued pressure may produce degenerative changes in the involved nerve, such as changes in sensation and deep tendon reflexes.

Clinical Manifestations

A herniated disk with accompanying pain may occur in any portion of the spine: cervical, thoracic (rare), or lumbar. The clinical manifestations depend on the location, the rate of development (acute or chronic), and the effect on the surrounding structures.

Assessment and Diagnostic Findings

A thorough health history and physical examination are important to rule out potentially serious conditions that may manifest as low back pain, including fracture, tumor, infection, or cauda equina syndrome (Hickey, 2009).

The MRI scan has become the diagnostic tool of choice for localizing even small disk protrusions, particularly for lumbar spine disease. If the clinical symptoms are not consistent with the pathology seen on MRI, CT scanning and

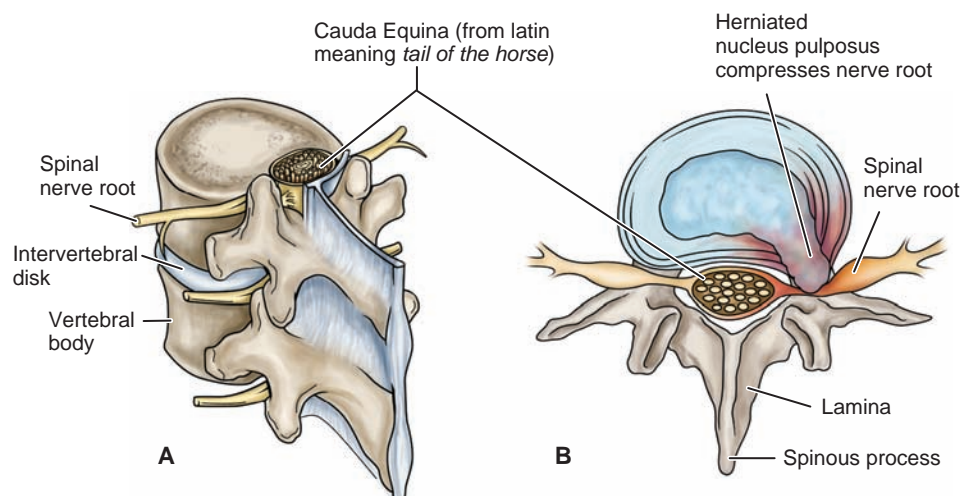

Figure 65-7 A, Normal lumbar spine vertebrae, intervertebral disks, and spinal nerve root. B, Ruptured vertebral disc.

myelography are performed. A neurologic examination is carried out to determine whether reflex, sensory, or motor impairment from root compression is present and to provide a baseline for future assessment. Electromyography may be used to localize the specific spinal nerve roots involved.

Medical Management

Herniations of the cervical and the lumbar disks occur most commonly and are usually managed conservatively with bed rest and medication (Hickey, 2009). Surgery is sometimes necessary.

Surgical Management

Surgical excision of a herniated disk is performed if there is evidence of a progressing neurologic deficit (muscle weakness and atrophy, loss of sensory and motor function, loss of sphincter control) and continuing pain or **sciatica** (leg pain resulting from sciatic nerve involvement) that are unresponsive to conservative management (Weber & Kelley, 2007). The goal of surgical treatment is to reduce the pressure on the nerve root to relieve pain and reverse neurologic deficits (Hickey, 2009). Microsurgical techniques make it possible to remove only the amount of tissue that is necessary, which preserves the integrity of normal tissue better and imposes less trauma on the body. During these procedures, spinal cord function can be monitored electrophysiologically.

To achieve the goal of pain relief, several surgical techniques are used, depending on the type and location of disk herniation, surgical morbidity, and results of previous surgery. Some of the surgical techniques available include:

- Microdiscectomy: removal of herniated or extruded fragments of intervertebral disk material
- Laminectomy: removal of the bone between the spinal process and facet pedicle junction to expose the neural elements in the spinal canal (Hickey, 2009); this allows the surgeon to inspect the spinal canal, identify and remove pathologic tissue, and relieve compression of the cord and roots
- Hemilaminectomy: removal of part of the lamina and part of the posterior arch of the vertebra
- Partial laminectomy or laminotomy: creation of a hole in the lamina of a vertebra
- Discectomy with fusion: fusion of the vertebral spinous process with a bone graft (from iliac crest or bone bank); the object of spinal fusion is to bridge over the defective disk to stabilize the spine and reduce the rate of recurrence
- Foraminotomy: removal of the intervertebral foramen to increase the space for exit of a spinal nerve, resulting in reduced pain, compression, and edema

Herniation of a Cervical Intervertebral Disk

The cervical spine is subjected to stresses that result from disk degeneration (due to aging, occupational stresses) and **spondylosis** (degenerative changes occurring in a disk and adjacent vertebral bodies). Cervical disk degeneration may lead to lesions that can cause damage to the spinal cord and its roots.

Clinical Manifestations

A cervical disk herniation usually occurs at the C5–C6 or C6–C7 interspaces.

Pain and stiffness may occur in the neck, the top of the shoulders, and the region of the scapulae. Sometimes patients interpret these signs as symptoms of heart trouble or bursitis. Pain may also occur in the upper extremities and head, accompanied by **paresthesia** (tingling or a “pins and needles” sensation) and numbness of the upper extremities. Cervical MRI usually confirms the diagnosis.

Medical Management

The goals of treatment are to rest and immobilize the cervical spine to give the soft tissues time to heal and to reduce inflammation in the supporting tissues and the affected nerve roots in the cervical spine. Bed rest (usually 1 to 2 days) is important because it eliminates the stress of gravity and relieves the cervical spine of the need to support the head. It also reduces inflammation and edema in soft tissues around the disk, relieving pressure on the nerve roots. Proper positioning on a firm mattress may bring dramatic relief from pain.

The cervical spine may be rested and immobilized by a cervical collar, cervical traction, or a brace. A collar allows maximal opening of the intervertebral foramina and holds the head in a neutral or slightly flexed position. The patient may have to wear the collar 24 hours a day during the acute phase. The skin under the collar is inspected for irritation. After the patient is free of pain, cervical isometric exercises are started to strengthen the neck muscles.

Pharmacologic Therapy

Analgesic agents (nonsteroidal anti-inflammatory agents [NSAIDs], propoxyphene [Darvon], oxycodone [Tylox], or hydrocodone [Vicodin]) are prescribed during the acute phase to relieve pain, and sedatives may be administered to control the anxiety that is often associated with cervical disk disease. Muscle relaxants (cyclobenzaprine [Flexeril], methocarbamol [Robaxin], metaxalone [Skelaxin]) are administered to interrupt muscle spasm and to promote comfort. NSAIDs (aspirin, ibuprofen [Motrin, Advil], naproxen [Naprosyn, Anaprox]) or corticosteroids are prescribed to treat the inflammation that usually occurs in the affected nerve roots and supporting tissues. Occasionally, a corticosteroid is injected into the epidural space for relief of radicular (spinal nerve root) pain. NSAIDs are administered with food and antacids to prevent gastrointestinal irritation (Karch, 2008). Hot, moist compresses (for 10 to 20 minutes) applied to the back of the neck several times daily increase blood flow to the muscles and help relax the patient and reduce muscle spasm.

Surgical Management

Surgical excision of the herniated disk may be necessary if there is a significant neurologic deficit, progression of the deficit, evidence of cord compression, or pain that either worsens or fails to improve. A cervical discectomy, with or without fusion, may be performed to alleviate symptoms (Fowler, Anthony-Phillips, Mehta, et al., 2005). An anterior surgical approach may be used through a transverse

incision to remove disk material that has herniated into the spinal canal and foramina, or a posterior approach may be used at the appropriate level of the cervical spine. Potential complications with the anterior approach include carotid or vertebral artery injury, recurrent laryngeal nerve dysfunction, esophageal perforation, and airway obstruction. Complications of the posterior approach include damage to the nerve root or the spinal cord due to retraction or contusion of either of these structures, resulting in weakness of muscles supplied by the nerve root or cord.

Microsurgery, such as endoscopic microdiscectomy, may be performed in selected patients through a small incision, using magnification techniques. This usually results in less tissue trauma and pain, and patients consequently have a shorter hospital stay compared with those who have conventional surgery.

NURSING PROCESS

THE PATIENT UNDERGOING A CERVICAL DISCECTOMY

Assessment

The patient is asked about past injuries to the neck (whiplash), because unresolved trauma can cause persistent discomfort, pain and tenderness, and symptoms of arthritis in the injured joint of the cervical spine. Assessment includes determining the onset, location, and radiation of pain and assessing for paresthesias, limited movement, and diminished function of the neck, shoulders, and upper extremities. It is important to determine whether the symptoms are bilateral; with large herniations, bilateral symptoms may be caused by cord compression. The area around the cervical spine is palpated to assess muscle tone and tenderness. Range of motion in the neck and shoulders is evaluated.

The patient is asked about any health issues that may influence the postoperative course and quality of life (Fowler, et al., 2005). It is also important to assess mood and stress levels (Starkweather, Witek-Janusek, Nockels, et al., 2006). The nurse determines the patient's need for information about the surgical procedure and reinforces what the physician has explained. Strategies for pain management are discussed with the patient.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain related to the surgical procedure
- Impaired physical mobility related to the postoperative surgical regimen
- Deficient knowledge about the postoperative course and home care management

Other nursing diagnoses may include preoperative anxiety, postoperative constipation, urinary retention related to the surgical procedure, self-care deficits related to use of a neck orthosis, and sleep pattern disturbance related to disruption in lifestyle.

Collaborative Problems/Potential Complications

Based on all the assessment data, the potential complications may include the following:

- Hematoma at the surgical site, resulting in cord compression and neurologic deficit
- Recurrent or persistent pain after surgery

Planning and Goals

The goals for the patient may include relief of pain, improved mobility, increased knowledge and self-care ability, and prevention of complications.

Nursing Interventions

Relieving Pain

The patient may be kept flat in bed for 12 to 24 hours. If the patient has had a bone fusion with bone removed from the iliac crest, considerable pain may be experienced at the donor site. Interventions consist of monitoring the donor site for hematoma formation, administering the prescribed postoperative analgesic agent, positioning for comfort, and reassuring the patient that the pain can be relieved. If the patient experiences a sudden increase in pain, extrusion of the graft may have occurred, requiring reoperation. A sudden increase in pain should be promptly reported to the surgeon.

The patient may experience a sore throat, hoarseness, and dysphagia due to temporary edema. These symptoms are relieved by throat lozenges, voice rest, and humidification. A puréed diet may be given if the patient has dysphagia.

Improving Mobility

Postoperatively, a cervical collar (neck orthosis) is usually worn, which contributes to limited neck motion and altered mobility. The patient is instructed to turn the body instead of the neck when looking from side to side. The neck should be kept in a neutral (midline) position. The patient is assisted during position changes, to make sure that head, shoulders, and thorax are kept aligned. When assisting the patient to a sitting position, the nurse supports the patient's neck and shoulders. To increase stability, the patient should wear shoes when ambulating.

Monitoring and Managing Potential Complications

The patient is evaluated for bleeding and hematoma formation by assessing for excessive pressure in the neck or severe pain in the incision area. The dressing is inspected for serosanguineous drainage, which suggests a dural leak. If this occurs, meningitis is a threat. A complaint of headache requires careful evaluation. Neurologic checks are made for swallowing deficits and upper and lower extremity weakness, because cord compression may produce rapid or delayed onset of paralysis. The patient who has had an anterior cervical discectomy is also assessed for a sudden return of radicular (spinal nerve root) pain, which may indicate instability of the spine.

Throughout the postoperative course, the patient is monitored frequently to detect any signs of respiratory difficulty, because retractors used during surgery may injure the recurrent laryngeal nerve, resulting in hoarseness and the inability to cough effectively and clear pulmonary secretions. In addition, the blood pressure and pulse are monitored to evaluate cardiovascular status.

Bleeding at the surgical site and subsequent hematoma formation may occur. Severe localized pain not relieved by analgesic agents should be reported to the surgeon. A change in neurologic status (motor or sensory function) should be reported promptly, because it suggests hematoma formation that may necessitate surgery to prevent irreversible motor and sensory deficits.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient's hospital stay is likely to be short; therefore, the patient and family should understand the care that is important for a smooth recovery. A cervical collar is usually worn for about 6 weeks. The patient is instructed in use and care of the cervical collar. The patient is instructed to alternate tasks that involve minimal body movement (eg, reading) with tasks that require greater body movement.

The patient is instructed about strategies for pain management and about signs and symptoms that may indicate

complications that should be reported to the physician. The nurse assesses the patient's understanding of these management strategies, limitations, and recommendations. Additionally, the nurse assists the patient in identifying strategies to cope with ADLs (eg, self-care, childcare) and minimize risks to the surgical site (Chart 65-7). A discharge teaching plan is developed collaboratively by members of the health care team to decrease the risk of recurrent disk herniation. Topics include those previously discussed as well as proper body mechanics, maintenance of optimal weight, proper exercise techniques, and modifications in activity.

CONTINUING CARE. The patient is instructed to see the physician at prescribed intervals so that the physician can document the disappearance of old symptoms and assess the range of motion of the neck. Recurrent or persistent pain may occur despite removal of the offending disk or disk fragments. Patients who undergo discectomy usually have consented to surgery after prolonged pain; they have often

HOME CARE CHECKLIST

The Patient With Cervical Discectomy and Cervical Collar

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
<ul style="list-style-type: none"> Care for the surgical incision site. <ul style="list-style-type: none"> Keep staples or sutures clean and dry and cover with dry dressing. Notify physician if any signs or symptoms of infection occur, such as fever, redness or irritation, drainage, increased pain. 	✓	✓
<ul style="list-style-type: none"> Demonstrate proper body mechanics and prescribed exercise techniques. 	✓	
<ul style="list-style-type: none"> Modify activity: <ul style="list-style-type: none"> Avoid sitting or standing for more than 30 minutes. Avoid twisting, flexing, extending, or rotating the neck. Avoid long automobile rides. Avoid sleeping in a prone position or use of pillows, to minimize neck flexion in bed; keep head in a neutral position. Use adequate mattress and chair support. Wear low-heeled shoes. 	✓ ✓ ✓ ✓ ✓ ✓	
<ul style="list-style-type: none"> Follow physician's instructions regarding lifting, climbing stairs, driving a car, sexual activity, sports, exercise, and return to work. 	✓	
<ul style="list-style-type: none"> Practice stress reduction and relaxation techniques. 	✓	
<ul style="list-style-type: none"> Care of the cervical collar: <ul style="list-style-type: none"> Wear the collar at all times until directed otherwise by the physician. Wash the neck twice a day with mild soap. Keep the neck still while the collar is open. 	✓ ✓ ✓	✓
<ul style="list-style-type: none"> With the assistance of a helper, wash the neck in steps: <ul style="list-style-type: none"> Lie flat and supine. Open the Velcro tabs on each side of the collar and remove its front portion. Gently wash and dry the neck. Replace the front part of the collar and refasten the tabs. Turn to one side with a thin pillow under the head. Open one tab. Gently wash and dry the back of the neck. Refasten the tab. Turn to the other side and wash and dry this side. Refasten the tab. 	✓ ✓ ✓	✓ ✓ ✓ ✓ ✓
<ul style="list-style-type: none"> Place a wrinkle-free silk scarf under the collar to increase comfort. 	✓	✓
<ul style="list-style-type: none"> For men: Shave without twisting or moving the neck. This may be done with help while lying flat or sitting. Remove only the front part of the collar for shaving. 	✓	✓

undergone repeated courses of ineffective conservative management and previous surgeries to relieve the pain. Therefore, the recurrence or persistence of symptoms postoperatively, including pain and sensory deficits, is often discouraging for the patient and family. The patient who experiences recurrence of symptoms requires emotional support and understanding. Additionally, the patient is assisted in modifying activities and in considering options for subsequent treatment. The nurse reminds the patient and family members of the need to participate in health promotion and health screening practices.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Reports decreasing frequency and severity of pain
2. Demonstrates improved mobility
 - a. Demonstrates progressive participation in self-care activities
 - b. Identifies prescribed activity limitations and restrictions
 - c. Demonstrates proper body mechanics
3. Is knowledgeable about postoperative course, medications, and home care management
 - a. Lists the signs and symptoms to be reported postoperatively
 - b. Identifies dose, action, and potential side effects of medications
 - c. Identifies appropriate home care management activities and any restrictions
4. Has absence of complications
 - a. Reports no increase in incision pain or sensory symptoms
 - b. Demonstrates normal findings on neurologic assessment

Herniation of a Lumbar Disk

Approximately 90% to 95% of lumbar disk herniations occur at the L5–S1 region (Hickey, 2009). A herniated lumbar disk produces low back pain accompanied by varying degrees of sensory and motor impairment.

Clinical Manifestations

The patient complains of low back pain with muscle spasms, followed by radiation of the pain into one hip and down into the leg (sciatica). Pain is aggravated by actions that increase intraspinal fluid pressure, such as bending, lifting, or straining (as in sneezing or coughing), and usually is relieved by bed rest. Usually there is some type of postural deformity, because pain causes an alteration of the normal spinal mechanics. If the patient lies on the back and attempts to raise a leg in a straight position, pain radiates into the leg; this maneuver, called the straight leg-raising test, stretches the sciatic nerve. Additional signs include muscle weakness, alterations in tendon reflexes, and sensory loss.

Assessment and Diagnostic Findings

The diagnosis of lumbar disk disease is based on the history and physical findings and the use of imaging techniques such as MRI, CT, and myelography.

Medical Management

The objectives of treatment are to relieve pain, slow disease progression, and increase the patient's functional ability. Bed rest, previously standard in treatment of back pain, is recommended for 2 days or less (Hickey, 2009).

Because muscle spasm is prominent during the acute phase, muscle relaxants are used. NSAIDs and systemic corticosteroids may be administered to counter the inflammation that usually occurs in the supporting tissues and the affected nerve roots. Moist heat and massage help relax muscles. Strategies for increasing the patient's functional ability include weight reduction, physical therapy, and biofeedback. Exercises, prescribed by physical therapists, can help strengthen back muscles and decrease pain (Hickey, 2009). Chapter 13 describes nursing interventions for the patient with pain.

Surgical Management

In the lumbar region, surgical treatment includes lumbar disk excision through a posterolateral laminotomy and the newer techniques of microdiscectomy and percutaneous discectomy. In microdiscectomy, an operating microscope is used to visualize the offending disk and compressed nerve roots; it permits a small incision (2.5 cm [1 inch]) and minimal blood loss and takes about 30 minutes of operating time. Generally, the hospital stay is short, and the patient makes a rapid recovery. Several minimally invasive techniques in spinal surgery have led to improved patient outcomes and lower hospital costs, and research on these techniques is ongoing (Starkweather, Witek-Janusek, Nockels, et al., 2008). Research suggests that intraoperative wound infiltration with bupivacaine hydrochloride solution decreases pain and the need for opioids postoperatively (Ersayli, Gurget, Bekar, et al., 2006).

Complications of Disk Surgery

A patient undergoing a disk procedure at one level of the vertebral column may have a degenerative process at other levels. A herniation relapse may occur at the same level or elsewhere, so the patient may become a candidate for another disk procedure. Arachnoiditis (inflammation of the arachnoid membrane) may occur after surgery (and after myelography); it involves an insidious onset of diffuse, frequently burning pain in the lower back, radiating into the buttocks. Disk excision can leave adhesions and scarring around the spinal nerves and dura, which then produce inflammatory changes that create chronic neuritis and neurofibrosis. Disk surgery may relieve pressure on the spinal nerves, but it does not reverse the effects of neural injury and scarring and the pain that results. Failed disk syndrome (recurrence of sciatica after lumbar discectomy) remains a cause of disability (Hickey, 2009).

Figure 65-8 Before the patient undergoes laminectomy surgery, the logrolling technique that will be used for turning the patient should be demonstrated. The patient's arms will be crossed and the spine aligned. To avoid twisting the spine, the head, shoulders, knees, and hips are turned at the same time so that the patient rolls over like a log. When in a side-lying position, the patient's back, buttocks, and legs are supported with pillows.

Nursing Management

Providing Preoperative Care

Most patients fear surgery on any part of the spine and therefore need explanations about the surgery and reassurance that it will not weaken the back. When data are being collected for the health history, any reports of pain, paresthesia, or muscle spasm are recorded to provide a baseline for comparison after surgery. Health issues that may influence the postoperative course and quality of life (eg, fatigue, mood, stress, patient expectations) are important to assess (Saban & Penckofer, 2007; Starkweather, et al., 2008). Preoperative assessment also includes an evaluation of movement of the extremities as well as bladder and bowel function. To facilitate the postoperative turning procedure, the patient is taught to turn as a unit (called logrolling) as part of the preoperative preparation (see Fig. 65-8). Before surgery, the patient is also encouraged to take deep breaths, cough, and perform muscle-setting exercises to maintain muscle tone.

Assessing the Patient After Surgery

After lumbar disk excision, vital signs are checked frequently and the wound is inspected for hemorrhage, because vascular injury is a complication of disk surgery. Because postoperative neurologic deficits may occur from nerve root injury, the sensation and motor strength of the lower extremities are evaluated at specified intervals, along with the color and temperature of the legs and sensation of the toes. It is important to assess for urinary retention, another sign of neurologic deterioration.

In discectomy with fusion, the patient has an additional surgical incision if bone fragments were taken from the iliac crest or fibula to serve as wedges in the spine. The recovery period is longer than for those patients who underwent discectomy without spinal fusion, because bony union must take place.

Positioning the Patient

To position the patient, a pillow is placed under the head, and the knee rest is elevated slightly to relax the back muscles. When the patient is lying on one side, however, extreme knee flexion must be avoided. The patient is encouraged to move from side to side to relieve pressure and is reassured that no injury will result from moving. When the patient is ready to turn, the bed is placed in a flat position and a pillow is placed between the patient's legs. The patient turns as a unit (logrolls) without twisting the back.

To get out of bed, the patient lies on one side while pushing up to a sitting position. At the same time, the nurse or family member eases the patient's legs over the side of the bed. Coming to a sitting or standing posture is accomplished in one long, smooth motion. Most patients walk to the bathroom on the same day as the surgery. Sitting is discouraged except for defecation.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient is advised to increase activity gradually, as tolerated, because it takes up to 6 weeks for the ligaments to heal. Excessive activity may result in spasm of the paraspinal muscles.

Activities that produce flexion strain on the spine (eg, driving a car) should be avoided until healing has taken place. Heat may be applied to the back to relax muscle spasms. Scheduled rest periods are important, and the patient is advised to avoid heavy work for 2 to 3 months after surgery. Exercises are prescribed to strengthen the abdominal and erector spinal muscles. A back brace or corset may be necessary if back pain persists.

Continuing Care

Referral for inpatient or outpatient rehabilitation may be warranted to improve self-care abilities after medical or surgical treatment for herniation of a lumbar disk. A home care referral may be indicated and provides the home care nurse with the opportunity to assess the patient's physical and psychological status, as well as his or her ability to adhere to recommended management strategies. During the home visit, the nurse determines whether changes in neurologic function have occurred. The adequacy of pain management is assessed, and modifications are made to ensure adequate pain relief.

Postpolio Syndrome

People who survived the polio epidemic of the 1950s, many of whom are now elderly, are developing new symptoms of weakness, fatigue, and musculoskeletal pain. Researchers estimate that as many as 80% of the 1,000,000 polio survivors are experiencing the phenomenon known as postpolio syndrome. Men and women appear to be equally at risk for this condition (Bartels & Omura, 2005; Elrod, Jabben, Oswald, et al., 2005).

Pathophysiology

The exact cause of postpolio syndrome is not known, but researchers suspect that, with aging or muscle overuse, the neurons not destroyed by the poliovirus continue generating axon sprouts (Bartels & Omura, 2005). These new terminal axon sprouts reinnervate the affected muscles after the initial insult but may become more vulnerable as the body ages.

Assessment and Diagnostic Findings

No specific diagnostic test exists for postpolio syndrome. Clinical diagnosis is made on the basis of the history and physical examination and exclusion of other medical conditions that could be causing the new symptoms. Patients report a history of paralytic poliomyelitis followed by partial or complete recovery of function, with a plateau of function and then the recurrence of symptoms. Signs and symptoms may occur decades after the original onset of poliomyelitis (Elrod, et al., 2005).

Management

No specific medical or surgical treatment is available for this syndrome, and therefore nurses play a pivotal role in the team approach to assisting patients and families in dealing with the symptoms of progressive loss of muscle strength and significant fatigue. Other health care professionals who may assist in patient care include physical, occupational, speech, and respiratory therapists. Nursing interventions are aimed at maintaining the patient's strength as well as physical, psychological, and social well-being.

The patient needs to plan and coordinate activities to conserve energy and reduce fatigue. Rest periods should be planned and assistive devices used to reduce weakness and fatigue. Important activities should be planned for the morning, because fatigue often increases in the afternoon and evening (Bartels & Omura, 2005; Elrod, et al., 2005).

One study proposed an explanatory model of health promotion and quality of life in patients with postpolio syndrome (Stuifbergen, Seraphine, Harrison, et al., 2005). The results suggested that quality of life is the result of a complex interplay among contextual factors such as severity of impairment, antecedent variables, and health-promoting behaviors.

Pain in muscles and joints may be a problem. Non-pharmacologic techniques such as the application of heat and cold are most appropriate, because older patients may not tolerate or may have strong reactions to medications.

Maintaining a balance between adequate nutritional intake and avoiding excess calories that can lead to obesity in this sedentary group of patients is a challenge. Pulmonary hygiene and adequate fluid intake can help with airway management. Several interventions can improve sleep, including limiting caffeine intake before bedtime and assessing for nocturia. If nocturia is an issue, the patient needs to be evaluated for obstructive sleep apnea. Supportive ventilation may be appropriate, with continuous positive airway pressure if sleep apnea is a problem.

Bone density testing in patients with postpolio syndrome has revealed low bone mass and osteoporosis (Smeltzer, Zimmerman & Capriotti, 2005). Therefore, the importance of identifying risks, preventing falls, and treating osteoporosis must be discussed with patients and families. Families also need to be made aware of the possibility of changes in individual and family relationships due to the many symptoms of postpolio syndrome (Ward, 2008). The nurse also needs to remind patients and family members of the need for health promotion activities and health screening.

CRITICAL THINKING EXERCISES

1 A 48-year-old man is married with two young children and has been newly diagnosed with a metastatic spinal cord tumor. Assess and prioritize the patient's physiologic and psychosocial needs. Identify appropriate nursing interventions to alleviate the patient's and family's physiologic and emotional stressors. Address the patient's need for emotional support from both the nursing staff and the family.

2 A 75-year-old woman newly diagnosed with Parkinson's disease asks what type of medication she will be given. What are the possible medication regimens that may be used to treat her disease and the common side effects of each? How would your discharge teaching targeted toward medications be modified if the patient lives alone and is hearing impaired?

EBP 3 A 45-year-old patient with Huntington disease has been referred for end-of-life care. What resources would you use to identify the current guidelines for end-of-life care? What is the current evidence base for end-of-life nursing care? Identify the criteria used to evaluate the strength of the evidence for end-of-life nursing care.

4 A 60-year-old patient with low back pain is seen in the clinic. What nursing interventions and actions would you suggest to assist in the management of low back pain? What strategies would you advise the patient to avoid? What is the rationale for your suggestions? State the types of health promotion activities you would recommend to this patient and the rationale for your recommendations.

Musculoskeletal Function

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Musculoskeletal Limitations Complicated by a Medical Illness

Mrs. Waterman is a 70-year-old woman with severe osteoarthritis of the spine and a recent history of left total hip replacement. She has been attending outpatient physical therapy sessions three times a week and uses a rolling walker at home. She has been admitted to the hospital with a partial small bowel obstruction. The health care team anticipates that the obstruction will resolve with medical treatment, and her expected length of stay is 5 to 7 days. Currently she is allowed nothing by mouth, has a Salem sump tube in place, and is receiving peripheral parenteral nutrition.

The nurse is concerned that Mrs. Waterman's already impaired physical mobility will decline further secondary to her illness and the medical treatments that make independent ambulation difficult.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
IMPAIRED PHYSICAL MOBILITY —Limitation in independent, purposeful physical movement of the body or of one or more extremities	EXERCISE PROMOTION —Facilitation of regular physical exercise to maintain or advance a higher degree of fitness	MOBILITY LEVEL —Ability to move purposefully in own environment independently with or without assistive device
RISK FOR DISUSE SYNDROME —At risk for deterioration of body systems as the result of prescribed or unavoidable musculoskeletal inactivity	EXERCISE PROMOTION: STRENGTH TRAINING —Facilitating regular resistive muscle training to retain or increase muscle strength	IMMOBILITY CONSEQUENCES: PHYSIOLOGICAL —Severity of compromise in physiological functioning due to impaired physical mobility
	EMBOLUS PRECAUTIONS —Reduction of the risk of embolus in a patient with thrombi or at risk for developing thrombus formation	
	PRESSURE ULCER PREVENTION —Prevention of pressure ulcers for an individual at high risk for developing them	
	SURVEILLANCE —Purposeful and ongoing acquisition, interpretation, and synthesis of patient data for clinical decision-making

Assessment of Musculoskeletal Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the basic structure and function of the musculoskeletal system.
- 2 Discuss the significance of the health history to the assessment of musculoskeletal health.
- 3 Describe the significance of physical assessment to the diagnosis of musculoskeletal dysfunction.
- 4 Specify the diagnostic tests used for assessment of musculoskeletal function.

GLOSSARY

atonic: without tone; denervated muscle that atrophies
atrophy: shrinkagelike decrease in the size of a muscle
bursa: fluid-filled sac found in connective tissue, usually in the area of joints
callus: cartilaginous/fibrous tissue at fracture site
cancellous bone: latticelike bone structure; trabecular bone
cartilage: tough, elastic, avascular tissue at ends of bone
clonus: rhythmic contraction of muscle
contracture: abnormal shortening of muscle or joint, or both; fibrosis
cortical bone: compact bone
crepitus: grating or crackling sound or sensation; may occur with movement of ends of a broken bone or irregular joint surface
diaphysis: shaft of long bone
effusion: excess fluid in joint
endosteum: a thin, vascular membrane covering the marrow cavity of long bones and the spaces in cancellous bone
epiphysis: end of long bone
fascia (epimysium): fibrous tissue that covers, supports, and separates muscles

GLOSSARY (Continued)

fasciculation: involuntary twitch of muscle fibers
flaccid: limp; without muscle tone
hypertrophy: enlargement; increase in size of muscle
isometric contraction: muscle tension increased, length unchanged, no joint motion
isotonic contraction: muscle tension unchanged, muscle shortened, joint moved
joint: area where bone ends meet; provides for motion and flexibility
joint capsule: fibrous tissue that encloses bone ends and other joint surfaces
kyphosis: increase in the convex curvature of the spine
lamellae: mature compact bone structures that form concentric rings of bone matrix; lamellar bone
ligament: fibrous band connecting bones
lordosis: increase in lumbar curvature of the spine
ossification: process in which minerals (calcium) are deposited in bone matrix
osteoblast: bone-forming cell
osteoclast: bone resorption cell
osteocyte: mature bone cell
osteogenesis: bone formation
osteon: microscopic functional bone unit
paresthesia: abnormal sensation (eg, burning, tingling, numbness)
periosteum: fibrous connective tissue covering bone
remodeling: process that ensures bone maintenance through simultaneous bone resorption and formation
resorption: removal/destruction of tissue, such as bone
scoliosis: lateral curving of the spine
spastic: having greater-than-normal muscle tone
synovium: membrane in joint that secretes lubricating fluid
tendon: cord of fibrous tissue connecting muscle to bone
tone (tonus): normal tension (resistance to stretch) in resting muscle
trabeculae: latticelike bone structure; cancellous bone

The musculoskeletal system includes the bones, joints, muscles, tendons, ligaments, and bursae of the body. The functions of these components are highly integrated; therefore, disease in or injury to one component adversely affects the others. For instance, an infection in a joint (septic arthritis) causes degeneration of the articular surfaces of the bones within the joint and local muscle atrophy.

Diseases and injuries that involve the musculoskeletal system are commonly implicated in disability and death. For example, the leading cause of disability in the United States is arthritis (Centers for Disease Control and Prevention [CDC], 2005). Osteoporosis-related fractures account for more than 432,000 hospitalizations yearly in the United States (National Osteoporosis Foundation, 2008). Musculoskeletal diseases and injuries can significantly affect overall productivity, independence, and quality of life in people of all ages. Nurses in all practice areas encounter patients with malfunction in the musculoskeletal system.

Anatomic and Physiologic Overview

The musculoskeletal system provides protection for vital organs, including the brain, heart, and lungs; provides a sturdy framework to support body structures; and makes mobility possible. Muscles and tendons hold the bones together and joints allow the body to move. **Tendons** attach muscles to bones. They also move to produce heat that helps maintain body temperature. Movement facilitates the return of deoxygenated blood to the right side of the heart by massaging the venous vasculature. The musculoskeletal system serves as a reservoir for immature blood cells and essential minerals, including calcium, phosphorus, magnesium, and fluoride. More than 98% of total body calcium is present in bone.

Structure and Function of the Skeletal System

There are 206 bones in the human body, divided into four categories: long bones (eg, femur), short bones (eg, metacarpals), flat bones (eg, sternum), and irregular bones (eg, vertebrae). The shape and construction of a specific bone are determined by its function and the forces exerted on it. Bones are constructed of **cancellous** (trabecular) or **cortical** (compact) bone tissue. Long bones are shaped like rods or shafts with rounded ends (Fig. 66-1). The shaft, known as the **diaphysis**, is primarily cortical bone. The ends of the long bones, called **epiphyses**, are primarily cancellous bone. The epiphyseal plate separates the epiphyses from the diaphysis and is the center for longitudinal growth in children. It is calcified in adults. The ends of long bones are covered at the joints by articular **cartilage**, which is tough, elastic, avascular tissue. Long bones are designed for weight bearing and movement. Short bones consist of cancellous bone covered by a layer of compact bone. Flat bones are important sites of hematopoiesis and frequently protect vital organs. They are made of cancellous bone layered between compact bone. Irregular bones have unique shapes related to their function. Generally, irregular bone structure is similar to that of flat bones.

Bone is composed of cells, protein matrix, and mineral deposits. The cells are of three basic types—**osteoblasts**,

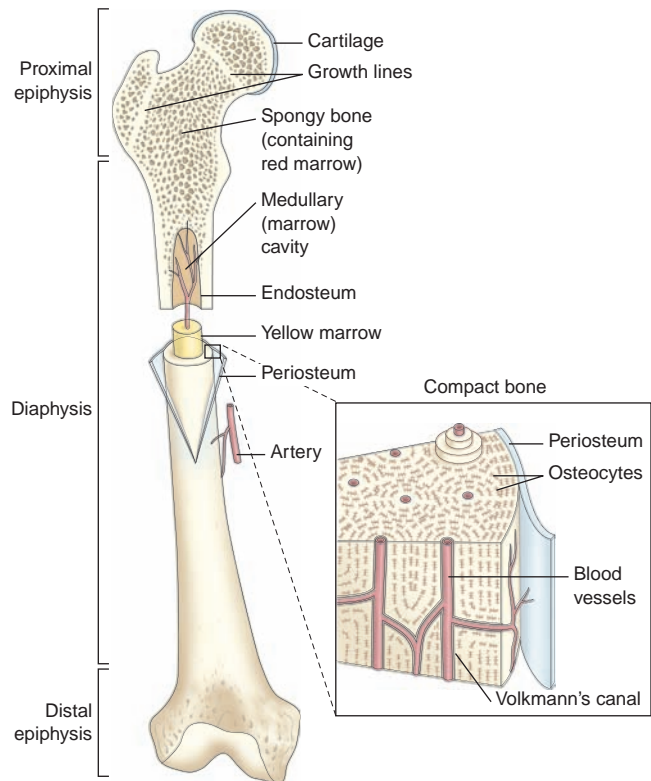

Figure 66-1 Structure of a long bone; composition of compact bone.

osteocytes, and **osteoclasts**. Osteoblasts function in bone formation by secreting bone matrix. The matrix consists of collagen and ground substances (glycoproteins and proteoglycans) that provide a framework in which inorganic mineral salts are deposited. These minerals are primarily composed of calcium and phosphorus. Osteocytes are mature bone cells involved in bone maintenance; they are located in lacunae (bone matrix units). Osteoclasts, located in shallow Howship's lacunae (small pits in bones), are multinuclear cells involved in dissolving and resorbing bone. The microscopic functioning unit of mature cortical bone is the **osteon** (Haversian system). The center of the osteon, the Haversian canal, contains a capillary. Around the capillary are circles of mineralized bone matrix called **lamellae**. Within the lamellae are lacunae that contain osteocytes. These are nourished through tiny structures, canaliculi (canals), which communicate with adjacent blood vessels within the Haversian system. Lacunae in cancellous bone are layered in an irregular lattice network (**trabeculae**). Red bone marrow fills the lattice network. Capillaries nourish the osteocytes located in the lacunae (Porth & Matfin, 2009).

Covering the bone is a dense, fibrous membrane known as the **periosteum**. This membranous structure nourishes bone and facilitates its growth. The periosteum contains nerves, blood vessels, and lymphatics. It also provides for the attachment of tendons and ligaments (Porth & Matfin, 2009).

The **endosteum** is a thin, vascular membrane that covers the marrow cavity of long bones and the spaces in cancellous bone. Osteoclasts, which dissolve bone matrix to maintain the marrow cavity, are located near the endosteum in Howship's lacunae (Porth & Matfin, 2009).

Bone marrow is a vascular tissue located in the medullary (shaft) cavity of long bones and in flat bones. Red bone marrow, located mainly in the sternum, ilium, vertebrae, and ribs in adults, is responsible for producing red blood cells, white blood cells, and platelets through a process called hematopoiesis. In adults, the long bone is filled with fatty, yellow marrow (Porth & Matfin, 2009).

Bone tissue is well vascularized. Cancellous bone receives a rich blood supply through metaphyseal and epiphyseal vessels. Periosteal vessels carry blood to compact bone through minute Volkmann's canals. In addition, nutrient arteries penetrate the periosteum and enter the medullary cavity through foramina (small openings). Arteries supply blood to the marrow and bone. The venous system may accompany arteries or may exit independently (Porth & Matfin, 2009).

Bone Formation

Osteogenesis (bone formation) begins long before birth. **Ossification** is the process by which the bone matrix is formed and hard mineral crystals composed of calcium and phosphorus (eg, hydroxyapatite) are bound to the collagen fibers. These mineral components give bone its characteristic strength, whereas the proteinaceous collagen gives bone its resilience (Porth & Matfin, 2009).

Bone Maintenance

Bone is a dynamic tissue in a constant state of turnover. During childhood, bones grow and form by a process called modeling. By early adulthood (ie, early 20s), **remodeling** is the primary process that occurs. Remodeling maintains bone structure and function through simultaneous **resorption** and osteogenesis, and as a result, complete skeletal turnover occurs every 10 years (U.S. Department of Health and Human Services [DHHS], 2004).

The balance between bone resorption and formation is influenced by the following factors: physical activity; dietary intake of certain nutrients, especially calcium; and several hormones, including calcitriol (ie, activated vitamin D), parathyroid hormone (PTH), calcitonin, thyroid hormone, cortisol, growth hormone, and the sex hormones estrogen and testosterone (DHHS, 2004).

Physical activity, particularly weight-bearing activity, acts to stimulate bone formation and remodeling. Bones subjected to continued weight bearing tend to be thick and strong. Conversely, people who are unable to engage in regular weight-bearing activities, such as those on prolonged bed rest or those with some physical disabilities, have increased bone resorption from calcium loss, and their bones become osteopenic and weak. These weakened bones may fracture easily.

Good dietary habits are integral to bone health. In particular, absorption of approximately 1000–1200 mg of calcium daily is essential to maintaining adult bone mass. This may be achieved through ingesting calcium-rich foods on a daily basis (eg, through drinking 16 to 24 ounces of milk daily).

Several hormones are vital in ensuring that calcium is properly absorbed and available for bone mineralization and matrix formation. Calcitriol functions to increase the amount of calcium in the blood by promoting absorption of calcium from the gastrointestinal tract. It also facilitates

mineralization of osteoid tissue. A deficiency of vitamin D results in bone mineralization deficit, deformity, and fracture (DHHS, 2004).

PTH and calcitonin are the major hormonal regulators of calcium homeostasis. PTH regulates the concentration of calcium in the blood, in part by promoting movement of calcium from the bone. In response to low calcium levels in the blood, increased levels of PTH prompt the mobilization of calcium, the demineralization of bone, and the formation of bone cysts. Calcitonin, secreted by the thyroid gland in response to elevated blood calcium levels, inhibits bone resorption and increases the deposit of calcium in bone (DHHS, 2004).

Both thyroid hormone and cortisol have multiple systemic effects with specific effects on bones. Excessive thyroid hormone production in adults (eg, Graves' disease) can result in increased bone resorption and decreased bone formation. Increased levels of cortisol have these same effects. Patients receiving long-term synthetic cortisol or corticosteroids (ie, prednisone) are at increased risk for steroid-induced osteopenia and fractures.

Growth hormone has direct and indirect effects on skeletal growth and remodeling. It stimulates the liver and to a lesser degree the bones to produce insulinlike growth factor-1 (IGF-I), which accelerates bone modeling in children and adolescents. Growth hormone also directly stimulates skeletal growth in children and adolescents. It is believed that the low levels of both growth hormone and IGF-I that occur with aging may be partly responsible for decreased bone formation and resultant osteopenia (DHHS, 2004).

The sex hormones testosterone and estrogen have important effects on bone remodeling. Estrogen stimulates osteoblasts and inhibits osteoclasts; therefore, bone formation is enhanced and resorption is inhibited. Testosterone has both direct and indirect effects on bone growth and formation. It directly causes skeletal growth in adolescence and has continued effects on skeletal muscle growth throughout the lifespan. Increased muscle mass results in greater weight-bearing stress on bones, resulting in increased bone formation. In addition, testosterone converts to estrogen in adipose tissue, providing an additional source of bone-preserving estrogen for aging men.

During the process of bone remodeling, osteoblasts produce a receptor for activated nuclear factor-kappa B ligand (RANKL) that binds to the receptor for activated nuclear factor-kappa B (RANK) present on the cell membranes of osteoclast precursors, causing them to differentiate and mature into osteoclasts, which causes bone resorption. Conversely, osteoblasts may produce osteoprotegerin (OPG), which blocks the effects of RANKL, thereby turning off the process of bone resorption. T cells that may become activated as a result of the inflammatory process may also produce RANKL, overriding the effects of OPG and causing continued bone resorption during times of stress and injury, which can lead to loss of bone matrix and fractures. Research is currently focused on developing medications that block the effects of RANKL and on developing useful laboratory tests of RANKL levels that may guide therapy aimed at reducing the risk of fractures (McCormick, 2007).

Blood supply to the bone also affects bone formation. With diminished blood supply or hyperemia (congestion),

osteogenesis and bone density decrease. Bone necrosis occurs when the bone is deprived of blood.

Bone Healing

Most fractures heal through a combination of intramembranous and endochondral ossification processes. When a bone is fractured, the bone fragments are not patched together with scar tissue. Instead, the bone regenerates itself.

Fracture healing occurs in the bone marrow, where endothelial cells rapidly differentiate into osteoblasts; in the bone cortex, where new osteons are formed; in the periosteum, where a hard **callus** (fibrous tissue) is formed through intramembranous ossification peripheral to the fracture, and where cartilage is formed through endochondral ossification adjacent to the fracture site; and in adjacent soft tissue, where a bridging callus forms that provides stability to the fractured bones.

The process of fracture healing occurs over three phases. These include the following:

Phase I: Reactive phase: When a fracture occurs, the body's response is similar to that after injury elsewhere in the body. There is bleeding into the injured tissue and formation of a hematoma at the site of the fracture. Cytokines are released that initiate the fracture healing processes by causing the proliferation of fibroblasts and that cause angiogenesis to occur (ie, the growth of new blood vessels). Granulation tissue begins to form within the clot and becomes dense.

Phase II: Reparative phase: During this phase, the granulation tissue is initially replaced with a callus precursor, called procallus. Fibroblasts invade the procallus and produce a denser type of callus that is composed mostly of fibrocartilage. This fibrocartilaginous callus is replaced with denser bony callus within approximately 3 to 4 weeks postinjury. Lamellar bone then forms as the bony callus calcifies months postinjury.

Phase III: Remodeling phase: The final phase of fracture healing results in remodeling the new bone into its former structural arrangement. Remodeling may take months to years, depending on the extent of bone modification needed, the function of the bone, and the functional stresses on the bone.

Serial x-rays are used to monitor the progress of bone healing. The type of bone fractured, the adequacy of blood supply, the surface contact of the fragments, the immobility of the fracture site, and the age and general health of the person influence the rate of fracture healing. Adequate immobilization is essential until there is x-ray evidence of bone formation with ossification.

When fractures are treated with open rigid compression plate fixation techniques, the bony fragments can be placed in direct contact. Primary bone healing occurs through cortical bone (Haversian) remodeling. Little or no cartilaginous callus develops. Immature bone develops from the endosteum. There is an intensive regeneration of new osteons, which develop in the fracture line by a process similar to normal bone maintenance. Fracture strength is obtained when the new osteons have become established.

Structure and Function of the Articular System

The junction of two or more bones is called a **joint** (articulation). There are three basic kinds of joints: synarthrosis, amphiarthrosis, and diarthrosis joints. Synarthrosis joints are immovable (eg, the skull sutures). Amphiarthrosis joints (eg, the vertebral joints and the symphysis pubis) allow limited motion; the bones of amphiarthrosis joints are joined by fibrous cartilage. Diarthrosis joints are freely movable joints (Fig. 66-2).

There are several types of diarthrosis joints:

- **Ball-and-socket** joints (eg, the hip and the shoulder) permit full freedom of movement.
- **Hinge** joints permit bending in one direction only (eg, the elbow and the knee).
- **Saddle** joints allow movement in two planes at right angles to each other. The joint at the base of the thumb is a saddle, biaxial joint.
- **Pivot** joints are characterized by the articulation between the radius and the ulna. They permit rotation for such activities as turning a doorknob.
- **Gliding** joints allow for limited movement in all directions and are represented by the joints of the carpal bones in the wrist.

The ends of the articulating bones of a typical movable joint are covered with smooth hyaline cartilage. A tough, fibrous sheath called the **joint capsule** surrounds the articulating bones. The capsule is lined with a membrane, the **synovium**, which secretes the lubricating and shock-absorbing synovial fluid into the joint capsule. Therefore, the bone surfaces are not in direct contact. In some synovial joints (eg, the knee), fibrocartilage disks (eg, medial meniscus) are located between the articular cartilage surfaces. These disks provide shock absorption (Porth & Matfin, 2009).

Ligaments (fibrous connective tissue bands) bind the articulating bones together. Ligaments and muscle tendons, which pass over the joint, provide joint stability. In some joints, interosseous ligaments (eg, the cruciate ligaments of

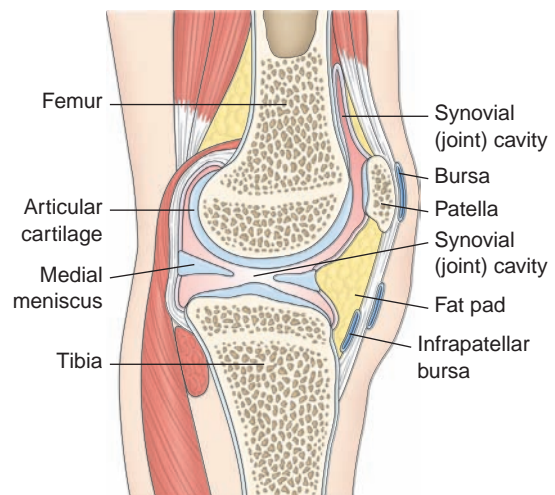

Figure 66-2 Hinge joint of the knee.

the knee) are found within the capsule and add anterior and posterior stability to the joint.

A **bursa** is a sac filled with synovial fluid that cushions the movement of tendons, ligaments, and bones at a point of friction. Bursae can be found in the joints of the elbow, shoulder, hip, and knee.

Structure and Function of the Skeletal Muscle System

Muscles are attached by tendons to bones, connective tissue, other muscles, soft tissue, or skin. The muscles of the body are composed of parallel groups of muscle cells (fasciculi) encased in fibrous tissue called **fascia** (epimysium). The more fasciculi contained in a muscle, the more precise the movements. Muscles vary in shape and size according to the activities for which they are responsible. Skeletal (striated) muscles are involved in body movement, posture, and heat-production functions. Muscles contract to bring the two points of attachment closer together, resulting in movement.

Skeletal Muscle Contraction

Each muscle cell (also referred to as a muscle fiber) contains myofibrils, which in turn are composed of a series of sarcomeres, the actual contractile units of skeletal muscle. Sarcomeres contain thick myosin and thin actin filaments.

Muscle cells contract in response to electrical stimulation delivered by an effector nerve cell at the motor end plate. When stimulated, the muscle cell depolarizes and generates an action potential in a manner similar to that described for nerve cells. These action potentials propagate along the muscle cell membrane and lead to the release of calcium ions that are stored in specialized organelles called sarcoplasmic reticula. When there is a local increase in calcium ion concentration, the myosin and actin filaments slide across one another. Shortly after the muscle cell membrane is depolarized, it recovers its resting membrane voltage. Calcium is rapidly removed from the sarcomeres by active reaccumulation in the sarcoplasmic reticulum. When the calcium concentration in the sarcomere decreases, the myosin and actin filaments cease to interact, and the sarcomere returns to its original resting length (relaxation). Actin and myosin do not interact in the absence of calcium (Porth & Matfin, 2009).

Energy is consumed during muscle contraction and relaxation. The primary source of energy for the muscle cells is adenosine triphosphate (ATP), which is generated through cellular oxidative metabolism. At low levels of activity (ie, sedentary activity), the skeletal muscle synthesizes ATP from the oxidation of glucose to water and carbon dioxide. During periods of strenuous activity, when sufficient oxygen may not be available, glucose is metabolized primarily to lactic acid, an inefficient process compared with that of oxidative pathways. Stored muscle glycogen is used to supply glucose during periods of activity. Muscle fatigue is thought to be caused by depletion of glycogen and accumulation of lactic acid. As a result, the cycle of muscle contraction and relaxation cannot continue.

During muscle contraction, the energy released from ATP is not completely used. The excess energy is dissipated in the form of heat. During isometric contraction, almost all

of the energy is released in the form of heat; during isotonic contraction, some of the energy is expended in mechanical work. In some situations (eg, shivering), the need to generate heat is the primary stimulus for muscle contraction.

The contraction of muscle fibers can result in either isotonic or isometric contraction of the muscle. In **isometric contraction**, the length of the muscles remains constant but the force generated by the muscles is increased; an example of this is pushing against an immovable wall. **Isotonic contraction**, on the other hand, is characterized by shortening of the muscle with no increase in tension within the muscle; an example of this is flexing the forearm. In normal activities, many muscle movements are a combination of isometric and isotonic contraction. For example, during walking, isotonic contraction results in shortening of the leg, and isometric contraction causes the stiff leg to push against the floor.

The speed of the muscle contraction is variable. Myoglobin is a hemoglobinlike protein pigment present in striated muscle cells that transports oxygen. Muscles containing large quantities of myoglobin (red muscles) have been observed to contract slowly and powerfully (eg, respiratory and postural muscles). Muscles containing little myoglobin (white muscles) contract quickly (eg, extraocular eye muscles). Most muscles contain both red and white muscle fibers (Porth & Matfin, 2009).

Muscle Tone

Relaxed muscles demonstrate a state of readiness to respond to contraction stimuli. This state of readiness, known as muscle **tone** (tonus), is produced by the maintenance of some of the muscle fibers in a contracted state. Muscle spindles, which are sense organs in the muscles, monitor muscle tone. Muscle tone is minimal during sleep and is increased when the person is anxious. A muscle that is limp and without tone is described as **flaccid**; a muscle with greater-than-normal tone is described as **spastic**. In conditions characterized by lower motor neuron destruction (eg, polio), denervated muscle becomes **atonic** (soft and flabby) and atrophies.

Muscle Actions

Muscles accomplish movement by contraction. Through the coordination of muscle groups, the body is able to perform a wide variety of movements (Fig. 66-3). The prime mover is the muscle that causes a particular motion. The muscles assisting the prime mover are known as synergists. The muscles causing movement opposite to that of the prime mover are known as antagonists. An antagonist must relax to allow the prime mover to contract, producing motion. For example, when contraction of the biceps causes flexion of the elbow joint, the biceps are the prime movers, and the triceps are the antagonists. A person with muscle paralysis (a loss of movement, possibly from nerve damage) may be able to retrain functioning muscles within the synergistic group to produce the needed movement. Muscles of the synergistic group then become the prime movers.

Exercise, Disuse, and Repair

Muscles need to be exercised to maintain function and strength. When a muscle repeatedly develops maximum or

FIGURE 66-3 Body movements produced by muscle contraction.

Musculoskeletal System	Structural Changes	Functional Changes	History and Physical Findings
Bones	Gradual, progressive loss of bone mass after age 30 yr Vertebrae collapse	Bones fragile and prone to fracture: vertebrae, hip, wrist	Loss of height Posture changes Kyphosis Loss of flexibility Flexion of hips and knees Back pain Osteoporosis Fracture
Muscles	Increase in collagen and resultant fibrosis Muscles diminish in size (atrophy); wasting Tendons less elastic	Loss of strength and flexibility Weakness Fatigue Stumbling Falls	Loss of strength Diminished agility Decreased endurance Prolonged response time (diminished reaction time) Diminished tone Broad base of support History of falls
Joints	Cartilage—progressive deterioration Thinning of intervertebral disks	Stiffness, reduced flexibility, and pain interfere with activities of daily living	Diminished range of motion Stiffness
Ligaments	Lax ligaments (less-than-normal strength; weakness)	Postural joint abnormality Weakness	Loss of height Joint pain on motion; resolves with rest Crepitus Joint swelling/enlargement Osteoarthritis (degenerative joint disease)

close to maximum tension over a long time, as in regular exercise with weights, the cross-sectional area of the muscle increases. This enlargement, known as **hypertrophy**, results from an increase in the size of individual muscle fibers without an increase in their number. Hypertrophy persists only if the exercise is continued. The opposite phenomenon occurs with disuse of muscle over a long period of time. Age and disuse cause loss of muscular function as fibrotic tissue replaces the contractile muscle tissue. The decrease in the size of a muscle is called **atrophy**. Bed rest and immobility cause loss of muscle mass and strength. When immobility is the result of a treatment modality (eg, casting, traction, or bedrest), the patient can decrease the effects of immobility by isometric exercise of the muscles of the immobilized part. Quadriceps contraction exercises (tightening the muscles of the thigh) and gluteal setting exercises (tightening of the muscles of the buttocks) help maintain the larger muscle groups that are important in ambulation. Active and weight-resistance exercises of uninjured parts of the body maintain muscle strength. When muscles are injured, they need rest and immobilization until tissue repair occurs. The healed muscle then needs progressive exercise to resume its preinjury strength and functional ability.

Gerontologic Considerations

Multiple changes in the musculoskeletal system occur with aging (Table 66-1). There is a loss of height due to osteoporosis (abnormal excessive bone loss), kyphosis, thinned intervertebral disks, compressed vertebral bodies, and flexion of the knees and hips. Numerous metabolic changes, including menopausal withdrawal of estrogen and decreased activity, contribute to osteoporosis (DHHS, 2004; McCormick, 2007). Women lose more bone mass than

men. In addition, bones change in shape and have reduced strength. Fractures are common. Collagen structures are less able to absorb energy. Increased inactivity, diminished neuron stimulation, and nutritional deficiencies contribute to loss of muscle strength. In addition, remote musculoskeletal problems for which the patient has compensated may become new problems with age-related changes. For example, people who have had polio and who have been able to function normally by using synergistic muscle groups may discover increasing incapacity because of a reduced compensatory ability. However, many of the effects of aging can be slowed if the body is kept healthy and active through positive lifestyle behaviors.

Assessment

Health History

The nursing assessment of the patient with musculoskeletal dysfunction includes an evaluation of the effects of the musculoskeletal disorder on the patient. The nurse is concerned with assisting patients who have musculoskeletal problems to maintain their general health, accomplish their activities of daily living, and manage their treatment programs. The nurse encourages optimal nutrition and prevents problems related to immobility. Through an individualized plan of nursing care, the nurse helps the patient achieve maximum health.

Common Symptoms

During the interview and physical assessment, the patient with a musculoskeletal disorder may report pain, tenderness, tightness, and abnormal sensations. The nurse assesses and documents this information.

Pain

Most patients with diseases and traumatic conditions or disorders of the muscles, bones, and joints experience pain. Bone pain is characteristically described as a dull, deep ache that is “boring” in nature, whereas muscular pain is described as soreness or aching and is referred to as “muscle cramps.” Fracture pain is sharp and piercing and is relieved by immobilization. Sharp pain may also result from bone infection with muscle spasm or pressure on a sensory nerve.

Rest relieves most musculoskeletal pain. Pain that increases with activity may indicate joint sprain, muscle strain, or compartment syndrome, whereas steadily increasing pain points to the progression of an infectious process (osteomyelitis), a malignant tumor, or neurovascular complications. Radiating pain occurs in conditions in which pressure is exerted on a nerve root. Pain is variable, and its assessment and nursing management must be individualized.

The nurse assesses the patient’s pain as described in Chapter 13. Specific assessments that the nurse should make regarding the pain include the following:

- Is the body in proper alignment?
- Is there pressure from traction, bed linens, a cast, or other appliances?
- Is there tension on the skin at a pin site?

It is important that the patient’s pain and discomfort be managed successfully. Not only is pain exhausting, but also, if prolonged, it can force the patient to become increasingly preoccupied and dependent (see Chapter 13).

Altered Sensations

Sensory disturbances are frequently associated with musculoskeletal problems. The patient may describe **paresthesias**, which are burning, tingling sensations or numbness. These sensations may be caused by pressure on nerves or by circulatory impairment. Soft tissue swelling or direct trauma to these structures can impair their function. The nurse assesses the neurovascular status of the involved musculoskeletal area.

Questions that the nurse should ask regarding altered sensations include the following:

- Is the patient experiencing any abnormal sensations or numbness?
- If the abnormal sensation or feeling of numbness involves an extremity, how does this feeling compare to sensation in the unaffected extremity?
- When did the condition begin? Is it getting worse?
- Does the patient also have pain? (If the patient has pain, then the questions and assessments for pain discussed previously should be followed.)

Assessments that the nurse should make regarding the altered sensations include the following:

- If the affected part is an extremity, how does its overall appearance compare to the unaffected extremity?
- Can the patient move the affected part? If an extremity is involved, does each toe/finger have normal sensation and motion (flexion and extension), and is the skin warm or cool?
- What is the color of the part distal to the affected area? Is it pale? Dusky? Mottled? Cyanotic?
- Does rapid capillary refill occur? (The nurse can gently squeeze a nail until it blanches, then release the

pressure. The amount of time for the color under the nail to return to normal is noted. Color normally returns within 3 seconds. The return of color is evidence of capillary refill.)

- Is a pulse distal to the affected area palpable? If the affected area is an extremity, how does the pulse compare to the pulse of the unaffected extremity?
- Is edema present?
- Is any constrictive device or clothing causing nerve or vascular compression?
- Does elevating the affected part or modifying its position affect the symptoms?

Past Health, Social, and Family History

When assessing the musculoskeletal system, the nurse should gather pertinent data to include in the patient’s health history, such as occupation (eg, does the patient’s work require physical activity or heavy lifting?), exercise patterns, and dietary intake (eg, calcium and vitamin D). Concurrent health conditions (eg, diabetes, heart disease, chronic obstructive pulmonary disease, infection, pre-existing disability) and related problems, such as familial or genetic abnormalities (Chart 66-1), also need to be considered when developing and implementing the plan of care.

Physical Assessment

An examination of the musculoskeletal system ranges from a basic assessment of functional capabilities to sophisticated physical examination maneuvers that facilitate diagnosis of specific bone, muscle, and joint disorders. The extent of assessment depends on the patient’s physical complaints, health history, and physical clues that warrant further exploration. The nursing assessment is primarily a functional evaluation, focusing on the patient’s ability to perform activities of daily living.

Techniques of inspection and palpation are used to evaluate the patient’s posture, gait, bone integrity, joint function, and muscle strength and size. In addition, assessing the skin and neurovascular status is an important part of a complete musculoskeletal assessment. The nurse also should understand and be able to perform correct assessment techniques on patients with musculoskeletal trauma. When specific symptoms or physical findings of musculoskeletal dysfunction are apparent, the nurse carefully documents the examination findings and shares the information with the physician, who may decide that a more extensive examination and a diagnostic workup are necessary.

Posture

The normal curvature of the spine is convex through the thoracic portion and concave through the cervical and lumbar portions. Common deformities of the spine include **kyphosis**, an increased forward curvature of the thoracic spine; **lordosis**, or swayback, an exaggerated curvature of the lumbar spine; and **scoliosis**, a lateral curving deviation of the spine (Fig. 66-4). Kyphosis is frequently seen in elderly patients with osteoporosis and in some patients with neuromuscular diseases. Scoliosis may be congenital, idiopathic (without an identifiable cause), or the result of damage to the paraspinal muscles, as in polio. Lordosis

CHART
66-1

GENETICS IN NURSING PRACTICE

Musculoskeletal Disorders

When assessing a patient with musculoskeletal complaints, nurses must not overlook the possibility of a genetic component to the patient's problems.

Musculoskeletal Impairments Influenced by Genetic Factors

- Achondroplasia
- Congenital talipes equinovarus (clubfoot)
- Developmental dysplasia of the hip (DDH) (congenital hip dysplasia)
- Ehlers-Danlos syndrome
- Marfan syndrome
- Stickler syndrome
- Osteogenesis imperfecta
- Osteoporosis
- Scoliosis

Nursing Assessments

Family History

- Assess for other similarly affected family members.
- Assess for the presence of other related genetic conditions (eg, hematologic, cardiac, integumentary conditions).
- Determine the age at onset (eg, fractures present at birth as in osteogenesis imperfecta, hip dislocation present at birth in DDH, or early-onset osteoporosis).

Patient Assessment

- Assess stature for general screening purposes (unusually short stature may be related to achondroplasia; unusually tall stature may be related to Marfan syndrome).
- Assess for disease-specific skeletal findings (eg, pectus excavatum, scoliosis, long fingers [Marfan syndrome], osteoarthritis of the hip and waddling gait [DDH]).

- Assess for disease-specific skin findings (eg, velvety texture with unusual scarring and/or thin fragile skin [Ehlers-Danlos syndrome]).
- Assess for other common disease-specific findings (eg, vision impairment [Stickler syndrome, Marfan syndrome], blue/gray sclerae, opalescent dentin, hearing impairment [osteogenesis imperfecta]).

Management Issues Specific to Genetics

- Inquire whether DNA gene mutation or other genetic testing has been performed on affected family members.
- If indicated, refer patient for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, and the availability of genetic testing and gene-based interventions.
- Offer appropriate genetic information and resources.
- Assess patient's understanding of genetic information.
- Provide support to families with newly diagnosed genetic-related musculoskeletal disorders.
- Participate in management and coordination of care of patients with genetic conditions and people predisposed to develop or pass on a genetic condition.

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; www.rarediseases.org

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions; www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM

is frequently seen during pregnancy as the woman adjusts her posture in response to changes in her center of gravity.

During inspection of the spine, the entire back, buttocks, and legs are exposed. The examiner inspects the spinal curves and trunk symmetry from posterior and lateral views. Standing behind the patient, the examiner notes any differences in the height of the shoulders or iliac crests. Shoulder and hip symmetry, as well as the line of the vertebral column, are inspected with the patient erect and with the patient bending forward (flexion). Scoliosis is evidenced by an abnormal lateral curve in the spine, shoulders that are not level, an asymmetric waistline, and a prominent scapula, accentuated by bending forward. Older adults experience a loss in height due to loss of vertebral cartilage and osteoporosis-related vertebral compression fractures. Therefore, an adult's height should be measured during health screenings.

Gait

Gait is assessed by having the patient walk away from the examiner for a short distance. The examiner observes the patient's gait for smoothness and rhythm. Any unsteadiness

or irregular movements (frequently noted in elderly patients) are considered abnormal. Limping motion is most frequently caused by painful weight bearing. In such instances, the patient can usually pinpoint the area of discomfort, thus guiding further examination. If one extremity is shorter than another, a limp may also be observed as the patient's pelvis drops downward on the affected side with each step. Limited joint motion may affect gait and a knee may be implicated. Evaluation of the knee involves the joints, bones, ligaments, tendons, and cartilage, and may include tests for the anterior and collateral ligaments, medial and lateral ligaments, and medial meniscus. In addition, a variety of neurologic conditions are associated with abnormal gaits, such as a spastic hemiparesis gait (stroke), step-page gait (lower motor neuron disease), and shuffling gait (Parkinson's disease).

Bone Integrity

The bony skeleton is assessed for deformities and alignment. Symmetric parts of the body, such as extremities, are compared. Abnormal bony growths due to bone tumors may be

Figure 66-4 A normal spine and three abnormalities. **A**, Kyphosis: an increased convexity or roundness of the spine's thoracic curve. **B**, Lordosis: swayback; exaggeration of the lumbar spine curve. **C**, Scoliosis: a lateral curvature of the spine.

observed. Shortened extremities, amputations, and body parts that are not in anatomic alignment are noted. Fracture findings may include abnormal angulation of long bones, motion at points other than joints, and **crepitus** (a grating sound) at the point of abnormal motion. Movement of fracture fragments must be minimized to avoid additional injury.

Joint Function

The articular system is evaluated by noting range of motion, deformity, stability, and nodular formation. Range of motion is evaluated both actively (the joint is moved by the muscles surrounding the joint) and passively (the joint is moved by the examiner). The examiner is familiar with the normal range of motion of major joints (see Chapter 11). Precise measurement of range of motion can be made by a goniometer (a protractor designed for evaluating joint motion). Limited range of motion may be the result of skeletal deformity, joint pathology, or **contracture** (shortening of surrounding joint structures) of the surrounding muscles, tendons, and joint capsule. In elderly patients, limitations of range of motion associated with osteoarthritis may reduce their ability to perform activities of daily living.

If joint motion is compromised or the joint is painful, the joint is examined for **effusion** (excessive fluid within the capsule), swelling, and increased temperature that may reflect active inflammation. An effusion is suspected if the joint is swollen and the normal bony landmarks are obscured. The most common site for joint effusion is the knee. If large amounts of fluid are present in the joint spaces beneath the patella, it may be identified by assessing for the balloon sign and for ballottement of the knee (Fig. 66-5). If

inflammation or fluid is suspected in a joint, consultation with a physician is indicated.

Joint deformity may be caused by contracture, dislocation (complete separation of joint surfaces), subluxation (partial separation of articular surfaces), or disruption of structures surrounding the joint. Weakness or disruption of joint-supporting structures may result in a weak joint that requires an external supporting appliance (eg, brace).

Palpation of the joint while it is passively moved provides information about the integrity of the joint. Normally, the joint moves smoothly. A snap or crack may indicate that a ligament is slipping over a bony prominence. Slightly roughened surfaces, as in arthritic conditions, result in crepitus (grating, crackling sound or sensation) as the irregular joint surfaces move across one another.

The tissues surrounding joints are examined for nodule formation. Rheumatoid arthritis, gout, and osteoarthritis may produce characteristic nodules. The subcutaneous nodules of rheumatoid arthritis are soft and occur within and along tendons that provide extensor function to the joints. The nodules of gout are hard and lie within and immediately adjacent to the joint capsule itself. They may rupture, exuding white uric acid crystals onto the skin surface. Osteoarthritic nodules are hard and painless and represent bony overgrowth that has resulted from destruction of the cartilaginous surface of bone within the joint capsule. They are frequently seen in older adults.

Often, the size of the joint is exaggerated by atrophy of the muscles proximal and distal to that joint. This is seen in rheumatoid arthritis of the knees, in which the quadriceps muscle may atrophy dramatically. In rheumatoid arthritis,

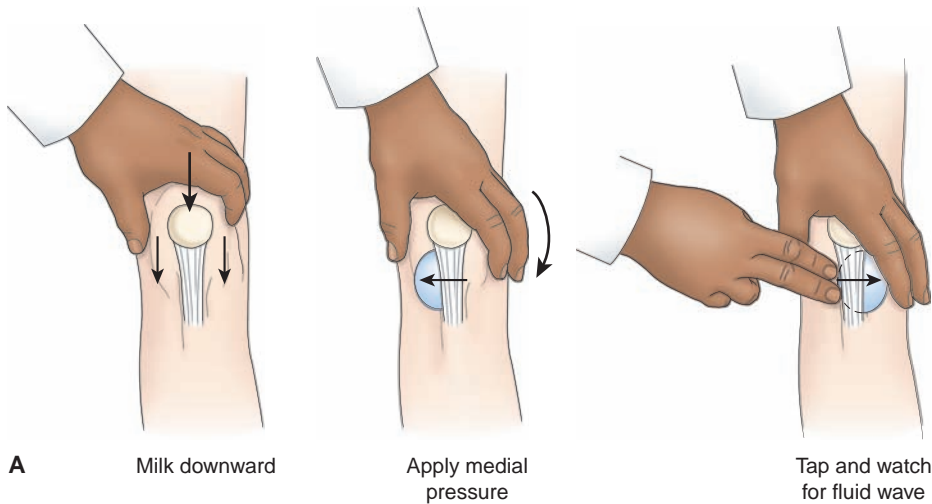

Figure 66-5 Tests for detecting fluid in the knee. **A**, Technique for balloon sign. The medial and lateral aspects of the extended knee are milked firmly in a downward motion, which displaces any fluid downward. The examiner feels for any fluid entering the space directly inferior to the patella. When larger amounts of fluid are present, the subpatellar region feels as if it is “ballooning,” and the balloon sign test is positive. **B**, Technique for ballottement sign. The medial and lateral aspects of the extended knee are milked firmly in a downward motion. The examiner pushes the patella toward the femur and observes for fluid return to the region superior to the patella. When larger amounts of fluid are present, the patella elevates, there is visible return of fluid to the region directly superior to the patella, and the ballottement test is positive. Photograph used with permission from Bickley, L. S. (2007). *Bates’ guide to physical examination and history taking* (9th ed.). Philadelphia: Lippincott Williams & Wilkins.

B

joint involvement assumes a symmetric pattern (Fig. 66-6). (See Chapter 54 for further information about rheumatoid arthritis.)

Muscle Strength and Size

The muscular system is assessed by noting muscular strength and coordination, the size of individual muscles, and the patient’s ability to change position. Weakness of a group of muscles might indicate a variety of conditions, such as polyneuropathy, electrolyte disturbances (particularly potassium and calcium), myasthenia gravis, poliomyelitis, and muscular dystrophy. By palpating the muscle while passively moving the relaxed extremity, the nurse can determine the muscle tone. The nurse assesses muscle strength by having the patient perform certain maneuvers with and without added resistance. For example, when the biceps are tested, the patient is asked to extend the arm fully and then

Figure 66-6 Rheumatoid arthritis joint deformity with ulnar deviation of fingers and “swan neck” deformity of fingers (ie, hyperextension of proximal interphalangeal joints with flexion of distal interphalangeal joints).

to flex it against resistance applied by the nurse. A simple handshake may provide an indication of grasp strength.

The nurse may elicit muscle **clonus** (rhythmic contractions of a muscle) in the ankle or wrist by sudden, forceful, sustained dorsiflexion of the foot or extension of the wrist. **Fasciculation** (involuntary twitching of muscle fiber groups) may be observed.

The nurse measures the girth of an extremity to monitor increased size due to exercise, edema, or bleeding into the muscle. Girth may decrease due to muscle atrophy. The unaffected extremity is measured and used as the reference standard for the affected extremity. Measurements are taken at the maximum circumference of the extremity. It is important that the measurements be taken at the same location on the extremity, and with the extremity in the same position, with the muscle at rest. Distance from a specific anatomic landmark (eg, 10 cm below the medial aspect of the knee for measurement of the calf muscle) should be indicated in the patient's record so that subsequent measurements can be made at the same point. For ease of serial assessment, the nurse may indicate the point of measurement by marking the skin. Variations in size greater than 1 cm are considered significant.

Skin

In addition to assessing the musculoskeletal system, the nurse inspects the skin for edema, temperature, and color. Palpation of the skin can reveal whether any areas are warmer, suggesting increased perfusion or inflammation, or cooler, suggesting decreased perfusion, and whether edema is present. Cuts, bruises, skin color, and evidence of decreased circulation or inflammation can influence nursing management of musculoskeletal conditions.

Neurovascular Status

It is important for the nurse to perform frequent neurovascular assessments of patients with musculoskeletal disorders (especially of those with fractures) because of the risk for tissue and nerve damage. Chart 66-2 describes tests of peripheral nerve function that the nurse may perform. One complication that the nurse needs to be alert for when assessing the patient is compartment syndrome, which is described in detail later in this unit. This major neurovascular problem is caused by pressure within a muscle compartment that increases to such an extent that microcirculation diminishes, leading to nerve and muscle anoxia and necrosis. Function can be permanently lost if the anoxic situation continues for longer than 6 hours. Assessment of neurovascular status (Chart 66-3) is frequently referred to as assessment of CMS (circulation, motion, and sensation).

Diagnostic Evaluation

Imaging Procedures

X-Ray Studies

X-ray studies are important in evaluating patients with musculoskeletal disorders. Bone x-rays determine bone density, texture, erosion, and changes in bone relationships. X-ray study of the cortex of the bone reveals any widening,

CHART 66-2 Assessing for Peripheral Nerve Function

Assessment of peripheral nerve function has two key elements: evaluation of sensation and evaluation of motion. The nurse may perform one or all of the following during a musculoskeletal assessment.

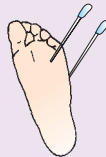

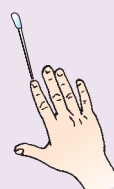

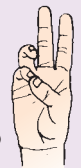

Nerve	Test of Sensation	Test of Movement
Peroneal nerve	Prick the skin midway between the great and second toe. 	Ask the patient to dorsiflex the foot and extend the toes. 
Tibial nerve	Prick the medial and lateral surface of the sole. 	Ask the patient to plantar flex toes and foot. 
Radial nerve	Prick the skin midway between the thumb and second finger. 	Ask the patient to stretch out the wrist, then the fingers at the metacarpal joints. 
Ulnar nerve	Prick the distal fat pad of the small finger. 	Ask the patient to abduct all fingers. 
Median nerve	Prick the top or distal surface of the index finger. 	Ask the patient to touch the thumb to the little finger. Also observe whether the patient can flex the wrist.

narrowing, or signs of irregularity. Joint x-rays reveal fluid, irregularity, spur formation, narrowing, and changes in the joint structure. Multiple x-rays, with multiple views (eg, anterior-posterior, lateral), are needed for full assessment of the structure being examined. Serial x-rays may be indicated to determine the status of the healing process. After being positioned for the study, the patient must remain still while the x-rays are obtained.

Computed Tomography

A computed tomography (CT) scan, which may be performed with or without the use of contrast agents, shows in detail a specific plane of involved bone and can reveal tumors of the soft tissue or injuries to the ligaments or tendons. It is used to identify the location and extent of fractures in areas that are difficult to evaluate (eg, acetabulum). The patient must remain still during the procedure (Goodhart & Page, 2007).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive imaging technique that uses magnetic fields, radiowaves, and computers to demonstrate abnormalities (ie, tumors or narrowing of tissue pathways through bone) of soft tissues such as muscle, tendon, cartilage, nerve, and fat. Because an electromagnet is used, patients with any metal implants, clips, or pacemakers are not candidates for MRI.

NURSING ALERT

Jewelry, hair clips, hearing aids, credit cards with magnetic strips, and other metal-containing objects must be removed before the MRI is performed; otherwise, they can become dangerous projectile objects or cause burns. Credit cards with magnetic strips may be erased, and nonremovable cochlear devices can become inoperable. Also, transdermal patches (eg, NicoDerm, Transderm-Nitro, Transderm Scopolamine, Catapres-TTS) that have a thin layer of aluminized backing must be removed before MRI because they can cause burns. The physician should be notified before the patches are removed.

To enhance visualization of anatomic structures, intravenous (IV) contrast agent may be used. During the MRI, the patient must lie still and will hear a rhythmic knocking sound. Patients who experience claustrophobia may be unable to tolerate the confinement of closed MRI equipment without sedation. Open MRI systems are available, but they use lower-intensity magnetic fields, which produce lower-quality images. Advantages of open MRI include increased patient comfort, reduced problems with claustrophobic reactions, and reduced noise.

Arthrography

Arthrography is useful in identifying acute or chronic tears of the joint capsule or supporting ligaments of the knee, shoulder, ankle, hip, or wrist. A radiopaque contrast agent or air is injected into the joint cavity to visualize irregular surfaces. The joint is put through its range of motion to distribute the contrast agent while a series of x-rays is obtained. If a tear is present, the contrast agent leaks out of the joint and is evident on the x-ray image.

After an arthrogram, a compression elastic bandage is applied as prescribed and the joint is usually rested for 12 hours. The nurse provides additional comfort measures (mild analgesia, ice) as appropriate and explains to the patient that it is normal to experience clicking or crackling in the joint for a day or two after the procedure, until the contrast agent or air is absorbed.

Nursing Interventions for Imaging Studies

Before the patient undergoes an imaging study, the nurse assesses for conditions that may require special consideration during the study or that may be contraindications to the study (eg, pregnancy; claustrophobia; inability to tolerate required positioning due to age, debility, or disability; metal implants). If contrast agents will be used for CT scan, MRI, or arthrography, the patient is assessed for possible allergies (Goodhart & Page, 2007).

Bone Densitometry

Bone densitometry is used to estimate bone mineral density (BMD). This can be performed through the use of x-rays or ultrasound. The most common modalities used include dual-energy x-ray absorptiometry (DXA or DEXA), quantitative computed tomography (QCT), and quantitative ultrasound (QUS). DXA BMD measures of the hip and spine are very accurate in estimating the extent of osteoporosis and monitoring a patient's response to treatment for osteoporosis. Peripheral DXA (pDXA) may be an alternative test that measures BMD of the forearm, finger, or heel, though its ability to project hip or spine fracture risk is less accurate than DXA. While the BMD of the heel can be used to diagnose and monitor osteoporosis, predicting hip fracture risk related to osteoporosis is best achieved through DXA of the hip; hence, it is the most commonly prescribed diagnostic test for determining BMD (Bonnick, 2005; National Osteoporosis Foundation, 2008). (See Chapter 68 for a further discussion of osteoporosis risks.)

Bone Scan

A bone scan is performed to detect metastatic and primary bone tumors, osteomyelitis, some fractures, and aseptic necrosis. A bone-seeking radioisotope is injected

IV. The scan is performed 2 to 3 hours after the injection. At this point, distribution and concentration of the isotope in the bone are measured. The degree of nuclide uptake is related to the metabolism of the bone. An increased uptake of isotope is seen in primary skeletal disease (osteosarcoma), metastatic bone disease, inflammatory skeletal disease (osteomyelitis), and fractures that do not heal as expected.

Nursing Interventions

Before the patient undergoes a bone scan, the nurse inquires about possible allergies to the radioisotope and assesses for any condition that would contraindicate performing the procedure (eg, pregnancy). In addition, the patient is encouraged to drink plenty of fluids to help distribute and eliminate the isotope. Before the scan, the nurse asks the patient to empty the bladder, because a full bladder interferes with accurate scanning of the pelvic bones.

Arthroscopy

Arthroscopy is a procedure that allows direct visualization of a joint to diagnose joint disorders. Treatment of tears, defects, and disease processes may be performed through the arthroscope. The procedure is performed in the operating room under sterile conditions; injection of a local anesthetic agent into the joint or general anesthesia is used. A large-bore needle is inserted, and the joint is distended with saline. The arthroscope is introduced, and joint structures, synovium, and articular surfaces are visualized. After the procedure, the puncture wound is closed with adhesive strips or sutures and covered with a sterile dressing. Complications are rare but may include infection, hemarthrosis, neurovascular compromise, thrombophlebitis, stiffness, effusion, adhesions, and delayed wound healing.

Nursing Interventions

After the arthroscopic procedure, the joint is wrapped with a compression dressing to control swelling. In addition, ice may be applied to control edema and enhance comfort. Frequently, the joint is kept extended and elevated to reduce swelling. It is important to monitor and document the neurovascular status. Analgesic agents are administered as needed. The patient is instructed about activities and exercises that may be performed. The patient and family are informed of the symptoms (eg, swelling, numbness, cool skin) to watch for in order to determine whether complications are occurring and of the importance of notifying the physician of these observations.

Arthrocentesis

Arthrocentesis (joint aspiration) is carried out to obtain synovial fluid for purposes of examination or to relieve pain due to effusion. Examination of synovial fluid is helpful in the diagnosis of septic arthritis and other inflammatory arthropathies and reveals the presence of hemarthrosis (bleeding into the joint cavity), which suggests trauma or a bleeding disorder. Normally, synovial fluid is clear, pale, straw colored, and scanty in volume. Using aseptic technique, the physician inserts a needle into the joint and aspirates fluid. Anti-inflammatory medications may be in-

jected into the joint. A sterile dressing is applied after aspiration. There is a risk of infection after this procedure.

Electromyography

Electromyography (EMG) provides information about the electrical potential of the muscles and the nerves leading to them. The test is performed to evaluate muscle weakness, pain, and disability. The purpose of the procedure is to determine any abnormality of function and to differentiate muscle and nerve problems. Needle electrodes are inserted into selected muscles, and responses to electrical stimuli are recorded on an oscilloscope. Warm compresses may relieve residual discomfort after the study.

Biopsy

Biopsy may be performed to determine the structure and composition of bone marrow, bone, muscle, or synovium to help diagnose specific diseases. The nurse teaches the patient about the procedure and assures the patient that analgesic agents will be provided. The nurse monitors the biopsy site for edema, bleeding, pain, and infection. Ice is applied as prescribed to control bleeding and edema. In addition, analgesic agents are administered as prescribed for comfort.

Laboratory Studies

Examination of the patient's blood and urine can provide information about a primary musculoskeletal problem (eg, Paget's disease of the bone), a developing complication (eg, infection), the baseline for instituting therapy (eg, anticoagulant therapy), or the response to therapy. Before surgery, coagulation studies are performed to detect bleeding tendencies (because bone is vascular tissue).

Serum calcium levels are altered in patients with osteomalacia, parathyroid dysfunction, Paget's disease, metastatic bone tumors, or prolonged immobilization. Serum phosphorus levels are inversely related to calcium levels and are diminished in osteomalacia associated with malabsorption syndrome. Acid phosphatase is elevated in Paget's disease and metastatic cancer. Alkaline phosphatase is elevated during early fracture healing and in diseases with increased osteoblastic activity (eg, metastatic bone tumors). Bone metabolism may be evaluated through thyroid studies and determination of calcitonin, PTH, and vitamin D levels. Serum enzyme levels of creatine kinase and aspartate aminotransferase become elevated with muscle damage. Serum osteocalcin (bone GLA protein) indicates the rate of bone turnover. Urine calcium levels increase with bone destruction (eg, parathyroid dysfunction, metastatic bone tumors, multiple myeloma) (McCormick, 2007).

Specific urine and serum biochemical markers can be used to provide information about bone formation. These include urinary N-telopeptide of type 1 collagen (N-Tx) and deoxypyridinoline (Dpd), both of which reflect increased osteoclast activity and increased bone resorption. Conversely, elevated serum levels of bone-specific alkaline phosphatase (ALP), osteocalcin, and intact N-terminal propeptide of type 1 collagen (P1NP) reflect increased activity of osteoblasts and enhanced bone remodeling activity (McCormick, 2007).

CRITICAL THINKING EXERCISES

EBP 1 A 72-year-old Caucasian woman arrives at the emergency department where you are the triage nurse. She is complaining of severe pain in her right groin area and has some discomfort when she puts weight on or moves her right hip. She stated that she did not fall or injure the extremity; she just was walking down the steps and felt a “force” on her right leg. There are no deformities noted. What are the first evaluation assessments that you would perform? What is the evidence base that indicates that this woman may be at increased risk for osteoporosis-related fractures? What recommendations might be made for appropriate testing in this patient? What are the most important medical history questions you would ask her?

2 A 15-year-old high school football player came into the orthopedic office after sustaining a “direct blow” to the left knee last night during a game. He has slight edema and complains of pain with movement and weight bearing. What is your first physical assessment activity? How would you assess the stability of his left knee? What diagnostic tests are most likely indicated?

EBP 3 You are a parish nurse teaching a class to senior citizens in your parish centered on age-associated changes in the musculoskeletal system. The participants have experienced many of the changes you identify and ask you what they can do about them. What is the evidence base that supports the strategies that these elderly citizens might implement to minimize these changes and maximize musculoskeletal health? What is the strength of the evidence of the effectiveness of these strategies? Focus your teaching strategies on prevention of falls and on prevention of osteoporosis.

Musculoskeletal Care Modalities

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify the preventive and health teaching needs of the patient with a cast, brace, or splint.
- 2 Describe the nursing management of the patient with a cast, brace, or splint.
- 3 Describe the various types of traction and the principles of effective traction.
- 4 Identify the preventive nursing care needs of the patient in traction.
- 5 Describe the nursing management of the patient in traction.
- 6 Compare the nursing needs of the patient undergoing total hip replacement with those of the patient undergoing total knee replacement.
- 7 Use the nursing process as a framework for care of the patient undergoing orthopedic surgery.

GLOSSARY

- abduction:** movement away from the center or median line of the body
- adduction:** movement toward the center or median line of the body
- avascular necrosis:** death of tissue due to insufficient blood supply
- brace:** externally applied device to support the body or a body part, control movement, and prevent injury
- cast:** rigid external immobilizing device molded to contours of body part
- cast syndrome:** psychological (claustrophobic reaction) or physiologic (superior mesenteric artery syndrome) responses to confinement in body cast
- continuous passive motion (CPM) device:** a device that promotes range of motion, circulation, and healing
- edema:** soft tissue swelling due to fluid accumulation
- external fixator:** external metal frame attached to bone fragments to stabilize them
- fracture:** a break in the continuity of the bone
- heterotopic ossification:** misplaced formation of bone
- neurovascular status:** neurologic (motor and sensory components) and circulatory functioning of a body part
- open reduction with internal fixation (ORIF):** open surgical procedure to repair and stabilize a fracture
- osteomyelitis:** infection of the bone
- osteotomy:** surgical cutting of bone
- slings:** bandage used to support an arm
- splint:** device designed specifically to support and immobilize a body part in a desired position
- traction:** application of a pulling force to a part of the body
- trapeze:** overhead assistive device to promote patient mobility in bed

The management of musculoskeletal injuries and disorders frequently includes the use of casts, braces, splints, traction, surgery, or a combination of these. Patient education is essential for optimal outcomes. The nurse prepares the patient for immobilization with casts or traction, and for surgery, when indicated. Nursing care is planned to maximize the effectiveness of these treatment modalities and to prevent potential complications associated with each of the interventions. The patient is taught to manage care at home and how to safely resume activities.

The Patient in a Cast, Splint, or Brace

Casts

A **cast** is a rigid external immobilizing device that is molded to the contours of the body. A cast is used specifically to immobilize a reduced **fracture**, to correct a deformity, to apply uniform pressure to underlying soft tissue, or to support and stabilize weakened joints (Altizer, 2004). Generally, casts permit mobilization of the patient while restricting movement of a body part.

The condition being treated influences the type and thickness of the cast applied. Generally, the joints proximal and distal to the area to be immobilized are included in the cast. However, with some fractures, cast construction and molding may allow movement of a joint while immobilizing a fracture (eg, three-point fixation in a patellar tendon weight-bearing cast). Various types of casts include the following:

Short-arm cast: Extends from below the elbow to the palmar crease, secured around the base of the thumb. If the thumb is included, it is known as a *thumb spica* or *gauntlet* cast.

Long-arm cast: Extends from the axillary fold to the proximal palmar crease. The elbow usually is immobilized at a right angle.

Short-leg cast: Extends from below the knee to the base of the toes. The foot is flexed at a right angle in a neutral position.

Long-leg cast: Extends from the junction of the upper and middle third of the thigh to the base of the toes. The knee may be slightly flexed.

Walking cast: A short- or long-leg cast reinforced for strength.

Body cast: Encircles the trunk.

Shoulder spica cast: A body jacket that encloses the trunk, shoulder, and elbow.

Hip spica cast: Encloses the trunk and a lower extremity. A double hip spica cast includes both legs.

Figure 67-1 illustrates long-arm and long-leg casts and areas in which pressure problems commonly occur with these casts.

Fiberglass Casts

Fiberglass casts are composed of water-activated polyurethane materials that have the versatility of plaster (see later discussion) but are lighter in weight, stronger, and more durable than plaster. In addition, they are water resistant (Altizer, 2004). They consist of an open-weave, nonabsorbent fabric impregnated with cool water-activated hardeners that bond and reach full rigid strength in minutes. Heat is given off (an exothermic reaction) while the cast is applied. Therefore, a newly applied fiberglass cast should not be placed on a plastic surface. The heat given off during this reaction can be uncomfortable, and the nurse should prepare the patient for the sensation of increasing warmth so that the patient does not become alarmed. While the cast is setting, it can be dented. Therefore, it must be handled with the palms of the hands and not allowed to rest on hard surfaces or sharp edges. Cast dents may press on the skin, causing irritation and skin breakdown.

Some fiberglass casts use a waterproof lining (Gore-Tex), which permits the patient to shower, swim, or engage in hydrotherapy (use of water for treatment). When the cast is wet, the patient is instructed to shake or drain water out of it; thorough drying is important to prevent skin breakdown. The best results are achieved with casts that can easily drain, such as short-arm casts. Heels and elbows encased in wet casts may become macerated from the trapped water and therefore are associated with more skin breakdown.

Figure 67-1 Pressure areas in common types of casts. **Left**, Long-arm cast. **Right**, Short-leg cast.

Plaster Casts

Casts made of plaster are less costly and achieve a better mold than fiberglass casts; however, they are not as durable and take longer to dry. Rolls of plaster of Paris-impregnated bandages are wet in cool water and applied smoothly to the body. These will also cause an exothermic reaction, similar to that seen with fiberglass casts. The crystallization process produces a rigid dressing in 15 to 20 minutes. After the plaster sets, the cast remains wet and somewhat soft. It does not have its full strength until it is dry. The plaster cast requires 24 to 72 hours to dry completely, depending on its thickness and the environmental drying conditions. A freshly applied cast should be exposed to circulating air to dry and should not be covered with clothing or bed linens or placed on plastic-coated mats or bedding. A wet plaster cast appears dull and gray, sounds dull on percussion, feels damp, and smells musty. A dry plaster cast is white and shiny, resonant to percussion, odorless, and firm.

Splints and Braces

Many injuries that were previously treated with casts may now be treated with other immobilization devices (eg, braces, splints) (Nash, Mickan, Del Mar, et al., 2005).

Contoured **splints** of plaster or pliable thermoplastic materials may be used for conditions that do not require rigid immobilization, for those in which swelling may be anticipated, and for those that require special skin care. Splints made of thermoplastics are warmed and molded to fit the patient (eg, hand splints and thoracolumbosacral orthotics [TLSOs], clamshell-type back braces). The splint needs to immobilize and support the body part in a functional position and it must be well padded to prevent pressure, skin abrasion, and skin breakdown. The splint is overwrapped with an elastic bandage applied in a spiral fashion and with pressure uniformly distributed so that circulation is not restricted. Splints are generally indicated for short-term use (Gravlee & Van Durme, 2007).

Braces (ie, orthoses) are used to provide support, control movement, and prevent additional injury. They are custom fitted to various parts of the body. The orthotist adjusts the brace for fit, positioning, and motion so that movement is enhanced, any deformities are corrected, and discomfort is minimized. Braces are generally indicated for longer use than splints (Gravlee & Van Durme, 2007).

Many splints and braces are prefabricated. They may be made of plastic and other materials such as cloth, leather, metal, elastic and Velcro. Knee immobilizers, ankle stirrups, and cock-up wrist splints are types of prefabricated splints and braces.

General Nursing Management of a Patient in a Cast, Splint, or Brace

Before the cast, brace, or splint is applied, the nurse completes an assessment of the patient's general health, presenting signs and symptoms, emotional status, understanding of the need for the device, and condition of the body part to be immobilized. Physical assessment of the part to be immobilized must include assessment of the **neurovascular status** (ie, neurologic and circulatory functioning) of the body part and degree and location of swelling, bruising, and

skin abrasions. In addition, the nurse gives the patient information about the underlying pathologic condition and the purpose and expectations of the prescribed treatment regimen. This knowledge promotes the patient's active participation in and compliance with the treatment program. It is important to prepare the patient for the application of the cast, brace, or splint by describing the anticipated sights, sounds, and sensations (eg, heat from the hardening reaction of the fiberglass or plaster). The patient needs to know what to expect during application and the reason the body part must be immobilized (Chart 67-1).

The nurse must carefully evaluate pain associated with the musculoskeletal condition, asking the patient to indicate the exact site and to describe the character and intensity of the pain to help determine its cause. Most pain can be relieved by elevating the involved part, applying cold packs, and administering analgesic agents as prescribed.

NURSING ALERT

A patient's unrelieved pain must be immediately reported to the physician to avoid possible paralysis and necrosis.

Pain associated with the underlying condition (eg, fracture) is frequently controlled by immobilization. Pain due to **edema** that is associated with trauma, surgery, or bleeding into the tissues can frequently be controlled by elevation and, if prescribed, intermittent application of cold packs. Ice bags (one-third to one-half full) or cold application devices are placed on each side of the cast, if prescribed, making sure not to indent or wet the cast.

Pain may be indicative of complications. Pain associated with compartment syndrome (see Chapter 69 and later in this chapter) is relentless and is not controlled by modalities such as elevation, application of cold if prescribed, and usual dosages of analgesic agents. Severe burning pain over bony prominences, especially the heels, anterior ankles, and elbows, warns of an impending pressure ulcer. These may also occur from too-tight ace wraps used to hold splints in place. Pain decreases when ulceration occurs. Discomfort due to pressure on the skin may be relieved by elevation that controls edema or by positioning that alters pressure. It may be necessary to modify the dressing, ace wrap, or cast, or to apply a new cast.

NURSING ALERT

The nurse must never ignore complaints of pain from the patient in a cast because of the possibility of problems, such as impaired tissue perfusion or pressure ulcer formation.

Every joint that is not immobilized should be exercised and moved through its range of motion to maintain function. If the patient has a leg cast, brace, or splint, the nurse encourages toe exercises. If the patient has an arm immobilized, the nurse encourages finger exercises.

To promote healing, it is important to treat any skin lacerations and abrasions that may have occurred as a result of the trauma that caused the fracture before the cast, brace, or

 CHART
67-1

Guidelines for Applying a Cast

Equipment

- Drape for patient
- Knitted material (eg, stockinette)
- Nonwoven roll padding
- Casting material
- Water and basin
- Cast knife or cutter

Implementation

Procedure

1. Support extremity or body part to be casted.
2. Position and maintain part to be casted in position indicated by physician during casting procedure.
3. Drape patient.
4. Wash and dry part to be casted.
5. Place at least three layers of knitted material* (eg, stockinette) over part to be casted.
 - Apply in smooth and nonconstrictive manner.
 - Allow additional material.
6. Wrap soft, nonwoven roll padding* smoothly and evenly around part.
 - Use additional padding around bony prominences to protect superficial nerves (eg, head of fibula, olecranon process).
7. Apply plaster or fiberglass casting material evenly on body part.
 - Choose appropriate-width bandage.
 - Overlap preceding turn by half the width of the bandage.
 - Use continuous motion, maintaining constant contact with body part.
 - Use additional casting material (splints) at joints and at points of anticipated cast stress.
8. "Finish" cast.
 - Smooth edges.
 - Trim and reshape with cast knife or cutter.
9. Remove particles of casting materials from skin.
10. Support cast during hardening.
 - Handle hardening casts with palms of hands.
 - Support cast on firm, smooth surface.
 - Do not rest cast on hard surfaces or on sharp edges.
 - Avoid pressure on cast.
11. Promote drying of cast.
 - Leave cast uncovered and exposed to air.
 - Turn patient every 2 hours, supporting major joints.
 - Fans may be used to increase air flow and speed drying.

Rationale

1. Minimizes movement; maintains reduction and alignment; increases comfort
2. Facilitates casting; reduces incidence of complications (eg, malunion, nonunion, contracture)
3. Avoids undue exposure; protects other body parts from contact with casting materials
4. Reduces incidence of skin breakdown
5. Protects skin from casting materials
Protects skin from pressure
Folds over edges of cast when finishing application; creates smooth, padded edge; protects skin from abrasion
6. Protects skin from pressure of cast
Protects skin at bony prominences
Protects superficial nerves
7. Creates smooth, solid, well-contoured cast
Facilitates smooth application
Creates smooth, solid, immobilizing cast
Shapes cast properly for adequate support
Strengthens cast
8. Protects skin from abrasion
Allows full range of motion of adjacent joints
9. Prevents particles from loosening and sliding underneath cast
10. Casting materials begin to harden in minutes. Maximum hardness of nonplaster cast occurs in minutes. Maximum hardness of plaster cast occurs with drying (24 to 72 hours, depending on environment and thickness of cast).
Avoids denting of cast and development of pressure areas
11. Facilitates drying

*Nonabsorbent materials are used with nonplaster casts.

splint is applied. The nurse thoroughly cleans the skin and treats it as prescribed. The patient may require a tetanus booster if the wound is dirty and if the last known booster was administered more than 5 years ago. Sterile dressings are used to cover the injured skin. If the skin wounds are extensive, an alternative method (eg, external fixator) may be chosen to immobilize the body part. While the cast is on, the nurse observes the patient for systemic signs of infection; odors from the cast, brace, or splint; and purulent

drainage staining the cast. It is important to notify the physician if any of these occur.

The nurse monitors circulation, motion, and sensation of the affected extremity, assessing the fingers or toes of the affected extremity and comparing them with those of the opposite extremity. Normal findings include minimal edema, minimal discomfort, pink color, warm to touch, rapid capillary refill response, normal sensations, and ability to exercise fingers or toes (Konstantakos, Dalstrom, Nelles,

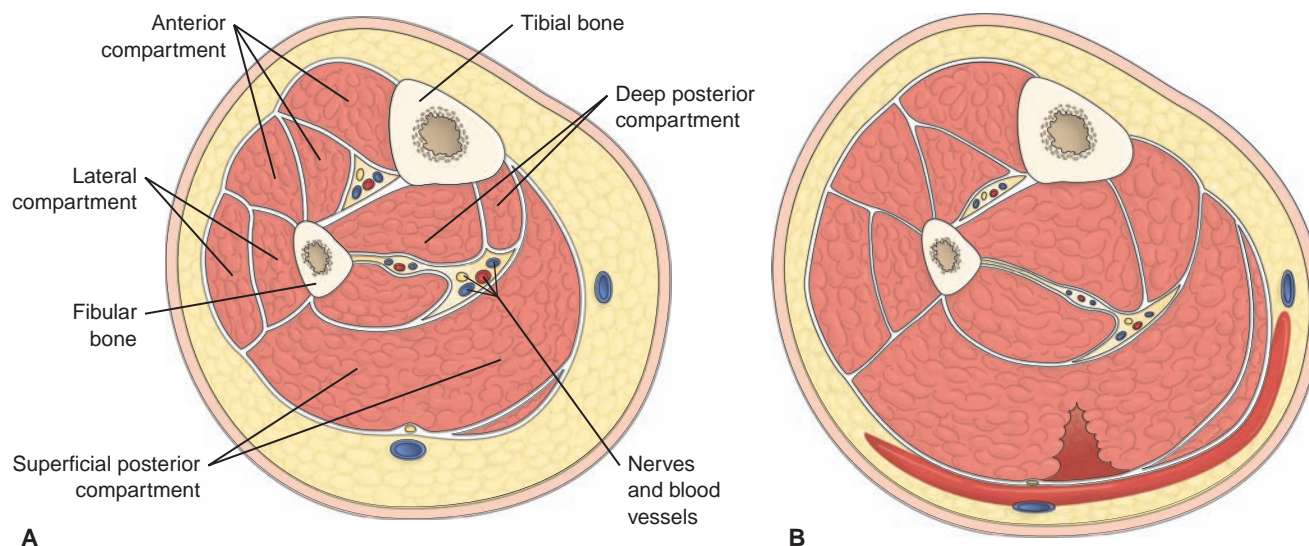

Figure 67-2 A, Cross-section of normal lower leg with muscle compartments. B, Cross-section of lower leg with compartment syndrome. Swelling of muscles causes compression of nerves and blood vessels.

et al., 2007). The nurse encourages the patient to move all fingers or toes hourly when awake to stimulate circulation.

It is important to perform frequent, regular assessments of neurovascular status. The “five P’s” that require assessment are symptoms of neurovascular compromise: *p*ain, *p*allor, *p*ulselessness, *p*aresthesia, and *p*aralysis. Early recognition of diminished circulation and nerve function is essential to prevent loss of function. The nurse adjusts the extremity so that it is no higher than heart level to enhance arterial perfusion and control edema and notifies the physician at once if signs of compromised neurovascular status are present.

Monitoring and Managing Potential Complications

Potential complications related to casts, braces, and splints include compartment syndrome, pressure ulcer formation, and disuse syndrome. These most commonly occur when a cast is applied, because the cast is not easily removable, and are least commonly associated with use of a splint, because splints tend to be used for the short term.

Compartment Syndrome

Edema is a natural response of the tissue to trauma. The patient may complain that the cast, brace, or splint is too tight. Vascular insufficiency and nerve compression due to unrelieved swelling can result in compartment syndrome (Fig. 67-2). Compartment syndrome occurs when there is increased tissue pressure within a limited space (eg, cast, muscle compartment) that compromises the circulation and the function of the tissue within the confined area. To relieve the pressure, the cast must be bivalved (cut in half longitudinally) while maintaining alignment, and the extremity must be elevated no higher than heart level to ensure arterial perfusion (Chart 67-2). If pressure is not relieved and circulation is not restored, a fasciotomy may be necessary to relieve the pressure within the muscle compartment. The nurse closely monitors the patient’s response to conservative and surgical management of compartment syndrome (Konstantakos, et al., 2007). The nurse records

neurovascular responses and promptly reports changes to the physician. (See Chapter 69 for further discussion of compartment syndrome.)

Pressure Ulcers

Pressure of a cast or an inappropriately applied brace on soft tissues may cause tissue anoxia and pressure ulcers. Lower extremity sites most susceptible to pressure ulcers are the heel, malleoli, dorsum of the foot, head of the fibula, and anterior surface of the patella. The main pressure sites on the upper extremity are located at the medial epicondyle of the humerus and the ulnar styloid (see Fig. 67-1).

Usually, the patient with a pressure ulcer reports pain and tightness in the area. A warm area on the cast or brace suggests underlying tissue erythema. Skin breakdown may occur. The drainage may stain the cast or brace and emit an odor. Even if discomfort does not occur with skin breakdown and tissue necrosis, there may still be extensive loss of tissue. The nurse must monitor the patient with a cast or brace for pressure ulcer development and report findings to the physician.

Chart 67-2 • Procedure for Bivalving a Cast

The following procedure is followed when a cast is bivalved.

1. With a cast cutter, a longitudinal cut is made to divide the cast in half.
2. The underpadding is cut with scissors.
3. The cast is spread apart with cast spreaders to relieve pressure and to inspect and treat the skin without interrupting the reduction and alignment of the bone.
4. After the pressure is relieved, the anterior and posterior parts of the cast are secured together with an elastic compression bandage to maintain immobilization.
5. To control swelling and promote circulation, the extremity is elevated (but no higher than heart level, to minimize the effect of gravity on perfusion of the tissues).

To inspect the pressure ulcer area, the brace may be removed. For a patient with a cast, the physician may bivalve or cut an opening (window) in the cast. If the physician elects to create a window to inspect the pressure site, a portion of the cast is cut out. The affected area is inspected and possibly treated. The portion of the cast is replaced and held in place by an elastic compression dressing or tape. This prevents window edema, which is the swelling of soft tissue through the area unopposed by casting material (National Association of Orthopedic Nurses [NAON], 2007).

Disuse Syndrome

Immobilization in a cast, brace, or splint can cause muscle atrophy and loss of strength, known as *disuse syndrome*. To prevent this, the patient needs to learn to tense or contract muscles (eg, isometric muscle contraction) without moving the part. The nurse teaches the patient with a leg cast, brace, or splint to “push down” the knee and teaches the patient in an arm cast, brace, or splint to “make a fist.” Muscle-setting exercises (eg, quadriceps-setting and gluteal-setting exercises) are important in maintaining muscles essential for walking (Chart 67-3). Isometric exercises should be performed hourly while the patient is awake.

Promoting Home and Community-Based Care

Teaching the Patient Self-Care

Self-care deficits occur when a portion of the body is immobilized. The nurse encourages the patient to participate actively in personal care and to use assistive devices safely. The nurse must assist the patient in identifying areas of self-

Chart 67-3 • Muscle-Setting Exercises

Isometric contractions of the muscle maintain muscle mass and strength and prevent atrophy.

Quadriceps-Setting Exercise

- Position patient supine with leg extended.
- Instruct patient to push knee back onto the mattress by contracting the anterior thigh muscles.
- Encourage patient to hold the position for 5 to 10 seconds.
- Let patient relax.
- Have patient repeat the exercise 10 times each hour when awake.

Gluteal-Setting Exercise

- Position patient supine with legs extended, if possible.
- Instruct patient to contract the muscles of the buttocks.
- Encourage patient to hold the contraction for 5 to 10 seconds.
- Let the patient relax.
- Have patient repeat the exercise 10 times each hour when awake.

care deficit and in developing strategies to achieve independence in activities of daily living (ADLs) (Chart 67-4). The patient's participation in planning and accomplishing ADLs is an important aspect of self-care, independence, maintaining control, and avoiding untoward psychological reactions, such as depression. Patient and caregiver education is also described in Chart 67-4.

CHART
67-4

HOME CARE CHECKLIST

The Patient With a Cast, Splint, or Brace

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe techniques to promote cast drying (eg, do not cover, leave exposed to circulating air, handle damp plaster cast with palms of hands and do not rest the cast on hard surfaces or sharp edges that can dent soft cast).	✓	✓
• Describe approaches to controlling swelling and pain (eg, elevate immobilized extremity to heart level, apply intermittent ice bag if prescribed, take analgesic agents as prescribed).	✓	✓
• Report pain uncontrolled by elevating the immobilized limb and by analgesic agents (may be an indicator of impaired tissue perfusion—compartment syndrome or pressure ulcer).	✓	
• Demonstrate ability to transfer (eg, from a bed to a chair).	✓	
• Use mobility aids safely.	✓	
• Avoid excessive use of injured extremity; observe prescribed weight-bearing limits.	✓	
• Manage minor skin irritations (eg, for skin irritation from edge of cast, splint, or brace; pad rough edges with tape; to relieve itching, blow cool air from hair dryer; do not insert objects inside the cast, splint, or brace).	✓	✓
• Demonstrate exercises to promote circulation and minimize disuse syndrome.	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage staining cast; signs of systemic infection; cast, splint, or brace breaks).	✓	✓
• Describe care of extremity following cast, splint, or brace removal (eg, skin care; gradual resumption of normal activities to protect limb from undue stresses; management of swelling).	✓	✓

Continuing Care

For the patient with a cast that is ready for removal, the nurse should prepare the patient by explaining what to expect. The cast is cut with a cast cutter, which vibrates. The patient can feel the vibration and pressure during its use. The cutter does not penetrate deeply enough to injure the patient's skin. The cast padding is cut with scissors.

After removal of a splint, and especially after removal of a brace or cast, both of which are typically applied for longer periods of time, the formerly immobilized body part is weak from disuse, is stiff, and may appear atrophied. There may be extreme stiffness even after only a few weeks of immobilization. Therefore, support is needed when the cast, brace, or splint is removed. The skin, which is usually dry and scaly from accumulated dead skin, is vulnerable to injury from scratching. The skin needs to be washed gently and lubricated with an emollient lotion.

The nurse and physical therapist teach the patient to resume activities gradually within the prescribed therapeutic regimen. Exercises prescribed to help the patient regain joint motion are explained and demonstrated. Because the muscles are weak from disuse, the body part that has been immobilized cannot withstand normal stresses immediately. In addition, the nurse teaches the patient with noticeable swelling of the affected extremity after removal of the immobilizing device (eg, cast, brace, or splint) to continue to elevate the extremity to control swelling until normal muscle tone and use are reestablished.

Nursing Management of the Patient With an Immobilized Upper Extremity

The patient whose arm is immobilized must readjust to many routine tasks. The unaffected arm must assume all the upper extremity activities. The nurse, in consultation with an occupational therapist, suggests devices designed to aid one-handed activities. The patient may experience fatigue due to modified activities and the weight of the cast, brace, or splint. Frequent rest periods are necessary.

To control swelling, the immobilized arm is elevated. When the patient is lying down, the arm is elevated so that each joint is positioned higher than the preceding proximal joint (eg, elbow higher than the shoulder, hand higher than the elbow).

A **sling** may be used when the patient ambulates. To prevent pressure on the cervical spinal nerves, the sling should distribute the supported weight over a large area and not on the back of the neck. The nurse encourages the patient to remove the arm from the sling and elevate it frequently.

Circulatory disturbances in the hand may become apparent with signs of cyanosis, swelling, and an inability to move the fingers. One serious effect of impaired circulation in the arm is Volkmann's contracture, a specific type of compartment syndrome. Contracture of the fingers and wrist occurs as the result of obstructed arterial blood flow to the forearm and hand. The patient is unable to extend the fingers, describes abnormal sensation (eg, unrelenting pain, pain on passive stretch), and exhibits signs of diminished circulation to the hand. Permanent damage develops

within a few hours if action is not taken (see Chapter 69). This serious complication can be prevented with nursing surveillance and proper care.

Neurovascular checks must be done frequently (see Chapter 66). If a cast is used for immobility, compartment syndrome is managed in part by bivalving (cutting) the cast and releasing the constricting cast and dressings. A fasciotomy may be necessary to improve vascular status.

Nursing Management of the Patient With an Immobilized Lower Extremity

The application of a leg cast, brace, or splint imposes a degree of immobility on the patient. Casts may include short-leg casts, extending to the knees, or long-leg casts, extending to the groin. Hinged knee braces and immobilizers typically extend from ankle to groin.

The patient's leg must be supported on pillows to heart level to control swelling, and ice packs should be applied as prescribed over the fracture site for 1 or 2 days. The patient is taught to elevate the immobilized leg when seated. The patient should also assume a recumbent position several times a day with the immobilized leg elevated to promote venous return and control swelling.

The nurse assesses circulation by observing the color, temperature, and capillary refill of the exposed toes. Nerve function is assessed by observing the patient's ability to move the toes and by asking about the sensations in the foot. Numbness, tingling, and burning may be caused by peroneal nerve injury from pressure at the head of the fibula.

NURSING ALERT

Injury to the peroneal nerve as a result of pressure is a cause of footdrop (the inability to maintain the foot in a normally flexed position). Consequently, the patient drags the foot when ambulating.

The nurse and physical therapist teach the patient how to transfer and ambulate safely with assistive devices (eg, crutches, walker) (see Chapter 11). The gait to be used depends on whether the patient is permitted to bear weight. If weight bearing is allowed, the cast, splint, or brace is reinforced to withstand the body weight. A cast boot, worn over the casted foot, provides a broad, nonskid walking surface.

Nursing Management of the Patient With a Body or Spica Cast

Casts that encase the trunk (body cast) and portions of one or two extremities (spica cast) require special nursing strategies. Body casts are used to immobilize the spine. Hip spica casts are used for some femoral fractures and after some hip joint surgeries, and shoulder spica casts are used for some humeral neck fractures.

Nursing responsibilities include preparing and positioning the patient, assisting with skin care and hygiene, and monitoring for **cast syndrome**, (see discussion on next page) (NAON, 2007). Explaining the casting procedure helps reduce the patient's apprehension about being encased in a large cast. The nurse reassures the patient that several

people will provide care during the application, support for the injured area will be adequate, and care providers will be as gentle as possible. Medications for pain relief and relaxation administered before the procedure enable the patient to cooperate during application of the cast.

The nurse turns the patient as a unit toward the uninjured side every 2 hours to relieve pressure and to allow the cast to dry. It is important to avoid twisting the patient's body within the cast. Sufficient personnel (at least three people) or mechanical assistive devices are needed when the patient is turned because of the added weight of the cast. The nurse encourages the patient to assist in the repositioning, if not contraindicated, by use of the **trapeze** or bed rail. A stabilizing abduction bar incorporated into a spica cast should never be used as a turning device. The nurse adjusts the pillows to provide support without creating areas of pressure.

The nurse turns the patient to a prone position, twice daily if tolerated, to provide postural drainage of the bronchial tree and to relieve pressure on the back. A small pillow under the abdomen enhances comfort. The nurse can either place a pillow lengthwise under the dorsa of the feet or allow the toes to hang over the edge of the bed to prevent the toes from being forced into the mattress.

The nurse inspects the skin around the edges of the cast frequently for signs of irritation. The nurse can inspect some of the skin under the cast by pulling the skin taut and using a flashlight. The skin can be bathed and massaged by reaching under the cast edges with the fingers.

The perineal opening must be large enough for hygienic care. To protect the cast from soiling, Gore-Tex liners are used prior to hip spica casting. If the cast is not Gore-Tex lined, the nurse can insert clean dry plastic sheeting under the dry cast and over the cast edge before elimination by the patient. Usually, fracture bedpans are easier to use than regular bedpans for patients with a hip spica cast.

Patients immobilized in large casts may develop cast syndrome that may include psychological or physiologic manifestations. The psychological component is similar to a claustrophobic reaction. The patient exhibits an acute anxiety reaction characterized by behavioral changes and autonomic responses (eg, increased respiratory rate, diaphoresis, dilated pupils, increased heart rate, elevated blood pressure). The nurse needs to recognize the anxiety reaction and provide an environment in which the patient feels secure.

Physiologic cast syndrome responses (eg, superior mesenteric artery syndrome) are associated with immobility in a body cast. With decreased physical activity, gastrointestinal motility decreases, intestinal gases accumulate, intestinal pressure increases, and ileus may occur. The patient exhibits abdominal distention, abdominal discomfort, nausea, and vomiting. As with other instances of adynamic ileus, the patient is treated conservatively with decompression (nasogastric intubation connected to suction) and intravenous (IV) fluid therapy until gastrointestinal motility is restored (Adams, Hawkins, Ferdinand, et al., 2007). If the cast restricts the abdomen, the abdominal window must be enlarged. After the ileus resolves and bowel sounds resume, the patient gradually resumes an oral diet. Rarely, the distention places traction on the superior mesenteric artery,

reducing the blood supply to the bowel, which can result in gangrenous bowel. The descending aorta may also sustain pressure as it may be compressed between the spine and pressure of abdominal distention, which results in ischemia. If the descending aorta becomes ischemic, its rupture could cause exsanguination and death.

NURSING ALERT

The nurse monitors the patient in a large body cast for potential cast syndrome, noting bowel sounds every 4 to 8 hours, and reports distention, nausea, and vomiting to the physician.

The patient with a body or spica cast is often cared for at home. The nurse teaches family members how to care for the patient, which includes providing hygienic and skin care, ensuring proper positioning, preventing complications, and recognizing symptoms that should be reported to the health care provider.

The Patient With an External Fixator

External fixators are used to manage open fractures with soft tissue damage. They provide stable support for severe comminuted (crushed or splintered) fractures while permitting active treatment of damaged soft tissues (Fig. 67-3). Complicated fractures of the humerus, forearm, femur, tibia, and pelvis are managed with external skeletal fixators. The fracture is reduced, aligned, and immobilized by a series of pins inserted in the bone. Pin position is maintained through attachment to a portable frame. The fixator facilitates patient comfort, early mobility, and active exercise of adjacent uninvolved joints; thus, complications due to disuse and immobility are minimized (Holmes & Brown, 2005).

Nursing Management

It is important to prepare the patient psychologically for application of the external fixator. The apparatus looks clumsy and foreign. Reassurance that the discomfort associated with the device is minimal and that early mobility is anticipated promotes acceptance of the device.

After the external fixator is applied, the extremity is elevated to reduce swelling. If there are sharp points on the fixator or pins, they are covered with caps to prevent device-induced injuries. The nurse monitors the neurovascular status of the extremity every 2 to 4 hours and assesses each pin site for redness, drainage, tenderness, pain, and loosening of the pin. Some serous drainage from the pin sites is to be expected. The nurse must be alert for potential problems caused by pressure from the device on the skin, nerves, or blood vessels and for the development of compartment syndrome (see Chapter 69). The nurse carries out pin care as prescribed to prevent pin tract infection. This typically includes cleaning each pin site separately one or two times a day with cotton-tipped applicators soaked in chlorhexidine solution (Holmes & Brown, 2005). If signs of infection are present or if the pins or clamps seem loose, the nurse notifies the physician.

Figure 67-3 External fixation device. Pins are inserted into bone. The fracture is reduced and aligned and then stabilized by attaching the pins to a rigid portable frame. The device facilitates treatment of soft tissue damaged in complex fractures.

NURSING ALERT

The nurse never adjusts the clamps on the external fixator frame. It is the physician's responsibility to do so.

The nurse encourages isometric and active exercises as tolerated. When the swelling subsides, the nurse helps the patient become mobile within the prescribed weight-bearing limits (non-weight bearing to full weight bearing). Adherence to weight-bearing instructions minimizes the chance of loosening of the pins when stress is applied to the bone-pin interface. The fixator is removed after the soft tissue heals. The fracture may require additional stabilization by a cast or molded orthosis while healing.

The Ilizarov external fixator is a special device used to correct angulation and rotational defects, to treat nonunion (failure of bone fragments to heal), and to lengthen limbs. Tension wires are attached to fixator rings, which are joined by telescoping rods. Bone formation is stimulated by prescribed daily adjustment of the telescoping rods. It is important to teach the patient how to adjust the telescoping rods and how to perform skin care. Generally, the nurse can encourage weight bearing. After the desired correction has been achieved, no additional adjustments are made, and the fixator is left in place until the bone heals.

The nurse teaches the patient to perform pin site care according to the prescribed protocol (clean technique can be used at home [Holmes & Brown, 2005]) and to report promptly any signs of pin site infection: redness, tenderness, increased or purulent pin site drainage, or fever. The nurse also instructs the patient and family to monitor neurovascular status and report any changes promptly. The nurse teaches the patient or family member to check the integrity of the fixator frame daily and to report loose pins or clamps. A physical therapy referral is helpful in teaching the patient how to transfer, use ambulatory aids safely, and adjust to weight-bearing limits and altered gait patterns (Chart 67-5).

CHART
67-5

HOME CARE CHECKLIST

The Patient With an External Fixator

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate prescribed pin site care.	✓	✓
• State signs of pin site infection (eg, redness, tenderness, increased or purulent pin site drainage) to be reported promptly.	✓	✓
• Describe approaches to controlling swelling and pain (eg, elevate extremity to heart level, take analgesic agents as prescribed).	✓	✓
• Report pain uncontrolled by elevation and analgesic agents (may be an indicator of impaired tissue perfusion, compartment syndrome, or pin tract infection).	✓	
• Demonstrate ability to transfer.	✓	
• Use mobility aids safely.	✓	
• Avoid excessive use of injured extremity; observe prescribed weight-bearing limits.	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage; signs of systemic infection; loose fixator pins or clamps).	✓	✓
• Describe care of extremity after fixator removal (eg, gradual resumption of normal activities to protect limb from undue stresses).	✓	✓

Figure 67-4 Traction may be applied in different directions to achieve the desired therapeutic line of pull. Adjustments in applied forces may be prescribed over the course of treatment.

The Patient in Traction

Traction is the application of a pulling force to a part of the body. Traction is used to minimize muscle spasms; to reduce, align, and immobilize fractures; to reduce deformity; and to increase space between opposing surfaces. Traction must be applied in the correct direction and magnitude to obtain its therapeutic effects. As muscle and soft tissues relax, the amount of weight used may be changed to obtain the desired effect (NAON, 2007).

At times, traction needs to be applied in more than one direction to achieve the desired line of pull. When this is done, one of the lines of pull counteracts the other. These lines of pull are known as the vectors of force. The actual resultant pulling force is somewhere between the two lines of pull (Fig. 67-4). The effects of traction are evaluated with x-ray studies, and adjustments are made if necessary.

Traction is used primarily as a short-term intervention until other modalities, such as external or internal fixation, are possible. These modalities reduce the risk of disuse syndrome and minimize the length of hospitalization, often allowing the patient to be cared for in the home setting (NAON, 2007).

PRINCIPLES OF EFFECTIVE TRACTION

Whenever traction is applied, countertraction must be used to achieve effective traction. Countertraction is the force acting in the opposite direction. Usually, the patient's body weight and bed position adjustments supply the needed countertraction.

The following are additional principles to follow when caring for the patient in traction:

- Traction must be continuous to be effective in reducing and immobilizing fractures.
- Skeletal traction is *never* interrupted.
- Weights are not removed unless intermittent traction is prescribed.
- Any factor that might reduce the effective pull or alter its resultant line of pull must be eliminated:

Figure 67-5 Buck's extension traction. Lower extremity in unilateral Buck's extension traction is aligned in a foam boot and traction applied by the free-hanging weight.

- The patient must be in good body alignment in the center of the bed when traction is applied.
- Ropes must be unobstructed.
- Weights must hang freely and not rest on the bed or floor.
- Knots in the rope or the footplate must not touch the pulley or the foot of the bed.

TYPES OF TRACTION

There are several types of traction. *Straight* or *running traction* applies the pulling force in a straight line with the body part resting on the bed. Buck's extension traction (Fig. 67-5) is an example of straight traction. *Balanced suspension traction* (Fig. 67-6) supports the affected extremity off the bed and allows for some patient movement without disruption of the line of pull.

Traction may be applied to the skin (*skin traction*) or directly to the bony skeleton (*skeletal traction*). The mode of application is determined by the purpose of the traction. Traction can be applied with the hands (*manual traction*). This is temporary traction that may be used when applying a cast, giving skin care under a Buck's extension foam boot, or adjusting the traction apparatus.

Skin Traction

Skin traction is used to control muscle spasms and to immobilize an area before surgery. Skin traction is accomplished by using a weight to pull on traction tape or on a foam boot attached to the skin. The amount of weight applied must not exceed the tolerance of the skin. No more than 2 to 3.5 kg (4.5 to 8 lb) of traction can be used on an extremity. Pelvic traction is usually 4.5 to 9 kg (10 to 20 lb), depending on the weight of the patient.

Types of skin traction used for adults include Buck's extension traction (applied to the lower leg) (described below), the cervical head halter (occasionally used to treat neck pain), and the pelvic belt (sometimes used to treat back pain).

Figure 67-6 Balanced suspension skeletal traction with Thomas leg splint. The patient can move vertically as long as the resultant line of pull is maintained.

Buck's Extension Traction

Buck's extension traction (unilateral or bilateral) is skin traction to the lower leg. The pull is exerted in one plane when partial or temporary immobilization is desired (see Fig. 67-5). It is used to immobilize fractures of the proximal femur before surgical fixation.

Before the traction is applied, the nurse inspects the skin for abrasions and circulatory disturbances. The skin and circulation must be in healthy condition to tolerate the traction. The extremity should be clean and dry before the foam boot or traction tape is applied.

To apply Buck's traction, one nurse elevates and supports the extremity under the patient's heel and knee while another nurse places the foam boot under the leg, with the patient's heel in the heel of the boot. Next, the nurse secures Velcro straps around the leg. Traction tape overwrapped with elastic bandage in a spiral fashion may be used instead of the boot. Excessive pressure is avoided over the malleolus and proximal fibula during application to prevent pressure ulcers and nerve damage. The nurse then passes the rope affixed to the spreader or footplate over a pulley fastened to the end of the bed and attaches the prescribed weight—usually 5 to 8 pounds—to the rope.

Nursing Interventions

Ensuring Effective Traction

To ensure effective skin traction, it is important to avoid wrinkling and slipping of the traction bandage and to maintain countertraction. Proper positioning must be maintained to keep the leg in a neutral position. To prevent bony fragments from moving against one another, the patient should not turn from side to side; however, the patient may shift position slightly with assistance.

Monitoring and Managing Potential Complications

Skin Breakdown. During the initial assessment, the nurse identifies sensitive, fragile skin (common in older adults). The nurse also closely monitors the status of the skin in

contact with tape or foam to ensure that shearing forces are avoided. The nurse performs the following procedures to monitor and prevent skin breakdown:

- Removes the foam boots to inspect the skin, the ankle, and the Achilles tendon three times a day. A second nurse is needed to support the extremity during the inspection and skin care.
- Palpates the area of the traction tapes daily to detect underlying tenderness.
- Provides back care at least every 2 hours to prevent pressure ulcers. The patient who must remain in a supine position is at increased risk for development of a pressure ulcer.
- Uses special mattress overlays (eg, air-filled, high-density foam) to prevent pressure ulcers.

Nerve Damage. Skin traction can place pressure on peripheral nerves. When traction is applied to the lower extremity, care must be taken to avoid pressure on the peroneal nerve at the point at which it passes around the neck of the fibula just below the knee. Pressure at this point can cause foot-drop. The nurse regularly questions the patient about sensation and asks the patient to move the toes and foot. The nurse should immediately investigate any complaint of a burning sensation under the traction bandage or boot. Dorsiflexion of the foot demonstrates function of the peroneal nerve. Weakness of dorsiflexion or foot movement and inversion of the foot might indicate pressure on the common peroneal nerve. Plantar flexion demonstrates function of the tibial nerve. In addition, the nurse should promptly report altered sensation or impaired motor function.

Circulatory Impairment. After skin traction is applied, the nurse assesses circulation of the foot within 15 to 30 minutes and then every 1 to 2 hours. Circulatory assessment consists of the following:

- Peripheral pulses, color, capillary refill, and temperature of the fingers or toes
- Indicators of deep vein thrombosis (DVT), including unilateral calf tenderness, warmth, redness, and swelling

The nurse also encourages the patient to perform active foot exercises every hour when awake.

Skeletal Traction

Skeletal traction is applied directly to the bone. This method of traction is used occasionally to treat fractures of the femur, the tibia, and the cervical spine. The traction is applied directly to the bone by use of a metal pin or wire (eg, Steinmann pin, Kirschner wire) that is inserted through the bone distal to the fracture, avoiding nerves, blood vessels, muscles, tendons, and joints. Tongs applied to the head (eg, Gardner-Wells or Vinke tongs) are fixed to the skull to apply traction that immobilizes cervical fractures.

The orthopedic surgeon applies skeletal traction, using surgical asepsis. The insertion site is prepared with a surgical scrub agent such as povidone-iodine solution. A local anesthetic agent is administered at the insertion site and periosteum. The surgeon makes a small skin incision and drills the sterile pin or wire through the bone. The patient feels pressure during this procedure and possibly some pain when the periosteum is penetrated.

After insertion, the pin or wire is attached to the traction bow or caliper. The ends of the pin or wire are covered with caps to prevent injury to the patient or caregivers. The weights are attached to the pin or wire bow by a rope-and-pulley system that exerts the appropriate amount and direction of pull for effective traction. Skeletal traction frequently uses 7 to 12 kg (15 to 25 lb) to achieve the therapeutic effect. The weights applied initially must overcome the shortening spasms of the affected muscles. As the muscles relax, the traction weight is reduced to prevent fracture dislocation and to promote healing.

Often, skeletal traction is balanced traction, which supports the affected extremity, allows for some patient movement, and facilitates patient independence and nursing care while maintaining effective traction. The Thomas splint with a Pearson attachment is frequently used with skeletal traction for fractures of the femur (see Fig. 67-6). Because upward traction is required, an overbed frame is used.

When skeletal traction is discontinued, the extremity is gently supported while the weights are removed. The pin is cut close to the skin and removed by the physician. Internal fixation, casts, or splints are then used to immobilize and support the healing bone.

Nursing Interventions

Maintaining Effective Traction

When skeletal traction is used, the nurse checks the traction apparatus to see that the ropes are in the wheel grooves of the pulleys, that the ropes are not frayed, that the weights hang freely, and that the knots in the rope are tied securely. The nurse also evaluates the patient's position, because slipping down in bed results in ineffective traction.

NURSING ALERT

The nurse must never remove weights from skeletal traction unless a life-threatening situation occurs. Removal of the weights completely defeats their purpose and may result in injury to the patient.

Maintaining Positioning

The nurse must maintain alignment of the patient's body in traction as prescribed to promote an effective line of pull. The nurse positions the patient's foot to avoid foot-drop (plantar flexion), inward rotation (inversion), and outward rotation (eversion). The patient's foot may be supported in a neutral position by orthopedic devices (eg, foot supports).

Preventing Skin Breakdown

The patient's elbows frequently become sore, and nerve injury may occur if the patient repositions by pushing on the elbows. In addition, patients frequently push on the heel of the unaffected leg when they raise themselves. This digging of the heel into the mattress may injure the tissues. Therefore, the nurse should protect the elbows and heels and inspect them for pressure ulcers. To encourage movement without using the elbows or heel, a trapeze can be suspended overhead within easy reach of the patient. The trapeze helps the patient move about in bed and move on and off the bedpan.

Specific pressure points are assessed for redness and skin breakdown. Areas that are particularly vulnerable to pressure caused by a traction apparatus applied to the lower extremity include the ischial tuberosity, popliteal space, Achilles tendon, and heel. If the patient is not permitted to turn on one side or the other, the nurse must make a special effort to provide back care and to keep the bed dry and free of crumbs and wrinkles. The patient can assist by holding the overhead trapeze and raising the hips off the bed. If the patient cannot do this, the nurse can push down on the mattress with one hand to relieve pressure on the back and bony prominences and to provide for some shifting of weight. A pressure-relieving air-filled or high-density foam mattress overlay may reduce the risk of pressure ulcer.

For change of bed linens, the patient raises the torso while nurses on both sides of the bed roll down and replace the upper mattress sheet. Then, as the patient raises the buttocks off the mattress, the nurses slide the sheets under the buttocks. Finally, the nurses replace the lower section of the bed linens while the patient rests on the back. Sheets and blankets are placed over the patient in such a way that the traction is not disrupted.

Monitoring Neurovascular Status

The nurse assesses the neurovascular status of the immobilized extremity at least every hour initially and then every 4 hours. The nurse instructs the patient to report any changes in sensation or movement immediately so that they can be promptly evaluated. DVT is a significant risk for the immobilized patient. The nurse encourages the patient to do active flexion-extension ankle exercises and isometric contraction of the calf muscles (calf-pumping exercises) 10 times an hour while awake to decrease venous stasis. In addition, anti-embolism stockings, compression devices, and anticoagulant therapy may be prescribed to help prevent thrombus formation.

NURSING ALERT

The nurse must promptly investigate every report of discomfort expressed by the patient in traction. Prompt recognition of a developing neurovascular problem is essential so that corrective measures can be instituted promptly.

Providing Pin Site Care. The wound at the pin insertion site requires attention. The goal is to avoid infection and development of **osteomyelitis**. For the first 48 hours after insertion, the site is covered with a sterile absorbent nonstick dressing and a rolled gauze or Ace-type bandage. After this time, a loose cover dressing or no dressing is recommended. (A bandage is necessary if the patient is exposed to airborne dust.) Pin site care is performed initially one or two times a day. The frequency of pin care needs to be increased if mechanical looseness of pins or early signs of infection are present (eg, edema, purulent drainage, erythema, tenderness). Chlorhexidine solution is recommended as the most effective cleansing solution; however, water and saline are alternate choices (Holmes & Brown, 2005). Although hydrogen peroxide and Betadine solutions have been used, they are believed to be cytotoxic to osteoblasts and may actually damage healthy tissue (Lethaby, Temple & Santy, 2008).

The nurse must inspect the pin sites every 8 hours for reaction (ie, normal changes that occur at the pin site after insertion) and infection. Signs of reaction may include redness, warmth, and serous or slightly sanguinous drainage at the site. These signs subside after 72 hours. Signs of infection may mirror those of reaction but also include the presence of purulent drainage, pin loosening, and odor. Minor infections may be readily treated with antibiotics, whereas infections that result in systemic manifestations may additionally warrant pin removal until the infection resolves (Holmes & Brown, 2005). When pins are mechanically stable (after 48 to 72 hours), weekly pin site care is recommended.

NURSING ALERT

The nurse must inspect the pin site at least every 8 hours for signs of inflammation and evidence of infection.

Due to a lack of evidence-based research findings, controversy remains about management of crusts that may form at the pin insertion site, frequency of pin care and showering, and use of massage to release skin adherence to pins (Holmes & Brown, 2005). The patient should be taught to perform any prescribed pin site care prior to discharge from the hospital and should be provided with written follow-up instructions that include the signs and symptoms of infection. Patients permitted to take showers within 5 to 10 days of pin insertion are encouraged to leave the pins exposed to water flow. The sites are dried with a clean towel and left open to air, or dressings are applied as prescribed.

Promoting Exercise. Patient exercises, within the therapeutic limits of the traction, assist in maintaining muscle strength and tone and in promoting circulation. Active exercises include pulling up on the trapeze, flexing and

extending the feet, and range-of-motion and weight-resistance exercises for noninvolved joints. Isometric exercises of the immobilized extremity (quadriceps-setting and gluteal-setting exercises) are important for maintaining strength in major ambulatory muscles (see Chart 67-3). Without exercise, the patient will lose muscle mass and strength, and rehabilitation will be greatly prolonged.

Nursing Management

Assessing Anxiety

The nurse must consider the psychological and physiologic impact of the musculoskeletal problem, traction device, and immobility. Traction restricts mobility and independence. The equipment often looks threatening, and its application can be frightening. Confusion, disorientation, and behavioral problems may develop in patients who are confined in a limited space for an extended time. Therefore, the nurse must assess and monitor the patient's anxiety level and psychological responses to traction.

Assisting With Self-Care

Initially, the patient may require assistance with self-care activities. The nurse helps the patient eat, bathe, dress, and toilet. Convenient arrangement of items such as the telephone, tissues, water, and assistive devices (eg, reachers, overbed trapeze) may facilitate self-care. With resumption of self-care activities, the patient feels less dependent and less frustrated and experiences improved self-esteem. Because some assistance is required throughout the period of immobility, the nurse and the patient can creatively develop routines that maximize the patient's independence.

It is important to evaluate the body part to be placed in traction and its neurovascular status (ie, color, temperature, capillary refill, edema, pulses, ability to move, and sensations) and compare it to the unaffected extremity. The nurse also assesses skin integrity along with body system functioning for baseline data. Ongoing assessment is indicated for the patient in traction.

Monitoring and Managing Potential Complications

Immobility-related complications may include pressure ulcers, atelectasis, pneumonia, constipation, loss of appetite, urinary stasis, urinary tract infections, and venous thromboemboli formation. Early identification of preexisting or developing conditions facilitates prompt interventions to resolve them.

Atelectasis and Pneumonia

The nurse auscultates the patient's lungs every 4 to 8 hours to assess respiratory status and teaches the patient deep-breathing and coughing exercises to aid in fully expanding the lungs and clearing pulmonary secretions. If the patient history and baseline assessment indicate that the patient is at risk for development of respiratory complications, specific therapies (eg, use of incentive spirometer) may be indicated. If a respiratory complication develops, prompt institution of prescribed therapy is needed.

Constipation and Anorexia

Reduced gastrointestinal motility results in constipation and anorexia. A diet high in fiber and fluids may help

stimulate gastric motility. If constipation develops, therapeutic measures may include stool softeners, laxatives, suppositories, and enemas. To improve the patient's appetite, the patient's food preferences are included, as appropriate, within the prescribed therapeutic diet.

Urinary Stasis and Infection

Incomplete emptying of the bladder related to positioning in bed can result in urinary stasis and infection. In addition, the patient may find use of the bedpan uncomfortable and may limit fluids to minimize the frequency of urination. The nurse monitors the fluid intake and the character of the urine. The nurse teaches the patient to consume adequate amounts of fluid and to void every 3 to 4 hours. If the patient exhibits signs or symptoms of urinary tract infection, the nurse notifies the physician.

Venous Thromboembolism

Venous stasis that predisposes the patient to venous thromboembolism occurs with immobility. The nurse teaches the patient to perform ankle and foot exercises within the limits of the traction therapy every 1 to 2 hours when awake to prevent DVT. The patient is encouraged to drink fluids to prevent dehydration and associated hemoconcentration, which contribute to stasis. The nurse monitors the patient for signs of DVT, including unilateral calf tenderness, warmth, redness, and swelling (increased calf circumference). The nurse promptly reports findings to the physician for definitive evaluation and therapy.

During traction therapy, the nurse encourages the patient to exercise muscles and joints that are not in traction to prevent deterioration, deconditioning, and venous stasis. The physical therapist can design bed exercises that minimize loss of muscle strength. During the patient's exercise, the nurse ensures that traction forces are maintained and that the patient is properly positioned to prevent complications resulting from poor alignment.

The Patient Undergoing Orthopedic Surgery

Many patients with musculoskeletal dysfunction undergo surgery to correct the condition. Conditions that may be corrected by surgery include unstabilized fracture, deformity, joint disease, necrotic or infected tissue, and tumors. Frequent surgical procedures include **open reduction with internal fixation (ORIF)** and closed reduction with internal fixation (fracture fragments are not surgically exposed) for fractures; arthroplasty, meniscectomy, and joint replacement for joint conditions; amputation for severe extremity conditions (eg, gangrene, massive trauma); bone graft for joint stabilization, defect filling, or stimulation of bone healing; and tendon transfer for improving motion. The goals include improving function by restoring motion and stability and relieving pain and disability. Chart 67-6 describes common orthopedic surgeries.

Indications for a surgical procedure are based on the patient's age, underlying orthopedic condition, and general physical health and the impact of joint disability on daily activities. Timing of these procedures is important to ensure

Chart 67-6 • Common Orthopedic Surgical Procedures

Open reduction: the correction and alignment of the fracture after surgical dissection and exposure of the fracture

Internal fixation: the stabilization of the reduced fracture by the use of metal screws, plates, wires, nails, and pins

Arthroplasty: the repair of joint problems through the operating arthroscope (an instrument that allows the surgeon to operate within a joint without a large incision) or through open joint surgery

Hemiarthroplasty: the replacement of one of the articular surfaces (eg, in a hip hemiarthroplasty, the femoral head and neck are replaced with a femoral prosthesis—the acetabulum is not replaced)

Joint arthroplasty or replacement: the replacement of joint surfaces with metal or synthetic materials

Total joint arthroplasty or replacement: the replacement of both articular surfaces within a joint with metal or synthetic materials

Meniscectomy: the excision of damaged joint fibrocartilage

Amputation: the removal of a body part

Bone graft: the placement of bone tissue (autologous or homologous grafts) to promote healing, to stabilize, or to replace diseased bone

Tendon transfer: the insertion of tendon to improve function

Fasciotomy: the incision and diversion of the muscle fascia to relieve muscle constriction, as in compartment syndrome, or to reduce fascia contracture

maximum function. In general, surgery should be performed before surrounding muscles become contracted and atrophied and serious structural abnormalities occur.

Because most of these are elective procedures, many patients donate their own blood during the weeks preceding their surgery. This blood is used to replace blood lost during surgery. Autologous blood transfusions eliminate many of the risks of transfusion therapy (see Chapter 33).

Blood is conserved during surgery to minimize loss. During orthopedic surgery on a limb (eg, total knee replacement [TKR]), a pneumatic tourniquet may be applied to produce a “bloodless field.” This technique has the advantages of keeping the surgical field dry, minimizing blood loss, and providing some additional limb anesthesia (O'Connor & Murphy, 2007). Intraoperative blood salvage with reinfusion is used when a large volume of blood loss is anticipated. Postoperative blood salvage with intermittent autotransfusion also reduces the need for blood transfusion.

JOINT REPLACEMENT

Patients with severe joint pain and disability may undergo joint replacement. Conditions contributing to joint degeneration include osteoarthritis, rheumatoid arthritis, trauma, and congenital deformity. Some fractures (eg, femoral neck fracture) may cause disruption of the blood supply and subsequent **avascular necrosis**; management with joint replacement may be elected over ORIF. Joints frequently replaced include the hip, knee (Fig. 67-7), and finger joints.

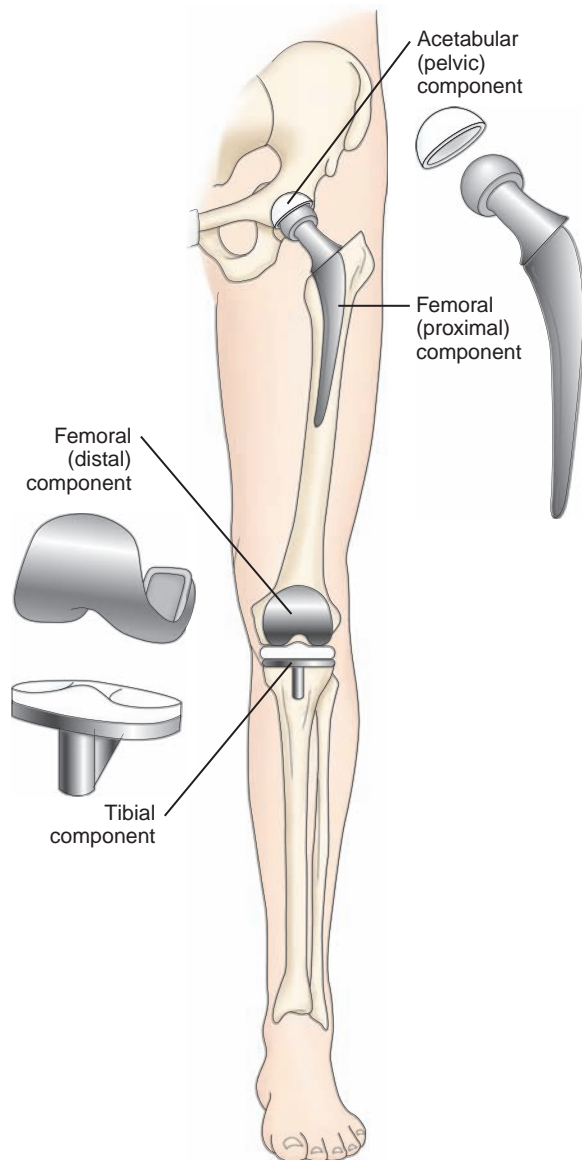

Figure 67-7 Examples of hip and knee replacement.

Less frequently, more complex joints (shoulder, elbow, wrist, ankle) are replaced.

Most joint replacements consist of metal (eg, cobalt-chromium, titanium) and high-density polyethylene components. The joint implants may be cemented in the prepared bone with polymethylmethacrylate (PMMA), a bone-bonding agent that has properties similar to bone. Loosening of the prosthesis due to cement–bone interface failure is a common cause of prosthesis failure. Press-fit, ingrowth prostheses (porous-coated, cementless artificial joint components) that allow the patient’s bone to grow into and securely fix the prosthesis in the bone are alternatives to cemented prostheses. Accurate fitting and the presence of healthy bone with adequate blood supply are important in the use of cementless components (Lucas, 2008a). Much progress has been made in reducing prosthesis failure rates through improved techniques, improved materials, and use of bone grafts.

With joint replacement, excellent pain relief is obtained in most patients. Return of motion and function depends on preoperative soft tissue condition, soft tissue reactions, and general muscle strength. Early failure of joint replacement is associated with excessive activity and preoperative joint and bone pathology.

Nursing Interventions

Assessment of the patient and preoperative management are aimed at having the patient in optimal health at the time of surgery. Preoperatively, it is important to evaluate cardiovascular, respiratory, renal, and hepatic functions. Age, obesity, preoperative leg edema, a history of any venous thromboemboli, and varicose veins increase the risk for postoperative DVT and pulmonary embolism.

Preoperatively, it is important to assess the neurovascular status of the extremity undergoing joint replacement (Lucas, 2008a). Postoperative assessment data are compared with preoperative assessment data to identify changes and deficits. For example, an absent pulse postoperatively is of concern unless the pulse was also absent preoperatively. Nerve palsy could occur as a result of surgery.

Preventing Infection

Preoperative assessment of the patient for infections, including urinary tract infection, is necessary because of the risk for postoperative infection. Any infection 2 to 4 weeks before planned surgery may result in postponement of surgery. Preoperative skin preparation frequently begins 1 or 2 days before the surgery. Airborne bacteria that contaminate the wound at the time of surgery cause most deep infections. Therefore, as with any surgery, there is strict adherence to aseptic principles, and the operating area is made as bacteria free as possible (Lucas, 2008a).

Research findings suggest that prophylactic antibiotics given 60 minutes prior to incision are effective in preventing postoperative infection (Hawn, Gray, Vick, et al., 2006). Culture of the joint during surgery may be important in identifying and treating subsequent infections.

If osteomyelitis develops, it is difficult to treat. Persistent infection at the site of the prosthesis usually requires removal of the implant and joint revision. It is not always possible to achieve a functional joint when the reconstruction procedure has to be repeated.

Promoting Ambulation

Patients with total hip or total knee replacement begin ambulation with a walker or crutches within a day after surgery. The nurse and the physical therapist assist the patient in achieving the goal of independent ambulation. At first, the patient may be able to stand for only a brief period because of orthostatic hypotension. Specific weight-bearing limits on the prosthesis are based on the patient’s condition, the procedure, and the fixation method. Usually, patients with cemented prostheses can proceed to weight bearing as tolerated. If the patient has a press-fit, cementless, ingrowth prosthesis, weight bearing immediately after surgery may be limited to minimize micromotion of the prosthesis in the bone (Lucas, 2008b). As the patient is able to tolerate more activity, the nurse encourages transferring to a chair several times a day for short periods and walking for progressively greater distances.

Total Hip Replacement

Total hip replacement is the replacement of a severely damaged hip with an artificial joint. Indications for this surgery include osteoarthritis, rheumatoid arthritis, femoral neck fractures, failure of previous reconstructive surgeries (failed prosthesis, **osteotomy**), and conditions resulting from developmental dysplasia or Legg-Calve-Perthes (avascular necrosis of the hip in childhood). A variety of total hip prostheses are available. Most consist of a metal femoral component topped by a spherical ball, of metal, ceramic, or plastic, fitted into a plastic or metal acetabular socket (see Fig. 67-7).

The surgeon selects the prosthesis that is best suited to the individual patient, considering various factors, including skeletal structure and activity level. The patient has irreversibly damaged hip joints, and the potential benefits, including improved quality of life (Chart 67-7), outweigh the surgical risks. With the advent of improved prosthetic materials and operative techniques, the life of the prosthesis has been extended, and today younger patients with severely damaged and painful hip joints are undergoing total hip replacement.

Nursing Interventions

The nurse must be aware of and monitor for specific potential complications associated with total hip replacement. Complications that may occur include dislocation of the hip prosthesis, excessive wound drainage, thromboembolism, infection, and heel pressure ulcer (Chart 67-8). Other complications for which the nurse must monitor include those

Figure 67-8 An abduction pillow may be used after a total hip replacement to prevent dislocation of the prosthesis.

associated with immobility. Long-term complications include **heterotopic ossification** (formation of bone in the periprosthetic space), avascular necrosis (bone death caused by loss of blood supply), and loosening of the prosthesis.

Preventing Dislocation of the Hip Prosthesis

For patients undergoing a posterior or posterior-lateral approach for total hip arthroplasty, maintenance of the femoral head component in the acetabular cup is essential. The nurse teaches the patient about positioning the leg in **abduction**, which helps prevent dislocation of the prosthesis. The use of an abduction splint, a wedge pillow (Fig. 67-8), or two or three pillows between the legs keeps the hip in abduction. When the nurse turns the patient in bed, it is important to keep the operative hip in abduction.

The patient's hip is never flexed more than 90 degrees. For use of the fracture bedpan, the nurse instructs the patient to flex the unaffected hip and to use the trapeze to lift

NURSING RESEARCH PROFILE

Quality of Life Over the Long-Term for Patients With Total Hip Replacements

McMurray, A., Grant, S., Griffiths, S., et al. (2005). Mapping recovery after total hip replacement surgery: Health-related quality of life after three years. *Australian Journal of Advanced Nursing*, 22(4), 20–25.

Purpose

Total hip replacement (THR) surgery is generally considered a cost-effective and successful surgical intervention that results in improved mobility and quality of life. While many studies have examined quality-of-life outcomes among patients who have had THR, few have measured quality-of-life outcomes beyond a few weeks or months during the postoperative period. This study compared quality-of-life outcomes among patients who had THR at 12 weeks and at 3 years after hospital discharge postsurgery.

Design

Patients who had participated in a previous study of postoperative patients who had THR were called and invited to participate in this study. Of the original cohort of 95 participants, 62 agreed to participate in this study. Thirty-two (52%) of these patients were female, and 37 (60%) were over 75 years of age. These participants were asked to respond to items from the Short Form health survey (SF-36), which they had previously completed at 1, 2, 4, 8, and 12 weeks post-hospital discharge.

Findings

Thirty-six (58%) participants reported being readmitted to the hospital during the previous 3 years for health problems that were not related to their THR. Approximately half ($n = 33$) reported unmet health needs that were mostly related to non-hip-related problems. There were no significant changes found on any SF-36 scores from 12 weeks to 3 years post-hospital discharge for THR. However, the overall physical functioning scores for women were less than population-based norms, while the physical function scores among men were higher than population-based norms. Twenty-six (42%) participants reported an increase in participation of social activities from the preoperative period.

Nursing Implications

Many patients who have had hip replacement surgery report greater mobility and less pain that improves their ability to resume social activities postoperatively. Findings from this study suggest that gains made in engagement in social activities after THR may continue for several years postoperatively among patients with THR. Gains in other quality-of-life indicators may also persist for at least 3 years postoperatively. While men who have had THR may enjoy long-term improvements in physical function, this may not be the case for women who have had THR. Women who have had THR may require more vigilant long-term follow-up.

CHART
67-8

PLAN OF NURSING CARE
The Patient With a Total Hip Replacement

NURSING DIAGNOSIS: Pain related to total hip replacement
GOAL: Relief of pain

Nursing Interventions

1. Assess patient for pain using a standard pain intensity scale.
2. Ask patient to describe discomfort.
3. Acknowledge existence of pain; inform patient of available analgesic agents or muscle relaxants.
4. Use pain-modifying techniques.
 - a. Administer analgesic agents as prescribed.
 - b. Change position within prescribed limits.
 - c. Modify environment.
 - d. Notify surgeon about persistent pain.
5. Evaluate and record discomfort and effectiveness of pain-modifying techniques.

Rationale

1. Pain is expected after a surgical procedure because of the surgical trauma and tissue response. Muscle spasms occur after total hip replacements. Immobility causes discomfort at pressure points.
2. Pain characteristics may help to determine the cause of discomfort. Pain may be due to complications (hematoma, infection, dislocation). Pain is an individual experience—it means different things to different people.
3. The nurse can reduce the stress experienced by patient by communicating concern and availability of assistance to help the patient deal with the pain.
4.
 - a. Patient will require parenteral opioids during the first 24–48 hours, and then will progress to oral analgesic agents.
 - b. Use of pillows to provide adequate support and relief of pressure on bony prominences assists in minimizing pain.
 - c. Interactions with others, distractions, and sensory overload or deprivation may affect pain experience.
 - d. Surgical intervention may be necessary if pain is due to hematoma or excessive edema.
5. Effectiveness of action is based on experience; data provide a baseline about pain experiences, management, and pain relief.

Expected Outcomes

- Describes discomfort
- Expresses confidence in efforts to control pain
- States pain is reduced; pain intensity scores are decreasing
- Appears comfortable and relaxed
- Uses physical, psychological, and pharmacologic measures to reduce pain and discomfort

NURSING DIAGNOSIS: Impaired physical mobility related to positioning, weight-bearing, and activity restrictions after hip replacement
GOAL: Achieves pain-free, functional, stable hip joint

Nursing Interventions

1. Maintain proper positioning of hip joint (abduction, neutral rotation, limited flexion).
2. Keep pressure off heel.
3. Instruct and assist in position changes and transfers.
4. Instruct and supervise isometric quadriceps- and gluteal-setting exercises.
5. In consultation with physical therapist, instruct and supervise progressive safe ambulation within limitations of weight-bearing prescription.

Rationale

1. Prevents dislocation of hip prosthesis
2. Prevents pressure ulcer on heel
3. Encourages patient's active participation while preventing dislocation
4. Strengthens muscles needed for walking
5. Amount of weight-bearing depends on patient's condition and prosthesis; ambulatory aids are used to assist the patient with non-weight-bearing and partial weight-bearing ambulation.

Expected Outcomes

- Maintains prescribed position
- No heel pressure
- Assists in position changes
- Shows increased independence in transfers
- Exercises hourly
- Participates in progressive ambulation program
- Actively participates in exercise regimen
- Uses ambulatory aids correctly and safely

CHART
67-8

PLAN OF NURSING CARE

The Patient With a Total Hip Replacement (Continued)

Nursing Interventions	Rationale	Expected Outcomes
6. Offer encouragement and support exercise regimen. 7. Instruct and supervise safe use of ambulatory aids.	6. Reconditioning exercises can be uncomfortable and fatiguing; encouragement helps patient comply with exercise program. 7. Prevents injury from unsafe use and prevents falls	

COLLABORATIVE PROBLEMS: Hemorrhage; neurovascular compromise; dislocation of prosthesis; deep vein thrombosis; infection related to surgery
GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
<p>Hemorrhage</p> 1. Monitor vital signs, observing for shock. 2. Note character and amount of drainage. 3. Notify surgeon if patient develops shock or excessive bleeding and prepare for administration of fluids, blood component therapy, and medications. 4. Monitor hemoglobin and hematocrit values.	1. Changes in pulse, blood pressure, and respirations may indicate development of shock. Blood loss and stress of surgery may contribute to development of shock. 2. Within 48 hours, bloody drainage collected in portable suction device should decrease to 25–30 mL per 8 hours. Excessive drainage (more than 250 mL in first 8 hours after surgery) and bright red drainage may indicate active bleeding. 3. Corrective measures need to be instituted. 4. Anemia due to blood loss may develop. Blood replacement or iron supplementation may be needed.	<ul style="list-style-type: none"> • Vital signs stabilize within normal limits. • Amount of drainage decreases. • No bright red bloody drainage. • Hematology values are within normal limits.
<p>Neurovascular Dysfunction</p> 1. Assess affected extremity for color and temperature. 2. Assess toes for capillary refill response. 3. Assess extremity for edema and swelling. Report patient complaints of leg tightness. 4. Elevate extremity (keep leg lower than hip when in chair). 5. Assess for deep, throbbing, unrelenting pain. 6. Assess for pain on passive flexion of foot. 7. Assess for change in sensations and numbness.	1. The skin becomes pale and feels cool with decreased tissue perfusion. Venous congestion may produce cyanosis. 2. After compression of the nail, rapid return of pink color indicates good capillary perfusion. 3. The trauma of surgery will cause edema. Excessive swelling and hematoma formation can compromise circulation and function. 4. Minimizes dependent edema 5. Surgical pain can be controlled; pain due to neurovascular compromise is not relieved by treatment. 6. With nerve ischemia, there will be pain on passive stretch. Additionally, pain or tenderness may indicate deep vein thrombosis. 7. Diminished pain and sensory function may indicate nerve damage. Sensation in web between great and second toe—peroneal nerve; sensation on sole of foot—tibial nerve	<ul style="list-style-type: none"> • Color normal • Extremity warm • Normal capillary refill • Moderate edema and swelling; tissue not palpably tense • Pain controllable • No pain with passive dorsiflexion • Normal sensations • No paresthesia • Normal motor abilities • No paresis or paralysis • Pulses strong and equal

CHART
67-8

PLAN OF NURSING CARE

The Patient With a Total Hip Replacement (Continued)

Nursing Interventions

8. Assess ability to move foot and toes.
9. Assess pedal pulses in both feet.
10. Notify surgeon if altered neurovascular status is noted.

Dislocation of Prosthesis

1. Position patient as prescribed.
2. Use abductor splint or pillows to maintain position and to support extremity.
3. Support leg and place pillows between legs when patient is turning and side-lying; turn to the unaffected side.
4. Avoid acute flexion of hip (head of bed at 60 degrees or less).
5. Avoid crossing legs.
6. Assess for dislocation of prosthesis (extremity shortens, internally or externally rotated, severe hip pain, patient unable to move extremity)
7. Notify surgeon of possible dislocation.

Deep Vein Thrombosis

1. Use anti-embolism stocking or sequential compression device as prescribed.
2. Remove stocking for 20 minutes twice a day and provide skin care.
3. Assess popliteal, dorsalis pedis, and posterior tibial pulses.
4. Assess skin temperature of legs.
5. Assess for unilateral calf pain or tenderness every 8 hours.
6. Avoid pressure on popliteal blood vessels from equipment (eg, abductor splint straps, sequential compression stockings) or pillows.
7. Change position and increase activity as prescribed.
8. Supervise ankle exercises hourly.
9. Monitor body temperature.
10. Encourage fluids.

Infection

1. Monitor vital signs.

Rationale

8. Dorsiflexion of ankle and extension of toes indicate function of peroneal nerve. Plantar flexion of ankle and flexion of toes indicate function of tibial nerve.
9. Indicator of extremity circulation
10. Function of extremity needs to be preserved.

1. Hip component positioning (femoral component in acetabular component) needs to be maintained.
2. Keeps hip in abduction and in a neutral rotation to prevent dislocation

3–5. Prevent dislocation

6. Findings may indicate dislocation of prosthesis.

7. Joint dislocations compromise neurovascular status and future function of extremity.

1. Aids in venous blood return and prevents stasis
2. Skin care is necessary to avoid breakdown. Extended removal of stockings defeats purpose of stockings.
3. Pulses indicate arterial perfusion of extremity.
4. Local inflammation will increase local skin temperature.
5. Pain or tenderness may indicate deep vein thrombosis.
6. Compression of blood vessels diminishes blood flow.

7. Activity promotes circulation and diminishes venous stasis.
8. Muscle exercise promotes circulation.
9. Body temperature increases with inflammation.
10. Dehydration increases blood viscosity.

1. Temperature, pulse, and respirations increase in response to infection. (Magnitude of response may be minimal in an elderly patient.)

Expected Outcomes

- Prosthesis not dislocated
- Adheres to recommendations to prevent dislocation

- Wears anti-embolism stockings; uses compression device
- No skin breakdown
- Pulses equal and strong
- Skin temperature normal
- No calf pain or tenderness
- Changes position with assistance and supervision
- Participates in exercise regimen
- Well hydrated
- No chest pain; lungs clear to auscultation; no evidence of pulmonary emboli

- Vital signs normal
- Well-approximated incision without drainage or excessive inflammatory response

Exercise instructions c. Safe use of ambulatory aids d. Wound care e. Measures to promote healing f. Medications, if any g. Potential problems h. Continuing health care supervision and management 	<ol style="list-style-type: none"> 1. Physical barriers (especially stairs, bathrooms) may limit patient's ability to ambulate and care for self at home. 2. Patient may have special problems that need to be identified and resolved. 3. Because of limitation of mobility and limited hip range of motion, patient may require some assistance in routine health care. 4. Understanding of rehabilitative regimen is necessary for compliance. 5. Lack of knowledge and poor preparation for care at home contribute to patient anxiety, insecurity, and non-adherence to therapeutic regimen. 	<ul style="list-style-type: none"> • Home is accessible for patient at time of discharge • Appears relaxed and develops strategies to deal with identified problems • Personal assistance is available • Demonstrates ability to provide necessary assistance within therapeutic prescription • Complies with home care program • Keeps follow-up health care appointments

the pelvis onto the pan. The patient is also reminded not to flex the affected hip.

Limited flexion is maintained during transfers and when sitting. When the patient is initially assisted out of bed, an abduction splint or pillows are kept between the legs. The nurse encourages the patient to keep the affected hip in extension, instructing the patient to pivot on the unaffected leg with assistance by the nurse, who protects the affected hip from **adduction**, flexion, internal or external rotation, and excessive weight bearing.

High-seat (orthopedic) chairs, semireclining wheelchairs, and raised toilet seats are used to minimize hip joint flexion. When sitting, the patient's hips should be higher than the knees. The patient's affected leg should not be elevated when sitting. The patient may flex the knee.

The nurse teaches the patient protective positioning, which includes maintaining abduction and avoiding inter-

nal and external rotation, hyperextension, and acute flexion. A cradle boot may be used to prevent leg rotation and to support the heel off the bed, preventing development of a pressure ulcer. The patient should use pillows between the legs when in a supine or side-lying position and when turning. Generally, the nurse instructs the patient not to sleep on the side on which the surgery was performed. At no time should the patient cross his or her legs. The patient should not bend at the waist to put on shoes and socks. Occupational therapists can provide the patient with devices to assist with dressing below the waist (Lucas, 2008b). Hip precautions should be enforced for 4 or more months after surgery (Chart 67-9). A patient who has had an anterior surgical approach may not need these precautions.

Dislocation may occur with positioning that exceeds the limits of the prosthesis. The nurse must recognize dislocation of the prosthesis. Indicators are as follows:

CHART
67-9

PATIENT EDUCATION

Avoiding Hip Dislocation After Replacement Surgery With Posterior or Posterolateral Approach

Until the hip prosthesis stabilizes after hip replacement surgery, it is necessary to follow instructions for proper positioning so that the prosthesis remains in place. Dislocation of the hip is a serious complication of surgery that causes pain and loss of function and necessitates reduction under anesthesia to correct the dislocation. Desirable positions include abduction, neutral rotation, and flexion of less than 90 degrees. When you are seated, the knees should be lower than the hip.

Methods for avoiding displacement include the following:

- Keep the knees apart at all times.
- Put a pillow between the legs when sleeping.
- Never cross the legs when seated.
- Avoid bending forward when seated in a chair.
- Avoid bending forward to pick up an object on the floor.
- Use a high-seated chair and a raised toilet seat.
- Do not flex the hip to put on clothing such as pants, stockings, socks, or shoes. Positions to avoid after total hip replacement are illustrated below.

Affected leg should not cross the center of the body

Hip should not bend more than 90 degrees

Affected leg should not turn inward

- Increased pain at the surgical site, swelling, and immobilization
- Acute groin pain in the affected hip or increased discomfort
- Shortening of the leg
- Abnormal external or internal rotation
- Restricted ability or inability to move the leg
- Reported “popping” sensation in the hip

If a prosthesis becomes dislocated, the nurse (or the patient, if at home) immediately notifies the surgeon, because the hip must be reduced and stabilized promptly so that the leg does not sustain circulatory and nerve damage. After closed reduction, the hip may be stabilized with Buck's traction or a brace to prevent recurrent dislocation. As the muscles and joint capsule heal, the chance of dislocation diminishes. Stresses to the new hip joint should be avoided for the first 8 to 12 weeks, when the risk of dislocation is greatest (Lucas, 2008b).

Monitoring Wound Drainage

Fluid and blood accumulating at the surgical site are usually drained with a portable suction device. This prevents accumulation of fluid, which could contribute to discomfort and provide a site for infection. Drainage of 200 to 500 mL in the first 24 hours is expected; by 48 hours postoperatively, the total drainage in 8 hours usually decreases to 30 mL or less, and the suction device is then removed. The nurse promptly notifies the physician of any drainage volumes greater than anticipated.

If extensive blood loss is anticipated after total joint replacement surgery, an autotransfusion drainage system (in which the drained blood is filtered and reinfused into the patient during the immediate postoperative period) may be used to decrease the need for homologous blood transfusions.

Preventing Deep Vein Thrombosis

The risk of venous thromboembolism (VTE) is particularly great after reconstructive hip surgery. The incidence of DVT is 48% for patients who have not had any type of VTE preventive measures instituted, which includes mechanical prophylaxis (eg, anti-embolism stockings) and pharmacologic prophylaxis (eg, antithrombotic medications) (Haas, Barrack, Westrich, et al., 2008). DVT formation can lead to pulmonary embolism (PE), which can be fatal. Therefore, the nurse must institute preventive measures and monitor the patient closely for the development of DVT and PE. Signs of DVT include calf pain, swelling, and tenderness. Medications that include fondaparinux (Arixtra) or low-molecular-weight heparin (eg, enoxaparin [Lovenox], dalteparin [Fragmin]) are indicated as prophylaxis for VTE after hip replacement surgery (Hirsh, Guyatt, Albers, et al., 2008).

Preventing Infection

Infection, a serious complication of total hip replacement, may necessitate removal of the prosthesis. Patients who are elderly, are obese, are poorly nourished, smoke cigarettes, or

use corticosteroid medications (eg, prednisone) and patients who have diabetes, rheumatoid arthritis, concurrent infections (eg, urinary tract infection, dental abscess), or hematomas are at high risk for infection (Doherty & Way, 2006).

Potential sources of infection are avoided. If indwelling urinary catheters or portable wound suction devices are used, they are removed as soon as possible to avoid infection. Prophylactic antibiotics are prescribed if the patient needs any future surgical or invasive procedures, such as tooth extraction or cystoscopic examination.

Acute infections may occur within 3 months after surgery and are associated with progressive superficial infections or hematomas. Delayed surgical infections may appear 4 to 24 months after surgery and may cause return of discomfort in the hip. Infections occurring more than 2 years after surgery are attributed to the spread of infection through the bloodstream from another site in the body. If an infection occurs, antibiotics are prescribed. These infections may cause the prosthesis to loosen (Lucas, 2008b). Severe infections may require surgical débridement or removal of the prosthesis.

Promoting Home and Community-Based Care

Teaching the Patient Self-Care. Before the patient prepares to leave the acute care setting, the nurse provides thorough teaching to promote continuity of the therapeutic regimen and active participation in the rehabilitation process (Chart 67-10). The nurse advises the patient of the importance of the daily exercise program in maintaining

the functional motion of the hip joint and strengthening the abductor muscles of the hip, and reminds the patient that it will take time to strengthen and retrain the muscles.

Assistive devices (crutches, walker, or cane) are used for a time. After sufficient muscle tone has developed to permit a normal gait without discomfort, these devices are not necessary. In general, by 3 months, the patient can resume routine ADLs. Stair climbing is permitted as prescribed but is kept to a minimum for 3 to 6 months. Frequent walks, swimming, and use of a high rocking chair are excellent for hip exercises. Sexual intercourse should be carried out with the patient in the dependent position (flat on the back) for 3 to 6 months to avoid excessive adduction and flexion of the new hip.

At no time during the first 4 months should the patient cross the legs or flex the hip more than 90 degrees. Assistance in putting on shoes and socks may be needed. The patient should avoid low chairs and sitting for longer than 45 minutes at a time. These precautions minimize hip flexion and the risks of prosthetic dislocation, hip stiffness, and flexion contracture. Traveling long distances should be avoided unless frequent position changes are possible. Other activities to avoid include tub baths, jogging, lifting heavy loads, and excessive bending and twisting (eg, lifting, shoveling snow, forceful turning).

Continuing Care. A home care nurse may assess the patient at home to assess for potential problems and monitor wound healing (see Chart 67-11 later in this chapter). The nurse, physical therapist, or occupational therapist assesses the home environment for physical barriers that may impede

Chart 67-10 • Providing Home Care After Hip Replacement

Considerations

- Pain management
- Wound care
- Mobility
- Self-care (activities of daily living)
- Potential complications

Nursing Interventions

Discuss with patient methods to reduce pain:

- Periodic rest
- Distraction and relaxation techniques
- Medication therapy (eg, nonsteroidal anti-inflammatory drugs, opioid analgesic agents): actions of medications, administration, schedule, side effects

Instruct patient in the following:

- Keeping incision clean and dry
- Taking care of the wound and changing the dressing
- Recognizing signs of wound infection (eg, pain, swelling, drainage, fever)

Explain that sutures or staples will be removed 10 to 14 days after surgery.

Teach patient about the following:

- Safe use of assistive devices
- Weight-bearing limits
- How to change positions frequently
- Limitations on hip flexion and adduction (eg, avoid acute flexion and crossing legs)

- How to stand without flexing hip acutely
- Avoidance of low-seated chairs
- Sleeping with pillow between legs to prevent adduction
- Gradual increase in activities and participation in prescribed exercise regimen
- Use of important medications such as warfarin (Coumadin) and aspirin

Assess home environment for physical barriers.

Instruct patient to use elevated toilet seat and to use reachers to aid in dressing.

Encourage patient to accept assistance with activities of daily living during early convalescence until mobility and strength improve.

Arrange services and accommodations to address the patient's disability or illness, as appropriate.

Assess patient for development of potential problems, and instruct patient to report signs of potential complications:

- Dislocation of prosthesis (eg, increased pain, shortening of leg, inability to move leg, popping sensation in hip, abnormal rotation)
- Deep vein thrombosis (eg, calf pain, swelling)
- Wound infection (eg, swelling, purulent drainage, pain, fever)
- Pulmonary emboli (eg, sudden dyspnea, tachypnea, pleuritic chest pain)

Discuss with patient the need to continue regular health care (routine physical examinations) and screenings.

the patient's rehabilitation. In addition, the nurse or therapist may need to assist the patient in acquiring devices such as reachers or long-handled tongs to help with dressing, or toilet seat extenders to elevate the toilet.

After successful surgery and rehabilitation, the patient can expect a hip joint that is free or almost free of pain, has good motion, is stable, and permits normal or near-normal ambulation.

Total Knee Replacement

Total knee replacement surgery is considered for patients who have severe pain and functional disabilities related to destruction of joint surfaces by osteoarthritis or rheumatoid arthritis. Metal and acrylic prostheses designed to provide the patient with a functional, painless, stable joint may be used. If the patient's ligaments have weakened, a fully constrained (hinged) or semiconstrained prosthesis may be used to provide joint stability. A nonconstrained prosthesis depends on the patient's ligaments for joint stability.

Nursing Interventions

Postoperatively, the knee is dressed with a compression bandage. Ice may be applied to control edema and bleeding. The nurse assesses the neurovascular status of the leg. It is important to encourage active flexion of the foot every hour when the patient is awake. Efforts are directed at preventing complications (thromboembolism, peroneal nerve palsy, infection, limited range of motion) (Lucas, 2008b).

A wound suction drain removes fluid accumulating in the joint. Drainage ranges from 200 to 400 mL during the first 24 hours after surgery and diminishes to less than 25 mL by 48 hours, at which time the surgeon removes the drains. If extensive bleeding is anticipated, an autotransfusion drainage system may be used during the immediate postoperative period. The color, type, and amount of drainage are documented, and any excessive drainage or change in characteristics of the drainage is promptly reported to the physician.

Use of a **continuous passive motion (CPM) device** in conjunction with physical therapy is associated with decreased hospital length of stay as well as improved patient postoperative knee mobility and decreased use of analgesic agents (Milne, Brosseau, Robinson, et al., 2008). The patient's leg is placed in this device, which increases circulation and range of motion of the knee joint. The rate and amount of extension and flexion are prescribed. Usually, 10 degrees of extension and 50 degrees of flexion are prescribed initially, increasing to 90 degrees of flexion with full extension (0 degrees) by discharge (Fig. 67-9).

The nurse encourages the patient to use the CPM device. The physical therapist supervises exercises for strength and range of motion. If satisfactory flexion is not achieved, gentle manipulation of the knee joint under general anesthesia may be necessary about 2 weeks after surgery.

The nurse assists the patient to get out of bed on the evening or the day after surgery. The knee is usually protected with a knee immobilizer (eg, cast, brace, splint) and is elevated when the patient sits in a chair. The physician prescribes weight-bearing limits. Progressive ambulation, using assistive devices and within the prescribed weight-bearing limits, begins on the day after surgery.

Figure 67-9 Lower-limb continuous passive motion (CPM) device. The Otto Bock 480E Knee CPM is 11 kg (24 lb) and combines durable construction with portability and ease of operation. CPM is best applied immediately after surgery and continued, uninterrupted, for up to 6 weeks as prescribed by the physician. Photo courtesy of Otto Bock Healthcare, Minneapolis, MN.

After discharge from the hospital, the patient may continue to use the CPM device at home and may undergo physical therapy on an outpatient basis. Late complications that may occur include infection and loosening of prosthetic components (Lucas, 2008b). Patients usually can achieve a pain-free, functional joint and participate more fully in life activities than before the surgery (Marx, Jones, Atwan, et al., 2005; Rasanen, Paavoalinen, Sintonen, et al., 2007).

NURSING PROCESS

PREOPERATIVE CARE OF THE PATIENT UNDERGOING ORTHOPEDIC SURGERY

Assessment

Assessment of the patient is focused on hydration status, current medication history, and possible infection. Adequate hydration is an important goal for orthopedic patients. Immobilization and bed rest contribute to the following complications: DVT, PE, urinary stasis and associated bladder infections, and kidney stone formation. Adequate hydration decreases blood viscosity and venous stasis and ensures adequate urine flow. To determine preoperative hydration status, the nurse assesses the skin and mucous membranes, vital signs, urinary output, and laboratory values.

The medication history provides information for perioperative management. The patient with chronic illness (eg, adrenal insufficiency, rheumatoid arthritis, chronic pulmonary disease, multiple sclerosis) or with a transplanted organ frequently has received long-term administration of corticosteroid medications to control disease symptoms or prevent rejection. The corticosteroid should be administered preoperatively, intraoperatively, and postoperatively as prescribed to prevent the occurrence of acute adrenal insufficiency from suppressed adrenal function. The patient's

use of other medications, such as anticoagulants, cardiovascular agents, or insulin, needs to be documented and discussed with the surgeon and anesthesiologist to ensure adequate management.

The nurse asks the patient specifically about the occurrence of colds, dental problems, urinary tract infections, and other infections within the 2 weeks before surgery. Osteomyelitis could develop through hematogenous spread. Permanent disability can result if infection occurs within a bone or joint. Preexisting infections must be resolved before elective orthopedic surgery is performed.

Nursing Diagnoses

Based on the nursing assessment data, the patient's major preoperative nursing diagnoses related to orthopedic status may include the following:

- Acute pain related to fracture, joint degeneration, swelling, or inflammation
- Risk for peripheral neurovascular dysfunction related to swelling, constricting devices, or impaired venous return
- Risk for ineffective therapeutic regimen management related to insufficient knowledge or lack of available support and resources
- Impaired physical mobility related to pain, swelling, and possible presence of an immobilization device
- Risk for situational low self-esteem and/or disturbed body image related to impact of musculoskeletal disorder

Planning and Goals

The major goals for the patient before orthopedic surgery may include relief of pain, adequate neurovascular function, health promotion, improved mobility, and positive self-esteem.

Nursing Interventions

Relieving Pain

Discomfort is decreased with immobilization of a fractured bone or an injured, inflamed joint. Elevation of an edematous extremity promotes venous return and reduces associated discomfort. Ice, if prescribed, relieves swelling and reduces discomfort by diminishing nerve stimulation.

Analgesic agents are frequently prescribed to control the acute pain of musculoskeletal injury or surgery and associated muscle spasm. During the immediate postoperative period, the nurse needs to discuss and coordinate the administration of effective analgesic medications (eg, opioids, nonsteroidal anti-inflammatory drugs) with the anesthesia provider and surgeon. (See Chapter 13 for a further discussion of assessment and management of pain.)

Maintaining Adequate Neurovascular Function

Trauma, edema, or immobilization devices may interrupt tissue perfusion. The nurse must frequently assess neurovascular status (ie, color, temperature, capillary refill, pulses, edema, pain, sensation, motion) of the extremity and document the findings. If circulation is compromised, the nurse institutes measures to restore adequate circulation. These include promptly notifying the physician, elevating the

extremity, and releasing constricting wraps or assisting with bivalving constrictive casts as prescribed.

Promoting Health

The nurse assists the patient in performing activities that promote health during the perioperative period. The nurse assesses nutritional status and hydration. The nurse monitors fluid intake, urinary output, and urinalysis findings. At times, patients may intentionally limit their fluid intake to minimize the use of a bedpan. A small fracture bedpan may be more comfortable for the patient to use. An indwelling catheter should be used only when necessary to minimize the risk of urinary tract infection. A preexisting urinary tract infection must be effectively treated prior to surgery.

If the surgery is elective, the orthopedic surgeon may instruct the patient to shower with a germicidal soap at home prior to surgery. The patient may also be asked to mark the operative site prior to surgery to minimize the risk that the wrong site is selected in the operating room.

The nurse discusses with the patient and the family the need for assistance with ADLs and the therapeutic regimen during convalescence so that adequate support is available when the patient is discharged. Modification of the home environment may be necessary to accommodate the altered mobility of the patient after surgery. Referral to a social worker and case manager may be needed to ensure a smooth transition to home care.

Improving Mobility

Preoperatively, the patient's mobility may be impaired by pain, swelling, and immobilizing devices (eg, splints, casts, traction). The nurse should elevate and adequately support edematous extremities with pillows. It is important to control pain before an injured part is moved by administering analgesic medication in time for it to take effect. The injured part is supported when it is moved. The nurse encourages movement within the limits of therapeutic immobility. The patient should perform active range-of-motion exercises of uninvolved joints, and, unless contraindicated, the nurse teaches gluteal-setting and quadriceps-setting isometric exercises to maintain the muscles needed for ambulation (see Chart 67-3). The patient who will be using assistive devices postoperatively may exercise to strengthen the upper extremities and shoulders. If the use of assistive devices (eg, crutches, walker, wheelchair) is anticipated, the nurse encourages the patient to practice with them preoperatively to facilitate their safe use and to promote earlier independent mobility.

Helping the Patient Maintain Self-Esteem

Preoperatively, orthopedic patients may need assistance in accepting changes in body image, diminished self-esteem, or inability to perform their roles and responsibilities. The degree of assistance required in this area varies greatly, depending on the events preceding hospitalization, the surgery and rehabilitation planned, and the temporary or permanent nature of the problems. The nurse promotes a trusting relationship so that the patient feels comfortable expressing concerns and anxieties, and helps the patient examine his or her feelings about changes in self-concept. The nurse clarifies any misconceptions the patient may have and

helps the patient work through modifications needed to adapt to alterations in physical capacity and to reestablish positive self-esteem.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Reports relief of pain
 - a. Uses multiple approaches to reduce pain
 - b. States that medication is effective in relieving pain
 - c. Moves with increasing comfort
2. Exhibits adequate neurovascular function
 - a. Exhibits normal skin color
 - b. Has warm skin
 - c. Has normal capillary refill response
 - d. Reports normal sensation and demonstrates joint motion
 - e. Demonstrates reduced swelling
3. Promotes health
 - a. Consumes diet appropriate to meet nutritional needs
 - b. Maintains adequate hydration
 - c. Abstains from smoking
 - d. Practices respiratory exercises
 - e. Repositions self to relieve skin pressure
 - f. Engages in strengthening and preventive exercises
 - g. Plans for assistance during convalescence at home
4. Maximizes mobility within therapeutic limits
 - a. Requests assistance when moving
 - b. Elevates edematous extremity after transfer
 - c. Uses immobilizing devices and assistive devices safely as prescribed
5. Expresses positive self-esteem
 - a. Acknowledges temporary or permanent changes in body image
 - b. Discusses role performance changes
 - c. Participates in decisions about care

NURSING PROCESS

POSTOPERATIVE CARE OF THE PATIENT UNDERGOING ORTHOPEDIC SURGERY

Assessment

After orthopedic surgery, the nurse continues the preoperative care plan, modifying it to match the patient's current postoperative status. The nurse reassesses the patient's needs related to pain, neurovascular status, health promotion, mobility, and self-esteem. Skeletal trauma and surgery performed on bones, muscles, or joints can produce significant pain, especially during the first 1 or 2 postoperative days. Tissue perfusion must be monitored closely, because edema and bleeding into the tissues can compromise circulation and result in compartment syndrome. Inactivity contributes to venous stasis and the development of venous thromboemboli that may include DVTs or PEs. General anesthesia, analgesia, and immobility can result in altered

functioning of the respiratory, gastrointestinal, and urinary systems.

The nurse notes the prescribed limits on mobility and assesses the patient's understanding of the mobility restrictions. The nurse discusses the plan of care with the patient and encourages his or her active participation in the plan.

Frequent assessment of vital signs including pain, level of consciousness, neurovascular status, wound drainage, breath sounds, bowel sounds, and fluid balance provides the nurse with data that may suggest the possible development of complications. The nurse reports abnormal findings to the physician promptly.

With major orthopedic surgery, there is a risk for hypovolemic shock because of blood loss. Muscle dissection frequently produces wounds in which hemostasis is poor. Wounds that are closed under tourniquet control may bleed during the postoperative period. The nurse must be alert for signs of hypovolemic shock.

Changes in the patient's pulse rate, respiratory rate, or color of the skin or mucous membranes may indicate pulmonary or cardiovascular complications. Atelectasis and pneumonia are common and may be related to preexisting pulmonary disease, deep anesthesia, decreased activity, and reduced respiratory reserve due to advanced age or an underlying musculoskeletal disorder (eg, restrictive lung expansion secondary to kyphosis, rheumatoid arthritis, or osteoporosis).

Voiding in unnatural positions may contribute to urinary retention. In addition, elderly men usually have some degree of prostate enlargement and may already have difficulty voiding. Therefore, it is important to monitor urinary output.

Temperature elevations within the first 48 hours are frequently related to atelectasis or other respiratory problems. Temperature elevations during the next few days are frequently associated with urinary tract infections. Superficial wound infections take 4 to 6 days to develop. Fever from phlebitis usually occurs during the end of the first week through the second week.

Venous thromboembolus (see discussions of DVT in Chapter 31 and PE in Chapter 23) is one of the most common and most dangerous of all complications occurring in the postoperative orthopedic patient. Advanced age, venous stasis, lower extremity orthopedic surgery, and immobilization are significant risk factors. The nurse assesses the patient daily for unilateral calf swelling, tenderness, warmth, and redness. The nurse promptly reports abnormal findings to the physician.

In addition, fat emboli syndrome (FES) (see Chapter 69) may occur with orthopedic surgery. The nurse must be alert to any signs and symptoms that may suggest the development of FES. These may include respiratory distress; onset of delirium or any acute change in level of consciousness; and development of unusual skin rashes, especially a papular rash on the upper torso.

Diagnosis

Nursing Diagnoses

Based on all assessment data, the patient's major nursing diagnoses after orthopedic surgery may include the following:

- Acute pain related to the surgical procedure, swelling, and immobilization
- Risk for peripheral neurovascular dysfunction related to swelling, constricting devices, or impaired circulation
- Risk for ineffective therapeutic regimen management related to insufficient knowledge or available support and resources
- Impaired physical mobility related to pain, edema, or the presence of an immobilizing device (eg, splint, cast, or brace)
- Risk for situational low self-esteem, disturbed body image, or ineffective role performance related to impact of the musculoskeletal disorder

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include the following:

- Hypovolemic shock
- Atelectasis; pneumonia
- Urinary retention
- Infection
- Venous thromboembolism, including DVT or PE
- Constipation and fecal impaction

Planning and Goals

The major goals for the patient after orthopedic surgery may include relief of pain, adequate neurovascular function, health promotion, improved mobility, positive self-esteem, and absence of complications.

Nursing Interventions

Relieving Pain

After orthopedic surgery, pain can be intense. Edema, hematomas, and muscle spasms contribute to the pain. Some patients report that the pain is less than that experienced preoperatively, and only moderate amounts of analgesic agents are needed. The nurse assesses the patient's level of pain, evaluates the patient's response to therapeutic measures, and makes every effort to relieve the pain and discomfort. Pain assessment must occur on an ongoing basis and take place at least as often as vital signs are assessed.

Multiple pharmacologic approaches to pain management exist. Patient-controlled analgesia (PCA) and epidural analgesia may be prescribed to relieve the pain. If the patient is receiving preemptive analgesia on an ongoing basis via a PCA IV pump, the nurse ensures that the patient receives boluses of the analgesic agent prior to performing planned physical activities. If intramuscular and oral analgesic agents are prescribed on an as-needed basis (PRN), the nurse should administer medications on a preventive basis within the prescribed intervals if the onset of pain can be predicted (eg, 30 minutes before planned activity such as transfer or exercise). The nurse should offer the medication at set intervals.

In addition to pharmacologic approaches to controlling pain, elevation of the operative extremity and application of cold packs, if prescribed, help control edema and pain. Surgical drains inserted in the wound decrease fluid accumulation and hematoma formation. The nurse may find

that repositioning, relaxation, distraction, and guided imagery help in reducing the patient's pain.

The nurse should report increasing and uncontrollable pain to the orthopedic surgeon for evaluation. Pain should diminish rapidly after the initial postoperative period. After 2 to 3 days, most patients require only occasional oral analgesia for residual muscle soreness and spasm.

Maintaining Adequate Neurovascular Function

The nurse monitors the neurovascular status of the involved body part and notifies the physician promptly of any indications of diminished tissue perfusion. The patient is reminded to perform muscle-setting, ankle, and calf-pumping exercises hourly while awake to enhance circulation.

Maintaining Health

It is important to encourage the patient to participate in the postoperative treatment regimen. A diet that includes adequate protein and vitamins is essential for wound healing. The patient progresses to a regular diet as soon as possible.

The nurse assesses the patient for early manifestations of pressure ulcers (eg, redness over bony prominences), which are a threat to any patient who must spend an extended time in bed or who is elderly, malnourished, or unable to move without assistance. Turning the patient frequently at preset intervals (eg, at least every 2 hours), washing and drying the skin, and minimizing pressure over bony prominences are necessary to avoid skin breakdown.

Improving Physical Mobility

Patients are frequently reluctant to move after orthopedic surgery. Preoperative education about the planned postoperative treatment regimen promotes patient adherence to an optimal rehabilitation regimen. Patients often increase their mobility once they have been reassured that movement within therapeutic limits is beneficial, that the nurse will provide assistance, and that discomfort can be controlled.

Metal pins, screws, rods, and plates used for internal fixation are designed to maintain the position of the bone until ossification occurs. They are not designed to support the body's weight, and they can bend, loosen, or break if stressed. The estimated strength of the bone, the stability of the fracture, reduction and fixation, and the amount of bone healing are important considerations in determining weight-bearing limits. Although the incision may appear healed, the underlying bone requires more time to repair and regain normal strength. Some orthopedic procedures require weight-bearing restrictions. The orthopedic surgeon will prescribe the weight-bearing limits and the use of protective devices (orthoses), if necessary, after surgery.

The physical therapist tailors the rehabilitation program to each patient's needs. The goal is the patient's return to the highest level of function in the shortest time possible. Rehabilitation involves progressive increases in the patient's activities and exercises. Assistive devices (crutches, walker) may be used for postoperative mobility. Preoperative practice with assistive devices helps the patient use them appropriately postoperatively. The nurse makes sure that the patient uses these devices safely (see discussions of crutch walking and use of a walker in Chapter 11).

Maintaining Self-Esteem

The nurse and the patient set realistic goals. Increased ability to perform self-care activities within the limits of the therapeutic regimen and resumption of roles facilitate the patient's recognition of abilities and promote self-esteem, personal identity, and role performance. Acceptance of altered body image is facilitated by support provided by the nurse, family, and others.

Monitoring and Managing Potential Complications

HYPOVOLEMIC SHOCK. Excessive loss of blood during or after surgery can result in shock. The nurse monitors the patient for signs and symptoms of hypovolemic shock: increased pulse rate (eg, greater than 100 bpm), decreased blood pressure (eg, less than 90/60 mm Hg), narrowed pulse pressure (eg, less than 20 mm Hg), urine output less than 30 mL/h, restlessness, change in mentation, thirst, and decreased hemoglobin and hematocrit. The nurse reports these findings to the orthopedic surgeon and assists in appropriate management. (See Chapter 15 for a discussion of managing shock.)

ATELECTASIS AND PNEUMONIA. The nurse monitors the patient's breath sounds and encourages deep-breathing and coughing exercises. Full expansion of the lungs prevents the accumulation of pulmonary secretions and the development of atelectasis and pneumonia. Incentive spirometry use is encouraged. If signs of respiratory problems develop (eg, increased respiratory rate, productive cough, diminished or adventitious breath sounds, fever), the nurse reports the findings to the surgeon.

URINARY RETENTION. The nurse closely monitors the patient's urinary output after surgery. The nurse encourages the patient to void every 3 to 4 hours to prevent urinary retention and bladder distention. It is important to provide privacy during toileting. Because the patient may need to void in an unusual position, the nurse assists the patient with positioning. Fracture bedpans may be more comfortable to use than other bedpans. Voiding in the side-lying position may be helpful to the male patient. Some male patients can void only if standing, and clarification with the surgeon of the activity prescription may be needed before the patient is assisted to a standing position.

If the patient cannot void, intermittent catheterizations may be prescribed until the patient can void independently. Indwelling urinary catheters should be used only when necessary and should be removed as soon as possible. The patient may follow a catheterization protocol that incorporates the use of a bladder scanner to estimate the amount of urine in the bladder, thereby determining if catheterization is necessary. Catheterization protocol use has decreased the number of nosocomial urinary tract infections associated with unnecessary catheterizations (Wald, Ma, Bratzler, et al., 2008).

INFECTION. Infection is a risk after any surgery, but it is of particular concern for the postoperative orthopedic patient because of the risk of osteomyelitis. Osteomyelitis often requires prolonged courses of IV antibiotics. At times, the infected bone and prosthesis or internal fixation device must be surgically removed. Therefore, prophylactic systemic an-

tibiotics are usually prescribed during the perioperative and immediate postoperative periods. The nurse assesses the patient's response to these antibiotics. When changing dressings and emptying wound drainage devices, aseptic technique is essential. The nurse monitors the patient's vital signs, incision, and drainage. The nurse monitors the patient for signs of urinary tract infection. Prompt assessment for and treatment of infection are essential.

VENOUS THROMBOEMBOLISM AND DEEP VEIN THROMBOSIS. Prevention of DVT requires use of ankle and calf-pumping exercises, anti-embolism stockings, and sequential compression devices. Adequate hydration and early mobilization are equally important. Prophylactic fondaparinux, low-molecular-weight heparin (eg, enoxaparin, dalteparin), warfarin (Coumadin), or low-dose unfractionated heparin may be prescribed in the immediate postoperative period. Typically, fondaparinux, a low-molecular-weight heparin, or warfarin is prescribed during the later rehabilitation period for DVT prophylaxis (Hirsh, et al., 2008). The nurse monitors the patient for signs of DVT and promptly reports findings to the physician for management.

CONSTIPATION. Constipation is a frequently overlooked complication, because patients are discharged to a rehabilitation or home setting in 3 or 4 days. Constipation occurs because of decreased mobility and hydration, coupled with the use of opioids. Prevention of constipation requires continual monitoring of bowel function. Adequate hydration, early mobilization, and stool softeners may be prescribed to prevent fecal impaction (see Chapter 38).

Promoting Home and Community-Based Care

TEACHING THE PATIENT SELF-CARE. Because the length of stay in the hospital after orthopedic surgery is usually 3 or 4 days, most convalescence and rehabilitation take place at home or in a nonacute care setting. The nurse teaches the patient and the family to recognize complications that must be reported promptly to the orthopedic surgeon. The patient must understand the prescribed medication regimen. The nurse should demonstrate proper wound care. The patient gradually resumes physical activities and adheres to weight-bearing limits. The patient must be able to perform transfers and to use mobility aids safely. If the patient has a cast or other immobilizing device, family members are instructed about how to assist the patient in a way that is safe for the patient and for the family member (eg, using proper body mechanics when assisting the patient). Specific exercises need to be taught and practiced before discharge. The nurse discusses recovery and health promotion, emphasizing a healthy lifestyle and diet (Chart 67-11).

CONTINUING CARE. If special equipment or home modifications are needed for safe care at home, they must be in place before the patient is discharged home. Discharge planning begins immediately after surgery. The nurse, physical therapist, and social worker can assist the patient and family in identifying their needs and in getting ready to care for the patient at home.

Frequently, home health nursing and home physical therapy are part of the discharge plan of care. These referrals provide resources and help the patient and the family

CHART
67-11

HOME CARE CHECKLIST

The Patient Who Has Had Orthopedic Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe wound care.	✓	✓
• State indicators of wound infections (eg, redness, swelling, tenderness, purulent drainage, fever).	✓	✓
• Consume a healthy diet to promote wound and bone healing.	✓	
• Participate in prescribed exercise regimen to promote circulation and mobility.	✓	
• Use mobility aids safely.	✓	
• Observe prescribed weight-bearing and activity limits.	✓	
• Take prescribed therapeutic and prophylactic medications (eg, antibiotics, anticoagulants, analgesic agents).	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage; signs of systemic infection; signs of deep vein thrombosis or pulmonary embolism).	✓	✓
• Identify modifications of home environment to promote safe environment and independence during recovery and rehabilitation.	✓	✓

cope with the demands of care during recovery and rehabilitation. The nurse assesses the patient's progress and monitors for possible complications. Regular medical follow-up care after discharge needs to be arranged. The nurse reminds the patient and family about the importance of continuing health promotion and screening practices.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Reports decreased level of pain
 - a. Uses multiple approaches to reduce pain
 - b. Uses oral analgesic medication as needed to control discomfort
 - c. Elevates extremity to control edema and discomfort
 - d. Moves with greater comfort
2. Exhibits adequate neurovascular function
 - a. Exhibits normal color and temperature of skin
 - b. Has warm skin
 - c. Has normal capillary refill response
 - d. Demonstrates intact sensory and motor function
 - e. Demonstrates reduced swelling
3. Promotes health
 - a. Eats diet appropriate for nutritional needs
 - b. Maintains adequate hydration
 - c. Abstains from smoking
 - d. Practices respiratory exercises
 - e. Repositions self to relieve pressure on skin
 - f. Engages in strengthening and preventive exercises
4. Maximizes mobility within the therapeutic limits
 - a. Requests assistance when moving
 - b. Elevates edematous extremity after transfer
 - c. Uses immobilizing devices as prescribed
 - d. Complies with prescribed weight-bearing limitation

5. Expresses positive self-esteem
 - a. Discusses temporary or permanent changes in body image
 - b. Discusses role performance
 - c. Views self as capable of assuming responsibilities
 - d. Actively participates in planning care and in the therapeutic regimen
6. Exhibits absence of complications
 - a. Does not experience shock
 - b. Maintains normal vital signs and blood pressure
 - c. Has clear lung sounds
 - d. Demonstrates wound healing without signs of infection
 - e. Does not experience urinary retention
 - f. Voids clear urine
 - g. Exhibits no signs of DVT or PE
 - h. Does not experience constipation

CRITICAL THINKING EXERCISES

EBP 1 A 64-year-old man has had a right total knee replacement for osteoarthritis. On his second postoperative day, he complains to you that he would rather not use his CPM device, and wonders why his participation in physical therapy alone is not sufficient. How would you respond to him? Why is CPM indicated for patients who have had knee replacement surgery? What is the strength of the evidence that supports the use of CPM either singly or in tandem with physical therapy postoperatively in this patient population?

2 A 50-year-old woman has had a repair of a fracture of her right tibia. She has a plaster cast over her right leg, with a window placed over her incision. During the

evening of her second postoperative day, she complains of increasing pain and slight paresthesias of her right toes. Opioid analgesic agents have only moderately relieved her pain. The night-shift nurse documents her findings and asks you, as the oncoming day-shift nurse, to report these findings to the orthopedic surgeon when he makes his rounds. You assess the patient after report and find that she now describes her right lower leg as “feeling tight” and that she has sensations of “pins and needles.” Capillary refill of her right toes is longer than 3 seconds, and they feel much cooler than the left toes. What additional assessments might you make at this time? What is your priority nursing diagnosis and intervention?

EBP 3 You are an experienced perioperative nurse. You note that different orthopedic surgical groups have different preoperative hygiene protocols for patients undergoing total knee replacement surgery who come to the surgical center where you work. One surgical group tells its patients to shower with Betadine solution once daily for 2 days prior to surgery; another tells its patients to shower with chlorhexidine solution the morning of surgery; while another does not give any specific preoperative hygiene instructions. What is the strength of the evidence that identifies which preoperative hygiene protocol is most effective for patients scheduled to have total knee replacement surgery?

4 A 70-year-old woman with a long-standing history of osteoarthritis has had a right total hip replacement. On the second postoperative day, a physical therapy assistant helps the patient get out of bed. She has been sitting out of bed for approximately an hour when she requests to be placed back in bed. What is the best way to accomplish this transfer from chair to bed? What specific precautions might you follow?

Management of Patients With Musculoskeletal Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the nursing management, rehabilitation, and health education needs of the patient with low back pain.
- 2 Identify common conditions of the hand or wrist and nursing care of the patient undergoing surgery of the hand or wrist.
- 3 Describe common conditions of the foot and nursing care of the patient undergoing foot surgery.
- 4 Explain the pathophysiology, pathogenesis, prevention, and management of osteoporosis.
- 5 Use the nursing process as a framework for care of the patient with osteoporosis.
- 6 Identify the causes and related medical management of osteomalacia.
- 7 Identify medication modalities for the patient with Paget's disease.
- 8 Use the nursing process as a framework for care of the patient with osteomyelitis.
- 9 Describe the nursing management of the patient with a bone tumor.

GLOSSARY

bursitis: inflammation of a fluid-filled sac in a joint

contracture: abnormal shortening of muscle or fibrosis of joint structures

involucrum: new bone growth around a sequestrum

radiculopathy: disease of a nerve root

sciatica: sciatic nerve pain; pain travels down back of thigh into foot

sequestrum: dead bone in abscess cavity

tendinitis: inflammation of muscle tendons

Musculoskeletal disorders, particularly impairment of the back and spine, are leading health problems and causes of disability. The functional and psychological limitations imposed on the patient may be severe. The economic costs, in terms of loss of productivity, medical expenses, and other costs that are not compensated, are estimated to exceed \$100 billion in direct and indirect costs in North America yearly (Sahar, Cohen, Matan, et al., 2008).

Low Back Pain

The number of visits to primary care providers resulting from low back pain is second only to the number of visits for upper respiratory illnesses (Sahar, et al., 2008). Most low back pain is caused by one of many musculoskeletal problems, including acute lumbosacral strain, unstable lumbosacral ligaments and weak muscles, osteoarthritis of the spine, spinal stenosis, intervertebral disk problems, and unequal leg length. Obesity, stress, and occasionally depression may contribute to low back pain. Back pain due to musculoskeletal disorders usually is aggravated by activity, whereas pain due to other conditions is not.

Older patients may experience back pain associated with osteoporotic vertebral fractures, osteoarthritis of the spine and spinal stenosis (Weiner, Sakamoto, Perera, et al., 2006). Other causes include kidney disorders, pelvic problems, retroperitoneal tumors, and abdominal aortic aneurysms.

Pathophysiology

The spinal column can be considered an elastic rod constructed of rigid units (vertebrae) and flexible units (intervertebral disks) held together by complex facet joints, multiple ligaments, and paravertebral muscles. Its unique construction allows for flexibility while providing maximum protection for the spinal cord. The spinal curves absorb vertical shocks from running and jumping. The trunk muscles help stabilize the spine. The abdominal and thoracic muscles are important in lifting activities, working together to minimize stress on the spinal units. Disuse weakens these supporting muscular structures. Obesity, postural problems, structural problems, and overstretching of the spinal supports may result in back pain (Porth & Matfin, 2009).

The intervertebral disks change in character as a person ages. A young person's disks are mainly fibrocartilage with a gelatinous matrix. As a person ages, the fibrocartilage becomes dense and irregularly shaped. Disk degeneration is a common cause of back pain. The lower lumbar disks, L4–L5 and L5–S1, are subject to the greatest mechanical stress and the greatest degenerative changes. Disk protrusion (herniated nucleus pulposus) or facet joint changes can cause pressure on nerve roots as they leave the spinal canal, which results in pain that radiates along the nerve (Porth & Matfin, 2009). Management of intervertebral disk disease is discussed in Chapter 65.

Clinical Manifestations

The typical patient reports either acute back pain (lasting less than 3 months) or chronic back pain (lasting more than 3 months without improvement) and fatigue. The patient

may report pain radiating down the leg, which is known as **radiculopathy** or **sciatica**; presence of this symptom suggests nerve root involvement. The patient's gait, spinal mobility, reflexes, leg length, leg motor strength, and sensory perception may be affected. Physical examination may disclose paravertebral muscle spasm (greatly increased muscle tone of the back postural muscles) with a loss of the normal lumbar curve and possible spinal deformity.

Assessment and Diagnostic Findings

The initial evaluation of acute low back pain includes a focused history and physical examination, including general observation of the patient, back examination, and neurologic testing (reflexes, sensory impairment, straight-leg raising, muscle strength, and muscle atrophy). The findings suggest either nonspecific back symptoms or potentially serious problems, such as sciatica, spine fracture, cancer, infection, or rapidly progressing neurologic deficit. If the initial examination does not suggest a serious condition, no additional testing is performed during the first 4 weeks of symptoms.

The diagnostic procedures described in Chart 68-1 may be indicated for the patient with potentially serious or prolonged low back pain. The nurse prepares the patient for these studies, provides the necessary support during the testing period, and monitors the patient for any adverse responses to the procedures.

Medical Management

Most back pain is self-limited and resolves within 4 weeks with analgesic agents, rest, and relaxation. Based on initial assessment findings, the patient is reassured that the assessment indicates that the back pain is not due to a serious condition. Management focuses on relief of pain and discomfort, activity modification, and patient education.

Nonprescription analgesic agents such as acetaminophen (Tylenol) and nonsteroidal anti-inflammatory drugs (NSAIDs) (eg, ibuprofen [Motrin]) and prescription muscle

Chart 68-1 • Diagnostic Procedures for Low Back Pain

- X-ray of the spine**—may demonstrate a fracture, dislocation, infection, osteoarthritis, or scoliosis
- Bone scan and blood studies**—may disclose infections, tumors, and bone marrow abnormalities
- Computed tomography (CT)**—useful in identifying underlying problems, such as obscure soft tissue lesions adjacent to the vertebral column and problems of vertebral disks
- Magnetic resonance imaging (MRI)**—permits visualization of the nature and location of spinal pathology
- Electromyogram (EMG) and nerve conduction studies**—used to evaluate spinal nerve root disorders (radiculopathies)
- Myelogram**—permits visualization of segments of the spinal cord that may have herniated or may be compressed
- Ultrasound**—useful in detecting tears in ligaments, muscles, tendons, and soft tissues in the back

relaxants (eg, cyclobenzaprine [Flexeril]) are effective in relieving acute low back pain, while tricyclic antidepressants (eg, amitriptyline [Elavil]) are effective in relieving chronic low back pain. Other medications, including opioids (eg, morphine), tramadol (Ultram), benzodiazepines (eg, diazepam [Valium]), and gabapentin (Neurontin) (ie, prescribed for pain from radiculopathy) are also effective, though the evidence of their effectiveness is not as strong as that for the previously noted medications. Systemic corticosteroids are generally not considered effective in alleviating low back pain (Chou & Huffman, 2007b).

Effective nonpharmacologic interventions for acute low back pain include the application of superficial heat and spinal manipulation (eg, chiropractic therapy). Cognitive-behavioral therapy (eg, biofeedback), exercise regimens, spinal manipulation, physical therapy, acupuncture, massage, and yoga are all effective nonpharmacologic interventions for treating chronic low back pain but not acute low back pain (Chou & Huffman, 2007a).

Most patients need to alter their activity patterns to avoid aggravating the pain. They should avoid twisting, bending, lifting, and reaching, all of which stress the back. The patient is taught to change position frequently. Sitting should be limited to 20 to 50 minutes based on level of comfort. Bed rest is recommended for 1 to 2 days, for a maximum of 4 days and *only* if pain is severe. A gradual return to activities and a program of low-stress aerobic exercise are recommended. Conditioning exercises for the trunk muscles are begun after about 2 weeks.

If there is no improvement within 1 month, additional assessments for physiologic abnormalities are performed. Management is based on findings.

Nursing Assessment

The nurse asks the patient with low back pain to describe the discomfort (eg, location, severity, duration, characteristics, radiation, associated weakness in the legs). Descriptions of how the pain occurred—with a specific action (eg, opening a garage door) or with an activity in which weak muscles were overused (eg, weekend gardening)—and how the patient has dealt with the pain often suggest areas for intervention and patient teaching.

If back pain is a recurrent problem, information about previous successful pain control methods helps in planning current management. The nurse also asks how the back pain affects the patient's lifestyle. Information about work and recreational activities helps identify areas for back health education. Because stress and anxiety can evoke muscle spasms and pain, the nurse assesses environmental variables, work situations, and family relationships. In addition, the nurse assesses the effect of chronic pain on the emotional well-being of the patient. Referral to a mental health professional (eg, psychiatric advanced practice nurse) for assessment and management of stressors contributing to the low back pain and related depression may be appropriate.

During the interview, the nurse observes the patient's posture, position changes, and gait. Often, the patient's movements are guarded, with the back kept as still as possible. The patient often selects a chair of standard seat height with arms for support. The patient may sit and stand in an

unusual position, leaning away from the most painful side, and may ask for assistance when undressing for the physical examination.

On physical examination, the nurse assesses the spinal curve, any leg length discrepancy, and pelvic crest and shoulder symmetry. The nurse palpates the paraspinal muscles and notes spasm and tenderness. When the patient is in a prone position, the paraspinal muscles relax, and any deformity caused by spasm subsides. The nurse asks the patient to bend forward and then laterally and notes any discomfort or limitations in movement. It is important to determine the effect of these limitations in movement on activities of daily living (ADLs). The nurse evaluates nerve involvement by assessing deep tendon reflexes, sensations (eg, paresthesia), and muscle strength. Back and leg pain on straight-leg raising (with the patient supine, the patient's leg is lifted upward with the knee extended) suggest nerve root involvement. Obesity can contribute to low back pain. If the patient is obese, the nurse completes a nutritional assessment (see Chapter 5) (Bickley, 2007).

Nursing Management

The major nursing goals for the patient may include relief of pain, improved physical mobility, use of back-conserving techniques of body mechanics, improved self-esteem, and weight reduction (as necessary) (Chart 68-2).

The nurse assesses the patient's response to analgesic agents. As the acute pain subsides, medication dosages are reduced. The nurse evaluates and notes the patient's response to various pain management modalities. (Other generic interventions that may relieve pain are discussed in Chapter 13.)

The nurse instructs the patient with severe pain to limit activities for 1 to 2 days. Extended periods of inactivity are not effective and result in deconditioning. A firm, nonsagging mattress (a bed board may be used) is recommended. Lumbar flexion is increased by elevating the head and thorax 30 degrees using pillows or a foam wedge and slightly flexing the knees supported on a pillow. Alternatively, the patient can assume a lateral position with knees and hips flexed (curled position) with a pillow between the knees and legs and a pillow supporting the head (Fig. 68-1). A prone position should be avoided because it accentuates lordosis. The nurse instructs the patient to get out of bed by rolling to one side and placing the legs down while pushing the torso up, keeping the back straight (National Institute of Neurological Disorders and Stroke [NINDS], 2009).

As the patient achieves comfort, activities are gradually resumed, and an exercise program is initiated. Initially, low-stress aerobic exercises, such as short walks or swimming, are suggested. After 2 weeks, conditioning exercises for the abdominal and trunk muscles are started. The physical therapist designs an exercise program for the individual patient to reduce lordosis, increase flexibility, and reduce strain on the back. It may include hyperextension exercises to strengthen the paravertebral muscles, flexion exercises to increase back movement and strength, and isometric flexion exercises to strengthen trunk muscles. Each exercise period begins with relaxation. Exercise begins gradually and increases as the patient recovers.

CHART
68-2

PATIENT EDUCATION

Strategies for Treating and Preventing Acute Low Back Pain

Treatment

- Limit bed rest; keep your knees flexed to decrease strain on your back.
- Try nonpharmacologic approaches such as application of superficial heat or chiropractic therapy.
- Pharmacologic approaches: Take nonsteroidal anti-inflammatory drugs, acetaminophen (Tylenol), and muscle relaxants as prescribed.
- Weight reduction as needed: Modify diet to achieve ideal body weight.

Prevention

Exercise

- Stretch to enhance flexibility. Do strengthening exercises.
- Perform prescribed back exercises to increase function, gradually increasing time and repetitions.

Body Mechanics

- Practice good posture.
- Avoid twisting your body.
- Push objects rather than pull them.
- Keep load close to your body when lifting.
- Bend your knees and tighten abdominal muscles when lifting.
- Avoid overreaching.
- Use a wide base of support.

Work Modifications

- Adjust work area to avoid stress on back.
- Adjust height of chair or work table.
- Use lumbar support in chair.
- Avoid prolonged standing and repetitive tasks.
- Avoid bending, twisting, and lifting heavy objects.
- Avoid work involving continuous vibrations.

The nurse encourages the patient to adhere to the prescribed exercise program. The patient should exercise 30 minutes daily using low-impact activities that may include speed walking, swimming, stationary bike riding, or yoga. Some patients may find it difficult to adhere to a program of prescribed exercises for a long period; in these instances, alternating activities may help facilitate compliance (NINDS, 2009). Patients are encouraged to improve their posture and use good body mechanics on a regular basis. Activities should not cause excessive lumbar strain, twisting, or discomfort; for example, activities such as horseback riding and weight lifting should be avoided.

Good body mechanics and posture are essential to avoid recurrence of back pain. The patient must be taught how to stand, sit, lie, and lift properly (Fig. 68-2). Providing the patient with a list of suggestions helps in making these long-term changes (Chart 68-3). The patient who wears high heels is encouraged to change to low heels with good arch support. The patient who is required to stand for long periods should shift weight frequently and should rest one foot on a low stool, which decreases lumbar lordosis. Patients who stand in place for a long period of time (eg, cashiers)

Figure 68-2 Proper and improper standing postures. **Left**, Abdominal muscles contracted, giving a feeling of upward pull, and gluteal muscles contracted, giving a downward pull. **Right**, Slouch position, showing abdominal muscles relaxed and body out of proper alignment.

CHART
68-3

HEALTH PROMOTION

Activities to Promote a Healthy Back

Standing. Advise the patient to adhere to the following guidelines:

- Avoid prolonged standing and walking.
- When standing for any length of time, rest one foot on a small stool or box to relieve lumbar lordosis.
- Avoid forward flexion work positions.
- Avoid high heels.

Sitting. Discuss the following strategies with the patient:

- Avoid sitting for prolonged periods.
- Sit in a straight-back chair with back well supported and arm rests to support some of the body weight; use a footstool to position knees higher than hips if necessary.
- Eradicate the hollow of the back by sitting with the buttocks “tucked under.”
- Maintain back support; use a soft support at the small of the back.
- Avoid knee and hip extension. When driving a car, have the seat pushed forward as far as possible for comfort.
- Guard against extension strains—reaching, pushing, sitting with legs straight out.
- Alternate periods of sitting with walking.

Lying. Encourage the patient to do the following:

- Rest at intervals; fatigue contributes to spasm of the back muscles.

- Place a firm bed board under the mattress.
- Avoid sleeping in a prone position.
- When lying on the side, place a pillow under the head and one between the legs, with the legs flexed at the hips and knees.
- When supine, use a pillow under the knees to decrease lordosis.

Lifting. Emphasize the importance of the following strategies:

- When lifting, keep the back straight and hold the load as close to the body as possible.
- Lift with the large leg muscles, not the back muscles.
- Use trunk muscles to stabilize the spine.
- Squat while keeping the back straight when it is necessary to pick something off the floor.
- Avoid twisting the trunk of the body, lifting above waist level, and reaching up for any length of time.

Exercising. Daily exercise is important in the prevention of back problems.

- Walk daily and gradually increase the distance and pace of walking.
- Perform prescribed back exercises twice daily, increasing exercise gradually.
- Avoid jumping and jarring activities.

should stand on a foot cushion made of foam or rubber. The proper posture can be verified by looking in a mirror to see whether the chest is up, the abdomen is tucked in, and the shoulders are down and relaxed. Locking the knees when standing is avoided, as is bending forward for long periods.

When the patient is sitting, the knees and hips should be flexed, and the knees should be level with the hips or higher to minimize lordosis. The feet should be flat on the floor. The back needs to be supported, so patients should avoid sitting on stools or chairs that do not provide firm back support. The patient should sleep on the side with knees and hips flexed, or supine with knees supported in a flexed position. Sleeping prone should be avoided (NINDS, 2009).

The nurse instructs the patient in the safe and correct way to lift objects—using the strong quadriceps muscles of the thighs, with minimal use of weak back muscles (Fig. 68-3). With feet placed hip-width apart to provide a wide base of support, the patient should bend the knees, tighten the abdominal muscles, and lift the object close to the body with a smooth motion, avoiding twisting and jarring motions. To prevent recurrence of acute low back pain, the nurse may instruct the patient to avoid lifting more than one third of his or her weight without help.

Because of the immobility associated with low back pain, the patient may depend on other people to do various tasks. Role-related responsibilities may have been modified with the onset of low back pain. As recovery from acute low back pain and immobility progresses, the patient may resume former role-related responsibilities.

However, if these activities contributed to the development of low back pain, it may be difficult to resume them without the development of chronic low back pain, with associated disability and depression. If the patient experi-

ences secondary gains associated with low back disability (eg, worker's compensation, easier lifestyle or workload, increased emotional support), a “low back neurosis” may develop. The patient may need help in coping with specific stressors and in learning how to control stressful situations. Psychotherapy or counseling may be needed to assist the person in resuming a full, productive life. Back clinics use multidisciplinary approaches to help the patient with pain and with resumption of role-related responsibilities.

Obesity contributes to back strain by stressing the relatively weak back muscles. Exercises are less effective and more difficult to perform when the patient is overweight. Weight reduction through diet modification may prevent

Figure 68-3 Proper and improper lifting techniques. **Left**, Correct position for lifting. This person is using the long and strong muscles of the arms and legs and holding the object so that the line of gravity falls within the base of support. **Right**, Incorrect position for lifting because pull is exerted on the back muscles and leaning causes the line of gravity to fall outside the base.

recurrence of back pain. Weight reduction is based on a sound nutritional plan that includes a change in eating habits to maintain desirable weight. Monitoring weight reduction, noting achievement, and providing encouragement and positive reinforcement facilitate adherence. Frequently, back problems resolve as optimal weight is achieved (NINDS, 2009).

Common Upper Extremity Problems

The structures in the upper extremities are frequently the sites of painful syndromes. The structures most frequently affected are the shoulder, wrist, and hand.

BURSITIS AND TENDINITIS

Bursitis and **tendinitis** are inflammatory conditions that commonly occur in the shoulder. Bursae are fluid-filled sacs that prevent friction between joint structures during joint activity. When inflamed, they are painful. Similarly, muscle tendon sheaths become inflamed with repetitive stretching. The inflammation causes proliferation of synovial membrane and pannus formation, which restricts joint movement. Traditional conservative treatment includes rest of the extremity, intermittent ice and heat to the joint, and NSAIDs to control the inflammation and pain. Newer therapies that include extracorporeal shock wave therapy (ie, use of focused high-intensity acoustic radiation), pulsed magnetic field therapy, laser phototherapy, and radiofrequency coblation therapy (ie, use of focused radiowaves) may accelerate tendon healing, although further research is needed to determine their overall effectiveness (Sharma & Maffulli, 2005). Arthroscopic synovectomy may be considered if shoulder pain and weakness persist.

LOOSE BODIES

Loose bodies may occur in a joint as a result of articular cartilage wear and bone erosion. These fragments interfere with joint movement, locking the joint, resulting in painful movement. Loose bodies are removed by arthroscopic surgery.

IMPINGEMENT SYNDROME

Impingement syndrome is a general term that describes all lesions that involve the rotator cuff of the shoulder (Trampas & Kitsios, 2006). Impingement usually occurs from repetitive overhead movement of the arm or from acute

trauma (Trojian, Stevenson & Agrawal, 2005), resulting in irritation and eventual inflammation of the rotator cuff tendons or the subacromial bursa as they grate against the coracoacromial arch. Stage I impingement syndrome is characterized by edema and hemorrhage of the rotator cuff tendons or subacromial bursa (Trampas & Kitsios, 2006). The patient experiences pain, shoulder tenderness, limited movement, muscle spasm, and eventual atrophy. The process may progress to a partial or complete rotator cuff tear (referred to as Stage II or Stage III impingement syndrome, respectively) (Trojian, et al., 2005) (see Chapter 69 for a discussion of rotator cuff tears).

Medications used to treat Stage I impingement syndrome include oral NSAIDs (eg, ibuprofen) or intra-articular (ie, subacromial) injections of corticosteroids (eg, triamcinolone [Aristocort]). Treatment with corticosteroids generally results in speedier symptomatic improvement than that with NSAIDs, though the use of both medications concomitantly does not appear to confer any additional improvements (Trojian, et al., 2005). Application of superficial cold or heat does not improve patients' symptoms, but a therapeutic exercise program (eg, physical therapy) does reduce pain and improve shoulder function (Trampas & Kitsios, 2006) (Chart 68-4).

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is an entrapment neuropathy that occurs when the median nerve at the wrist is compressed by a thickened flexor tendon sheath, skeletal encroachment, edema, or a soft tissue mass. It most commonly occurs in women between 30 and 60 years of age. It is commonly caused by repetitive hand and wrist movements, but it may also be associated with arthritis, diabetes, tumors, or trauma (Schoen, 2005). Patients who perform repetitive movements or those whose hands are repeatedly exposed to cold temperatures, vibrations, or extreme direct pressure are at an increased risk for carpal tunnel syndrome. The patient experiences pain, numbness, paresthesia, and possibly weakness along the median nerve (thumb, index, and middle fingers). Tinel's sign may be used to help identify carpal tunnel syndrome (Fig. 68-4). Night pain is common.

Treatment of carpal tunnel syndrome is based on the cause of the condition. Research findings suggest that intra-articular injections of corticosteroids (eg, methylprednisolone [Medrol]) or oral corticosteroids (eg, prednisone) are very effective at relieving symptoms. Application of wrist splints to prevent hyperextension and prolonged

CHART
68-4

PATIENT EDUCATION

Measures to Promote Shoulder Healing of Impingement Syndrome

- Rest the joint in a position that minimizes stress on the joint structures to prevent further damage and the development of adhesions.
- Support the affected arm on pillows while sleeping to keep from turning onto the shoulder.
- Gradually resume motion and use of the joint. Assistance with dressing and other activities of daily living may be needed.
- Avoid working and lifting above shoulder level or pushing an object against a "locked" shoulder.
- Perform the prescribed daily range-of-motion and strengthening exercises.

Figure 68-4 Tinel's sign may be elicited in patients with carpal tunnel syndrome by percussing lightly over the median nerve, located on the inner aspect of the wrist. If the patient reports tingling, numbness, and pain, the test for Tinel's sign is considered positive. From Weber, J. W. & Kelley, J. (2006). *Health assessment in nursing* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins. © B. Proud.

flexion of the wrist are also effective interventions. However, yoga, laser therapy, and ultrasound therapy are ineffective therapies, as are the use of NSAIDs, diuretics, and vitamin B₆ (Piazzini, Aprile, Ferrara, et al., 2007).

Traditional open nerve release or endoscopic laser surgery are the two most common surgical management options for treatment of carpal tunnel syndrome. Both of these procedures are performed under local anesthesia and involve making small incisions into the affected wrist, cutting the carpal ligament so that the carpal tunnel is widened. Smaller incisions are made with the endoscopic laser procedure, and there is less scar formation and a shorter recovery time than with the open method. Following either of these procedures, the patient wears a hand splint and limits hand use during healing. The patient may need assistance with personal care and ADLs. Full recovery of motor and sensory function after either type of nerve release surgery may take several weeks or months.

GANGLION

A ganglion, a collection of gelatinous material near the tendon sheaths and joints, appears as a round, firm, cystic swelling, usually on the dorsum of the wrist. It most frequently occurs in women younger than 50 years. The ganglion is locally tender and may cause an aching pain. When a tendon sheath is involved, weakness of the finger occurs. Treatment may include aspiration, corticosteroid injection, or surgical excision. After treatment, a compression dressing and immobilization splint are used.

DUPUYTREN'S DISEASE

Dupuytren's disease results in a slowly progressive **contracture** of the palmar fascia, called Dupuytren's contracture, which causes flexion of the fourth and fifth fingers, and frequently the middle finger. This renders the fingers more or less useless (Fig. 68-5). It is caused by an inherited autosomal dominant trait and occurs most frequently in men who

Figure 68-5 Dupuytren's contracture, a flexion deformity caused by an inherited trait, is a slowly progressive contracture of the palmar fascia, which severely impairs the function of the fourth, fifth, and, sometimes, middle finger.

are older than 50 years and who are of Scandinavian or Celtic origin. It is also associated with arthritis, diabetes, gout, cigarette smoking, and alcoholism (Childs, 2005). It starts as a nodule of the palmar fascia. The nodule may not change, or it may progress so that the fibrous thickening extends to involve the skin in the distal palm and produces a contracture of the fingers. The patient may experience dull aching discomfort, morning numbness, cramping, and stiffness in the affected fingers. This condition starts in one hand, but eventually both hands are affected. Finger-stretching exercises or intranodular injections of corticosteroids (eg, triamcinolone) may prevent contractures (Trojan & Chu, 2007). With contracture development, palmar and digital fasciectomy are performed to improve function. Finger exercises are begun on postoperative day 1 or 2.

NURSING MANAGEMENT OF THE PATIENT UNDERGOING SURGERY OF THE HAND OR WRIST

Surgery of the hand or wrist, unless related to major trauma, is generally an ambulatory procedure. Before surgery, the nurse assesses the patient's level and type of discomfort and limitations in function caused by the ganglion, carpal tunnel syndrome, Dupuytren's contracture, or other condition of the hand.

Neurovascular assessment of the exposed fingers every hour for the first 24 hours following surgery is essential for monitoring function of the nerves and perfusion of the hand. The nurse instructs the patient and any family caregivers on these parameters for periodic neurovascular assessment and gives instructions on when to notify the physician. The nurse compares the affected hand with the unaffected hand and the postoperative status with the documented preoperative status. The patient describes sensations in the hands and demonstrates finger mobility. With tendon repairs and nerve, vascular, or skin grafts, motor function is tested as necessary. The temperature of the affected hand is assessed. Dressings provide support but are nonconstrictive. Pain uncontrolled by analgesic agents suggests compromised neurovascular functioning.

Pain may be related to surgery, edema, hematoma formation, or restrictive bandages. To control swelling that may increase the patient's pain and discomfort, the nurse instructs the patient to elevate the hand to heart level with pillows. If the patient is ambulatory, the arm is elevated in a conventional sling with the hand at heart level.

CHART
68-5

HOME CARE CHECKLIST

Hand Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate how to assess neurovascular status.	✓	✓
• State abnormal findings (eg, unrelenting pain; paralysis; paresthesia; cool, nonblanching fingers) to report to physician promptly.	✓	✓
• Demonstrate control of edema by elevating hand above elbow and applying ice intermittently if prescribed.	✓	✓
• Identify signs and symptoms of infection (eg, elevated temperature, purulent drainage).	✓	✓
• Demonstrate finger exercises to promote circulation, unless contraindicated.	✓	
• Describe methods to prevent wound infection (eg, keeping hand dressing clean and dry during activities of daily living).	✓	✓
• Describe use of prescribed medications.	✓	✓
• Demonstrate use of assistive devices, if appropriate.	✓	

Intermittent use of ice packs to the surgical area during the first 24 to 48 hours may be prescribed to control edema. Unless contraindicated, active extension and flexion of the fingers to promote circulation are encouraged, even though movement is limited by the bulky dressing.

Generally, the pain and discomfort can be controlled by oral analgesic agents. If the patient is hospitalized, the nurse evaluates the patient's response to analgesic agents and to other pain control measures. Patient education concerning analgesic agents is important.

During the first few days after surgery, the patient needs assistance with ADLs because one hand is bandaged and independent self-care is impaired. The patient may need to arrange for assistance with feeding, bathing and hygiene, dressing, grooming, and toileting. Within a few days, the patient develops skills in one-handed ADLs and is usually able to function with minimal assistance and use of assistive devices. The nurse encourages the patient to use the involved hand, unless contraindicated, within the limits of discomfort. As rehabilitation progresses, the patient resumes use of the injured hand. Physical or occupational therapy-directed exercises may be prescribed. The nurse emphasizes compliance with the therapeutic regimen.

As with all surgery, there is a risk of infection. The nurse teaches the patient to monitor temperature and signs and symptoms that suggest an infection. It also is important to instruct the patient to keep the dressing clean and dry and to report any drainage, foul odor, or increased pain and swelling. Patient education includes aseptic wound care as well as education related to prescribed prophylactic antibiotics.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

After the patient has undergone hand surgery, the nurse teaches the patient how to monitor neurovascular status and the signs of complications that need to be reported to the surgeon (eg, paresthesia, paralysis, uncontrolled pain, coolness of fingers, extreme swelling, excessive bleeding, purulent drainage, fever). The nurse discusses prescribed medications with the patient. In addition, the nurse teaches the

patient to elevate the hand above the elbow and to apply ice (if prescribed) to control swelling. Unless contraindicated, the nurse encourages extension and flexion exercises of the fingers to promote circulation. The use of assistive devices is encouraged if they would be helpful in promoting accomplishment of ADLs. For bathing, the nurse instructs the patient to keep the dressing dry by covering it with a secured plastic bag. Generally, the wound is not redressed until the patient's follow-up visit with the surgeon (Chart 68-5).

Common Foot Problems

Disorders of the foot may be caused by poorly fitting shoes, which distort normal anatomy while inducing deformity and pain. Dermatologic problems commonly affect the feet in the form of fungal infections and plantar warts. Several systemic diseases affect the feet. Patients with diabetes are prone to develop corns and peripheral neuropathies with diminished sensation, leading to ulcers at pressure points of the foot. Patients with peripheral vascular disease and arteriosclerosis complain of burning and itching feet, resulting in scratching and skin breakdown. Foot deformities may occur with rheumatoid arthritis. Obesity can cause a host of foot anomalies, including plantar fasciitis (Cole, Seto & Gazewood, 2005).

The discomforts of foot strain are treated with rest, elevation, physiotherapy, supportive strappings, and orthotic devices. The patient must inspect the foot and skin under pads and orthotic devices for pressure and skin breakdown daily. If a "window" is cut into shoes to relieve pressure over a bony deformity, the skin must be monitored daily for breakdown from pressure exerted at the "window" area. Active foot exercises promote circulation and help strengthen the feet. Walking in properly fitting shoes is considered the ideal exercise.

PLANTAR FASCIITIS

Plantar fasciitis, an inflammation of the foot-supporting fascia, presents as an acute onset of heel pain experienced with the first steps in the morning. The pain is localized to the

anterior medial aspect of the heel and diminishes with gentle stretching of the foot and Achilles tendon. Management includes stretching exercises, wearing shoes with support and cushioning to relieve pain, orthotic devices (eg, heel cups, arch supports, night splints), and corticosteroid injections (Cole, et al., 2005). Unresolved plantar fasciitis may progress to fascial tears at the heel and eventual development of heel spurs.

CORN

A corn is an area of hyperkeratosis (overgrowth of a horny layer of epidermis) produced by internal pressure (the underlying bone is prominent because of a congenital or acquired abnormality, commonly arthritis) or external pressure (ill-fitting shoes). The fifth toe is most frequently involved, but any toe may be involved.

Corns are treated by a podiatrist by soaking and scraping off the horny layer, by application of a protective shield or pad, or by surgical modification of the underlying offending osseous structure. Soft corns are located between the toes and are kept soft by moisture. Treatment consists of drying the affected spaces and separating the affected toes with lamb's wool or gauze. A wider shoe may be helpful. Usually, a podiatrist is consulted to treat the underlying cause.

CALLUS

A callus is a discretely thickened area of the skin that has been exposed to persistent pressure or friction. Faulty foot mechanics usually precede the formation of a callus. Treatment consists of eliminating the underlying causes and having the callus treated by a podiatrist if it is painful. A keratolytic ointment may be applied and a thin plastic cup worn over the heel if the callus is on this area. Felt padding with an adhesive backing is also used to prevent and relieve pressure. Orthotic devices can be made to remove the pressure from bony protuberances, or the protuberance may be excised.

INGROWN TOENAIL

An ingrown toenail (onychocryptosis) is a condition in which the free edge of a nail plate penetrates the surrounding skin, either laterally or anteriorly. A secondary infection or granulation tissue may develop. This painful condition is caused by improper self-treatment, external pressure (tight shoes or stockings), internal pressure (deformed toes, growth under the nail), trauma, or infection. Trimming the nails properly (clipping them straight across and filing the corners consistent with the contour of the toe) can prevent this problem. Active treatment consists of washing the foot twice a day, followed by the application of a local antibiotic ointment, and relieving the pain by decreasing the pressure of the nail plate on the surrounding soft tissue. Warm, wet soaks help drain an infection. A toenail may need to be excised by the podiatrist if there is severe infection.

HAMMER TOE

Hammer toe is a flexion deformity of the interphalangeal joint, which may involve several toes (Fig. 68-6A). The condition is usually an acquired deformity. Tight socks or shoes may push an overlying toe back into the line of the

Figure 68-6 Common foot deformities.

other toes. The toes usually are pulled upward, forcing the metatarsal joints (ball of the foot) downward. Corns develop on top of the toes, and tender calluses develop under the metatarsal area. The treatment consists of conservative measures: wearing open-toed sandals or shoes that conform to the shape of the foot, carrying out manipulative exercises, and protecting the protruding joints with pads. Surgery (osteotomy) may be used to correct a resulting deformity. There is little evidence to support treatment of hammer toe when the patient does not report pain or other symptoms (Badlissi, Dunn, Link, et al., 2005).

HALLUX VALGUS

Hallux valgus (commonly called a bunion) is a deformity in which the great toe deviates laterally (see Fig. 68-6C). Associated with this is a marked prominence of the medial aspect of the first metatarsophalangeal joint. There is also osseous enlargement (exostosis) of the medial side of the first metatarsal head, over which a bursa may form (secondary to pressure and inflammation). Acute bursitis symptoms include a reddened area, edema, and tenderness.

Factors contributing to bunion formation include heredity, ill-fitting shoes, and gradual lengthening and widening of the foot associated with aging. Osteoarthritis is frequently associated with hallux valgus. Treatment depends on the patient's age, the degree of deformity, and the severity of symptoms. If a bunion deformity is uncomplicated, wearing a shoe that conforms to the shape of the foot or that is molded to the foot to prevent pressure on the protruding portions may be the only treatment needed. Corticosteroid injections control acute inflammation. Surgical removal of the bunion (exostosis) and osteotomies to realign the toe may be required to improve function, appearance, and symptoms (Badlissi, et al., 2005). Complications related to bunionectomy include limited range of motion, paresthesias, tendon injury, and recurrence of deformity.

Postoperatively, the patient may have intense throbbing pain at the operative site, requiring opioid analgesia (eg, morphine). The foot is elevated to the level of the heart to decrease edema and pain. The neurovascular status of the toes is assessed. The duration of immobility and initiation of ambulation depend on the procedure used. Toe flexion and extension exercises are initiated to facilitate walking. Shoes that fit the shape and size of the foot are recommended.

PES CAVUS

Pes cavus (clawfoot) refers to a foot with an abnormally high arch and a fixed equinus deformity of the forefoot (see Fig. 68-6B). The shortening of the foot and increased pressure produce calluses on the metatarsal area and on the dorsum of the foot. Charcot-Marie-Tooth disease (a peripheral neuromuscular disease associated with a familial degenerative disorder), diabetes mellitus, and tertiary syphilis are common causes of pes cavus. Exercises are prescribed to manipulate the forefoot into dorsiflexion and relax the toes. Orthotic devices alleviate pain and can protect the foot (Burns, Landorf, Ryan, et al., 2008). In severe cases, arthrodesis (fusion) is performed to reshape and stabilize the foot.

MORTON'S NEUROMA

Morton's neuroma (plantar digital neuroma, neurofibroma) is a swelling of the third (lateral) branch of the median plantar nerve (see Fig. 68-6D). The third digital nerve, which is located in the third intermetatarsal (web) space, is most commonly involved. Microscopically, digital artery changes cause an ischemia of the nerve.

The result is a throbbing, burning pain in the foot that is usually relieved when the patient rests. Conservative treatment consists of inserting innersoles and metatarsal pads designed to spread the metatarsal heads and balance the foot posture. Local injections of a corticosteroid (eg, hydrocortisone [Acticort]) and a local anesthetic agent may provide relief. If these fail, surgical excision of the neuroma is necessary. Pain relief and loss of sensation are immediate and permanent.

FLATFOOT

Flatfoot (pes planus) is a common disorder in which the longitudinal arch of the foot is diminished. It may be caused by congenital abnormalities or associated with bone or

ligament injury, muscle and posture imbalances, excessive weight, muscle fatigue, poorly fitting shoes, or arthritis. Signs and symptoms include a burning sensation, fatigue, clumsy gait, edema, and pain.

Exercises to strengthen the muscles and to improve posture and walking habits are helpful. A number of foot orthoses are available to give the foot additional support.

NURSING MANAGEMENT OF THE PATIENT UNDERGOING FOOT SURGERY

Surgery of the foot may be necessary because of various conditions, including neuromas and foot deformities (bunion, hammer toe, clawfoot). Generally, foot surgery is performed on an outpatient basis. Before surgery, the nurse assesses the patient's ambulatory ability and balance and the neurovascular status of the foot. Additionally, the nurse considers the availability of assistance at home and the structural characteristics of the home in planning for care during the first few days after surgery.

After surgery, neurovascular assessment of the exposed toes every 1 to 2 hours for the first 24 hours is essential to monitor the function of the nerves and the perfusion of the tissues. If the patient is discharged within several hours after the surgery, the nurse teaches the patient and family how to assess for edema and neurovascular status (circulation, motion, sensation). Compromised neurovascular function can increase the patient's pain (see Chart 66-3 in Chapter 66).

Pain experienced by patients who undergo foot surgery is related to inflammation and edema. Formation of a hematoma may contribute to the discomfort. To control the edema, the foot should be elevated on several pillows when the patient is sitting or lying. Ice packs applied intermittently to the surgical area during the first 24 to 48 hours may be prescribed to control edema and provide some pain relief. As activity increases, the patient may find that dependent positioning of the foot is uncomfortable. Simply elevating the foot often relieves the discomfort. Oral analgesic agents may be used to control the pain. The nurse instructs the patient and family about appropriate use of these medications.

After surgery, the patient will have a bulky dressing on the foot, protected by a light cast or a special protective boot. Limits for weight bearing on the foot will be prescribed by the surgeon. Some patients are allowed to walk on the heel and progress to weight bearing as tolerated; other patients are restricted to non-weight-bearing activities. Assistive devices (eg, crutches, walker) may be needed. The choice of the devices depends on the patient's general condition and balance and on the weight-bearing prescription. Safe use of the assistive devices must be ensured through adequate patient education and practice before discharge. Strategies to move around the house safely while using assistive devices are discussed with the patient. As healing progresses, the patient gradually resumes ambulation within prescribed limits. The nurse emphasizes compliance with the therapeutic regimen.

Any surgery carries a risk of infection. In addition, percutaneous pins may be used to hold bones in position, and these pins serve as potential sites for infection. Care must be taken

CHART
68-6

PATIENT EDUCATION

Self-Care After Foot Surgery

Neurovascular Status

The following signs and symptoms indicate impaired circulation and should be reported to your health care provider right away:

- Change in sensation
- Inability to move toes
- Toes or foot cool to touch
- Color changes

Pain Management

Methods to reduce pain include the following:

- Elevate foot to heart level.
- Apply ice as prescribed.
- Use analgesic agents as prescribed.
- Report pain that is not relieved.

Mobility

- Use assistive devices safely.
- Comply with prescribed weight-bearing limits.
- Wear special protective shoe over the dressing.

Wound Care

- Keep the dressing or cast clean and dry.
- Report signs of wound infection (eg, pain, drainage, fever) immediately.
- Follow the prescribed antibiotic regimen.
- Keep your appointment with the surgeon for the initial dressing change.

to protect the surgical wound from dirt and moisture. When bathing, the patient can secure a plastic bag over the dressing to prevent it from getting wet. Patient instructions concerning aseptic wound care and pin care may be necessary.

The nurse teaches the patient to monitor for temperature changes and infection. Drainage on the dressing, a foul odor, or increased pain and swelling could indicate infection. The nurse instructs the patient to promptly report any of these findings to the physician. If prophylactic antibiotics are prescribed, the nurse provides instruction about their correct use. The nurse plans patient teaching for home care, focusing on neurovascular status, pain management, mobility, and wound care (Chart 68-6).

Metabolic Bone Disorders

OSTEOPOROSIS

Osteoporosis is the most prevalent bone disease in the world. More than 10 million Americans have osteoporosis and an additional 33.6 million have osteopenia, the precursor to osteoporosis. The consequence of osteoporosis is bone fracture. It is projected that one of every two Caucasian women and one of every five men will have an osteoporosis-related fracture at some point in their lives (National Osteoporosis Foundation [NOF], 2008). The costs incurred from treating osteoporosis-related fractures in the United States are estimated at \$20 billion annually (Sambrook & Cooper, 2006).

Prevention

Peak adult bone mass is achieved between the ages of 18 and 25 years in both females and males and is affected by genetic factors. Bone mass during these years is affected by nutrition, physical activity, medications, endocrine status, and general health (NOF, 2008). Risk factors for osteoporosis and their effects on bone remodeling and maintenance are noted in Figure 68-7.

Primary osteoporosis occurs in women after menopause (usually between the ages of 45 and 55 years) and in men later in life, but it is not merely a consequence of aging. Failure to develop optimal peak bone mass during childhood, adolescence, and young adulthood contributes to the development of osteoporosis. Early identification of at-risk

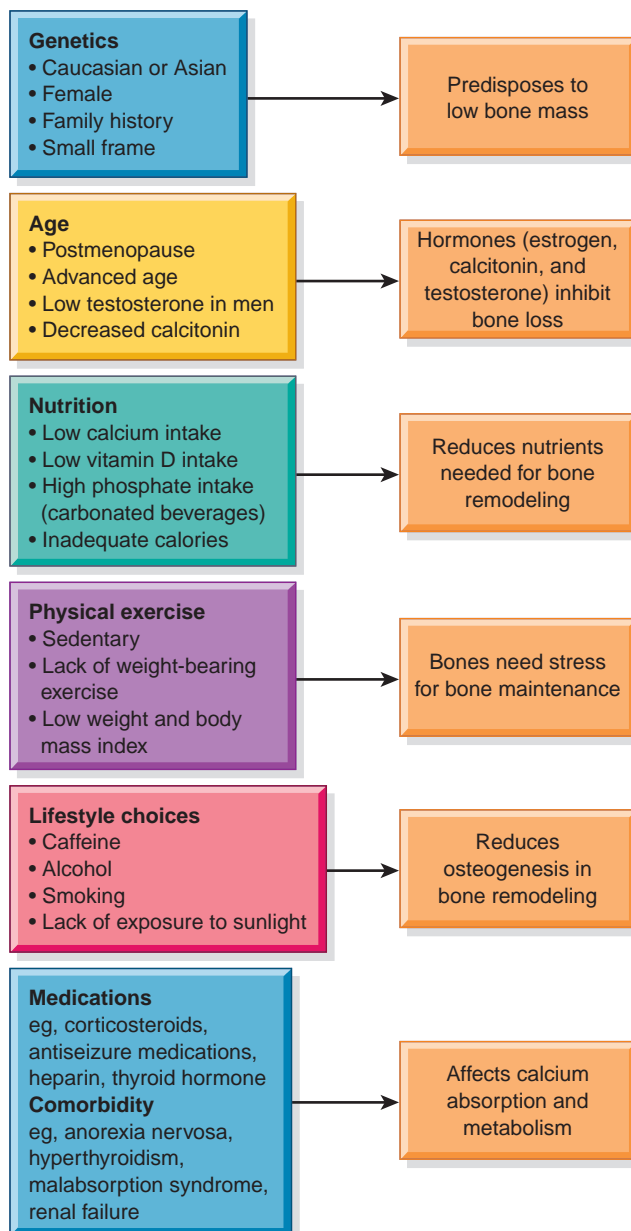

FIGURE 68-7 Risk factors for osteoporosis, and the effects of these factors on bone.

teenagers and young adults, increased calcium intake, participation in regular weight-bearing exercise, and modification of lifestyle (eg, reduced use of caffeine, cigarettes, carbonated soft drinks, and alcohol) are interventions that decrease the risk of osteoporosis, fractures, and associated disability later in life (NOF, 2008).

Secondary osteoporosis is the result of medications or other conditions and diseases that affect bone metabolism. Specific disease states (eg, celiac disease, hypogonadism) and medications (eg, corticosteroids, antiseizure medications) that place patients at risk need to be identified and therapies instituted to reverse the development of osteoporosis (NOF, 2008). The degree of osteoporosis is related to the duration of medication therapy. When the therapy is discontinued or the metabolic problem is corrected, the progression of osteoporosis is halted, but restoration of lost bone mass usually does not occur.

Gerontologic Considerations

The prevalence of osteoporosis in women older than 80 years is 50%. The average 75-year-old woman has lost 25% of her cortical bone and 40% of her trabecular bone. With the aging of the population, the incidence of fractures (more than 1.5 million osteoporotic fractures per year), pain, and disability associated with osteoporosis is increasing. Most residents of long-term care facilities have a low bone mineral density (BMD) and are at risk for bone fracture. It is estimated that the number of hip fractures and their associated costs will at least double by the year 2040 because of the projected aging of the U.S. population (NOF, 2008).

Asymptomatic osteoporotic-related vertebral fractures are associated with loss of height, respiratory dysfunction, increased risk of mortality, and increased risk of subsequent fractures. Elderly men are also at heightened risk for osteoporosis and fractures. One third of all hip fractures occur among men and these tend to be more lethal than those seen in women. Men are more likely than women to have secondary causes of osteoporosis that may lead to fractures, including use of corticosteroids (eg, prednisone) and excessive alcohol intake (Ebeling, 2008).

Elderly people absorb dietary calcium less efficiently and excrete it more readily through their kidneys; therefore, postmenopausal women and the elderly need to consume approximately 1200 mg of daily calcium; quantities larger than this may place patients at heightened risk for renal calculi (ie, kidney stones) or cardiovascular disease (NOF, 2008).

Pathophysiology

Osteoporosis is characterized by reduced bone mass, deterioration of bone matrix, and diminished bone architectural strength. Normal homeostatic bone turnover is altered; the rate of bone resorption that is maintained by osteoclasts is greater than the rate of bone formation that is maintained by osteoblasts, resulting in a reduced total bone mass. The bones become progressively porous, brittle, and fragile; they fracture easily under stresses that would not break normal bone. These increase susceptibility to fracture, which occur most commonly as compression fractures (Fig. 68-8) of the

Figure 68-8 Progressive osteoporotic bone loss and compression fractures. From Rubin, E., Gorstein, F., Swarting, R., et al. (2004). *Pathology* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

thoracic and lumbar spine, hip fractures, and Colles' fractures of the wrist. These fractures may be the first clinical manifestation of osteoporosis (NOF, 2008).

The gradual collapse of a vertebra may be asymptomatic; it is observed as progressive kyphosis. With the development of kyphosis (ie, "dowager's hump"), there is an associated loss of height (Fig. 68-9). The postural changes result in relaxation of the abdominal muscles and a protruding abdomen. The deformity may also produce pulmonary insufficiency.

Age-related loss begins soon after the peak bone mass is achieved (ie, in the fourth decade). Calcitonin, which inhibits bone resorption and promotes bone formation, is decreased. Estrogen, which inhibits bone breakdown, decreases with aging. On the other hand, parathyroid hormone (PTH) increases with aging, increasing bone turnover and resorption. The consequence of these changes is net loss of bone mass over time.

The withdrawal of estrogens at menopause or with oophorectomy causes an accelerated bone resorption that continues during the postmenopausal years. Women develop osteoporosis more frequently and more extensively than men because of lower peak bone mass and the effect of estrogen loss during menopause. More than half of all women older than 50 years show evidence of osteopenia.

Risk Factors

Small-framed, nonobese Caucasian women are at greatest risk for osteoporosis (see Fig. 68-7). Also, Asian women of slight build are at risk for low peak BMD. African American women, who have a greater bone mass than Caucasian women, are less susceptible to osteoporosis. Men have a greater peak bone mass and do not experience sudden

Figure 68-9 Typical loss of height associated with osteoporosis and aging.

estrogen reduction. As a result, osteoporosis occurs in men at a lower rate and at an older age (about one decade later). It is believed that testosterone and estrogen are important in achieving and maintaining bone mass in men. Risk for osteoporosis increases with increasing age (Chart 68-7).

Nutritional factors contribute to the development of osteoporosis. A diet that includes adequate calories and nutrients needed to maintain bone, calcium, and vitamin D must be consumed. Vitamin D is necessary for calcium absorption and for normal bone mineralization. Dietary calcium and vitamin D must be adequate to maintain bone remodeling and body functions. The best source of calcium and vitamin D is fortified milk. A cup of milk or calcium-fortified orange juice contains about 300 mg of calcium. The recommended adequate intake (RAI) level of calcium for all individuals is 1000 to 1200 mg daily (NOF, 2008). The recommended vitamin D intake for adults 50 years of age and older is 800 to 1000 international units (IU) daily (NOF, 2008). Patients who have had bariatric surgery are at increased risk for osteoporosis as the duodenum is bypassed, which is the primary site for absorption of calcium (Hogan, 2005), as are patients who have gastrointestinal diseases that cause malabsorption (eg, celiac disease).

Bone formation is enhanced by the stress of weight and muscle activity. Resistance and impact exercises are most beneficial in developing and maintaining bone mass. Immobility contributes to the development of osteoporosis. When immobilized by casts, general inactivity, paralysis, or

NURSING RESEARCH PROFILE

Beliefs of Osteoporosis Risks in Men and Women 50 Years of Age and Older

Doheny, M. O., Sedlak, C. A., Estok, P. J., et al. (2007). Osteoporosis knowledge, health beliefs, and DXA T-scores in men and women 50 years of age and older. *Orthopaedic Nursing, 26*(4), 243–250.

Purpose

Osteoporosis is prevalent among older adults, particularly women older than 65 years of age. Although older men and postmenopausal women are at lesser risk for osteoporosis than elderly women, these populations of adults are nonetheless at risk. Yet, contemporary society seems to identify that osteoporosis is a disease of elderly women. The threefold purposes of this study were to determine if there was a difference in knowledge about osteoporosis, a difference in health beliefs related to osteoporosis, and a difference in bone density scores between men older than 50 years of age and women between 50 and 65 years of age.

Design

This study utilized a secondary analysis of data from a prior study of 218 healthy community-based women who were between 50 and 65 years of age and 226 healthy community-based men who were at least 50 years of age. These study participants responded to the 24-item Osteoporosis Knowledge Test (OKT), the 42-item Osteoporosis Health Belief Scale (OHBS), and the 12-item Osteoporosis Self-Efficacy

Scale (OSSES). In addition, they had dual-energy x-ray absorptiometry (DXA) scans performed that yielded T-scores.

Findings

Neither the women nor men in the sample were knowledgeable about osteoporosis, although the women's mean OKT scores were higher than the men's scores. Men believed that they were less susceptible to osteoporosis, thought that it was less serious, had less faith in the efficacy of calcium in preventing and treating osteoporosis, and felt that there were fewer barriers to exercise to prevent osteoporosis than the sampled women. Less than half of the sampled men and women had normal DXA T-scores. Less than half of each group had T-scores that were consistent with osteopenia; approximately 10% of each sample had T-scores consistent with osteoporosis.

Nursing Implications

Both men and women are at risk for osteoporosis by the time they reach the age of 50, yet few of these adults believe that they are at risk. Results from this study suggest that as many as 10% of healthy men who are at least 50 years of age and healthy women who are between 50 and 65 years of age may already have osteoporosis. Nurses are in ideal positions to educate these adults about their risks and provide them with education aimed at preserving bone matrix and preventing fractures associated with osteoporosis.

other disability, the bone is resorbed faster than it is formed, and osteoporosis results (Porth & Matfin, 2009).

Assessment and Diagnostic Findings

Osteoporosis may be undetectable on routine x-rays until there has been 25% to 40% demineralization, resulting in radiolucency of the bones. When the vertebrae collapse, the thoracic vertebrae become wedge shaped and the lumbar vertebrae become biconcave. Osteoporosis is diagnosed by dual-energy x-ray absorptiometry (DXA), which provides information about BMD at the spine and hip (see Chapter 66 for further discussion of tests for BMD). The DXA scan data are analyzed and reported as T-scores (the number of standard deviations [SDs] above or below the average BMD value for a young, healthy Caucasian woman).

BMD testing is recommended for all women older than 65 years of age, for all men older than 70 years of age, for postmenopausal women and men older than 50 years of age with osteoporosis risk factors, and for all people who have had a fracture thought to occur as a consequence of osteoporosis (Bonnick, 2005; NOF, 2008). BMD studies are useful in identifying osteopenic and osteoporotic bone and in assessing response to therapy. Through early screening (using both assessment of risk factors and BMD scans), promotion of adequate dietary intake of calcium and vitamin D, encouragement of lifestyle changes, and early institution of preventive medications, bone loss and osteoporosis can be reduced, resulting in a reduced incidence of fracture.

Laboratory studies (eg, serum calcium, serum phosphate, serum alkaline phosphatase, urine calcium excretion, urinary hydroxyproline excretion, hematocrit, erythrocyte sedimentation rate [ESR]) and x-ray studies are used to exclude other possible disorders (eg, multiple myeloma, osteomalacia, hyperparathyroidism, malignancy) that contribute to bone loss.

Medical Management

A diet rich in calcium and vitamin D throughout life, with an increased calcium intake during adolescence, young adulthood, and the middle years, protects against skeletal demineralization. Such a diet includes three glasses of skim or whole vitamin D-enriched milk or other foods high in calcium (eg, cheese and other dairy products, steamed broccoli, canned salmon with bones) daily.

Regular weight-bearing exercise promotes bone formation. From 20 to 30 minutes of aerobic exercise (eg, walking), 3 days or more a week, is recommended. Weight training stimulates an increase in BMD. In addition, exercise improves balance, reducing the incidence of falls and fractures (Chart 68-8).

Pharmacologic Therapy

The first-line medications used to treat and prevent osteoporosis include calcium and vitamin D supplements and bisphosphonates. To ensure adequate calcium intake, a calcium supplement (eg, Caltrate, Citracal) with vitamin D may be prescribed and taken with meals or with a beverage high in vitamin C to promote absorption. The recommended daily dose should be split and not taken as a single dose. Common side effects of calcium supplements are

abdominal distention and constipation. Other medications that might be prescribed after these medications are tried include calcitonin, selective estrogen receptor modulators, and anabolic agents (Johnson, Clifford & Smith, 2008).

Bisphosphonates that include daily or weekly oral preparations of alendronate (Fosamax) or risedronate (Actonel), monthly oral preparations of ibandronate (Boniva), or yearly intravenous (IV) infusions of zoledronic acid (Reclast) increase bone mass and decrease bone loss by inhibiting osteoclast function (Johnson, et al., 2008). These medications have demonstrated cost-effectiveness in preventing osteoporotic-related fractures in women 65 years of age and older (Pfister, Welch, Lester, et al., 2006). In particular, alendronate is very effective therapy in preventing fractures in postmenopausal women with osteoporosis (Wells, Cranney, Peterson, et al., 2008).

Adequate calcium and vitamin D intake is needed for maximum effect, but these supplements should not be taken at the same time of day as bisphosphonates. Side effects of bisphosphonates include gastrointestinal symptoms (eg, dyspepsia, nausea, flatulence, diarrhea, constipation). Some patients may develop esophageal ulcers, gastric ulcers, or osteonecrosis of the jaw related to bisphosphonate use (Johnson, et al., 2008). Patients who take oral bisphosphonates must take these medications on an empty stomach on arising in the morning with a full glass of water and must sit upright for 30 to 60 minutes after their administration.

Calcitonin (Miacalcin) directly inhibits osteoclasts, thereby reducing bone loss and increasing BMD. Calcitonin is administered by nasal spray or by subcutaneous or intramuscular injection. Side effects include nasal irritation, flushing, gastrointestinal disturbances, and urinary frequency. It should not be prescribed for patients with seafood allergies (Johnson, et al., 2008).

Selective estrogen receptor modulators (SERMs), such as raloxifene (Evista), reduce the risk of osteoporosis by preserving BMD without estrogenic effects on the uterus. They are indicated for both prevention and treatment of osteoporosis. They are contraindicated in women with a history of venous thromboembolism (Johnson, et al., 2008).

Teriparatide (Forteo) is a subcutaneously administered anabolic agent that is administered once daily. As a recombinant PTH, it stimulates osteoblasts to build bone matrix and facilitates overall calcium absorption (Johnson, et al., 2008).

Fracture Management

Fractures of the hip that occur as a consequence of osteoporosis are managed surgically by joint replacement or by closed or open reduction with internal fixation (eg, hip pinning) as described in Chapters 67 and 69, respectively. Management of Colles' fractures is also described in Chapter 69. Patients need to be evaluated for osteoporosis and treated, as indicated, in order to prevent additional fractures.

Osteoporotic compression fractures of the vertebrae are managed conservatively. Additional vertebral fractures and progressive kyphosis are common. Pharmacologic and dietary treatments are aimed at increasing vertebral bone density. Most patients who experience these fractures are asymptomatic and do not require acute care management;

CHART
68-8

HOME CARE CHECKLIST

Osteoporosis

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
Adolescents and Young Adults		
• List risk factors for osteoporosis.	✓	✓
• Identify calcium- and vitamin D-rich foods.	✓	
• Consume diet with adequate calcium (1000–1200 mg/day) and vitamin D.	✓	
• Engage in weight-bearing exercise daily.	✓	
• Modify lifestyle choices—avoid smoking, alcohol, caffeine, and carbonated beverages.	✓	
Menopausal and Postmenopausal Women		
• List risk factors for osteoporosis.	✓	✓
• Identify calcium- and vitamin D-rich foods.	✓	
• Consume diet with adequate calcium (1000–1200 mg/day) and vitamin D.	✓	
• Discuss calcium supplements.	✓	
• Engage in weight-bearing exercise at least three times weekly.	✓	
• Engage in exercise that improves balance to reduce the incidence of falls.	✓	
• Demonstrate good body mechanics.	✓	
• Modify lifestyle choices—avoid smoking, alcohol, caffeine, and carbonated beverages.	✓	
• Discuss pharmacologic agents to maintain and enhance bone mass.	✓	
• Review concurrent medical conditions and medications with health care provider to identify factors that contribute to bone mass loss.	✓	✓
• Assess home environment for hazards contributing to falls.	✓	✓
Men		
• List risk factors associated with osteoporosis in men, including medications (eg, corticosteroids, antiseizure medications, aluminum-containing antacids); chronic diseases (eg, kidney, lung, gastrointestinal); and undiagnosed low testosterone levels.	✓	✓
• Modify lifestyle choices—avoid smoking, alcohol, caffeine, and carbonated beverages.	✓	
• Engage in weight-bearing exercise daily, such as walking, weight lifting, and resistance exercise.	✓	
• Consume diet with adequate calcium (1000–1200 mg/day) and vitamin D.	✓	
• Participate in screening for osteoporosis.	✓	
• Talk with health care provider about use of medications (eg, alendronate) to enhance bone mass or to correct testosterone deficiency.	✓	
• Assess home environment for hazards contributing to falls.	✓	✓

for those who experience pain, acute care management is indicated as outlined in the following Nursing Process section. Percutaneous vertebroplasty or kyphoplasty (injection of polymethylmethacrylate bone cement into the fractured vertebra, followed by inflation of a pressurized balloon to restore the shape of the affected vertebra) can provide rapid relief of acute pain and improve quality of life (NOF, 2008). Patients who have not responded to first-line approaches to the treatment of vertebral compression fracture can be considered for the procedure. It is contraindicated in the presence of infection, old fractures, and certain coagulopathies.

NURSING PROCESS

THE PATIENT WITH A SPONTANEOUS VERTEBRAL FRACTURE RELATED TO OSTEOPOROSIS

Assessment

Health promotion, identification of people at risk for osteoporosis, and recognition of problems associated with osteoporosis form the basis for nursing assessment. The health history includes questions concerning the

occurrence of osteopenia and osteoporosis and focuses on family history, previous fractures, dietary consumption of calcium, exercise patterns, onset of menopause, and use of corticosteroids as well as alcohol, smoking, and caffeine intake. Any symptoms the patient is experiencing, such as back pain, constipation, or altered body image, are explored.

Physical examination may disclose a fracture, kyphosis of the thoracic spine, or shortened stature. Problems in mobility and breathing may exist as a result of changes in posture and weakened muscles.

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses for the patient who experiences a spontaneous vertebral fracture related to osteoporosis may include the following:

- Deficient knowledge about the osteoporotic process and treatment regimen
- Acute pain related to fracture and muscle spasm
- Risk for constipation related to immobility or development of ileus (intestinal obstruction)
- Risk for injury: additional fractures related to osteoporosis

Planning and Goals

The major goals for the patient may include knowledge about osteoporosis and the treatment regimen, relief of pain, improved bowel elimination, and absence of additional fractures.

Nursing Interventions

Promoting Understanding of Osteoporosis and the Treatment Regimen

Patient teaching focuses on factors influencing the development of osteoporosis, interventions to arrest or slow the process, and measures to relieve symptoms. It is emphasized that all people continue to need sufficient calcium, vitamin D, and weight-bearing exercise to slow the progression of osteoporosis. Patient teaching related to medication therapy as described previously is important.

Relieving Pain

Relief of back pain resulting from compression fracture may be accomplished by resting in bed in a supine or side-lying position several times a day. The mattress should be firm and nonsagging. Knee flexion increases comfort by relaxing back muscles. Intermittent local heat and back rubs promote muscle relaxation. The nurse instructs the patient to move the trunk as a unit and to avoid twisting. The nurse encourages good posture and teaches body mechanics. When the patient is assisted out of bed, a trunk orthosis (eg, lumbosacral corset) may be worn for temporary support and immobilization, although such a device is frequently uncomfortable and is poorly tolerated by many elderly patients (NOF, 2008). The patient gradually resumes activities as pain diminishes.

Improving Bowel Elimination

Constipation is a problem related to immobility and medications. Early institution of a high-fiber diet, increased fluids, and the use of prescribed stool softeners help prevent or

minimize constipation. If the vertebral collapse involves the T10–L2 vertebrae, the patient may develop a paralytic ileus. The nurse therefore monitors the patient's intake, bowel sounds, and bowel activity.

Preventing Injury

Physical activity is essential to strengthen muscles, improve balance, prevent disuse atrophy, and retard progressive bone demineralization. Isometric exercises can strengthen trunk muscles. The nurse encourages walking, good body mechanics, and good posture. Daily weight-bearing activity, preferably outdoors in the sunshine to enhance the body's ability to produce vitamin D, is encouraged. Sudden bending, jarring, and strenuous lifting are avoided.

GERONTOLOGIC CONSIDERATIONS. Elderly people fall frequently as a result of environmental hazards, neuromuscular disorders, diminished senses and cardiovascular responses, and responses to medications. The patient and family need to be included in planning for care and preventive management regimens. For example, the home environment should be assessed for safety and elimination of potential hazards (eg, scatter rugs, cluttered rooms and stairwells, toys on the floor, pets underfoot). A safe environment can then be created (eg, well-lighted staircases with secure hand rails, grab bars in the bathroom, properly fitting footwear).

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Acquires knowledge about osteoporosis and the treatment regimen
 - a. States relationship of calcium and vitamin D intake and exercise to bone mass
 - b. Consumes adequate dietary calcium and vitamin D
 - c. Increases level of exercise
 - d. Takes prescribed medications, following instructions for administration
 - e. Adheres to prescribed screening and monitoring procedures
2. Achieves pain relief
 - a. Experiences pain relief at rest
 - b. Experiences minimal discomfort during ADLs
 - c. Demonstrates diminished tenderness at fracture site
3. Demonstrates normal bowel elimination
 - a. Has active bowel sounds
 - b. Reports regular pattern of bowel movements
4. Experiences no new fractures
 - a. Maintains good posture
 - b. Uses good body mechanics
 - c. Consumes a diet high in calcium and vitamin D
 - d. Engages in weight-bearing exercises (walks daily)
 - e. Rests by lying down several times a day
 - f. Participates in outdoor activities
 - g. Creates a safe home environment
 - h. Accepts assistance and supervision as needed

OSTEOMALACIA

Osteomalacia is a metabolic bone disease characterized by inadequate mineralization of bone. As a result of faulty mineralization, there is softening and weakening of the skeleton, causing pain, tenderness to touch, bowing of the bones, and pathologic fractures. On physical examination, skeletal deformities (spinal kyphosis and bowed legs) give patients an unusual appearance and a waddling or limping gait. These patients may be uncomfortable with their appearance. As a result of calcium deficiency, muscle weakness, and unsteadiness, there is an increased risk for falls and fractures, particularly pathologic fractures of the distal radius and the proximal femur (Porth & Matfin, 2009).

Pathophysiology

The primary defect in osteomalacia is a deficiency of activated vitamin D (calcitriol), which promotes calcium absorption from the gastrointestinal tract and facilitates mineralization of bone. The supply of calcium and phosphate in the extracellular fluid is low. Without adequate vitamin D, calcium and phosphate are not moved to calcification sites in bones.

Osteomalacia may result from failed calcium absorption (eg, malabsorption syndrome) or from excessive loss of calcium from the body. Gastrointestinal disorders (eg, celiac disease, chronic biliary tract obstruction, chronic pancreatitis, small bowel resection) in which fats are inadequately absorbed are likely to produce osteomalacia through loss of vitamin D (along with other fat-soluble vitamins) and calcium, the latter being excreted in the feces with fatty acids. In addition, liver and kidney diseases can produce a lack of vitamin D because these are the organs that convert vitamin D to its active form.

Severe renal insufficiency results in acidosis. The body uses available calcium to combat the acidosis, and PTH stimulates the release of skeletal calcium in an attempt to reestablish a physiologic pH. During this continual drain of skeletal calcium, bony fibrosis occurs, and bony cysts form. Chronic glomerulonephritis, obstructive uropathies, and heavy metal poisoning result in a reduced serum phosphate level and demineralization of bone.

Hyperparathyroidism leads to skeletal decalcification and thus to osteomalacia by increasing phosphate excretion in the urine. Prolonged use of antiseizure medication (eg, phenytoin [Dilantin], phenobarbital) poses a risk of osteomalacia, as does insufficient vitamin D (dietary, sunlight).

Osteomalacia that results from malnutrition (deficiency in vitamin D often associated with poor intake of calcium) is a result of poverty, poor dietary habits, and lack of knowledge about nutrition. It occurs most frequently in parts of the world where vitamin D is not added to food, where dietary deficiencies exist, and where sunlight is rare (Porth & Matfin, 2009).

Gerontologic Considerations

A nutritious diet is particularly important in elderly people. Adequate intake of calcium and vitamin D is promoted. Because sunlight is necessary for synthesizing vitamin D, people should be encouraged to spend some time in the sun. Prevention, identification, and management of osteomalacia in the elderly are essential to reduce the incidence of fractures. When osteomalacia is combined with osteoporosis, the incidence of fracture increases.

Assessment and Diagnostic Findings

On x-ray studies, generalized demineralization of bone is evident. Studies of the vertebrae may show a compression fracture with indistinct vertebral endplates. Laboratory studies show low serum calcium and phosphorus levels and a moderately elevated alkaline phosphatase concentration. Urine excretion of calcium and creatinine is low. Bone biopsy demonstrates an increased amount of osteoid, a demineralized, cartilaginous bone matrix that is sometimes referred to as “prebone.”

Medical Management

Physical, psychological, and pharmaceutical measures are used to reduce the patient's discomfort and pain. When assisting the patient to change positions, the nurse handles the patient gently, and pillows are used to support the body. As the patient responds to therapy, the skeletal discomfort diminishes.

If possible, the underlying cause of osteomalacia is corrected. Frequently, skeletal problems associated with osteomalacia resolve themselves when the underlying nutritional deficiency or pathologic process is adequately treated.

If osteomalacia is caused by malabsorption, increased doses of vitamin D, along with supplemental calcium, are usually prescribed (Lyman, 2005). Exposure to sunlight may be recommended; ultraviolet radiation transforms a cholesterol substance (7-dehydrocholesterol) present in the skin into vitamin D.

If osteomalacia is dietary in origin, a diet with adequate protein and increased calcium and vitamin D is provided. The patient is instructed about dietary sources of calcium and vitamin D (eg, fortified milk and cereals, eggs, chicken livers). The safe use of supplements is reviewed. Because high doses of vitamin D are toxic and increase the risk for hypercalcemia, the importance of monitoring serum calcium levels is stressed. Vitamin D raises the concentrations of calcium and phosphorus in the extracellular fluid and thus makes these ions available for mineralization of bone.

Long-term monitoring of the patient is appropriate to ensure stabilization or reversal of osteomalacia. Some persistent orthopedic deformities may need to be treated with braces or surgery (eg, osteotomy may be performed to correct long bone deformity).

PAGET'S DISEASE OF THE BONE

Paget's disease (osteitis deformans) is a disorder of localized rapid bone turnover, most commonly affecting the skull, femur, tibia, pelvic bones, and vertebrae. The disease occurs in about 2% to 3% of the population older than 50 years. The incidence is slightly greater in men than in women and increases with aging. A family history has been noted, with siblings often developing the disease. The cause of Paget's disease is not known (Josse, Hanley, Kendler, et al., 2007).

Pathophysiology

In Paget's disease, there is a primary proliferation of osteoclasts, which induce bone resorption. This is followed by a compensatory increase in osteoblastic activity that replaces the bone. As bone turnover continues, a classic mosaic (disorganized) pattern of bone develops. Because the diseased bone is highly vascularized and structurally weak, pathologic

fractures occur. Structural bowing of the legs causes malalignment of the hip, knee, and ankle joints, which contributes to the development of arthritis and back and joint pain (Josse, et al., 2007).

Clinical Manifestations

Paget's disease is insidious; most patients never experience symptoms. Some patients do not experience symptoms but have skeletal deformity; a few patients have symptomatic deformity and pain. The condition is most frequently identified on x-ray studies performed during a routine physical examination or during a workup for another problem. Sclerotic changes, skeletal deformities (eg, bowing of the femur and tibia, enlargement of the skull, deformity of pelvic bones), and cortical thickening of the long bones occur.

In most patients, skeletal deformity involves the skull or long bones. The skull may thicken, and the patient may report that a hat no longer fits. In some cases, the cranium, but not the face, is enlarged. This gives the face a small, triangular appearance. Most patients with skull involvement have impaired hearing from cranial nerve compression and dysfunction. Other cranial nerves may also be compressed.

The femurs and tibiae tend to bow, producing a waddling gait. The spine is bent forward and is rigid; the chin rests on the chest. The thorax is compressed and immobile on respiration. The trunk is flexed on the legs to maintain balance and the arms are bent outward and forward and appear long in relation to the shortened trunk (Porth & Matfin, 2009).

Pain, tenderness, and warmth over the bones may be noted. The pain is mild to moderate, deep, and aching; it increases with weight bearing if the lower extremities are involved. Pain and discomfort may precede skeletal deformities of Paget's disease by years and are often wrongly attributed by the patient to old age or arthritis.

The temperature of the skin overlying the affected bone increases because of increased bone vascularity. Patients with large, highly vascular lesions may develop high-output cardiac failure because of the increased vascular bed and metabolic demands.

Assessment and Diagnostic Findings

Elevated serum alkaline phosphatase concentration and urinary hydroxyproline excretion reflect increased osteoblastic activity. Higher values suggest more active disease. Patients with Paget's disease have normal blood calcium levels. X-rays confirm the diagnosis of Paget's disease. Local areas of demineralization and bone overgrowth produce characteristic mosaic patterns and irregularities. Bone scans demonstrate the extent of the disease. Bone biopsy may aid in the differential diagnosis (Porth & Matfin, 2009).

Medical Management

Pain usually responds to NSAIDs. Gait problems from bowing of the legs are managed with walking aids, shoe lifts, and physical therapy. Weight is controlled to reduce stress on weakened bones and malaligned joints. Asymptomatic patients may be managed with diets adequate in calcium and vitamin D and periodic monitoring.

Fractures, arthritis, and hearing loss are complications of Paget's disease. Fractures are managed according to location. Healing occurs if fracture reduction, immobilization,

and stability are adequate. Severe degenerative arthritis may require total joint replacement. Loss of hearing is managed with hearing aids and communication techniques used with hearing-impaired people (eg, speech reading, body language) (see Chapter 59).

Pharmacologic Therapy

Patients with moderate to severe disease may benefit from specific antiosteoclastic therapy. Several medications reduce bone turnover, reverse the course of the disease, relieve pain, and improve mobility.

Calcitonin, a polypeptide hormone, retards bone resorption by decreasing the number and availability of osteoclasts. Calcitonin therapy facilitates remodeling of abnormal bone into normal lamellar bone, relieves bone pain, and helps alleviate neurologic and biochemical signs and symptoms. Calcitonin is administered subcutaneously or by nasal inhalation. Side effects include flushing of the face and nausea. The effect of calcitonin therapy is evident in 3 to 6 months through reduction of bone loss and pain.

Bisphosphonates produce rapid reduction in bone turnover and relief of pain (Keating & Scott, 2007). They also reduce serum alkaline phosphatase and urinary hydroxyproline levels. Food inhibits absorption of these medications. Adequate daily intake of calcium and vitamin D is required during therapy.

Plicamycin (Mithracin), a cytotoxic antibiotic, may be used to control the disease. This medication is reserved for severely affected patients with neurologic compromise and for those whose disease is resistant to other therapy. This medication has dramatic effects on pain reduction and on serum calcium, alkaline phosphatase, and urinary hydroxyproline levels. It is administered by IV infusion; hepatic, renal, and bone marrow function must be monitored during therapy. Clinical remissions may continue for months after the medication is discontinued.

Gerontologic Considerations

Because Paget's disease tends to affect elderly people, careful assessment of a patient's pain and discomfort is necessary. Patient teaching helps the patient understand the treatment regimen, the need for a diet with adequate calcium and vitamin D, and how to compensate for altered musculoskeletal functioning. The home environment is assessed for safety to prevent falls and to reduce the risk of fracture. Strategies for coping with a chronic health problem and its effect on quality of life need to be developed.

Musculoskeletal Infections

OSTEOMYELITIS

Osteomyelitis is an infection of the bone that results in inflammation, necrosis, and formation of new bone (Davis, 2005). Osteomyelitis is classified as:

- Hematogenous osteomyelitis (ie, due to bloodborne spread of infection)
- Contiguous-focus osteomyelitis, from contamination from bone surgery, open fracture, or traumatic injury (eg, gunshot wound)

- Osteomyelitis with vascular insufficiency, seen most commonly among patients with diabetes and peripheral vascular disease, most commonly affecting the feet (Davis, 2005)

Patients who are at high risk for osteomyelitis include those who are poorly nourished, elderly, or obese. Other patients at risk include those with impaired immune systems, those with chronic illnesses (eg, diabetes, rheumatoid arthritis), and those receiving long-term corticosteroid therapy or other immunosuppressive agents.

Postoperative surgical wound infections occur within 30 days after surgery. They are classified as incisional (superficial, located above the deep fascia layer) or deep (involving tissue beneath the deep fascia). If an implant has been used, deep postoperative infections may occur within a year. Deep sepsis after arthroplasty may be classified as follows:

- Stage 1, acute fulminating: occurring during the first 3 months after orthopedic surgery; frequently associated with hematoma, drainage, or superficial infection
- Stage 2, delayed onset: occurring between 4 and 24 months after surgery
- Stage 3, late onset: occurring 2 or more years after surgery, usually as a result of hematogenous spread

Bone infections are more difficult to eradicate than soft tissue infections because the infected bone is mostly avascular and not accessible to the body's natural immune response. Also, there is decreased penetration by antibiotics. Osteomyelitis may become chronic and may affect the patient's quality of life.

Pathophysiology

Over 50% of bone infections are caused by *Staphylococcus aureus*. Other pathogens that are frequently found in osteomyelitis include gram-positive organisms that include streptococci and enterococci, followed by gram-negative bacteria that include *Pseudomonas* species (Venugopalan & Martin, 2007).

The initial response to infection is inflammation, increased vascularity, and edema. After 2 or 3 days, thrombosis of the local blood vessels occurs, resulting in ischemia with bone necrosis. The infection extends into the medullary cavity and under the periosteum and may spread into adjacent soft tissues and joints. Unless the infective process is treated promptly, a bone abscess forms. The resulting abscess cavity contains dead bone tissue (the **sequestrum**), which does not easily liquefy and drain. Therefore, the cavity cannot collapse and heal, as it does in soft tissue abscesses. New bone growth (the **involucrum**) forms and surrounds the sequestrum. Although healing appears to take place, a chronically infected sequestrum remains and produces recurring abscesses throughout the patient's life. This is referred to as chronic osteomyelitis.

Clinical Manifestations

When the infection is bloodborne, the onset is usually sudden, occurring often with the clinical and laboratory manifestations of sepsis (eg, chills, high fever, rapid pulse, general malaise). The systemic symptoms at first may overshadow the local signs. As the infection extends through the cortex of the bone, it involves the periosteum and the soft tissues. The infected area becomes painful, swollen, and extremely

tender. The patient may describe a constant, pulsating pain that intensifies with movement as a result of the pressure of the collecting purulent material (ie, pus). When osteomyelitis occurs from spread of adjacent infection or from direct contamination, there are no symptoms of sepsis. The area is swollen, warm, painful, and tender to touch (Davis, 2005; Forman, Forman & Rose, 2005).

The patient with chronic osteomyelitis presents with a nonhealing ulcer that overlies the infected bone with a connecting sinus that will intermittently and spontaneously drain pus (Davis, 2005).

Assessment and Diagnostic Findings

In acute osteomyelitis, early x-ray findings demonstrate soft tissue edema. In about 2 to 3 weeks, areas of periosteal elevation and bone necrosis are evident. Radioisotope bone scans, particularly the isotope-labeled white blood cell (WBC) scan, and magnetic resonance imaging (MRI) help with early definitive diagnosis. Blood studies reveal leukocytosis and an elevated ESR. Wound and blood culture studies are performed, although they are only positive in 50% of cases. Therefore, treatment with antibiotics may be prescribed without definitively isolating the offending organism (Davis, 2005).

With chronic osteomyelitis, large, irregular cavities; raised periosteum; sequestra; or dense bone formations are seen on x-ray. Bone scans may be performed to identify areas of infection. The ESR and the WBC count are usually normal. Anemia, associated with chronic infection, may be evident. Cultures of blood specimens and drainage from the sinus tract are frequently unreliable; antibiotic therapy is many times prescribed presumptively without isolating the offending pathogen (Davis, 2005).

Prevention

Prevention of osteomyelitis is the goal. Elective orthopedic surgery should be postponed if the patient has a current infection (eg, urinary tract infection, sore throat) or a recent history of infection. During orthopedic surgery, careful attention is paid to the surgical environment and to techniques to decrease direct bone contamination. Prophylactic antibiotics, administered to achieve adequate tissue levels at the time of surgery and for 24 hours after surgery, are helpful. Urinary catheters and drains are removed as soon as possible to decrease the incidence of hematogenous spread of infection.

Treatment of focal infections diminishes hematogenous spread. Aseptic postoperative wound care reduces the incidence of superficial infections and osteomyelitis. Prompt management of soft tissue infections reduces extension of infection to the bone. When patients who have had joint replacement surgery undergo dental procedures or other invasive procedures (eg, cystoscopy), prophylactic antibiotics are frequently recommended.

Medical Management

The initial goal of therapy is to control and halt the infective process. Antibiotic therapy depends on the results of blood and wound cultures. General supportive measures (eg, hydration, diet high in vitamins and protein, correction of anemia) should be instituted. The area affected with osteomyelitis is immobilized to decrease discomfort and to prevent pathologic fracture of the weakened bone (Sheff, 2005).

Pharmacologic Therapy

As soon as the culture specimens are obtained, IV antibiotic therapy begins, based on the assumption that infection results from a staphylococcal organism that is sensitive to a penicillin or cephalosporin. The aim is to control the infection before the blood supply to the area diminishes as a result of thrombosis. Around-the-clock dosing is necessary to maintain a high therapeutic blood level of the antibiotic. After results of the culture and sensitivity studies are known, an antibiotic to which the causative organism is sensitive is prescribed. IV antibiotic therapy continues for 3 to 6 weeks. After the infection appears to be controlled, the antibiotic may be administered orally for up to 3 months. To enhance absorption of the orally administered medication, antibiotics should not be administered with food (Davis, 2005; Sheff, 2005).

Surgical Management

If the infection is chronic and does not respond to antibiotic therapy, surgical débridement is indicated. The infected bone is surgically exposed, the purulent and necrotic material is removed, and the area is irrigated with sterile saline solution. Antibiotic-impregnated beads may be placed in the wound for direct application of antibiotics for 2 to 4 weeks (Kent, Rapp & Smith, 2006). IV antibiotic therapy is continued.

In chronic osteomyelitis, antibiotics are adjunctive therapy to surgical débridement. A sequestrectomy (removal of enough involucrum to enable the surgeon to remove the sequestrum) is performed. In many cases, sufficient bone is removed to convert a deep cavity into a shallow saucer (saucerization). All dead, infected bone and cartilage must be removed before permanent healing can occur. A closed suction irrigation system may be used to remove debris. Wound irrigation using sterile physiologic saline solution may be performed for 7 to 8 days.

The wound is either closed tightly to obliterate the dead space or packed and closed later by granulation or possibly by grafting. The débrided cavity may be packed with cancellous bone graft to stimulate healing. With a large defect, the cavity may be filled with a vascularized bone transfer or muscle flap (in which a muscle is moved from an adjacent area with blood supply intact). These microsurgery techniques enhance the blood supply. The improved blood supply facilitates bone healing and eradication of the infection. These surgical procedures may be staged over time to ensure healing. Because surgical débridement weakens the bone, internal fixation or external supportive devices may be needed to stabilize or support the bone to prevent pathologic fracture (Davis, 2005).

NURSING PROCESS

THE PATIENT WITH OSTEOMYELITIS

Assessment

The patient reports an acute onset of signs and symptoms (eg, localized pain, edema, erythema, fever) or recurrent drainage of an infected sinus with associated pain, edema, and low-grade fever. The nurse assesses the patient for risk factors (eg, older age, diabetes, long-term

corticosteroid therapy) and for a history of previous injury, infection, or orthopedic surgery. The patient avoids pressure and movement of the area. In acute hematogenous osteomyelitis, the patient exhibits generalized weakness due to the systemic reaction to the infection.

Physical examination reveals an inflamed, markedly edematous, warm area that is tender. Purulent drainage may be noted. The patient has an elevated temperature. With chronic osteomyelitis, the temperature elevation may be minimal, occurring in the afternoon or evening.

Nursing Diagnoses

Based on the nursing assessment data, nursing diagnoses for the patient with osteomyelitis may include the following:

- Acute pain related to inflammation and edema
- Impaired physical mobility related to pain, use of immobilization devices, and weight-bearing limitations
- Risk for extension of infection: bone abscess formation
- Deficient knowledge related to the treatment regimen

Planning and Goals

The patient's goals may include relief of pain, improved physical mobility within therapeutic limitations, control and eradication of infection, and knowledge of the treatment regimen.

Nursing Interventions

Relieving Pain

The affected part may be immobilized with a splint to decrease pain and muscle spasm. The nurse monitors the neurovascular status of the affected extremity. The wounds are frequently very painful, and the extremity must be handled with great care and gentleness. Elevation reduces swelling and associated discomfort. Pain is controlled with prescribed analgesic agents and other pain-reducing techniques.

Improving Physical Mobility

Treatment regimens restrict activity. The bone is weakened by the infective process and must be protected by immobilization devices and by avoidance of stress on the bone. The patient must understand the rationale for the activity restrictions. The joints above and below the affected part should be gently moved through their range of motion. The nurse encourages full participation in ADLs within the physical limitations to promote general well-being.

Controlling the Infectious Process

The nurse monitors the patient's response to antibiotic therapy and observes the IV access site for evidence of phlebitis, infection, or infiltration. With long-term, intensive antibiotic therapy, the nurse monitors the patient for signs of superinfection (eg, oral or vaginal candidiasis, loose or foul-smelling stools).

If surgery is necessary, the nurse takes measures to ensure adequate circulation to the affected area (wound suction to prevent fluid accumulation, elevation of the area to promote venous drainage, avoidance of pressure on the grafted area), to maintain needed immobility, and to ensure the

CHART
68-9

HOME CARE CHECKLIST

Osteomyelitis

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe osteomyelitis.	✓	✓
• Relieve pain with pharmacologic and nonpharmacologic interventions.	✓	
• State weight-bearing and activity restrictions.	✓	✓
• Demonstrate safe use of ambulatory aids and assistive devices.	✓	
• Describe use of prescribed medications.	✓	✓
• Comply with antibiotic regimen.	✓	
• Promote healing through aseptic dressing changes.	✓	✓
• Demonstrate proper wound care.	✓	✓
• Report signs and symptoms of continuing infection or superinfection.	✓	✓

patient's adherence to weight-bearing restrictions. The nurse changes dressings using aseptic technique to promote healing and to prevent cross-contamination.

The nurse continues to monitor the general health and nutrition of the patient. A diet high in protein promotes a positive nitrogen balance and healing. The nurse encourages adequate hydration as well.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient and family are taught about the importance of strictly adhering to the therapeutic regimen of antibiotics and preventing falls or other injuries that could result in bone fracture. They need to learn to maintain and manage the IV access and IV administration equipment in the home. Teaching includes medication name, dosage, frequency, administration rate, safe storage and handling, adverse reactions, and necessary laboratory monitoring. In addition, aseptic dressing and warm compress techniques are taught.

The nurse carefully monitors the patient for the development of additional sites that are painful or sudden increases in body temperature. The nurse instructs the patient and family to observe for and report elevated temperature, drainage, odor, signs of increased inflammation, adverse reactions, and signs of superinfection.

CONTINUING CARE. Management of osteomyelitis, including wound care and IV antibiotic therapy, is usually performed at home. The patient must be medically stable and physically able and motivated to adhere strictly to the therapeutic regimen of antibiotic therapy. The home care environment needs to be conducive to the promotion of health and to the requirements of the therapeutic regimen.

If warranted, the nurse completes a home assessment to determine the patient's and family's abilities regarding continuation of the therapeutic regimen. If the patient's support system is questionable or if the patient lives alone, a home care nurse may be needed to assist with IV administration of the antibiotics. The nurse monitors the patient for response to the treatment, signs and symptoms of superinfections, and adverse drug reactions. The nurse stresses the importance of

follow-up health care appointments and recommends age-appropriate health screening (Chart 68-9).

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Experiences pain relief
 - a. Reports decreased pain
 - b. Experiences no tenderness at site of previous infection
 - c. Experiences no discomfort with movement
2. Increases physical mobility
 - a. Participates in self-care activities
 - b. Maintains full function of unimpaired extremities
 - c. Demonstrates safe use of immobilizing and assistive devices
 - d. Modifies environment to promote safety and to avoid falls
3. Shows absence of infection
 - a. Takes antibiotic as prescribed
 - b. Reports normal temperature
 - c. Exhibits no edema
 - d. Reports absence of drainage
 - e. Laboratory results indicate normal white blood cell count and erythrocyte sedimentation rate
 - f. Wound cultures are negative
4. Adheres to therapeutic plan
 - a. Takes medications as prescribed
 - b. Protects weakened bones
 - c. Demonstrates proper wound care
 - d. Reports signs and symptoms of complications promptly
 - e. Consumes a diet high in protein
 - f. Keeps follow-up health care appointments
 - g. Reports increased strength
 - h. Reports no elevation of temperature or recurrence of pain, edema, or other symptoms at the site

SEPTIC (INFECTIOUS) ARTHRITIS

Joints can become infected through spread of infection from other parts of the body (hematogenous spread) or directly through trauma or surgical instrumentation. Previous trauma to joints, joint replacement, coexisting arthritis, and diminished host resistance contribute to the development of an infected joint. *S. aureus* causes at least 50% of all joint infections, and 80% of cases of septic arthritis in patients with rheumatoid arthritis and diabetes. The knee is the joint that is most commonly infected (50% of cases), followed by the hip and the shoulder, respectively (Davis, 2005). Prompt recognition and treatment of an infected joint are important because accumulating purulent material results in chondrolysis (destruction of hyaline cartilage).

Clinical Manifestations

The patient with acute septic arthritis usually presents with a warm, painful, swollen joint with decreased range of motion. Systemic chills, fever, and leukocytosis are present. Risk factors include advanced age, diabetes, rheumatoid arthritis, and preexisting joint disease or joint replacement. Elderly patients and patients taking corticosteroids or immunosuppressive medications are at heightened risk; yet, these patients may not exhibit typical clinical manifestations of infection. Therefore, they require ongoing assessment to detect infection as early as possible in the infectious process (Gavet, Tournadre, Soubrier, et al., 2005).

Assessment and Diagnostic Findings

An assessment for the source and cause of infection is performed. Diagnostic studies include aspiration, examination, and culture of the synovial fluid. Computed tomography (CT) and MRI may reveal damage to the joint lining. Radioisotope scanning may be useful in localizing the infectious process.

Medical Management

Prompt treatment is essential and may save a prosthesis for patients who have had joint replacement surgery. Broad-spectrum IV antibiotics are started promptly and then changed to organism-specific antibiotics after culture results are available. The IV antibiotics are continued until symptoms resolve. The synovial fluid is aspirated and analyzed periodically for sterility and decrease in WBCs.

In addition to prescribing antibiotics, the physician may aspirate the joint with a needle to remove excessive joint fluid, exudate, and debris. This promotes comfort and decreases joint destruction caused by the action of proteolytic enzymes in the purulent fluid. Occasionally, arthrotomy or arthroscopy is used to drain the joint and remove dead tissue (Davis, 2005).

The inflamed joint is supported and immobilized in a functional position by a splint that increases the patient's comfort. Analgesic agents, such as codeine, may be prescribed to relieve pain. After the infection has responded to antibiotic therapy, NSAIDs may be prescribed to limit joint damage. The patient's nutrition and fluid status is

monitored. Progressive range-of-motion exercises are prescribed as soon as the patient can begin movement without exacerbating symptoms of acute pain (Davis, 2005).

If septic joints are treated promptly, recovery of normal function is expected. The patient is assessed periodically for recurrence. If the articular cartilage was damaged during the inflammatory reaction, joint fibrosis and diminished function may result.

Nursing Management

The nurse describes the septic arthritis physiologic process to the patient and teaches the patient how to relieve pain using pharmacologic and nonpharmacologic interventions. The nurse also explains the importance of supporting the affected joint, adhering to the prescribed antibiotic regimen, and observing weight-bearing and activity restrictions. Additionally, the nurse demonstrates and encourages the patient to practice safe use of ambulatory aids and assistive devices.

The nurse teaches the patient strategies to promote healing through aseptic dressing changes and proper wound care. The patient is then encouraged to perform range-of-motion exercises after the infection subsides.

Bone Tumors

Neoplasms of the musculoskeletal system are of various types, including osteogenic, chondrogenic, fibrogenic, muscle (rhabdomyogenic), and marrow (reticulum) cell tumors as well as nerve, vascular, and fatty cell tumors. They may be primary tumors or metastatic tumors from primary cancers elsewhere in the body (eg, breast, lung, prostate, kidney). Metastatic bone tumors are more common than primary bone tumors (Weber, 2005).

Types

Benign Bone Tumors

Benign tumors of the bone and soft tissue are more common than malignant primary bone tumors. Benign bone tumors generally are slow growing, well circumscribed, and encapsulated; present few symptoms; and are not a cause of death.

Benign primary neoplasms of the musculoskeletal system include osteochondroma, enchondroma, bone cyst (eg, aneurysmal bone cyst), osteoid osteoma, rhabdomyoma, and fibroma. Some benign tumors, such as giant cell tumors, have the potential to become malignant.

Osteochondroma is the most common benign bone tumor. It usually occurs as a large projection of bone at the end of long bones (at the knee or shoulder). It develops during growth and then becomes a static bony mass. In fewer than 1% of patients, the cartilage cap of the osteochondroma may undergo malignant transformation after trauma, and a chondrosarcoma or osteosarcoma may develop.

Enchondroma is a common tumor of the hyaline cartilage that develops in the hand, femur, tibia, or humerus. Usually, the only symptom is a mild ache. Pathologic fractures may occur.

Bone cysts are expanding lesions within the bone. Aneurysmal (widening) bone cysts are seen in young adults, who present with a painful, palpable mass of the long bones, vertebrae, or flat bone. Unicameral (single cavity) bone cysts occur in children and cause mild discomfort and possible pathologic fractures of the upper humerus and femur, which may heal spontaneously.

Osteoid osteoma is a painful tumor that occurs in children and young adults. The neoplastic tissue is surrounded by reactive bone formation that can be identified by x-ray.

Giant cell tumors (osteoclastomas) are benign for long periods but may invade local tissue and cause destruction. They occur in young adults and are soft and hemorrhagic. Eventually, giant cell tumors may undergo malignant transformation and metastasize (Porth & Matfin, 2009).

Malignant Bone Tumors

Primary malignant musculoskeletal tumors are relatively rare and arise from connective and supportive tissue cells (sarcomas) or bone marrow elements (multiple myeloma; see Chapter 33). Malignant primary musculoskeletal tumors include osteosarcoma, chondrosarcoma, Ewing's sarcoma, and fibrosarcoma. Soft tissue sarcomas include liposarcoma, fibrosarcoma of soft tissue, and rhabdomyosarcoma. Bone tumor metastasis to the lungs is common.

Osteosarcoma (ie, osteogenic sarcoma) is the most common and most often fatal primary malignant bone tumor. Prognosis depends on whether the tumor has metastasized to the lungs at the time the patient seeks health care. Osteosarcoma appears most frequently in children, adolescents and young adults (in bones that grow rapidly), in older people with Paget's disease of the bone, and in people with a prior history of radiation exposure. Clinical manifestations typically include localized bone pain that may be accompanied by a tender, palpable soft tissue mass. The primary lesion may involve any bone, but the most common sites are the distal femur, the proximal tibia, and the proximal humerus (Skubitz & D'Adamo, 2007).

Malignant tumors of the hyaline cartilage are called chondrosarcomas. These tumors are the second most common primary malignant bone tumor. They are large, bulky, tumors that may grow and metastasize slowly or very fast, depending on the characteristics of the tumor cells involved (ie, grade). Patients with low-grade chondrosarcomas tend to have a much better prognosis than those with high-grade chondrosarcomas (see Chapter 16 for a discussion of tumor grades). The usual tumor sites include the pelvis, femur, humerus, spine, scapula, and tibia. Metastasis to the lungs occurs in less than half of patients. When these tumors are well differentiated, large bloc excision or amputation of the affected extremity results in increased survival rates. These tumors may recur, however (Skubitz & D'Adamo, 2007).

Metastatic Bone Disease

Metastatic bone disease (secondary bone tumor) is more common than primary bone tumors. Tumors arising from tissues elsewhere in the body may invade the bone and produce

localized bone destruction (lytic lesions) or bone overgrowth (blastic lesions). The most common primary sites of tumors that metastasize to bone are the kidney, prostate, lung, breast, ovary, and thyroid. Metastatic tumors most frequently attack the skull, spine, pelvis, femur, and humerus and often involve more than one bone (polyostotic) (Porth & Matfin, 2009).

Pathophysiology

A tumor in the bone causes the normal bone tissue to react by osteolytic response (bone destruction) or osteoblastic response (bone formation). Primary tumors cause bone destruction, which weakens the bone, resulting in bone fractures. Adjacent normal bone responds to the tumor by altering its normal pattern of remodeling. The bone's surface changes and the contours enlarge in the tumor area.

Malignant bone tumors invade and destroy adjacent bone tissue. Benign bone tumors, in contrast, have a symmetric, controlled growth pattern and place pressure on adjacent bone tissue. Malignant bone tumors invade and weaken the structure of the bone until it can no longer withstand the stress of ordinary use; pathologic fracture commonly results.

Clinical Manifestations

Patients with metastatic bone tumor may have a wide range of associated clinical manifestations. They may be symptom-free or have pain that ranges from mild and occasional to constant and severe, varying degrees of disability, and, at times, obvious bone growth. Weight loss, malaise, and fever may be present. The tumor may be diagnosed only after pathologic fracture has occurred.

With spinal metastasis, spinal cord compression may occur. It can progress rapidly or slowly. Neurologic deficits (eg, progressive pain, weakness, gait abnormality, paresthesia, paraplegia, urinary retention, loss of bowel or bladder control) must be identified early and treated with decompressive laminectomy to prevent permanent spinal cord injury.

Assessment and Diagnostic Findings

The differential diagnosis is based on the history, physical examination, and diagnostic studies, including CT, bone scans, myelography, arteriography, MRI, biopsy, and biochemical assays of the blood and urine. Serum alkaline phosphatase levels are frequently elevated with osteogenic sarcoma. With metastatic carcinoma of the prostate, serum acid phosphatase levels are elevated. Hypercalcemia is present with bone metastases from breast, lung, or kidney cancer. Symptoms of hypercalcemia include muscle weakness, fatigue, anorexia, nausea, vomiting, polyuria, cardiac dysrhythmias, seizures, and coma. Hypercalcemia must be identified and treated promptly.

A surgical biopsy is performed for histologic identification. Extreme care is taken during the biopsy to prevent seeding and resultant recurrence after excision of the tumor.

Chest x-rays are performed to determine the presence of lung metastasis. Surgical staging of musculoskeletal tumors is based on tumor grade and site (intracompartmental or extracompartmental), as well as on metastasis. Staging is used for planning treatment.

During the diagnostic period, the nurse explains the diagnostic tests and provides psychological and emotional support to the patient and family. The nurse assesses coping behaviors and encourages use of support systems.

Medical Management

Primary Bone Tumors

The goal of primary bone tumor treatment is to destroy or remove the tumor. This may be accomplished by surgical excision (ranging from local excision to amputation and disarticulation), radiation therapy if the tumor is radiosensitive, and chemotherapy (preoperative, intraoperative [neoadjuvant], postoperative, and adjunctive for possible micrometastases). Chemotherapy may be delivered intra-arterially for patients with osteosarcoma; this mode of delivery is associated with improved limb preservation (Matthews, Snell & Coats, 2006). Major gains are being made in the use of wide bloc excision with restorative grafting technique (Muscolo, Ayerza, Aponte-Tinco, et al., 2005). Survival and quality of life are important considerations in procedures that attempt to save the involved extremity.

Limb-sparing (salvage) procedures are used to remove the tumor and adjacent tissue. A customized prosthesis, total joint arthroplasty, or bone tissue from the patient (autograft) or from a cadaver donor (allograft) replaces the resected tissue. Soft tissue and blood vessels may need grafting because of the extent of the excision. Complications may include infection, loosening or dislocation of the prosthesis, allograft nonunion, fracture, devitalization of the skin and soft tissues, joint fibrosis, and recurrence of the tumor. Function and rehabilitation after limb salvage depend on positive encouragement and reducing the risk of complications.

Surgical removal of the tumor may require amputation of the affected extremity, with the amputation extending well above the tumor to achieve local control of the primary lesion (see Nursing Process: The Patient Undergoing an Amputation in Chapter 69).

Because of the danger of metastasis with malignant bone tumors, chemotherapy is started before and continued after surgery in an effort to eradicate micrometastatic lesions. The goal of combined chemotherapy is greater therapeutic effect at a lower toxicity rate with reduced resistance to the medications. There is an improved long-term survival rate when a localized osteosarcoma is removed and chemotherapy is initiated. Soft tissue sarcomas are treated with radiation, limb-sparing excision, and adjuvant chemotherapy (see Chapter 16).

Secondary Bone Tumors

The treatment of metastatic bone cancer is palliative. The therapeutic goal is to relieve the patient's pain and discomfort while promoting quality of life.

If metastatic disease weakens the bone, structural support and stabilization are needed to prevent pathologic fracture. At times, large bones with metastatic lesions are strengthened by prophylactic internal fixation. Internal fixation of pathologic fractures, arthroplasty, or methylmethacrylate (bone cement) reconstruction minimizes associated disability and pain. Patients with metastatic disease are at higher risk

than other patients for postoperative pulmonary congestion, hypoxemia, deep vein thrombosis (DVT), and hemorrhage.

Hypercalcemia results from breakdown of bone. It needs to be recognized promptly. Treatment includes hydration with IV administration of normal saline solution; diuresis; mobilization; and medications such as bisphosphonates, (eg, pamidronate [Aredia]) and calcitonin. Because inactivity leads to loss of bone mass and increased calcium in the blood, the nurse assists the patient to increase activity and ambulation.

Hematopoiesis is frequently disrupted by tumor invasion of the bone marrow or by treatment (chemotherapy or radiation). Blood component therapy restores hematologic factors. Pain can result from multiple factors, including the osseous metastasis, surgery, chemotherapy or radiation side effects, and arthritis. Pain must be assessed accurately and managed with adequate and appropriate opioid, nonopioid, and nonpharmaceutical interventions. External beam radiation to involved metastatic sites may be used. Patients with multiple bony metastases may achieve pain control with systemically administered "bone-seeking" isotopes (eg, strontium 89). See Chapter 13 for more information about pain management.

Additional therapies are used to treat the original cancer. Radiation and hormonal therapy may be effective in promoting healing of osteolytic lesions. Chemotherapy is used to control the primary disease (see Chapter 16).

Nursing Management

The nurse asks the patient about the onset and course of symptoms. During the interview, the nurse assesses the patient's understanding of the disease process, how the patient and the family have been coping, and how the patient has managed the pain. On physical examination, the nurse gently palpates the mass and notes its size and associated soft tissue swelling, pain, and tenderness. Assessment of the neurovascular status and range of motion of the extremity provides baseline data for future comparisons. The nurse evaluates the patient's mobility and ability to perform ADLs.

The nursing care of a patient who has undergone excision of a bone tumor is similar in many respects to that of other patients who have had skeletal surgery. Vital signs are monitored; blood loss is assessed; and observations are made to assess for the development of complications such as DVT, pulmonary embolism, infection, contracture, and disuse atrophy. The affected part is elevated to reduce edema, and the neurovascular status of the extremity is assessed.

Patient and family teaching about the disease process and diagnostic and management regimens is essential. Explanation of diagnostic tests, treatments (eg, wound care), and expected results (eg, decreased range of motion, numbness, change of body contours) helps the patient deal with the procedures and changes and comply with the therapeutic regimen. The nurse can most effectively reinforce and clarify information provided by the physician by being present during these discussions.

Accurate pain assessment and use of pharmacologic and nonpharmacologic pain management techniques are used

to relieve pain and increase the patient's comfort level. The nurse works with the patient in designing the most effective pain management regimen, thereby increasing the patient's control over the pain. The nurse prepares the patient and gives support during painful procedures. Prescribed IV or epidural analgesic medications are used during the early postoperative period. Later, oral or transdermal opioid or nonopioid analgesic agents are indicated to alleviate pain. In addition, external radiation or systemic radioisotopes (eg, strontium 89) may be prescribed to control pain (see Chapter 13 for further discussion of nursing management for patients in pain).

Bone tumors weaken the bone to a point at which normal activities or even position changes can result in fracture. During nursing care, the affected extremities must be supported and handled gently. External supports (eg, splints) may be used for additional protection. At times, the patient may elect to have surgery (eg, open reduction with internal fixation, joint replacement) in an attempt to prevent pathologic fracture. Prescribed weight-bearing restrictions must be followed. The nurse and physical therapist teach the patient how to use assistive devices safely and how to strengthen unaffected extremities.

The nurse encourages the patient and family to verbalize their fears, concerns, and feelings. They need to be supported as they deal with the impact of the malignant bone tumor. Feelings of shock, despair, and grief are expected. Referral to a psychiatric advanced practice nurse, psychologist, counselor, or spiritual advisor may be indicated for specific psychological help and emotional support.

Independence versus dependence is an issue for the patient who has a malignancy. Lifestyle is dramatically changed, at least temporarily. It is important to support the family in working through the adjustments that must be made. The nurse assists the patient in dealing with changes in body image due to surgery and possible amputation (see Chapter 69 for nursing management of a patient with an amputation). It is helpful to provide realistic reassurance about the future and resumption of role-related activities and to encourage self-care and socialization. The patient participates in planning daily activities. The nurse encourages the patient to be as independent as possible. Involvement of the patient and family throughout treatment encourages confidence, restoration of self-concept, and a sense of being in control of one's life.

Monitoring and Managing Potential Complications

Delayed Wound Healing

Wound healing may be delayed because of tissue trauma from surgery, previous radiation therapy, inadequate nutrition, or infection. The nurse minimizes pressure on the wound site to promote circulation to the tissues. An aseptic, nontraumatic wound dressing promotes healing. Monitoring and reporting of laboratory findings facilitate initiation of interventions to promote homeostasis and wound healing.

Repositioning the patient at frequent intervals reduces the incidence of skin breakdown and pressure ulcers. Special therapeutic beds or mattresses may be needed to

prevent skin breakdown and to promote wound healing after extensive surgical reconstruction and skin grafting.

Inadequate Nutrition

Because loss of appetite, nausea, and vomiting are frequent side effects of chemotherapy and radiation therapy, it is necessary to provide adequate nutrition for healing and health promotion. Antiemetics and relaxation techniques reduce the adverse gastrointestinal effects of chemotherapy. Stomatitis is controlled with anesthetic or antifungal mouthwash (see Chapter 16). Adequate hydration is essential. Nutritional supplements or parenteral nutrition may be prescribed to achieve adequate nutrition.

Osteomyelitis and Wound Infections

Prophylactic antibiotics and strict aseptic dressing techniques are used to diminish the occurrence of osteomyelitis and wound infections. During healing, other infections (eg, upper respiratory infections) need to be prevented so that hematogenous spread does not result in osteomyelitis. If the patient is receiving chemotherapy, it is important to monitor the WBC count and to instruct the patient to avoid contact with people who have colds or other infections.

Hypercalcemia

Hypercalcemia is a dangerous complication of bone cancer. The symptoms must be recognized and treatment initiated promptly. Symptoms include muscular weakness, incoordination, anorexia, nausea and vomiting, constipation, electrocardiographic changes (eg, shortened QT interval and ST segment, bradycardia, heart blocks), and altered mental states (eg, confusion, lethargy, psychotic behavior). See Chapter 14 for a discussion of hypercalcemia and its management.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Preparation for and coordination of continuing health care are begun early as a multidisciplinary effort. Patient teaching addresses medication, dressing changes, treatment regimens, and the importance of physical and occupational therapy programs. The nurse teaches weight-bearing limitations and special handling to prevent pathologic fractures. It is important that the patient and family know the signs and symptoms of possible complications as well as resources available for continuing care (Chart 68-10).

Continuing Care

Frequently, arrangements are made with a home health care agency for home care supervision and follow-up. The home care nurse assesses the patient's and family's abilities to meet the patient's needs and determines whether the services of other agencies are needed. The nurse advises the patient to have readily available the telephone numbers of people to contact in case concerns arise.

The nurse emphasizes the need for long-term health supervision to ensure cure or to detect tumor recurrence or metastasis and the need for recommended health screening. If the patient has metastatic disease, end-of-life issues may need to be explored. Referral for hospice care is made if appropriate.

CHART  HOME CARE CHECKLIST
68-10 Bone Tumor

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe tumor growth process.	✓	✓
• Control pain with pharmacologic and nonpharmacologic interventions.	✓	✓
• Support affected musculoskeletal area.	✓	
• Describe use of prescribed medications.	✓	✓
• Comply with medication regimen.	✓	
• Consume diet to promote healing and health.	✓	
• State weight-bearing and activity restrictions.	✓	✓
• Demonstrate safe use of ambulatory aids and assistive devices.	✓	
• Protect affected bone from pathologic fracture.	✓	✓
• Identify complications of tumor and therapy.	✓	✓
• Report signs and symptoms of complications promptly.	✓	✓
• Use effective coping strategies.	✓	
• Maintain role performance.	✓	

CRITICAL THINKING EXERCISES

EBP 1 You are a staff nurse employed at a family practice clinic. A 52-year-old mechanic has been seeking treatment at the clinic for low back pain of 2 weeks' duration. He has been prescribed a muscle relaxant and told to take over-the-counter NSAIDs. He is not reporting significant relief from his symptoms, though he reports taking his prescribed medications diligently. You note that this patient is obese. The patient tells you that he is getting frustrated that he continues to have significant low back pain that interferes with his ability to work. Identify other therapies or interventions that might be reasonable alternatives or adjuncts that might relieve this patient's low back pain. What is the strength of the evidence for each of these potential therapies or interventions?

2 Your 30-year-old cousin tells you that she was diagnosed 3 months ago with impingement syndrome of her right shoulder. She was treated with intra-articular corticosteroids and physical therapy and has had a very good response to these interventions. She is a flight attendant and is concerned whether she is likely to have recurrent episodes or whether she is at risk for worse shoulder injuries. What is the likelihood that she may have either recurrence of her symptoms or worse rotator cuff injuries? What advice might you share with her so that she might continue her career as a flight attendant?

EBP 3 On the general medical unit where you are a staff nurse, a 74-year-old man is admitted with pneumonia and a history of chronic obstructive pulmonary disease (COPD). He also has a history of heavy cigarette smoking and alcohol consumption. You note during his screening process that he has lost 1 inch in height over the past year, and he has notable kyphosis of his lumbar vertebrae. What musculoskeletal condition is he at risk of developing? What specific questions would you ask him to determine the status of his bone health? Discuss the strength of the evidence that supports any risk factor reduction strategies you consider implementing.

ing and alcohol consumption. You note during his screening process that he has lost 1 inch in height over the past year, and he has notable kyphosis of his lumbar vertebrae. What musculoskeletal condition is he at risk of developing? What specific questions would you ask him to determine the status of his bone health? Discuss the strength of the evidence that supports any risk factor reduction strategies you consider implementing.

EBP 4 At the orthopedic clinic where you work as a nurse, a 20-year-old college athlete presents for a workup because of persistent right shoulder pain with point tenderness at his proximal humerus and a palpable soft tissue mass. An extensive workup confirms an osteosarcoma. He is stunned with the diagnosis and tells you that he would rather die than have his right arm amputated (he is right-sided dominant and is his football team's quarterback). What is the evidence that supports limb salvage over amputation in patients with osteosarcoma of an extremity? What can he expect in terms of quality of life after an amputation versus more conservative limb salvage interventions? What support systems would you mobilize for this patient?

The Smeltzer suite offers these additional resources to enhance learning and facilitate understanding of this chapter:

Management of Patients With Musculoskeletal Trauma

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Differentiate between contusions, strains, sprains, dislocations, and subluxations.
- 2 Identify sport and occupational injuries and their signs, symptoms, and treatments.
- 3 Identify the signs and symptoms of an acute fracture.
- 4 Describe the treatment procedures of fracture reduction, fracture immobilization, and management of open and intra-articular fractures.
- 5 Describe the prevention and management of immediate and delayed complications of fractures.
- 6 Describe the rehabilitation needs of patients with fractures of the upper and lower extremities, pelvis, and hips.
- 7 Describe nursing management of the elderly patient with a fracture of the hip.
- 8 Describe the rehabilitation and health education needs of the patient who has had an amputation.
- 9 Use the nursing process as a framework for care of the patient with an amputation.

GLOSSARY

- allograft:** tissue harvested from a donor for use in another person
- amputation:** removal of a body part, usually a limb or part of a limb
- arthroscope:** surgical scope injected into the joint to examine or repair
- autograft:** tissue harvested from one area of the body and used for transplantation to another area of the same body
- avascular necrosis:** death of tissue secondary to a decrease or lack of perfusion
- contusion:** blunt force injury to soft tissue
- crepitus:** a grating sound or sensation by rubbing bony fragments together
- débridement:** surgical removal of contaminated and devitalized tissues and foreign material
- delayed union:** prolongation of expected healing time for a fracture
- disarticulation:** amputation through a joint
- dislocation:** complete separation of joint surfaces
- fracture:** a break in the continuity of a bone
- fracture reduction:** restoration of fracture fragments into anatomic alignment
- malunion:** healing of a fractured bone in a malaligned position
- nonunion:** failure of fractured bones to heal together
- phantom limb pain:** pain perceived in an amputated section
- RICE:** acronym for *rest*, *ice*, *compression*, *elevation*
- sprain:** an injury to ligaments and muscles and other soft tissues at a joint
- strain:** a musculotendinous stress injury
- subluxation:** partial separation of joint surfaces

Injury to one part of the musculoskeletal system results in malfunction of adjacent muscles, joints, and tendons. The type and severity of injury affects the mobility of the injured area. Treatment of injury to the musculoskeletal system involves providing support to the injured part until healing is complete. Some injuries or situations require traction to be applied to maintain proper anatomical alignment of the extremity. Pain assessment and management are essential. After the immediate painful effects of the injury have decreased, treatment efforts are focused on proper exercise and mobility, with assistance if needed.

Contusions, Strains, and Sprains

A **contusion** is a soft tissue injury produced by blunt force, such as a blow, kick, or fall, causing small blood vessels to rupture and bleed into soft tissues (ecchymosis, or bruising). A hematoma develops from bleeding at the site of impact. Local symptoms (pain, swelling, and discoloration) are controlled with intermittent application of cold packs applied with pressure to the site and elevation of the extremity above the heart level. Most contusions resolve in 1 to 2 weeks.

A **strain**, or a “pulled muscle or tendon,” is an injury caused by overuse, overstretching, or excessive stress. Strains are graded along a continuum based on postinjury symptoms and loss of function and reflect the degree of injury. Three types of strain are recognized:

- A first-degree strain is mild stretching of the muscle or tendon. Signs and symptoms may include minor edema, tenderness, and mild muscle spasm, without noticeable loss of function.
- A second-degree strain involves partial tearing of the muscle or tendon. Signs and symptoms include loss of load-bearing strength with accompanying edema, tenderness, muscle spasm, and ecchymosis.
- A third-degree strain is severe muscle or tendon stretching with rupturing and tearing of the involved tissue. Signs and symptoms include significant pain, muscle spasm, ecchymosis, edema, and loss of function. An x-ray should be obtained to rule out bone injury, because an avulsion fracture (in which a bone fragment is pulled away from the bone by a tendon) may be associated with a third-degree strain. Magnetic resonance imaging (MRI) will reveal a third-degree strain, but x-rays do not reveal injuries to soft tissue or muscles, tendons, or ligaments.

A **sprain** is an injury to the ligaments and tendons that surround a joint. It is caused by a twisting motion or hyperextension (forcible) of a joint. The function of a ligament is to stabilize a joint while permitting mobility. A torn ligament causes a joint to become unstable. Blood vessels rupture and edema occurs; the joint is tender, and movement of the joint becomes painful. The degree of disability and pain increases during the first 2 to 3 hours after the injury because of the associated swelling and bleeding, especially if treatment is delayed. Sprains are graded in a manner similar to the grading system used for strains:

- A first-degree sprain is caused by stretching the ligamentous fibers, resulting in minimum damage. It is manifested by mild edema, local tenderness, and pain that is elicited when the joint is moved.

- A second-degree sprain involves partial tearing of the ligament. It results in increased edema, tenderness, pain with motion, joint instability, and partial loss of normal joint function.
- A third-degree sprain occurs when a ligament is completely torn or ruptured. A third-degree sprain may also cause an avulsion of the bone. Symptoms include severe pain, tenderness, increased edema, and abnormal joint motion.

Nursing Management

Treatment of contusions, strains, and sprains consists of resting and elevating the affected part, applying cold, and using a compression bandage. (The acronym **RICE**—rest, ice, compression, elevation—is helpful for remembering treatment interventions.) Rest prevents additional injury and promotes healing. Intermittent application of moist or dry cold packs for 20 to 30 minutes during the first 24 to 48 hours after injury produces vasoconstriction, which decreases bleeding, edema, and discomfort. Care must be taken to avoid skin and tissue damage from excessive cold. An elastic compression bandage controls bleeding, reduces edema, and provides support for the injured tissues. Elevation controls the swelling. If the sprain or strain is third degree, surgical repair or immobilization by a splint, brace, or cast may be necessary so that the joint will not lose its stability. The neurovascular status (circulation, motion, sensation) of the injured extremity is monitored every 15 minutes for the first 1 to 2 hours after injury; then, every 30 minutes until stable. Decreases in sensation or motion and increases in pain level should be documented and reported to the physician immediately so that compartment syndrome can be prevented (see later discussion).

After the acute inflammatory stage (eg, 24 to 48 hours after injury), heat may be applied intermittently (for 15 to 30 minutes four times a day) to relieve muscle spasm and to promote vasodilation, absorption, and repair. Depending on the severity of injury, progressive passive and active exercises may begin in 2 to 5 days. Severe sprains and strains may require 1 to 3 weeks of immobilization before exercises are initiated. Excessive exercise early in the course of treatment delays recovery. Strains and sprains take weeks or months to heal because ligaments and tendons have minimal blood supply. Splinting may be used to maintain stability at the injury site.

Joint Dislocations

A **dislocation** of a joint is a condition in which the articular surfaces of the distal and proximal bones that form the joint are no longer in anatomic alignment. A **subluxation** is a partial dislocation and does not cause as much deformity as a complete dislocation. In complete dislocation, the bones are literally “out of joint.” Traumatic dislocations are orthopedic emergencies because the associated joint structures, blood supply, and nerves are displaced and may be entrapped with extensive pressure on them. If a dislocation or subluxation is not reduced immediately, **avascular necrosis** (AVN) may develop. AVN of bone is caused by ischemia, which leads to necrosis or death of the bone cells.

Signs and symptoms of a traumatic dislocation include acute pain, change in positioning of the joint, shortening of the extremity, deformity, and decreased mobility. X-rays confirm the diagnosis and reveal any associated fracture.

Medical Management

The affected joint needs to be immobilized at the scene and during transport to the hospital. The dislocation is promptly reduced and displaced parts are placed back in proper anatomic position to preserve joint function. Analgesia, muscle relaxants, and possibly anesthesia are used to facilitate closed reduction. The joint is immobilized by splints, casts, or traction and is maintained in a stable position. Neurovascular status is assessed at a minimum of every 15 minutes until stable. After reduction, if the joint is stable, gentle, progressive, active and passive movement is begun to preserve range of motion (ROM) and restore strength. The joint is supported between exercise sessions.

Nursing Management

Nursing attention is geared to frequent assessment and evaluation of the injury including complete neurovascular assessment with proper documentation and communication with the physician. The patient and supportive family members are educated regarding proper exercises and activities as well as danger signs and symptoms to look for, such as increasing pain (even with analgesics), “numbness or tingling,” and increased edema in the extremity. These signs and symptoms may indicate compartment syndrome, and if this is not identified and communicated to the treating physician, the patient may lose the extremity (see later discussion).

Injuries to the Tendons, Ligaments, and Menisci

ROTATOR CUFF TEARS

A rotator cuff tear is a tear in a tendon that connects one of the rotator muscles to the humeral head. The rotator cuff stabilizes the humeral head and is composed of four muscles and their tendons that include the supraspinatus, infraspinatus, teres minor, and subscapularis.

Rotator cuff tears may result from an acute injury or from chronic joint stresses. Patients complain of pain, limited ROM, and some joint dysfunction, including muscle weakness. In many cases, patients with a rotator cuff tear experience night pain and cannot sleep on the involved side. Patients cannot perform over-the-head activities. The acromioclavicular joint is tender. X-rays are helpful in evaluating the joint. Arthrography and MRI or ultrasound are used to determine soft tissue pathology and the extent of the rotator cuff tear.

Initial conservative management includes use of nonsteroidal anti-inflammatory drugs (NSAIDs), rest with modification of activities, injection of a corticosteroid into the shoulder joint, and progressive stretching, ROM, and lengthening exercises (Trojian, Stevenson & Agrawal, 2005). Some rotator cuff tears require arthroscopic *débridement* (removal of devitalized tissue) or arthroscopic or open acromioplasty with tendon repair. Postoperatively, the shoulder is immobilized for several days to 4 weeks. Physical

therapy with shoulder exercises is begun as prescribed, and the patient is instructed in how to perform the exercises at home. Full recovery is expected in 6 to 12 months.

EPICONDYLITIS

Epicondylitis is a chronic, painful condition that is caused by excessive, repetitive extension, flexion, pronation, and supination motions of the forearm. These motions result in inflammation (tendinitis) and minor tears in the tendons at the origin of the muscles on the lateral or medial epicondyles. Lateral epicondylitis (ie, tennis elbow) is frequently identified in someone who repeatedly extends the wrist or frequently pronates and supinates the forearm. Pain develops over the lateral epicondyle and in the extensor muscles. If action is continued, pain continues to increase (Clinton & Murthi, 2008). Medial epicondylitis (ie, golfer's or pitcher's elbow) is consistent with repetitive wrist flexion. Extreme tenderness occurs at the medial epicondyle. Pain greatly increases with wrist flexion against resistance.

Application of ice and administration of NSAIDs usually relieve the pain. In some instances, the arm is immobilized in a molded splint or cast. Because of its degenerative effects on tendons, local injection of a corticosteroid is reserved for patients with severe pain who do not respond to NSAIDs and immobilization. After pain subsides, rehabilitation exercises include gentle and gradual increased stretching of the tendons (Clinton & Murthi, 2008). A tennis elbow counterforce strap that limits extension of the elbow may be prescribed when activity is resumed.

LATERAL AND MEDIAL COLLATERAL LIGAMENT INJURY

Lateral and medial collateral ligaments of the knee (Fig. 69-1) provide stability lateral and medial to the knee. Injury to these ligaments occurs when the foot is firmly planted and the knee is struck—either medially, causing stretching and tearing injury to the lateral collateral ligament, or laterally, causing stretching and tearing injury to the medial collateral ligament. The patient experiences an acute onset of pain, point tenderness, joint instability, and inability to walk without assistance.

Medical Management

Early management includes RICE. The joint is evaluated for fracture. Hemarthrosis (bleeding into the joint) may develop, contributing to the pain. The joint fluid may be aspirated to relieve pressure.

Treatment depends on the severity of the injury. Conservative management includes limited weight bearing and use of a protective brace. As pain subsides, ROM exercise is encouraged. The patient's return to full activities, including sports, depends on return of motion, functional stability of the joint, and muscle strength.

If needed, surgical reconstruction may be performed immediately or it may be delayed. The leg is immobilized for approximately 6 to 8 weeks. A progressive rehabilitation program helps restore the function and strength of the knee. Rehabilitation occurs over many months, and the patient may need to wear a derotational brace while engaging in sports to prevent reinjury.

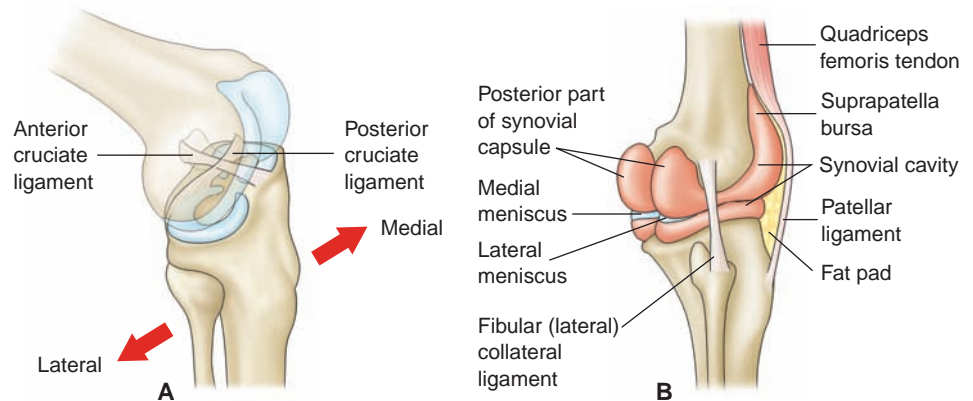

Figure 69-1 Knee ligaments, tendons, and menisci. **A**, Anterolateral view. **B**, Posterolateral view.

Nursing Management

The nurse instructs the patient about proper use of ambulatory devices, the healing process, and activity limitation to promote healing. Education addresses pain management, analgesic use, antibiotic use, brace use, wound care, signs and symptoms of possible complications (eg, altered neurovascular status, infection, skin breakdown), and self-care.

CRUCIATE LIGAMENT INJURY

The anterior cruciate ligament (ACL) and the posterior cruciate ligament (PCL) of the knee stabilize anterior and posterior motion of the tibia articulating with the femur (see Fig. 69-1). These ligaments cross each other in the center of the knee. Injury occurs when the foot is firmly planted and the leg sustains direct force, forward or backward. If the force is forward, the ACL suffers the impact from the force; whereas, backward force places force on the PCL. The injured person may report feeling and hearing a “pop” in the knee with this injury. If the patient exhibits significant swelling of the joint within 2 hours after the injury, the ACL or PCL may be torn. A torn cruciate ligament produces pain, joint instability, and pain with weight bearing. Immediate postinjury management includes RICE and stabilization of the joint until it is evaluated for a fracture. Severe joint effusion and hemarthrosis may require joint aspiration and wrapping with an elastic compression dressing.

Treatment depends on the severity of the injury and the effect of the injury on daily activities. Early treatment involves application of a brace and physical therapy. Surgical ACL or PCL reconstruction may be scheduled after near-normal joint ROM is achieved and includes tendon repair with grafting. This is typically performed as ambulatory arthroscopic surgery, a procedure in which the surgeon uses an **arthroscope** to visualize and repair the damage. The best surgical candidates include patients who are young and physically active. Older and less active patients, particularly with concomitant osteoarthritis, tend to benefit from non-surgical therapy (Alford & Bach, 2004). After surgery, the patient is taught to control pain with oral analgesics and cryotherapy (a cooling pad incorporated in a dressing). The patient and family are taught about monitoring the neurovascular status of the leg, wound care, and signs of complications

that need to be reported promptly to the surgeon. Exercises (ankle pumps, quadriceps sets, and hamstring sets) are encouraged during the early postoperative period. The patient must protect the graft by complying with exercise restrictions. The physical therapist supervises progressive ROM and weight bearing (as permitted). Continuous passive motion may be helpful in restoring full ROM.

MENISCAL INJURIES

Two crescent-shaped (semilunar) cartilages in the knee, called menisci, are located on the right and left side of the proximal tibia, between the tibia and the femur (see Fig. 69-1). These structures act as shock absorbers in the knee. Normally, little twisting movement is permitted in the knee joint. Twisting of the knee or repetitive squatting and impact may result in either tearing or detachment of the cartilage from its attachment to the head of the tibia. The peripheral third of the menisci have a small amount of blood flow, which allows that portion to heal if torn.

These injuries leave loose cartilage in the knee joint that may slip between the femur and the tibia, preventing full extension of the leg. If this happens during walking or running, the patient often describes the leg as “giving way.” The patient may hear or feel a click in the knee when walking, especially when extending the leg that is bearing weight. When the cartilage is attached to the front and back of the knee but torn loose laterally (bucket-handle tear), it may slide between the bones to lie between the condyles and prevent full flexion or extension. As a result, the knee “locks.”

When a meniscus is torn, the synovial membrane secretes additional synovial fluid due to the irritation and the knee becomes very edematous. Initial conservative treatment includes immobilization of the knee, use of crutches, anti-inflammatory agents, analgesics, and modification of activities to avoid those that cause the symptoms. An MRI is the diagnostic tool used to detect a torn meniscus. Damaged cartilage is surgically removed (meniscectomy) arthroscopically. After surgery, a pressure dressing is applied. The most common complication is an effusion into the knee joint, which produces pain. The patient is instructed to continue quadriceps-setting and ROM exercises.

RUPTURE OF THE ACHILLES TENDON

The Achilles tendon attaches the soleus and gastrocnemius muscles to the os calcis (ie, the heel). Traumatic rupture of the Achilles tendon, generally within the tendon sheath, occurs during activities when there is a sudden contraction of the calf muscle with the foot fixed firmly to the floor or ground. The patient experiences sharp pain and cannot plantar flex the foot because the Achilles tendon is the plantar flexor for the ankle.

Immediate surgical repair of complete Achilles tendon ruptures is usually recommended to obtain satisfactory results. After surgery, a cast or brace is used to immobilize the joint. In some situations, conservative management with a plantar-flexed cast for 6 to 8 weeks may be used. After immobilization, a heel lift is worn and progressive physical therapy to promote ankle ROM and strength is begun.

Fractures

A **fracture** is a complete or incomplete disruption in the continuity of bone structure and is defined according to its type and extent. Fractures occur when the bone is subjected to stress greater than it can absorb. Fractures may be caused by direct blows, crushing forces, sudden twisting motions, and extreme muscle contractions. When the bone is broken, adjacent structures are also affected, resulting in soft tissue edema, hemorrhage into the muscles and joints, joint dislocations, ruptured tendons, severed nerves, and damaged blood vessels. Body organs may be injured by the force that caused the fracture or by fracture fragments.

Types of Fractures

A *complete fracture* involves a break across the entire cross-section of the bone and is frequently displaced (removed from its normal position). An *incomplete fracture* (eg, greenstick fracture) involves a break through only part of the cross-section of the bone. A *comminuted fracture* is one that produces several bone fragments. A *closed fracture* (simple fracture) is one that does not cause a break in the skin. An *open fracture* (compound, or complex, fracture) is one in which the skin or mucous membrane wound extends to the fractured bone (Whiteing, 2008). Open fractures are graded according to the following criteria:

- Grade I is a clean wound less than 1 cm long.
- Grade II is a larger wound without extensive soft tissue damage.
- Grade III is highly contaminated, has extensive soft tissue damage, and is the most severe.

Fractures may also be described according to the anatomic placement of fragments. Specific types of fractures are reviewed in Figure 69-2.

An intra-articular fracture extends into the joint surface of a bone. Because each end of a long bone is cartilaginous, if the fracture is nondisplaced, x-rays will not always reveal the fracture because cartilage is nonradiopaque. An MRI or arthroscopy will identify the fracture and confirm the diagnosis. The joint is stabilized and immobilized with a splint or cast and no weight bearing is allowed until the fracture has healed. Intra-articular fractures often lead to posttraumatic arthritis.

Clinical Manifestations

The clinical signs and symptoms of a fracture include acute pain, loss of function, deformity, shortening of the extremity, crepitus, and localized edema and ecchymosis. Not all of these are present in every fracture (Whiteing, 2008).

Pain

The pain is continuous and increases in severity until the bone fragments are immobilized. The muscle spasms that accompany a fracture begin within 20 minutes after the injury and result in more intense pain than the patient reports at the time of injury. The muscle spasms can minimize further movement of the fracture fragments or can result in further bony fragmentation or malalignment.

Loss of Function

After a fracture, the extremity cannot function properly because normal function of the muscles depends on the integrity of the bones to which they are attached. Pain contributes to the loss of function. In addition, abnormal movement (false motion) may be present.

Deformity

Displacement, angulation, or rotation of the fragments in a fracture of the arm or leg causes a deformity that is detectable when the limb is compared with the uninjured extremity.

Shortening

In fractures of long bones, there is actual shortening of the extremity because of the compression of the fractured bone. Sometimes muscle spasms can cause the distal and proximal site of the fracture to overlap, causing the extremity to shorten.

Crepitus

When the extremity is gently palpated, a crumbling sensation, called **crepitus**, can be felt. It is caused by the rubbing of the bone fragments against each other.

NURSING ALERT

Testing for crepitus can produce further tissue damage and should be minimized as much as possible.

Localized Edema and Ecchymosis

Localized edema and ecchymosis occur after a fracture as a result of trauma and bleeding into the tissues. These signs may not develop for several hours after the injury or may develop within an hour, depending on the severity of the fracture.

Emergency Management

Immediately after injury, if a fracture is suspected, it is important to immobilize the body part before the patient is moved. Adequate splinting is essential. Joints proximal and distal to the fracture must be immobilized to prevent movement of fracture fragments. Immobilization of the long bones of the lower extremities may be accomplished by bandaging the legs together, with the unaffected extremity

Avulsion
A fracture in which a fragment of bone has been pulled away by a tendon and its attachment

Comminuted
A fracture in which bone has splintered into several fragments

Compression
A fracture in which bone has been compressed (seen in vertebral fractures)

Depressed
A fracture in which fragments are driven inward (seen frequently in fractures of skull and facial bones)

Epiphyseal
A fracture through the epiphysis

Greenstick
A fracture in which one side of a bone is broken and the other side is bent

Impacted
A fracture in which a bone fragment is driven into another bone fragment

Oblique
A fracture occurring at an angle across the bone (less stable than a transverse fracture)

Open
A fracture in which damage also involves the skin or mucous membranes, also called a compound fracture

Pathologic
A fracture that occurs through an area of diseased bone (eg, osteoporosis, bone cyst, Paget's disease, bony metastasis, tumor); can occur without trauma or fall

Simple
A fracture that remains contained, with no disruption of the skin integrity

Spiral
A fracture that twists around the shaft of the bone

Stress
A fracture that results from repeated loading of bone and muscle

Transverse
A fracture that is straight across the bone shaft

Figure 69-2 Specific types of fractures.

serving as a splint for the injured one. In an upper extremity injury, the arm may be bandaged to the chest, or an injured forearm may be placed in a sling. The neurovascular status distal to the injury should be assessed both before and after splinting to determine the adequacy of peripheral tissue perfusion and nerve function.

With an *open fracture*, the wound is covered with a sterile dressing to prevent contamination of deeper tissues. No attempt is made to reduce the fracture, even if one of the bone fragments is protruding through the wound. Splints are applied for immobilization.

In the emergency department, the patient is evaluated completely. The clothes are gently removed, first from the uninjured side of the body and then from the injured side. The patient's clothing may be cut away. The fractured extremity is moved as little as possible to avoid more damage.

Medical Management

Reduction

Fracture reduction refers to restoration of the fracture fragments to anatomic alignment and positioning. Either closed reduction or open reduction may be used to reduce a fracture. The specific method selected depends on the nature of the fracture; however, the underlying principles are the same. Usually, the physician reduces a fracture as soon as possible to prevent loss of elasticity from the tissues through infiltration by edema or hemorrhage. In most cases, fracture reduction becomes more difficult as the injury begins to heal.

Before fracture reduction and immobilization, the patient is prepared for the procedure; consent for the procedure is obtained, and an analgesic is administered as prescribed. Anesthesia may be administered. The injured extremity must be handled gently to avoid additional damage.

Closed Reduction

In most instances, closed reduction is accomplished by bringing the bone fragments into anatomic alignment through manipulation and manual traction. The extremity is held in the aligned position while the physician applies a cast, splint, or other device. Reduction under anesthesia with percutaneous pinning may also be used. The immobilizing device maintains the reduction and stabilizes the extremity for bone healing. X-rays are obtained to verify that the bone fragments are correctly aligned.

Traction (skin or skeletal) may be used until the patient is physiologically stable to undergo surgical fixation. Use of traction and the nursing management of a patient in traction are discussed more fully in Chapter 67.

Open Reduction

Some fractures require open reduction. Through a surgical approach, the fracture fragments are anatomically aligned. Internal fixation devices (metallic pins, wires, screws, plates, nails, or rods) may be used to hold the bone fragments in position until solid bone healing occurs. These devices may be attached to the sides of bone, or they may be inserted through the bony fragments or directly into the medullary cavity of the bone (Fig. 69-3). Internal fixation devices ensure firm approximation and fixation of the bony fragments.

Figure 69-3 Techniques of internal fixation. **A**, Plate and six screws for a transverse or short oblique fracture. **B**, Screws for a long oblique or spiral fracture. **C**, Screws for a long butterfly fragment. **D**, Plate and six screws for a short butterfly fragment. **E**, Medullary nail for a segmental fracture.

Immobilization

After the fracture has been reduced, the bone fragments must be immobilized and maintained in proper position and alignment until union occurs. Immobilization may be accomplished by external or internal fixation. Methods of external fixation include bandages, casts, splints, continuous traction, and external fixators.

Maintaining and Restoring Function

Reduction and immobilization are maintained as prescribed to promote bone and soft tissue healing. Edema is controlled by elevating the injured extremity and applying ice as prescribed. Neurovascular status (circulation, motion and sensation) is monitored routinely, and the orthopedic surgeon is notified immediately if signs of neurovascular compromise develop. Restlessness, anxiety, and discomfort are controlled with a variety of approaches, such as reassurance, position changes, and pain relief strategies, including use of analgesics. Isometric and muscle-setting exercises are encouraged to minimize atrophy and to promote circulation. Participation in activities of daily living (ADLs) is encouraged to promote independent functioning and self-esteem. Gradual resumption of activities is promoted within the therapeutic prescription. With internal fixation, the surgeon determines the amount of movement and weight-bearing stress the extremity can sustain and prescribes the level of activity.

(See Nursing Process sections in Chapter 67 for more information about caring for patients who have a cast, are in traction, or are undergoing orthopedic surgery.)

Nursing Management

Patients With Closed Fractures

The patient with a closed fracture has no opening in the skin at the fracture site. The fractured bones may be nondisplaced or slightly displaced, but the skin is intact. The nurse instructs the patient regarding the proper methods to control edema and pain (Chart 69-1). It is important to teach exercises to maintain the health of unaffected muscles and to increase the strength of muscles needed for transferring and for using assistive devices such as crutches, walkers, and special utensils. The patient is also taught how to use assistive devices safely. Plans are made to help patients modify the home environment as needed and to ensure safety, such as removing floor rugs or anything that obstructs walking paths throughout the house. Patient teaching includes self-care, medication information, monitoring for potential complications, and the need for continuing health care supervision. Fracture healing and restoration of strength and mobility may take an average maximum of 6 to 8 weeks, depending on the quality of the patient's bone tissue.

Patients With Open Fractures

In an open fracture, there is a risk for osteomyelitis, tetanus, and gas gangrene. The objectives of management are to prevent infection of the wound, soft tissue, and bone and to promote healing of bone and soft tissue. Intravenous (IV) antibiotics are administered immediately upon the patient's arrival in the hospital along with tetanus toxoid if needed.

Wound irrigation and débridement are initiated in the operating room as soon as possible. The wound is cultured

and bone grafting may be performed to fill in areas of bone defects. The fracture is carefully reduced and stabilized by external fixation and the wound is usually left open for 5 to 7 days for intermittent irrigation and cleansing (see Chapter 67). If there is any damage to blood vessels, soft tissue, muscles, nerves, or tendons, appropriate treatment is implemented.

With open fractures, primary wound closure is usually delayed. Heavily contaminated wounds are left unsutured and dressed with sterile gauze to permit edema and wound drainage. Wound irrigation and débridement may be repeated, removing infected and devitalized tissue and increasing vascularity in the region.

The extremity is elevated to minimize edema. It is important to assess neurovascular status frequently. Temperature is monitored at regular intervals and the patient is monitored for signs of infection. In 4 to 8 weeks, bone grafting may be necessary to bridge bone defects and to stimulate bone healing.

Fracture Healing and Complications

Weeks to months are required for most fractures to heal. Many factors influence the time frame of the healing process (Chart 69-2). With a comminuted fracture, fragments must be properly aligned to attain the best healing possible. It is essential for the fractured bone to have blood supply to the area to facilitate the healing process. In general, fractures of flat bones (pelvis, sternum, and scapula) heal rapidly. A complex, comminuted fracture may heal slower. Fractures at the ends of long bones, where the bone is more vascular and cancellous, heal more quickly than do fractures in areas where the bone is dense and less vascular (midshaft). Weight bearing stimulates healing of stabilized fractures of the long bones in the lower extremities.

CHART 69-1  HOME CARE CHECKLIST
Closed Fracture

At the completion of the home instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe approaches to control swelling and pain (eg, elevate extremity to heart level; take analgesics as prescribed).	✓	✓
• Report pain uncontrolled by elevation and analgesics (may be an indicator of impaired tissue perfusion or compartment syndrome).	✓	✓
• Describe management of immobilizing device or care of incision.	✓	✓
• Consume diet to promote bone healing.	✓	
• Demonstrate ability to transfer.	✓	
• Use mobility aids and assistive devices safely.	✓	
• Avoid excessive use of injured extremity; observe prescribed weight-bearing limits.	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; signs of local and systemic infection; signs of venous thromboembolism; problems with immobilization device).	✓	✓
• State possible delayed complications of fractures (ie, delayed union; nonunion; avascular necrosis; reaction to internal fixation device; complex regional pain syndrome [CRPS], formally called reflex sympathetic dystrophy syndrome; heterotopic ossification).	✓	✓
• Describe gradual resumption of normal activities when medically cleared, and discuss how to protect fracture site from undue stresses.	✓	✓

Chart 69-2 • Factors That Affect or Inhibit Fracture Healing

Factors That Enhance Fracture Healing

- Immobilization of fracture fragments
- Maximum bone fragment contact
- Sufficient blood supply
- Proper nutrition
- Exercise: weight bearing for long bones
- Hormones: growth hormone, thyroid, calcitonin, vitamin D, anabolic steroids
- Electric potential across fracture

Factors That Inhibit Fracture Healing

- Extensive local trauma
- Bone loss
- Weight bearing prior to approval
- Malalignment of the fracture fragments
- Inadequate immobilization
- Space or tissue between bone fragments
- Infection
- Local malignancy
- Metabolic bone disease (eg, Paget's disease of the bone)
- Irradiated bone (radiation necrosis)
- Avascular necrosis
- Intra-articular fracture (synovial fluid contains fibrolynsins, which lyse the initial clot and retard clot formation)
- Age (elderly persons heal more slowly)
- Corticosteroids (inhibit the repair rate)

If fracture healing is disrupted, bone union may be delayed or stopped completely. Factors that can impair fracture healing include inadequate fracture immobilization, inadequate blood supply to the fracture site or adjacent tissue, extensive space between bone fragments, interposition of soft tissue between bone ends, displacement of fracture fragments or ends, infection, and metabolic problems.

Complications of fractures may be either acute or chronic. Early complications include shock, fat embolism, compartment syndrome, and venous thromboemboli (deep vein thrombosis [DVT], pulmonary embolism [PE]). Delayed complications include delayed union, malunion, nonunion, AVN of bone, reaction to internal fixation devices, complex regional pain syndrome (CRPS, formerly called reflex sympathetic dystrophy [RSD]), and heterotopic ossification.

Early Complications

Shock

Hypovolemic shock resulting from hemorrhage is more frequently noted in trauma patients with pelvic fractures and in patients with a displaced or open femoral fracture in which the femoral artery is torn by bone fragments. Treatment of shock consists of stabilizing the fracture to prevent further hemorrhage, restoring blood volume and circulation, relieving the patient's pain, providing proper immobilization, and protecting the patient from further injury and other complications. (See Chapter 15 for a discussion of shock.)

Fat Embolism Syndrome

After fracture of long bones or pelvic bones, or crush injuries, fat emboli may develop. Fat embolism syndrome (FES) occurs

most frequently in adults younger than 40 years of age and in men. It is also more common in patients with multiple fractures (Stein, Yaekoub, Matta, et al., 2008). At the time of fracture, fat globules may diffuse from the marrow into the vascular compartment. The fat globules (ie, emboli) may occlude the small blood vessels that supply the lungs, brain, kidneys, and other organs. The onset of symptoms is rapid, typically within 12 to 48 hours of injury (Harvey, 2006), but may occur up to 10 days after injury (Whiteing, 2008).

Clinical Manifestations. Presenting features include hypoxia, tachypnea, tachycardia, and pyrexia. The respiratory distress response includes tachypnea, dyspnea, crackles, wheezes, precordial chest pain, cough, large amounts of thick white sputum, and tachycardia. Occlusion of a large number of small vessels causes the pulmonary pressure to rise. Edema and hemorrhages in the alveoli impair oxygen transport, leading to hypoxia. Arterial blood gas values show the partial pressure of oxygen (PaO_2) to be less than 60 mm Hg, with an early respiratory alkalosis and later respiratory acidosis. The chest x-ray shows a typical "snowstorm" infiltrate. Without prompt, definitive treatment, acute pulmonary edema, acute respiratory distress syndrome (ARDS), and heart failure may develop. Cerebral disturbances (due to hypoxia and the lodging of fat emboli in the brain) are manifested by mental status changes varying from headache and mild agitation to delirium and coma.

NURSING ALERT

Subtle personality changes, restlessness, irritability, or confusion in a patient who has sustained a fracture are indications for immediate arterial blood gas studies.

With systemic embolization, the patient appears pale. Petechiae, possibly due to a transient thrombocytopenia, are noted in the buccal membranes and conjunctival sacs, on the hard palate, and over the chest and anterior axillary folds. The patient develops a fever greater than 39.5°C (103°F). Free fat may be found in the urine if emboli are filtered by the renal tubules. Acute tubular necrosis and renal failure may develop (Harvey, 2006).

Prevention and Management. Immediate immobilization of fractures including early surgical fixation, minimal fracture manipulation, and adequate support for fractured bones during turning and positioning, and maintenance of fluid and electrolyte balance are measures that may reduce the incidence of fat emboli.

Prompt initiation of respiratory support, assessment, and monitoring is essential. The objectives of management are to support the respiratory system, to prevent respiratory failure, and to correct homeostatic disturbances. Acute pulmonary edema and ARDS are the most common causes of death. Respiratory support is provided with high-flow oxygen. Controlled-volume ventilation with positive end-expiratory pressure (PEEP) may be used to prevent or treat pulmonary edema. Corticosteroids may be administered IV to treat the inflammatory lung reaction and to control cerebral edema (Harvey, 2006) (see Chapter 23 for the nursing management of respiratory failure and Chapter 25 for care of the patient on a ventilator). Vasopressor medications to support

cardiovascular function are administered IV to prevent and treat hypotension, shock, and interstitial pulmonary edema. Accurate fluid intake and output records facilitate adequate fluid replacement therapy.

Compartment Syndrome

An anatomic compartment is an area of the body encased by bone or fascia (eg, the fibrous membrane that covers and separates muscles) that contains muscles, nerves, and blood vessels. The human body has 46 anatomic compartments, and 36 of these are located in the extremities (Fig. 69-4). Compartment syndrome in an extremity is a limb-threatening

condition that occurs when perfusion pressure falls below tissue pressure within a closed anatomic compartment.

Acute compartment syndrome involves a sudden and severe decrease in blood flow to the tissues distal to an area of injury that results in ischemic necrosis if prompt, decisive intervention does not occur. The patient complains of deep, throbbing, unrelenting pain, which continues to increase despite the administration of opioids and seems out of proportion to the injury. A hallmark sign is pain that occurs or intensifies with passive ROM (eg, pain intensifies with dorsiflexion of the wrist of the affected extremity). This pain can be caused by (1) a reduction in the size of the muscle

Figure 69-4 Cross-sections of anatomic compartments. **A**, Compartments of the left lower leg. **B**, Compartments of the left forearm. From Chapman, M. W., Szabo, R. M. & Marder, R. A. (2000). *Chapman's orthopaedic surgery* (3rd ed., pp. 395–396). Philadelphia: Lippincott Williams & Wilkins.

compartment because the enclosing muscle fascia is too tight or a cast or dressing is constrictive or (2) an increase in compartment contents because of edema or hemorrhage from the fracture site. The lower leg is most frequently involved, but the forearm is also at risk (see figure 67-2 for an illustration of compartment syndrome of the lower leg). The pressure within a muscle compartment may increase to such an extent that microcirculation diminishes, causing nerve and muscle anoxia and necrosis (Konstantakos, Dalstrom, Nelles, et al., 2007). Permanent function can be lost if the anoxic situation continues for longer than 6 hours (Harvey, 2006).

Assessment and Diagnostic Findings. Frequent assessment of neurovascular function after a fracture is essential and focuses on the “five Ps”: *pain, paralysis, paresthesias, pallor, and pulselessness* (Whiteing, 2008). Sensory deficits include deep, throbbing, escalating pain that increases with passive stretching. Paresthesia (burning or tingling sensation) and numbness are early signs of nerve involvement. Motion is evaluated by asking the patient to flex and extend the wrist or plantarflex and dorsiflex the foot. With continued nerve ischemia and edema, the patient experiences sensations of hypoesthesia (diminished sensation followed by complete numbness). Motor weakness may occur as a late sign of nerve ischemia. No movement (paralysis) indicates nerve damage.

Peripheral circulation is evaluated by assessing color, temperature, capillary refill time, edema, and pulses. Cyanotic (ie, blue-tinged) nail beds suggest venous congestion. Pallor or dusky and cold fingers or toes and prolonged capillary refill time suggest diminished arterial perfusion. Edema may obscure the function of arterial pulsation, and Doppler ultrasonography may be used to verify a pulse. Pulselessness is a very late sign that may signify lack of distal tissue perfusion, but it is possible to have compartment syndrome with a pulse (weak) to the extremity (Konstantakos, et al., 2007).

Palpation of the muscle, if possible, reveals it to be swollen and hard. The orthopedic surgeon may measure tissue pressure by inserting a tissue pressure-monitoring device, such as a Wick catheter, into the muscle compartment (Fig. 69-5). (Normal pressure is 8 mm Hg or less.) Nerve and muscle tissues deteriorate as compartment pressure increases. Prolonged pressure of more than 30 mm Hg can result in

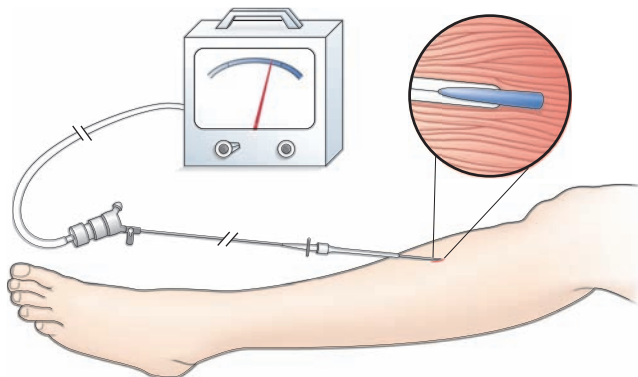

Figure 69-5 The Wick catheter is inserted into a muscle compartment and continuously monitors compartment pressure. From Chapman, M. W., Szabo, R. M. & Marder, R. A. (2000). *Chapman's orthopaedic surgery* (3rd ed., p. 401). Philadelphia: Lippincott Williams & Wilkins.

compromised microcirculation (Hessmann, Ingelfinger & Rommens, 2007).

Medical Management. Prompt management of acute compartment syndrome is essential. The surgeon needs to be notified immediately if neurovascular compromise is suspected. Delay in treatment may result in permanent nerve and muscle damage or even necrosis and amputation.

NURSING ALERT

Compartment syndrome is managed by maintaining the extremity at the heart level (*not above heart level*), and opening and bivalving the cast (see Chart 67-2) or opening the splint, if one or the other are present.

If conservative measures do not restore tissue perfusion and relieve pain within 1 hour, a fasciotomy (surgical decompression with excision of the fascia) is indicated to relieve the constrictive muscle fascia. After fasciotomy, the wound is not sutured but is left open to allow the muscle tissues to expand; it is covered with moist, sterile saline dressings or with artificial skin. The affected arm or leg is splinted in a functional position and elevated to heart level, and prescribed passive ROM exercises are usually performed every 4 to 6 hours. In 3 to 5 days, when the swelling has resolved and tissue perfusion has been restored, the wound is debrided and closed (possibly with skin grafts) (Hessmann, et al., 2007). Complications that may occur after fasciotomy include AVN and infection.

Other Early Complications

Venous thromboemboli, including DVT and PE, are associated with reduced skeletal muscle contractions and bed rest. Patients with fractures of the lower extremities and pelvis are at high risk for venous thromboemboli. PEs may cause death several days to weeks after injury. (See Chapter 31 for a discussion of DVT; Chapter 30 for a discussion of venous thromboemboli; and Chapter 23 for a discussion of PE.)

Disseminated intravascular coagulation (DIC) is a systemic disorder that results in widespread hemorrhage and microthrombosis with ischemia. Its causes are diverse and can include massive tissue trauma. Early manifestations of DIC include unexpected bleeding after surgery, and bleeding from the mucous membranes, venipuncture sites, and gastrointestinal and urinary tracts. The treatment of DIC is discussed in Chapter 33.

All open fractures are considered contaminated and are treated as soon as possible with IV antibiotics. Surgical internal fixation of fractures carries a risk of infection. The nurse must monitor and instruct the patient regarding signs and symptoms of infection, including tenderness, pain, redness, swelling, local warmth, elevated temperature, and purulent drainage.

Delayed Complications

Delayed Union, Malunion, and Nonunion

Delayed union occurs when healing does not occur within the expected time frame for the location and type of fracture. Delayed union may be associated with distraction (pulling apart) of bone fragments, systemic or local infection, poor

nutrition, or comorbidity (eg, diabetes mellitus, autoimmune disease). The healing time is prolonged; but the fracture eventually heals (Whiteing, 2008).

Nonunion results from failure of the ends of a fractured bone to unite, whereas **malunion** results from failure of the ends of a fractured bone to unite in normal alignment. In both of these instances, the patient complains of persistent discomfort and abnormal movement at the fracture site. Factors contributing to nonunion and malunion include infection at the fracture site, interposition of tissue between the bone ends, inadequate immobilization or manipulation that disrupts callus formation, excessive space between bone fragments, limited bone contact, and impaired blood supply resulting in AVN. In nonunion, fibrocartilage or fibrous tissue exists between the bone fragments; no bone salts have been deposited. A false joint (pseudarthrosis) often develops at the site of the fracture (Whiteing, 2008).

Medical Management. The physician treats nonunion with internal fixation, bone grafting, electrical bone stimulation, or a combination of these therapies. Internal fixation stabilizes the bone fragments and ensures bone contact.

Bone grafts promote osteogenesis, osteoconduction, and osteoinduction. *Osteogenesis* (bone formation) occurs after transplantation of bone because the graft contains osteoblasts, which build bony matrix. Building of this structural bony matrix promotes *osteoconduction*, the growth of blood vessels and osteoblasts within the matrix. *Osteoinduction* is the stimulation of host stem cells to differentiate into osteoblasts by several growth factors, including bone morphogenetic proteins (BMPs), particularly BMP-2, BMP-6, and BMP-9 (Boden, 2005).

Grafted bone undergoes a reconstructive process that results in a gradual replacement of the graft with new bone. During surgery the bone fragments are débrided and aligned, infection (if present) is removed, and a bone graft is placed in the bony defect. The bone graft may be an **autograft** (tissue, frequently from the iliac crest, harvested from the patient for his or her own use) or an **allograft** (tissue harvested from a donor). The bone graft fills the bone gap and provides a lattice structure for invasion by bone cells and actively promotes bone growth. The type of bone selected for grafting depends on function: cortical bone is used for structural strength, cancellous bone for osteogenesis, and corticocancellous bone for strength and rapid incorporation. Free vascularized bone autografts are grafted with their own blood supply, allowing for primary fracture healing.

After grafting, immobilization and non-weight-bearing exercises are required while the bone graft becomes incorporated and the fracture or defect heals. Depending on the type of bone grafted and the age of the patient, healing may take from 6 to 12 months or longer. Bone grafting complications include wound or graft infection, fracture of the graft, and nonunion (Boden, 2005). Specific problems associated with autografts include a limited quantity of bone available for harvest and harvest site pain that may persist for up to 2 years after harvest (Boden, 2005). Infrequent specific allograft complications include partial acceptance (lack of host and donor histocompatibility, which retards graft incorporation), graft rejection (rapid and complete resorption of the graft), and transmission of disease (rare).

Figure 69-6 Bone healing stimulator applied to the arm. Courtesy of EBI Medical Systems, Parsippany, NJ.

Osteogenesis may be stimulated by electrical impulses; the effectiveness is similar to that of bone grafting. Use of electrical impulses is not effective with large bone gaps. The electrical stimulation modifies the tissue environment, making it electronegative, which enhances mineral deposition and bone formation that promotes bone growth. In some situations, pins that act as cathodes are inserted percutaneously, directly into the fracture site, and electrical impulses are directed to the fracture continuously. This method cannot be used when infection is present.

Another method for stimulating osteogenesis is noninvasive inductive coupling. Pulsing electromagnetic fields are delivered to the fracture for approximately 10 hours each day by an electromagnetic coil over the nonunion site (Fig. 69-6). During the electrical stimulation treatment period, which takes 3 to 6 months or longer, rigid fracture fixation with adequate support is needed.

Nursing Management. The patient with a nonunion has experienced an extended time in fracture treatment and frequently becomes frustrated with prolonged therapy. The nurse provides emotional support and encouragement to the patient and encourages compliance with the treatment regimen. The orthopedic surgeon evaluates the progression of bone healing with periodic x-rays.

Nursing care for the patient with a bone graft includes pain management and monitoring the patient for possible complications. The nurse needs to reinforce educational information concerning the objectives of the bone graft, immobilization, non-weight-bearing exercises, wound care, monitoring for signs of infection, and the importance of follow-up care with the orthopedic surgeon.

Nursing care for the patient with electrical bone stimulation focuses on patient education that addresses immobilization, weight-bearing restrictions, and correct daily use of the stimulator as prescribed.

Avascular Necrosis of Bone

AVN occurs when the bone loses its blood supply and dies. It may occur after a fracture with disruption of the blood supply to the distal area. It is also seen with dislocations, bone transplantation, prolonged high-dose corticosteroid therapy, chronic renal disease, sickle cell anemia, and other diseases. The devitalized bone may collapse or reabsorb. The patient develops pain and experiences limited movement. X-rays reveal loss of mineralized matrix and structural collapse. Treatment generally consists of attempts to revitalize the bone with bone grafts, prosthetic replacement, or arthrodesis (joint fusion).

Reaction to Internal Fixation Devices

Internal fixation devices may be removed after bony union has taken place. However, in most patients, the device is not removed unless it produces symptoms. Pain and decreased function are the prime indications that a problem has developed. Problems may include mechanical failure (inadequate insertion and stabilization); material failure (faulty or damaged device); corrosion of the device, causing local inflammation; allergic response to the metallic alloy used; and osteoporotic remodeling adjacent to the fixation site (Bucholz, Heckman, Court-Brown, et al., 2005). If the device is removed, the bone needs to be protected from refracture related to osteoporosis, altered bone structure, and trauma.

Complex Regional Pain Syndrome

CRPS is a painful sympathetic nervous system problem. It occurs infrequently; but when it does occur, it is most often in an upper extremity after trauma and is seen more frequently in women. Clinical manifestations of CRPS include severe burning pain, local edema, hyperesthesia, stiffness, discoloration, vasomotor skin changes (ie, fluctuating warm, red, dry and cold, sweaty, cyanotic), and trophic changes that may include glossy, shiny skin and increased hair and nail growth. This syndrome is frequently chronic, with extension of symptoms to adjacent areas of the body. Disuse muscle atrophy and bone deossification (osteoporosis) may occur with persistent CRPS.

Nursing Management. Prevention may include elevation of the extremity after injury or surgery and selection of an immobilization device (eg, external fixator) that allows for the greatest ROM and functional use of the rest of the extremity. Early effective pain relief is the focus of management. Pain may need to be controlled with analgesics. NSAIDs, corticosteroids, and muscle relaxants also may be used. The nurse helps the patient to cope with CRPS manifestations and explores multiple ways to control pain (see Chapter 13).

NURSING ALERT

The nurse avoids using the affected extremity for blood pressure measurements and venipuncture in the patient with CRPS.

Heterotopic Ossification

Heterotopic ossification (myositis ossificans) is the abnormal formation of bone, near bones or in muscle, in response to

soft tissue trauma or fracture after blunt trauma or total joint replacement. The muscle is painful, and normal muscular contraction and movement are limited. Early mobilization may prevent its occurrence. Usually the bone lesion resorbs over time, but the abnormal bone eventually may need to be excised if symptoms persist.

Fractures of Specific Sites

CLAVICLE

Fracture of the clavicle (collar bone) is a common injury that results from a fall or a direct blow to the shoulder. The clavicle helps maintain the shoulder in the upward, outward, and backward position from the thorax. Therefore, when the clavicle is fractured, the patient assumes a protective position, slumping the shoulders and immobilizing the arm to prevent shoulder movements. The treatment goal is to align the shoulder in its normal position by means of closed reduction and immobilization.

Most of these fractures occur in the middle third of the clavicle. A clavicular strap, also called a *figure-eight bandage* (Fig. 69-7), may be used to pull the shoulders back, reducing and immobilizing the fracture. The nurse monitors the circulation and nerve function of the affected arm and compares it with the unaffected arm to determine variations, which may indicate disturbances in neurovascular status. A sling

Figure 69-7 Fracture of the clavicle. **A**, Anteroposterior view shows typical displacement in midclavicular fracture. **B**, Immobilization is accomplished with a clavicular strap.

may be used to support the arm and relieve pain. The patient may be permitted to use the arm for light activities within the range of comfort.

Fracture of the distal third of the clavicle, without displacement and ligament disruption, is treated with a sling and restricted motion of the arm. When a fracture in the distal third is accompanied by a disruption of the coracoclavicular ligament that connects the coracoid process of the scapula and the inferior surface of the clavicle, the bony fragments are frequently displaced. This type of injury may be treated by open reduction with internal fixation (ORIF) (see Chapter 67 for discussion of ORIF).

The nurse cautions the patient not to elevate the arm above shoulder level until the fracture has healed (about 6 weeks) but encourages the patient to exercise the elbow, wrist, and fingers as soon as possible. When prescribed, shoulder exercises are performed to obtain full shoulder motion (Fig. 69-8). Vigorous activity is limited for approximately 3 months.

Complications of clavicular fractures include trauma to the nerves of the brachial plexus, injury to the subclavian vein or artery from a bony fragment, and malunion.

HUMERAL NECK

Fractures of the proximal humerus may occur through the neck of the humerus. Impacted fractures of the surgical neck of the humerus are seen most frequently in older women after a fall on an outstretched arm. Active middle-aged patients who are injured in a fall may suffer severely displaced humeral neck fractures with associated rotator cuff damage.

The patient presents with the affected arm hanging limp at the side or supported by the uninjured hand. Neurovascular

Figure 69-9 Immobilizers for proximal humeral fractures. **A**, Commercial sling with immobilizing strap permits easy removal for hygiene and is comfortable on the neck. **B**, Conventional sling and swathe. **C**, Stockinette Velpeau and swathe are used when there is an unstable surgical neck component. This position relaxes the pectoralis major.

assessment of the extremity is essential to evaluate the full extent of injury and the possible involvement of the nerves and blood vessels of the arm.

Many impacted fractures of the surgical neck of the humerus are not displaced and do not require reduction. The arm is supported and immobilized by a sling and swathe that secure the supported arm to the trunk (Fig. 69-9). Limitation of motion and stiffness of the shoulder occur with disuse. Therefore, pendulum exercises begin as soon as tolerated by the patient. In pendulum or circumduction exercises, the physical therapist instructs the patient to lean forward and allow the affected arm to hang in abduction and rotate. These fractures require approximately 6 to 10 weeks to heal, and the patient should avoid vigorous arm activity for an additional 4 weeks. Residual stiffness, aching, and some limitation of ROM may persist for 6 months or longer.

When a humeral neck fracture is displaced, treatment consists of closed reduction, ORIF, or a total shoulder replacement. Exercises are begun after an adequate period of immobilization.

HUMERAL SHAFT

Fractures of the shaft of the humerus are most frequently caused by (1) direct trauma that results in a transverse, oblique, or comminuted fracture or (2) an indirect twisting force that results in a spiral fracture. The nerves and brachial blood vessels may be injured with these fractures, so neurovascular assessment is essential to monitor the status of the nerve or blood vessels. Damage to either requires immediate attention.

Well-padded splints are used to initially immobilize the upper arm and to support the arm in 90 degrees of flexion at the elbow. A sling or collar and cuff support the forearm. The weight of the hanging arm and splints puts traction on the fracture site. External fixators are used to treat open fractures of the humeral shaft (see Chapter 67). ORIF of a fracture of the humerus is necessary with nerve palsy, blood vessel damage, comminuted fracture, or displaced fracture.

Functional bracing is another form of treatment used for these fractures. A contoured thermoplastic sleeve is secured in place with interlocking fabric (Velcro) closures around

Figure 69-8 Exercises that promote shoulder range of motion include **(A)** pendulum exercise and **(B)** wall climbing. The unaffected arm is used to assist with **(C)** internal rotation, **(D)** external rotation, and **(E)** elevation. In C, D, and E, the unaffected arm is used for power.

Figure 69-10 Functional humeral brace with collar and cuff sling.

the upper arm, immobilizing the reduced fracture. As swelling decreases, the sleeve is tightened, and uniform pressure and stability are applied to the fracture. The forearm is supported with a collar and cuff sling (Fig. 69-10). Functional bracing allows active use of muscles, shoulder and elbow motion, and good approximation of fracture fragments. Pendulum shoulder exercises are performed as prescribed to provide active movement of the shoulder, thereby preventing a “frozen shoulder.” Isometric exercises may be prescribed to prevent muscle atrophy. The callus that develops is substantial, and the sleeve can be discontinued in about 8 weeks. Complications that are seen with humeral shaft fractures include delayed union and nonunion because of decreased blood supply in that area.

ELBOW

Fractures of the distal humerus result from motor vehicle crashes, falls on the elbow (in the extended or flexed position), or a direct blow. These fractures may result in injury to the median, radial, or ulnar nerves.

The patient is evaluated for paresthesia and signs of compromised circulation in the forearm and hand. The most serious complication of a supracondylar fracture of the humerus is Volkmann’s contracture (an acute compartment syndrome), which results from antecubital swelling or damage to the brachial artery (Chart 69-3). The nurse needs to monitor the patient regularly for compromised neurovascular status and signs and symptoms of acute compartment syndrome. Other potential complications are damage to the joint articular surfaces and hemarthrosis (ie, blood in the joint), which may be treated by needle aspiration by the physician to relieve the pressure and pain.

The goal of therapy is prompt reduction and stabilization of the distal humeral fracture, followed by controlled active motion after swelling has subsided and healing has begun. If

Chart 69-3 • Volkmann’s Contracture

- Observe the distal part of the extremity for swelling, skin color, nail bed capillary refill, and temperature. Compare affected and unaffected hands.
- Assess radial pulse.
- Assess for paresthesia (tingling and burning sensations) in the hand, which may indicate nerve injury or impending ischemia.
- Evaluate the patient’s ability to extend and flex all the fingers.
- Explore the intensity and character of the pain.
- Directly measure tissue pressure as prescribed.
- Report indications of diminished nerve function or diminished circulatory perfusion promptly before irreparable damage occurs; fasciotomy may become necessary.

the fracture is not displaced, the arm is immobilized in a cast or posterior splint with the elbow at 45 to 90 degrees of flexion and placed in a sling. A thermoplastic splint is used to support the fracture.

Usually a displaced fracture is treated with ORIF. Excision of bone fragments may be necessary. Additional external support with a splint is then applied. Active finger exercises are encouraged. Gentle ROM exercise of the injured joint is begun about 1 week after internal fixation. Motion promotes healing of injured joints by producing movement of synovial fluid into the articular cartilage. Active exercise to prevent residual limitation of motion is performed as prescribed.

RADIAL HEAD

Radial head fractures are common and are usually produced by a fall on an outstretched hand with the elbow extended. If blood has collected in the elbow joint, it is aspirated to relieve pain and to allow early active elbow and forearm ROM exercises. Immobilization for nondisplaced fractures is accomplished with a splint. The patient is instructed not to lift with the arm for approximately 4 weeks. If the fracture is displaced, surgery is typically indicated, with excision of the radial head when necessary. Postoperatively, the arm is immobilized in a posterior plaster splint and sling and an appropriate exercise regimen is prescribed.

RADIAL AND ULNAR SHAFTS

Fractures of the shaft of the bones of the forearm occur more frequently in children than in adults. The radius or the ulna may be fractured at any level. Frequently, displacement occurs when both bones are broken. The forearm’s unique functions of pronation and supination must be preserved with proper anatomic alignment.

If the fragments are not displaced, the fracture is treated by closed reduction with a long-arm cast applied from the upper arm to the proximal palmar crease. Circulation, motion, and sensation of the hand are assessed before and after the cast is applied. The arm is elevated to control edema. Frequent finger flexion and extension are encouraged to reduce edema. Active motion of the involved shoulder is

essential. The reduction and alignment are monitored closely by x-rays to ensure proper alignment. The fracture is immobilized for about 12 weeks; during the last 6 weeks, the arm may be in a functional forearm brace that allows exercise of the wrist and elbow. Lifting and twisting are avoided.

Displaced fractures are managed by ORIF, using a compression plate with screws, intramedullary nails, or rods. The arm is usually immobilized in a plaster splint or cast. Open and displaced fractures may be managed with external fixation devices. The arm is elevated to control swelling. Neurovascular status is assessed and documented. Elbow, wrist, and hand exercises are begun when prescribed by the physician.

WRIST

Fractures of the distal radius (Colles fracture) are common and are usually the result of a fall on an open, dorsiflexed hand. This fracture is frequently seen in elderly women with osteoporotic bones and weak soft tissues that do not dissipate the energy of the fall. The patient presents with a deformed wrist, pain, swelling, weakness, limited finger ROM, and complaints of “tingling” in the affected hand.

Treatment usually consists of closed reduction and immobilization with a short-arm cast. For fractures with extensive comminution, ORIF, arthroscopic percutaneous pinning, or external fixation is used to achieve and maintain reduction. The wrist and forearm are elevated for 48 hours after reduction to control swelling.

Active motion of the fingers and shoulder should begin promptly. The patient is taught to perform the following exercises to reduce swelling and prevent stiffness:

- Hold the hand at the level of the heart.
- Move the fingers from full extension to flexion. Hold and release. (Repeat at least 10 times every hour when awake.)
- Use the hand in functional activities.
- Actively exercise the shoulder and elbow, including complete ROM exercises of both joints.

The fingers may swell due to diminished venous and lymphatic return. The nurse assesses the sensory function of the median nerve by pricking the distal aspect of the index finger. The motor function is assessed by the patient's ability to touch the thumb to the little finger. Diminished circulation and nerve function must be treated promptly (see previous discussion of Compartment Syndrome).

HAND

Trauma to the hand often requires extensive reconstructive surgery. The objective of treatment is always to regain maximum function of the hand.

For a nondisplaced fracture of the phalanx (finger bone), the finger is splinted for 3 to 4 weeks to relieve pain and to protect the finger from further trauma. Displaced fractures and open fractures may require ORIF, using wires or pins.

The neurovascular status of the injured hand is evaluated and documented. Swelling is controlled by elevation of the hand. Functional use of the uninvolved portion of the hand is encouraged. Assistive devices might be recommended to aid the patient in performing ADLs until the hand has healed and functional status returns.

Figure 69-11 Pelvic bones.

PELVIS

The sacrum, ilium, pubis, and ischium bones form the pelvic bone, a fused, stable, bony ring in adults (Fig. 69-11). Falls, motor vehicle crashes, and crush injuries can cause pelvic fractures. Pelvic fractures are serious because at least two thirds of affected patients have significant and multiple injuries. Management of severe, life-threatening pelvic fractures is coordinated with the trauma team. Hemorrhage and thoracic, intra-abdominal, and cranial injuries have priority over treatment of fractures. There is a high mortality rate associated with pelvic fractures, related to hemorrhage, pulmonary complications, fat emboli, thromboembolic complications, and infection.

Signs and symptoms of pelvic fracture include ecchymosis; tenderness over the symphysis pubis, anterior iliac spines, iliac crest, sacrum, or coccyx; local edema; numbness or tingling of the pubis, genitals, and proximal thighs; and inability to bear weight without discomfort. Computed tomography (CT) of the pelvis helps determine the extent of injury by demonstrating sacroiliac joint disruption, soft tissue trauma, pelvic hematoma, and fractures. Neurovascular assessment of the lower extremities is completed to detect any injury to pelvic blood vessels and nerves (Kobziff, 2006).

Hemorrhage and shock are two of the most serious consequences that may occur. Bleeding arises mainly from the laceration of veins and arteries by bone fragments and possibly from a torn iliac artery. The peripheral pulses, especially the dorsalis pedis pulses of both lower extremities, are palpated; absence of a pulse may indicate a tear in the iliac artery or one of its branches. Peritoneal lavage or abdominal CT may be performed to detect intra-abdominal hemorrhage. The patient is handled gently to minimize further bleeding and shock (Bucholz, et al., 2005).

The nurse assesses for injuries to the bladder, rectum, intestines, other abdominal organs, and pelvic vessels and nerves. To assess for urinary tract injury, the patient's urine is analyzed for blood. A voiding cystourethrogram and an IV urogram may be performed. Laceration of the urethra is suspected in males with anterior fracture of the pelvis and blood at the urethral meatus (Bucholz, et al., 2005). Females

rarely experience a lacerated urethra. A urinary drainage catheter should not be inserted until the status of the urethra is known. Diffuse and intense abdominal pain, hyperactive or absent bowel sounds, and abdominal rigidity and resonance (free air) or dullness to percussion (blood) suggest injury to the intestines or abdominal bleeding.

Numerous classification systems have been used to describe pelvic fractures in relation to anatomy, stability, and mechanism of injury. Some fractures do not disrupt the pelvic ring; others disrupt the ring, which may be rotationally or vertically unstable. The severity of pelvic fractures varies. Long-term complications of pelvic fractures include malunion, nonunion, residual gait disturbances, and back pain from ligament injury.

Stable Pelvic Fractures

Stable fractures of the pelvis (Fig. 69-12) include fracture of a single pubic or ischial ramus, fracture of ipsilateral pubic and ischial rami, fracture of the pelvic wing of the ilium (Duverney fracture), and fracture of the sacrum or coccyx. If injury results in only a slight widening of the pubic symphysis or the anterior sacroiliac joint and the pelvic ligaments are intact, the disrupted pubic symphysis is likely to heal spontaneously with conservative management. Most fractures of the pelvis heal rapidly because the pelvic bones are mostly cancellous bone, which has a rich blood supply.

Stable pelvic fractures are treated with a few days of bed rest and symptom management until discomfort is controlled. Fluids, dietary fiber, ankle and leg exercises, anti-embolism stockings to aid venous return, logrolling, deep breathing, and skin care reduce the risk of complications and increase the patient's comfort. The patient with a fractured sacrum is at risk for paralytic ileus; therefore, bowel sounds should be monitored.

The patient with a fracture of the coccyx experiences pain when sitting and when defecating. Sitz baths may be prescribed to relieve pain, and stool softeners may be given to ease defecation. As pain resolves, activity is gradually resumed with the use of assistive mobility devices. Early mobilization reduces problems related to immobility.

Unstable Pelvic Fractures

Unstable fractures of the pelvis (Fig. 69-13) may result in rotational instability (eg, the “open book” type, in which a separation occurs at the symphysis pubis with sacroiliac

Figure 69-12 Stable pelvic fractures.

ligament disruption), vertical instability, or a combination of both. Lateral or anterior–posterior compression of the pelvis produces rotationally unstable pelvic fractures. Vertically unstable pelvic fractures occur when force is exerted on the pelvis vertically, as may occur when the patient falls onto extended legs or is struck from above by a falling object. Vertical shear pelvic fractures involve the anterior and posterior pelvic ring with vertical displacement, usually through the sacroiliac joint. There is generally complete disruption of the posterior sacroiliac, sacrospinous, and sacrotuberous ligaments.

Immediate treatment in the emergency department of a patient with an unstable pelvic fracture includes stabilizing the pelvic bones and compressing bleeding vessels with a pelvic girdle, an external binding and stabilizing device. If major vessels are lacerated, the bleeding may be stopped through embolization using interventional radiology techniques prior to surgery. Approximately 20% of patients with unstable pelvic fractures bleed excessively, requiring more than 15 units of blood products within the first 24 hours after injury (Bongiovanni, Bradley & Kelley, 2005). These patients are at risk for hemorrhagic shock (see Chapter 15 for nursing management of the patient in shock). When the

Figure 69-13 Unstable pelvic fracture. **A**, Rotationally unstable fracture. The symphysis pubis is separated and the anterior sacroiliac, sacrotuberous, and sacrospinous ligaments are disrupted. **B**, Vertically unstable fracture. The hemipelvis is displaced anteriorly and posteriorly through the symphysis pubis, and the sacroiliac joint ligaments are disrupted. **C**, Undisplaced fracture of the acetabulum.

patient is hemodynamically stable, treatment generally involves external fixation or ORIF. These measures promote hemostasis, hemodynamic stability, comfort, and early mobilization.

Acetabulum

Drivers and passengers sitting in the right front seat in motor vehicle crashes may forcibly propel their knees into the dashboard, injuring the knee-thigh-hip complex (Rupp & Schneider, 2004). The acetabulum is particularly vulnerable to fracture with injuries. Treatment depends on the pattern of fracture. Stable, nondisplaced fractures may be managed with traction and protective weight bearing so that the affected foot is only placed on the floor for balance. Displaced and unstable acetabular fractures are treated with open reduction, joint débridement, and internal fixation or arthroplasty. Internal fixation permits early non-weight-bearing ambulation and ROM exercise. Complications seen with acetabular fractures include nerve palsy, heterotopic ossification, and posttraumatic arthritis.

HIP

Elderly people (particularly women) who have low bone density from osteoporosis and who tend to fall frequently have a high incidence of hip fracture. Weak quadriceps muscles, general frailty due to age, and conditions that produce decreased cerebral arterial perfusion (transient ischemic attacks, anemia, emboli, cardiovascular disease, effects of medications) contribute to the incidence of falls. Mortality rates 1 year post-hip fracture range between 12% and 32% (Schoen, 2006).

There are two major types of hip fracture. *Intracapsular fractures* are fractures of the neck of the femur. *Extracapsular fractures* are fractures of the trochanteric region (between the base of the neck and the lesser trochanter of the femur) and of the subtrochanteric region (Fig. 69-14). Fractures of the neck of the femur may damage the vascular system that supplies blood to the head and the neck of the femur, and the bone may become ischemic. For this reason, AVN is common in patients with femoral neck fractures.

Extracapsular intertrochanteric fractures have an excellent blood supply and heal more rapidly. However, extensive soft

tissue damage may occur at the time of injury. It is not uncommon for the fracture to be comminuted and unstable. The elderly are particularly vulnerable to intertrochanteric fractures and do not have a prognosis as favorable as younger patients.

Clinical Manifestations

With fractures of the femoral neck, the leg is shortened, adducted, and externally rotated. The patient reports pain in the hip and groin or in the medial side of the knee. With most fractures of the femoral neck, the patient cannot move the leg without a significant increase in pain. The patient is most comfortable with the leg slightly flexed in external rotation. Impacted intracapsular femoral neck fractures cause moderate discomfort (even with movement), may allow the patient to bear weight, and may not demonstrate obvious shortening or rotational changes. With extracapsular femoral fractures of the trochanteric or subtrochanteric regions, the extremity is significantly shortened, externally rotated to a greater degree than intracapsular fractures, exhibits muscle spasm that resists positioning of the extremity in a neutral position, and has an associated area of ecchymosis. The diagnosis is confirmed by x-ray.

Gerontologic Considerations

Hip fractures cause more than 340,000 hospitalizations annually among adults 65 years of age and older (Schoen, 2006). They are frequent contributors to physical disability and institutionalization among the elderly (Schoen, 2006). Stress and immobility related to the trauma predispose the older adult to atelectasis, pneumonia, sepsis, venous thromboemboli, pressure ulcers, and reduced ability to cope with other health problems. Many elderly people hospitalized with hip fractures exhibit delirium as a result of the stress of the trauma, unfamiliar surroundings, sleep deprivation, and medications. In addition, delirium that develops in some elderly patients may be caused by mild cerebral ischemia or mild hypoxemia. Other factors associated with delirium include responses to medications and anesthesia, malnutrition, dehydration, infectious processes, mood disturbances, and blood loss (see Chapter 12).

To prevent complications, the nurse must assess the elderly patient for chronic conditions that require close monitoring. Examination of the legs may reveal edema due to heart failure or absence of peripheral pulses from peripheral vascular disease. Similarly, chronic respiratory problems may be present and may contribute to the possible development of atelectasis or pneumonia. Coughing and deep-breathing exercises are encouraged. Frequently, elderly people take cardiac, antihypertensive, or respiratory medications that need to be continued. The patient's responses to these medications should be monitored.

Dehydration and poor nutrition may be present. At times, elderly people who live alone cannot call for help at the time of injury. A day or two may pass before assistance is provided, and as a result dehydration occurs. Dehydration contributes to hemoconcentration and predisposes the patient to the development of venous thromboemboli. Dehydration, inadequate nutritional intake, and immobility contribute to the development of pressure ulcers. Therefore, the patient needs

Figure 69-14 Regions of the proximal femur.

to be encouraged to consume adequate fluids and a healthy diet.

Muscle weakness may have initially contributed to the fall and fracture. Bed rest and immobility cause an additional loss of muscle strength unless the nurse encourages the patient to move all joints except the involved hip and knee. Patients are encouraged to use their arms and the overhead trapeze to reposition themselves. This strengthens the arms and shoulders, which facilitates walking with assistive devices.

Medical Management

Buck's extension traction, a type of temporary skin traction, may be applied to reduce muscle spasm, to immobilize the extremity, and to relieve pain, although its efficacy has not been demonstrated in clinical trials (Parker & Handoll, 2006). The goal of surgical treatment of hip fractures is to obtain a satisfactory fixation so that the patient can be mobilized quickly and avoid secondary medical complications. Surgical treatment consists of (1) open or closed reduction of the fracture and internal fixation, (2) replacement of the femoral head with a prosthesis (hemiarthroplasty), or (3) closed reduction with percutaneous stabilization for an intracapsular fracture. Surgical intervention is carried out as soon as possible after injury. The preoperative objective is to ensure that the patient is in as favorable a condition as possible for the surgery. Displaced femoral neck fractures are treated as emergencies, with reduction and internal fixation performed within 12 to 24 hours after fracture. The femoral head is often replaced with a prosthesis if there is complete disruption of blood flow to the femoral head, which may cause AVN.

After general or spinal anesthesia, the hip fracture is reduced under x-ray visualization. A stable fracture is usually fixed with nails, a nail-and-plate combination, multiple pins, or compression screw devices (Fig. 69-15). The orthopedic surgeon determines the specific fixation device based on the fracture site or sites. Adequate reduction is important for fracture healing: the better the reduction, the better the healing.

Total hip replacement (see Chapter 67) may be used in selected patients with acetabular defects.

Nursing Management

The immediate postoperative care for a patient with a hip fracture is similar to that for other patients undergoing major surgery (see Chapters 20 and 67). Attention is given to pain management, prevention of secondary medical problems, and early mobilization of the patient so that independent functioning can be restored (Chart 69-4).

During the first 24 to 48 hours, relief of pain and prevention of complications are important, and continuous neurovascular assessment is essential. The nurse encourages deep breathing and dorsiflexion and plantar flexion exercises every 1 to 2 hours. Thigh-high anti-embolism stockings or pneumatic compression devices are used, and anticoagulants are administered as prescribed to prevent the formation of venous thromboemboli. The nurse administers prescribed prophylactic IV antibiotics and monitors the patient's hydration, nutritional status, and urine output. A pillow placed between the legs is essential to maintain abduction and alignment and provide needed support when turning the patient.

Repositioning the Patient

The most comfortable and safest way to turn the patient is to turn to the uninjured side. The standard method involves placing a pillow between the patient's legs to keep the affected leg in an abducted position. Proper alignment and supported abduction are maintained while turning.

Promoting Exercise

The patient is encouraged to exercise as much as possible by means of the overbed trapeze. This device helps strengthen the arms and shoulders in preparation for protected ambulation (eg, toe touch, partial weight bearing). On the first postoperative day, the patient transfers to a chair with assistance and begins assisted ambulation. The amount of weight bearing that can be permitted depends on the stability of the fracture reduction. The physician prescribes the degree of weight bearing. In general, hip flexion and internal rotation restrictions apply only if the patient has had a hemiarthroplasty or total arthroplasty (see Chapter 67). Physical therapists

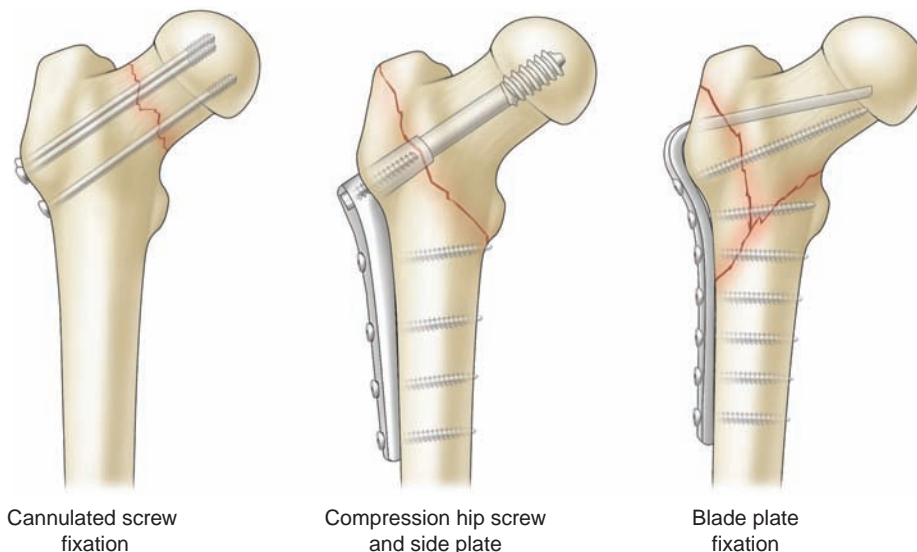

Figure 69-15 Examples of internal fixation for hip fractures. Internal fixation is achieved through the use of screws and plates specifically designed for stability and fixation.

NURSING RESEARCH PROFILE

Functional Recovery After Hip Fracture Surgery

Folden, S. & Tappen, R. (2007). Factors influencing function and recovery following hip repair surgery. *Orthopaedic Nursing*, 26(4), 234–241.

Purpose

The incidence of hip fractures will rise with the projected aging of the American population. Most hip fractures are repaired surgically and incur high rates of morbidity and mortality. Although prior research identifies factors associated with functional recovery following hip repair surgery for patients with hip fractures, these studies utilized data gathered close to the time of surgery. There is sparse research targeted at identifying factors that influence functional recovery following hip repair surgery more than 1 month postoperatively. Therefore, the purpose of this study was to identify factors that are associated with improved functional recovery 3 months post-hip repair surgery.

Design

Seventy-three patients who had hip repair surgery post-hip fracture and who were enrolled in a study on the effects of a postoperative educational intervention provided data for this study, which used secondary analysis of data from a previous study. The mean age of this sample was 73.93 years ($SD = 8.40$) and most participants were Caucasian (98.4%) and female (66.7%). All participants had hip repair surgery, were admitted to rehabilitation units posthospital discharge, and were planning to return to their communities postrehabilitation. Participants had to be able to read and write English and had to demonstrate satisfactory mental status by achieving a minimum score on the Mini-Mental Status Exam (MMSE) in order to be able to participate in the original study (and therefore also to provide data for this secondary analysis).

A variety of factors that affect functional recovery were assessed on these participants using self-report measures. These included fatigue, measured with the Fatigue Severity Scale (FSS); depression, measured with the Center for Epidemiologic Studies–Depression Scale (CES-D); fear of falling, measured with the Fall Efficacy Scale (FES); cognitive status, measured with the MMSE; pain, measured with a visual analog scale (VAS); performance of activities of daily living (ie, functional level), measured with the Functional Life Scale (FLS); and balance, measured with the Berg Balance Scale. Functional recovery was calculated by subtracting participants' FLS scores at 3 months from the FLS scores they reported preoperatively.

Findings

Cognitive status and balance were the best predictors of functional recovery 3 months postdischarge among sampled patients who had hip repair surgery. In addition, men had higher functional levels 3 months postdischarge and had a greater likelihood of returning to their preoperative functional level.

Nursing Implications

Results from this study suggest that the best predictors of functional recovery among patients who have hip repair surgery are improved balance and cognitive status. Women may be at higher risk of not achieving functional recovery. Nurses are in ideal positions to educate postoperative hip repair patients of the potential benefits of engaging in exercise regimens that improve balance, including resistance exercises, yoga, and tai chi.

work with the patient on transfers, ambulation, and the safe use of assistive devices.

The patient can anticipate discharge to home or to an extended care facility with the use of assistive devices (see Chapter 11). Some modifications in the home may be needed, such as installation of elevated toilet seats and grab bars.

Monitoring and Managing Potential Complications

Elderly people with hip fractures are prone to complications that may require more vigorous treatment. Achievement of homeostasis after injury and after surgery is accomplished through careful monitoring and collaborative management.

Neurovascular complications may occur from direct injury or edema in the area that causes compression of nerves and blood vessels. With hip fracture, bleeding into the tissues and edema are expected. Monitoring and documenting the neurovascular status of the affected leg are vital.

To prevent DVT, the nurse encourages intake of fluids and ankle and foot exercises. Anti-embolism stockings, pneumatic compression devices, and prophylactic anticoagulant therapy may be prescribed. Assessment of the patient's legs every 2 to 4 hours for signs of DVT, which may include unilateral calf tenderness, warmth, redness, and swelling, is indicated.

Pulmonary complications (eg, atelectasis, pneumonia) are a threat to elderly patients undergoing hip surgery. Coughing and deep-breathing exercises, a change of position at least every 2 hours, and the use of an incentive spirometer may help prevent respiratory complications. Pain must be treated with analgesic agents, typically opioids; otherwise, the patient may not be able to cough, deep breathe, or engage in prescribed activities. The nurse assesses breath sounds at least every 2 to 4 hours to detect adventitious or diminished sounds.

Skin breakdown is often seen in elderly patients with hip fracture. Blisters caused by tape are related to the tension of soft tissue edema under the nonelastic tape. An elastic hip wrap dressing or elastic tape applied in a vertical fashion may reduce the incidence of tape blisters. In addition, patients with hip fractures tend to remain in one position and may develop pressure ulcers. Proper skin care, especially on the bony prominences, helps to relieve pressure. High-density foam mattress overlays may provide protection by distributing pressure evenly.

Loss of bladder control (incontinence or retention) may occur. In general, the routine use of an indwelling catheter is avoided because of the high risk for urinary tract infection. If a catheter is inserted at the time of surgery, it usually

is removed on the first postoperative day. Because urinary retention is common after surgery, the nurse must assess the patient's voiding patterns. To ensure proper urinary tract function, the nurse encourages liberal fluid intake if the patient has no preexisting cardiac disease.

Delayed complications of hip fractures include infection, nonunion, AVN of the femoral head (particularly with femoral neck fractures), and fixation device problems (eg, protrusion of the fixation device through the acetabulum, loosening of hardware). Infection is suspected if the patient complains of constant pain in the hip and has an elevated erythrocyte sedimentation rate.

The nursing management of the elderly patient with a hip fracture is summarized in the Plan of Nursing Care (Chart 69-5).

Health Promotion

Osteoporosis screening of patients who have experienced hip fracture is important for prevention of future fractures. With dual-energy x-ray absorptiometry (DXA) scan testing, the risk for additional fracture can be predicted. Specific patient education regarding dietary requirements, lifestyle changes, and weight-bearing exercise to promote bone health is needed. Specific therapeutic interventions need to be initiated to slow bone loss and to build bone mineral density (see Chapter 68). Prevention of falls is also important and may be achieved through exercises to improve muscle tone and balance and through the elimination of environmental hazards.

FEMORAL SHAFT

Considerable force is required to break the shaft of a femur in adults. Most femoral fractures occur in young adults who have been involved in a motor vehicle crash or who have fallen from a high place. Frequently, these patients have associated multiple injuries.

The patient presents with an edematous, deformed, painful thigh and cannot move the hip or the knee. The fracture may be transverse, oblique, spiral, or comminuted. Frequently the patient develops shock, because the loss of 2 to 3 units of blood into the tissues is common with these fractures. The diameter of the thigh should be closely monitored because expansion may indicate continued bleeding. Types of femoral fractures are illustrated in Figure 69-16A.

Assessment and Diagnostic Findings

Assessment includes checking the neurovascular status of the extremity, especially circulatory perfusion of the lower leg and foot (popliteal, posterior tibial, and pedal pulses and toe capillary refill time). A Doppler ultrasound may be indicated to assess blood flow. Dislocation of the hip and knee may accompany these fractures. Knee effusion suggests ligament damage and possible instability of the knee joint.

Medical Management

Continued neurovascular monitoring and documentation are important. The fracture is immobilized so that additional soft tissue damage does not occur. Generally, skeletal traction (Fig. 69-16B,C) or splinting is used to immobilize fracture fragments until the patient is physiologically stable and ready for ORIF procedures.

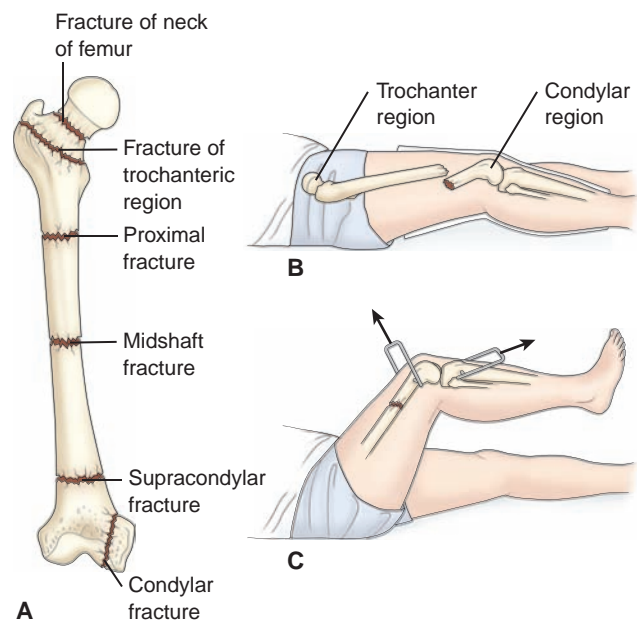

Figure 69-16 A, Types of femoral fractures. B, Example of deformity on admission to hospital. C, Adequate reduction is achieved when additional wire is inserted in the lower femoral fragment and vertical lift is secured.

Internal fixation usually is carried out within 24 hours after injury (Scalea, 2008). Intramedullary locking nail devices are used for midshaft (diaphyseal) fractures. Depending on the supracondylar fracture pattern, intramedullary nailing or screw plate fixation may be used. Internal fixation permits early mobilization. A thigh cuff orthosis may be used for external support. To preserve muscle strength, the patient is instructed to exercise the hip and the lower leg, foot, and toes on a regular basis. Active muscle movement enhances healing by increasing blood supply and electrical potentials at the fracture site. Prescribed weight-bearing limits are based on the type and location of the fracture and treatment approach. Physical therapy includes ROM and strengthening exercises, safe use of assistive devices, and gait training. Ambulation stimulates fracture healing in approximately 4 to 6 months.

Compression plates and intramedullary nails are sometimes removed after 12 to 18 months due to loosening. After the plates are removed, a thigh cuff orthosis is used for several months to provide support while bone remodeling takes place.

Infrequently because of patient risk associated with anesthesia and surgery, middle shaft and distal fractures may be managed with skeletal traction. Between 2 and 4 weeks after injury, when pain and swelling have subsided, skeletal traction is removed and the patient is placed in a cast brace. The cast brace is a total contact device (ie, encircles the limb) and holds the reduced fracture. The muscle, through hydrodynamic compression, stabilizes the bone and stimulates healing. Minimal partial weight bearing is begun and is progressed to full weight bearing as tolerated. The cast brace is worn for 12 to 14 weeks.

An external fixator may be used if the patient has experienced an open fracture, has extensive soft tissue trauma, has lost bone, has an infection, or has hip and tibial fractures.

CHART
69-5

PLAN OF NURSING CARE
Care of the Elderly Patient With a Fractured Hip

NURSING DIAGNOSIS: Acute pain related to fracture, soft tissue damage, muscle spasm, and surgery
GOAL: Relief of pain

Nursing Interventions

1. Assess type and location of patient's pain whenever vital signs are obtained and as needed.
2. Acknowledge existence of pain; inform patient of available analgesics; record patient's baseline discomfort.
3. Handle the affected extremity gently, supporting it with hands or pillow.
4. Apply Buck's traction if prescribed. Use trochanter roll.
5. Use pain-modifying strategies.
 - a. Modify the environment.
 - b. Administer prescribed analgesics as needed.
 - c. Encourage patient to use pain relief measures to relieve pain.
 - d. Evaluate patient's response to medications and other pain-reduction techniques.
 - e. Consult with physician if relief of pain is not obtained.
6. Position for comfort and function.
7. Assist with frequent changes in position.

Rationale

1. Pain is expected after fracture; soft tissue damage and muscle spasm contribute to discomfort; pain is subjective and is best evaluated on a pain scale of 0 to 10 and through description of characteristics and location, which are important for identifying cause of discomfort and for proposing interventions. Continuing pain may indicate development of neurovascular problems. Pain must be assessed periodically to gauge effectiveness of continuing analgesic therapy.
2. Reduces stress experienced by the patient by communicating concern and availability of help in dealing with pain. Documentation provides baseline data.
3. Movement of bone fragments is painful; muscle spasms occur with movement; adequate support diminishes soft tissue tension.
4. Immobilizes fracture to decrease pain, muscle spasm, and external rotation of hip.
5. Pain perception can be diminished by distraction and refocusing of attention.
 - a. Interaction with others, distraction, and environmental stimuli may modify pain experiences.
 - b. Analgesics reduce the pain; muscle relaxants may be prescribed to decrease discomfort associated with muscle spasm.
 - c. Mild pain is easier to control than severe pain.
 - d. Assessment of effectiveness of measures provides basis for future management interventions; early identification of adverse reactions is necessary for corrective measures and care plan modifications.
 - e. Change in treatment plan may be necessary.
6. Alignment of body facilitates comfort; positioning for function diminishes stress on musculoskeletal system.
7. Change of position relieves pressure and associated discomfort.

Expected Outcomes

- Patient describes and rates pain on scale of 0 to 10
- Expresses confidence in efforts to control pain
- Expresses comfort with position changes
- Expresses comfort when leg is positioned and immobilized
- Minimizes movement of extremity before reduction and fixation
- Uses physical, psychological, and pharmacologic measures to reduce discomfort
- Describes a decrease in pain in 24 to 48 hours after surgery
- Requests pain medications and uses pain relief measures early in pain cycle
- States that positioning provides comfort
- Appears comfortable and relaxed
- Moves with increasing comfort as healing progresses

 CHART
69-5

PLAN OF NURSING CARE
Care of the Elderly Patient With a Fractured Hip (Continued)
NURSING DIAGNOSIS: Impaired physical mobility related to fractured hip

GOAL: Achieves pain-free, functional, stable hip

Nursing Interventions

- Maintain neutral positioning of hip.
- Use trochanter roll; roll to uninjured side.
- Place pillow between legs when turning.
- Instruct and assist in position changes and transfers.
- Instruct in and supervise isometric, quadriceps-setting, and gluteal-setting exercises.
- Encourage use of trapeze.
- In consultation with physical therapist, instruct in and supervise progressive safe ambulation within limitations of weight-bearing prescription.
- Offer encouragement and support exercise regimen.
- Instruct in and supervise safe use of ambulatory aids.

Rationale

- Prevents stress at the site of fixation.
- Minimizes external rotation.
- Supports leg; prevents adduction.
- Encourages patient's active participation while preventing stress on hip fixation.
- Strengthens muscles needed for walking.
- Strengthens shoulder and arm muscles necessary for use of ambulatory aids.
- Amount of weight bearing depends on the patient's condition, fracture stability, and fixation device; ambulatory aids are used to assist the patient with non-weight-bearing and partial-weight-bearing ambulation.
- Reconditioning exercises can be uncomfortable and fatiguing; encouragement helps patient comply with the program.
- Prevents injury from unsafe use.

Expected Outcomes

- Patient engages in therapeutic positioning
- Uses pillow between legs when turning
- Assists in position changes; shows increased independence in transfers
- Exercises every 2 hours while awake
- Uses trapeze
- Participates in progressive ambulation program
- Actively participates in exercise regimen
- Uses ambulatory aids correctly and safely

NURSING DIAGNOSIS: Risk for infection related to surgical incision

GOAL: Maintains asepsis

Nursing Interventions

- Monitor vital signs.
- Perform aseptic dressing changes.
- Assess wound appearance and character of drainage.
- Assess report of pain.
- Administer prophylactic antibiotic if prescribed, and observe for side effects.

Rationale

- Temperature, pulse, and respiration increase in response to infection. (Magnitude of response may be minimal in elderly patients.)
- Avoids introducing infectious organisms.
- Red, swollen, draining incision is indicative of infection.
- Pain may be due to wound hematoma, a possible locus of infection, which needs to be surgically evacuated.
- Antibiotics reduce the risk for infection.

Expected Outcomes

- Patient maintains vital signs within normal range
- Exhibits well-approximated incision without drainage or excessive inflammatory response
- Relates minimal discomfort; demonstrates no hematoma
- Tolerates antibiotics; exhibits no evidence of osteomyelitis

NURSING DIAGNOSIS: Readiness for enhanced urinary elimination related to immobility

GOAL: Maintains normal urinary elimination patterns

Nursing Interventions

- Monitor intake and output.
- Avoid/minimize use of indwelling catheter.
- Perform intermittent catheterization for urinary retention.

Rationale

- Adequate fluid intake ensures hydration; adequate urinary output minimizes urinary stasis.
- Source of bladder infection.
- Empties bladder; reduces urinary tract infections.

Expected Outcomes

- Intake and output are adequate; patient exhibits normal voiding patterns
- Demonstrates no evidence of urinary tract infection

Continued

CHART
69-5

PLAN OF NURSING CARE

Care of the Elderly Patient With a Fractured Hip (Continued)

NURSING DIAGNOSIS: Readiness for enhanced coping related to injury, anticipated surgery, and dependence
GOAL: Uses effective coping mechanisms to modify stress

Nursing Interventions

1. Encourage patient to express concerns and to discuss the possible impact of fractured hip.
2. Support use of coping mechanisms. Involve significant others and support services as needed.
3. Contact social services, if needed.
4. Explain anticipated treatment regimen and routines to facilitate positive attitude in relation to rehabilitation.
5. Encourage patient to participate in planning.

Rationale

1. Verbalization helps patient deal with problems and feelings. Clarification of thoughts and feelings promotes problem solving.
2. Coping mechanisms modify disabling effects of stress; sharing concerns lessens the burden and facilitates necessary modification.
3. Anxiety may be related to financial or social problems; facilitates management of problems associated with continuing care.
4. Understanding of plan of care helps to diminish fears of the unknown.
5. Participating in care provides for some control of self and environment.

Expected Outcomes

- Patient describes feelings concerning fractured hip and implications for lifestyle
- Uses available resources and coping mechanisms; develops health promotion strategies
- Uses community resources as needed
- Participates in development of health care plan

NURSING DIAGNOSIS: Risk for disturbed thought process related to age, stress of trauma, unfamiliar surroundings, and medication therapy
GOAL: Remains oriented and participates in decision making

Nursing Interventions

1. Assess orientation status.
2. Interview family regarding patient's orientation and cognitive abilities before injury.
3. Assess patient for auditory and visual deficits.
 - a. Assist patient with use of sensory aids (eg, glasses, hearing aid)
 - b. Control environmental distractors
4. Orient to and stabilize environment.
 - a. Use orientation activities and aids (eg, clock, calendar, pictures, introduction of self).
 - b. Minimize number of staff working with patient.
5. Give simple explanations of procedures and plan of care.
6. Encourage participation in hygiene and nutritional activities.
7. Provide for safety.
 - a. Keep light on at night.
 - b. Have call bell available.
 - c. Provide prompt response to requests for assistance.

Rationale

1. Evaluate presenting orientation of patient; confusion may result from stress of fracture, unfamiliar surroundings, coexisting systemic disease, cerebral ischemia, hypoxemia, or other factors. Baseline data are important for determining change.
2. Provides data for evaluation of current findings.
3. Diminished vision and auditory acuity frequently occur with aging; glasses and hearing aid may increase patient's ability to interact with environment.
 - a. Aids must be in good working order and available for use.
 - b. Facilitates communication.
4.
 - a. Short-term memory may be faulty in the elderly; frequent reorientation helps.
 - b. Consistency of caregivers promotes trust.
5. Promotes understanding and active participation.
6. Participation in routine activities promotes orientation, increases awareness of self.
7. Mechanism for securing assistance is available to patient; independent activities based on faulty judgment may result in injury.

Expected Outcomes

- Patient establishes effective communication
- Demonstrates orientation to time, place, and person
- Participates in self-care activities
- Remains mentally alert
- Avoids episodes of confusion

Continued on following page

 CHART
69-5

PLAN OF NURSING CARE
Care of the Elderly Patient With a Fractured Hip (Continued)

Nursing Interventions	Rationale	Expected Outcomes
8. Assess mental responses to medications, especially sedatives and analgesics.	8. Elderly people tend to be more sensitive to medications; abnormal responses (eg, hallucinations, depression) may occur.	
COLLABORATIVE PROBLEMS: Hemorrhage; pulmonary complications; peripheral neurovascular dysfunction; deep vein thrombosis; pressure ulcers related to surgery and immobility GOAL: Absence of complications		
Nursing Interventions	Rationale	Expected Outcomes
Hemorrhage <ol style="list-style-type: none"> 1. Monitor vital signs, observing for shock. 2. Consider preinjury blood pressure values and management of coexisting hypertension, if present. 3. Note character and amount of drainage. 4. Notify surgeon if patient develops shock or excessive bleeding. 5. Note hemoglobin and hematocrit values, and report decreases in values. 	<ol style="list-style-type: none"> 1. Changes in pulse, blood pressure, and respirations may indicate development of shock; blood loss and stress may contribute to development of shock. 2. Necessary for interpretation of current blood pressure determinations. 3. Excessive drainage and bright red drainage may indicate active bleeding. 4. Corrective measures need to be instituted. 5. Anemia due to blood loss may develop; bleeding into tissues after hip fracture may be extensive; blood replacement may be needed. 	<ul style="list-style-type: none"> • Vital signs are stabilized within normal limits • Experiences no excessive or bright red drainage • Exhibits stable postoperative hemoglobin and hematocrit values • Patient has clear breath sounds • Breath sounds present in all fields • Exhibits no shortness of breath, chest pain, or elevated temperature
Pulmonary Complications <ol style="list-style-type: none"> 1. Assess respiratory status: respiratory rate, depth, and duration, breath sounds, sputum. Monitor temperature. 2. Report adventitious and diminished breath sounds and elevated temperature. 3. Supervise deep breathing and coughing exercises. Encourage use of incentive spirometer if prescribed. 4. Administer oxygen as prescribed. 5. Turn and reposition patient at least every 2 hours. Mobilize patient (assist patient out of bed) as soon as possible. 6. Ensure adequate hydration. 	<ol style="list-style-type: none"> 1. Anesthesia and bed rest diminish respiratory effort and cause pooling of respiratory secretions. Adventitious breath sounds, pain on respiration, shortness of breath, blood tinged sputum, cough, etc., indicate pulmonary dysfunction. 2. Elevated temperature in the early postoperative period may be due to atelectasis or pneumonia. 3. Promote optimal ventilation. Coexisting respiratory conditions diminish lung expansion. 4. Reduced ventilatory efforts may diminish PaO₂ when patient is breathing room air. 5. Promotes optimal ventilation. Diminishes pooling of respiratory secretions. 6. Liquefies respiratory secretions. Facilitates expectoration. 	<ul style="list-style-type: none"> • Vital signs are stabilized within normal limits • Patient has clear breath sounds • Breath sounds present in all fields • Exhibits no shortness of breath, chest pain, or elevated temperature • PaO₂ on room air within normal limits • Performs respiratory exercises; uses incentive spirometer as instructed • Changes position frequently • Consumes adequate fluids
Peripheral Neurovascular Dysfunction <ol style="list-style-type: none"> 1. Assess affected extremity for color and temperature. 2. Assess toes for capillary refill response. 	<ol style="list-style-type: none"> 1. The skin becomes pale and feels cool with decreased tissue perfusion. Venous congestion may cause cyanosis. 2. After compression of the nail, rapid return of pink color indicates good capillary perfusion. 	<ul style="list-style-type: none"> • Patient has normal color and the extremity is warm • Demonstrates normal capillary refill response • Exhibits moderate swelling; tissue not palpably tense • States pain is tolerable

Continued

CHART
69-5

PLAN OF NURSING CARE

Care of the Elderly Patient With a Fractured Hip (Continued)

Nursing Interventions

3. Assess affected extremity for edema and swelling.
4. Elevate affected extremity.
5. Assess for deep, throbbing, unrelenting pain.
6. Assess for pain on passive flexion of foot.
7. Assess for sensations and numbness.
8. Assess ability to move foot and toes.
9. Assess pedal pulses in both feet.
10. Notify surgeon if diminished neurovascular status occurs.

Deep Vein Thrombosis

1. Apply thigh-high anti-embolism stockings and/or sequential compression device as prescribed.
2. Remove stockings for 20 minutes twice a day, and provide skin care.
3. Assess popliteal, dorsalis pedis, and posterior tibial pulses.
4. Assess skin temperature of legs.
5. Assess calf every 4 hours for tenderness, warmth, redness, and swelling.
6. Measure calf circumference twice daily.
7. Avoid pressure on popliteal blood vessels from appliances or pillows.
8. Change patient's position and increase activity as prescribed.
9. Supervise ankle exercises hourly while patient is awake.
10. Ensure adequate hydration.
11. Monitor body temperature.

Rationale

3. The trauma of surgery will cause swelling; excessive swelling and hematoma formation can compromise circulation and function; edema may be due to coexisting cardiovascular disease.
4. Minimizes dependent edema.
5. Surgical pain can be controlled; pain due to neurovascular compromise is refractory to treatment with analgesics.
6. With nerve ischemia, there will be pain on passive stretch.
7. Diminished pain and paresthesia may indicate nerve damage. Sensation in web between great and second toe-peroneal nerve; sensation on sole of foot-tibial nerve.
8. Dorsiflexion of ankle and extension of toes indicate function of peroneal nerve. Plantar flexion of ankle and flexion of toes indicate functioning of tibial nerve.
9. Indicates circulatory status of extremities.
10. Function of extremity needs to be preserved.

1. Compression aids venous blood return and prevents stasis.
2. Skin care is necessary to avoid skin breakdown. Extended removal of stocking or device defeats purpose.
3. Pulses indicate arterial perfusion of extremity. With coexisting arteriosclerotic vascular disease, pulses may be diminished or absent.
4. Local inflammation increases local skin temperature.
5. Unilateral calf tenderness, warmth, redness, and swelling may indicate deep vein thrombosis.
6. Increased calf circumference indicates edema or altered perfusion.
7. Compression of blood vessels diminishes blood flow.
8. Activity promotes circulation and diminishes venous stasis.
9. Muscle exercise promotes circulation.
10. Elderly people may become dehydrated because of low fluid intake, resulting in hemoconcentration.
11. Body temperature increases with inflammation (magnitude of response minimal in elderly people).

Expected Outcomes

- Reports no pain with passive dorsiflexion
- Reports normal sensations and no paresthesia
- Demonstrates normal motor abilities and no paresis or paralysis
- Has strong and equal pulses
- Wears thigh-high anti-embolism stockings
- Uses sequential compression device
- Experiences no more warmth than usual in skin areas
- Exhibits no increase in calf circumference
- Demonstrates no evidence of calf tenderness, warmth, redness, or swelling
- Changes position with assistance and supervision
- Participates in exercise regimen
- Experiences no chest pain; has lungs clear to auscultation; presents no evidence of pulmonary emboli
- Exhibits no signs of dehydration; has normal hematocrit
- Maintains normal body temperature

 CHART
69-5

PLAN OF NURSING CARE
Care of the Elderly Patient With a Fractured Hip (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p>Pressure Ulcers</p> <ol style="list-style-type: none"> 1. Monitor condition of skin at pressure points (eg, heels, sacrum, shoulders); inspect heels at least twice a day. 2. Reposition patient at least every 2 hours. Avoid skin shearing. 3. Administer skin care, especially to pressure points. 4. Use special care mattress and other protective devices (eg, heel protectors); support heel off the mattress. 5. Institute care according to protocol at first indication of potential skin breakdown. 	<ol style="list-style-type: none"> 1. Elderly patients are subject to skin breakdown at points of pressure because of diminished subcutaneous tissue. 2. Avoids prolonged pressure and trauma to the skin. 3. Immobility causes pressure at bony prominences; position changes relieve pressure. 4. Devices minimize pressure on skin at bony prominences. 5. Early interventions prevent tissue destruction and prolonged rehabilitation. 	<ul style="list-style-type: none"> • Patient exhibits no signs of skin breakdown • Skin remains intact • Repositions self frequently • Uses protective devices
<p>NURSING DIAGNOSIS: Risk for ineffective health maintenance related to fractured hip and impaired mobility GOAL: Exhibits health maintenance/promotion behaviors</p>		
Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess home environment for discharge planning. 2. Encourage patient to express concerns about care at home; explore with patient possible solutions to problems. 3. Assess availability of physical assistance for ADLs and health care activities. 4. Teach caregiver the home health care regimen. 5. Instruct patient in posthospital care: <ol style="list-style-type: none"> a. Activity limitations. b. Reinforce exercise instructions. c. Safe use of ambulatory aids. d. Wound care. e. Measures to promote healing (nutrition, wound care). f. Medications. g. Potential problems. h. Continuing health care supervision. 	<ol style="list-style-type: none"> 1. Physical barriers (especially stairs, bathrooms) may limit patient's ability to ambulate and care for self at home. 2. Patient may have special problems that need to be identified so that solutions might be identified. 3. Because of limitation of mobility, patient requires some assistance in ADLs and routine health care. 4. Understanding of rehabilitative regimen is necessary for compliance. 5. Lack of knowledge and poor preparation for care at home contribute to patient anxiety, insecurity, and nonadherence to therapeutic regimen. 	<ul style="list-style-type: none"> • Home is accessible for patient at time of discharge • Patient appears relaxed and develops strategies to deal with identified problems • Has personal assistance available • Demonstrates ability to use necessary assistive devices within therapeutic prescription • Complies with home care program; keeps follow-up health care appointments

A common complication after fracture of the femoral shaft is restriction of knee motion. Active and passive knee exercises begin as soon as possible, depending on the stability of the fracture and knee ligaments. Other complications include malunion, delayed union or nonunion, pudendal nerve palsy, and infection.

KNEE

Fracture to the most distal portion of the femur, the patella (kneecap), and fracture to the most proximal portion of the tibia, may be defined as fractures of the knee. These fractures may be caused by motor vehicle crashes, direct blows to the knee from contact sports or intentionally inflicted trauma,

or falls. The patient typically presents with acute pain to the affected knee and cannot ambulate or bear weight on the affected extremity. The affected knee is notably edematous.

Assessment and Diagnostic Findings

If a patient presents with acute knee pain that occurs as a result of an injury (such as a fall or direct blow to the knee), a CT scan may be indicated to determine the extent of injury. Not all knee injuries are evident on x-ray. An MRI or CT scan can define the details of the injury of bone, cartilage, tendons, and ligaments. If the bones of the knee area are fractured, there is usually limited ROM and sometimes crepitus with motion.

Medical Management

Patients with significant joint effusions may benefit from arthrocentesis to provide relief of intra-articular pressure. Anti-inflammatory and analgesic effects of NSAIDs such as ibuprofen (Motrin, Advil) may be prescribed. Other treatments that may be prescribed depend on the knee bone that is fractured and the extent of the injury, including whether the fracture is displaced or nondisplaced. Nondisplaced fractures may be effectively treated with 6 weeks of immobilization and gradual increases in weight bearing, while displaced fractures typically require ORIF surgical procedures.

TIBIA AND FIBULA

The most common fractures below the knee are tibia and fibula fractures. Fractures of the tibia and fibula often occur in association with each other and tend to result from a direct blow, falls with the foot in a flexed position, or a violent twisting motion. The patient presents with pain, deformity, obvious hematoma, and considerable edema. Frequently, these fractures are open and involve severe soft tissue damage because there is little subcutaneous tissue in the area.

Assessment and Diagnostic Findings

The peroneal nerve is assessed and if damaged, the patient cannot dorsiflex the great toe and has diminished sensation in the first web space. The tibial artery is assessed for damage by evaluating pulses, skin temperature, and color and by testing the capillary refill response. Hemiarthrosis or ligament damage may occur with a fracture near the joint.

The patient is monitored for an anterior acute compartment syndrome. Signs and symptoms include pain that is not relieved by analgesics, pain that increases with plantar flexion, complaints of paresthesias, and sometimes a weak or absent pulse.

Medical Management

Most closed tibial fractures are treated with closed reduction and initial immobilization in a long-leg walking cast or a patellar tendon-bearing cast. As with other lower extremity fractures, the leg is elevated to control edema. Partial weight bearing is usually prescribed after 7 to 10 days, depending on the type of fracture. Activity decreases edema and increases circulation. The cast is changed to a short-leg cast or brace in 3 to 4 weeks, which allows for knee motion. Fracture healing takes 6 to 10 weeks. Percutaneous pins may be placed in the bone and held in position by an external fixator.

Comminuted fractures may be treated with skeletal traction, internal fixation with intramedullary nails or plates and screws, or external fixation. External support may be used with internal fixation. Hip, foot, and knee exercises are encouraged within the limits of the immobilizing device. Partial weight bearing is begun when prescribed and is progressed as the fracture heals in 4 to 8 weeks.

Open fractures are treated with external fixation. Distal fractures with extensive soft tissue damage heal slowly and may require bone grafting.

Continued neurovascular evaluation is important. The development of acute compartment syndrome requires prompt recognition and communication to the orthopedic surgeon. Other complications include delayed union, infection,

impaired wound edge healing due to limited soft tissue, and loosening of the internal fixation hardware.

RIB

Uncomplicated fractures of the lower ribs occur frequently in adults and usually result in no impairment of function. Because these fractures cause pain with respiratory effort, the patient tends to decrease respiratory excursions and refrains from coughing. As a result, tracheobronchial secretions are not mobilized, aeration of the lung is diminished, and a predisposition to atelectasis and pneumonia results. To help the patient cough and take deep breaths, the nurse may splint the chest with his or her hands. Occasionally, an anesthesia care provider administers intercostal nerve blocks to relieve pain and to permit productive coughing.

Chest strapping to immobilize the rib fracture is not used because decreased chest expansion may result in atelectasis and pneumonia. The pain associated with rib fracture diminishes significantly in 3 or 4 days, and the fracture heals within 6 weeks. In addition to atelectasis and pneumonia, complications may include a flail chest, pneumothorax, and hemothorax. The assessment and management of patients with these conditions are discussed in Chapter 23.

THORACOLUMBAR SPINE

Fractures of the thoracolumbar spine may involve (1) the vertebral body, (2) the laminae and articulating processes, and (3) the spinous processes or transverse processes. The T12 to L2 area of the spine is most vulnerable to fracture. Fractures generally result from indirect trauma caused by excessive loading, sudden muscle contraction, or excessive motion beyond physiologic limits. Osteoporosis contributes to vertebral body collapse (compression fracture) (Bucholz, et al., 2005).

Stable spinal fractures are caused by flexion, extension, lateral bending, or vertical loading. The anterior structural column (vertebral bodies and disks) or the posterior structural column (neural arch, articular processes, ligaments) are disrupted. Unstable fractures occur with fracture dislocations and involve disruption of both anterior and posterior structural columns. There is always the potential for neural damage (eg, spinal cord injury).

The patient with a spinal fracture presents with acute tenderness, swelling, paravertebral muscle spasm, and change in the normal curves or in the gap between spinous processes. Pain is greater with moving, coughing, or weight bearing. Immobilization is essential until initial assessments have determined if there is any spinal cord injury and whether the fracture is stable or unstable (see Chapter 63). If spinal cord injury with neurologic deficit does occur, it usually requires immediate surgery (laminectomy with spinal fusion) to decompress the spinal cord.

Stable spinal fractures are treated conservatively with limited bed rest. The head of the bed is elevated less than 30 degrees until the acute pain subsides (several days). Analgesics are prescribed for pain relief. The patient is monitored for a transient paralytic ileus caused by associated retroperitoneal hemorrhage. Sitting is avoided until the pain subsides. A spinal brace or plastic thoracolumbar orthosis may be applied for support during progressive ambulation and resumption of activities.

The patient with an unstable fracture is treated with bed rest, possibly with the use of a special turning device or bed to maintain spinal alignment. Within 24 hours after fracture, open reduction, decompression, and fixation with spinal fusion and instrument stabilization are usually accomplished. Neurologic status is monitored closely during the preoperative and postoperative periods. Postoperatively, the patient may be cared for on the turning device or in a bed with a firm mattress. Progressive ambulation is begun a few days after surgery, with the patient using a body brace orthosis. Patient teaching emphasizes good posture, good body mechanics, and, after healing is sufficient, back-strengthening exercises. (Spinal cord injury is discussed in Chapter 63.)

Sports-Related Injuries

Sport activities are very common, and, unfortunately, sports-related injuries are also common consequences. Table 69-1 displays common sports injuries, their mechanisms of injury, assessment findings, and acute care management.

Management

Patients who have experienced sports-related injuries are often highly motivated to return to their previous level of activity. Compliance with restriction of activities and gradual resumption of activities need to be reinforced. Injured athletes are at risk for reinjury and require follow-up and monitoring. With recurrence of symptoms, athletes need to diminish their level and intensity of activity to a comfortable level. The time required to recover from a sports-related injury can be as short as a few days or considerably longer than 6 weeks, depending on the severity of the injury. Increasing activities gradually to acclimate the muscles, tendons, and joints to the sport motions will assist in recovery and rehabilitation.

Prevention

Sports-related injuries can often be prevented by using proper equipment (eg, running shoes for joggers, wrist guards for skaters) and by effectively training and conditioning the body. Specific training needs to be tailored to the person and the sport. Stretching prior to engaging in sports or exercise had long been recommended; however, studies suggest that stretching may not prevent injury (Hart, 2005).

Occupation-Related Injuries

According to the U.S. Department of Labor, occupation-related musculoskeletal disorders are injuries or illnesses of the muscles, nerves, tendons, joints, cartilage, and bones that occur because of exposure to work-related risks. In 2005, more than 4.2 million cases of nonfatal musculoskeletal injuries and illnesses occurred in the workplace in the private sector (eg, not including the military or government agencies); of these, 1.4 million injuries resulted in lost work days (U.S. Department of Labor, Bureau of Labor Statistics, 2005).

The most frequent types of single injuries that occurred were sprains, strains, and tears (40.8%), cuts, lacerations,

and punctures (9.6%), bruises and contusions (8.7%), fractures, (7.8%), soreness and pain (5.3%), multiple injuries (4.1%), and back pain (2.9%) (U.S. Department of Labor, 2005). Management of sprains, strains, and fractures is described earlier in this chapter; management of low back pain is described in Chapter 68.

Amputation

Amputation is the removal of a body part, often an extremity. Amputation of a lower extremity is often necessary because of progressive peripheral vascular disease (often a sequela of diabetes mellitus), fulminating gas gangrene, trauma (crushing injuries, burns, frostbite, electrical burns, explosions, ballistic injuries), congenital deformities, chronic osteomyelitis, or malignant tumor. Of all these causes, peripheral vascular disease accounts for most amputations of lower extremities (see Chapter 31). Amputation of an upper extremity occurs less frequently than a lower extremity and is most often necessary because of either traumatic injury or a malignant tumor. It is estimated that 1.7 million Americans has had some type of an amputation (National Lower Limb Information Center, 2006).

Amputation is used to relieve symptoms, to improve function, and, most important, to save or improve the patient's quality of life. If the health care team communicates a positive attitude, the patient adjusts to the amputation more readily and actively participates in the rehabilitative plan, learning how to modify activities and how to use assistive devices for ADLs and mobility.

Levels of Amputation

Amputation is performed at the most distal point that will heal successfully. The site of amputation is determined by two factors: circulation in the part and functional usefulness (ie, meets the requirements for the use of a prosthesis).

The circulatory status of the extremity is evaluated through physical examination and diagnostic studies. Muscle and skin perfusion is important for healing. Doppler flow studies with duplex ultrasound, segmental blood pressure determinations, and transcutaneous PaO₂ of the extremity are valuable diagnostic aids. Angiography is performed if revascularization is considered an option.

The objective of surgery is to conserve as much extremity length as needed to preserve function and possibly to achieve a good prosthetic fit. Preservation of knee and elbow joints is desirable. Figure 69-17 shows the levels at which an extremity may be amputated. Most amputations involving extremities can be eventually fitted with a prosthesis.

The amputation of toes and portions of the foot can cause changes in gait and balance. A Syme amputation (modified ankle **disarticulation** amputation) is performed most frequently for extensive foot trauma and aims to produce a durable extremity end that can withstand full weight bearing. Below-knee amputation (BKA) is preferred to above-knee amputation (AKA) because of the importance of the knee joint and the energy requirements for walking. Knee disarticulations are most successful with young, active patients who can develop precise control of the prosthesis. When AKAs are performed, all possible length is preserved,

Table 69-1 COMMON SPORTS INJURIES

Anatomic Area	Mechanism of Injury	Assessment Findings	Sports Activity	Acute Management
Clavicle fracture	Fall on shoulder or outstretched arm Direct blow to the clavicle	Crepitus Holds arm closely to body Unable to raise affected arm above head Can feel movement of both ends of clavicle	Football Rugby Hockey Wrestling Gymnastics	Sling or shoulder immobilizer Ice NSAIDs
Dislocated shoulder	<i>Anterior:</i> Some combination of hyperextension, external rotation, and abduction Anterior blow to shoulder <i>Posterior:</i> Fall on flexed and adducted arm Direct axial load to humerus	Pain Lack of motion May feel empty shoulder socket Uneven posture in comparison to other shoulder Affected arm appears longer Abduction limited	Rugby Hockey Wrestling Skiing	Closed reduction Immobilizer Pendulum exercises
Dislocated elbow	Falling on a hand with a flexed elbow Elbow overextended	Intense pain Edema Limited motion Deformity Ecchymosis	Football Gymnastics Squash Wrestling Cycling Skiing	Immobilization Ice ROM exercises
Wrist sprain or fracture	Falling on an outstretched arm	Pain Edema Ecchymosis Deformity Limited motion	Skating Hockey Wrestling Skiing Soccer Handball Horseback riding	Ice Elevation Immobilization Gentle ROM for 4 to 6 weeks (for sprain only)
Knee sprain	Twisting injury that produces incomplete tear of ligaments and capsule around the joint	Pain Limited motion Edema Ecchymosis Tenderness over joint Joint appears stable	Basketball Football High jump	Ice Elevation Compression wrap Active ROM exercises Isometric exercises May immobilize
Knee strain	Sudden forced motion causing muscle to be stretched beyond normal capacity	Pain Limited motion Pain aggravated by activity	Soccer Swimming Skiing	Ice Elevation Rest Gradual return to activities
Meniscal tears of knee	Sharp, sudden pivot Direct blow to knee Forced internal rotation Wear from repetitive squatting or climbing Torsional weight-bearing force	Edema <i>Medial tear:</i> Pain occurs with hyperflexion, hyperextension, and turning in of knee with knee flexed <i>Lateral tear:</i> Pain occurs with hyperflexion and hyperextension and internal rotation of foot with knee flexed <i>Displaced fragment:</i> Inability to extend knee; "locked" Positive McMurray's sign*	Hockey Basketball Football	<i>Conservative:</i> RICE Exercising of quadriceps and hamstrings Resistive exercising NSAIDs Physical therapy <i>Surgical:</i> Arthroscopy
Ankle sprain	Foot is twisted, causing stretching or tearing of ligaments	Pain Edema Limited motion Ecchymosis	Tennis Basketball Football Skating	Immobilization in cast or brace Ice Elevation Rest
Ankle strain	Sudden forced motion, stretching muscles beyond normal capacity	<i>Acute:</i> Severe pain <i>Chronic:</i> Achy pain	Running All ball sports	Immobilization in cast or brace Ice Elevation Rest

Continued on following page

Table 69-1 COMMON SPORTS INJURIES (Continued)				
Anatomic Area	Mechanism of Injury	Assessment Findings	Sports Activity	Acute Management
Ankle fracture	Inward turning on sole of foot and front of foot Supination with internal rotation Pronation with external rotation	Pain Edema Deformity Inability to bear weight	Contact sports Tennis Basketball	Ice Elevation Cast (4 to 6 weeks) Surgery if fracture is displaced or unstable
Metatarsal stress fracture	Occurs with repeated loading of bone; often in an unconditioned extremity	Forefoot pain that progressively worsens with activity Minimal or no forefoot swelling	Running Dance Skating	Rest Stop sports-related activity for 6 weeks Ice Weight-bearing as indicated

NSAIDs, nonsteroidal anti-inflammatory drugs; ROM, range of motion; RICE, rest, ice, compression, elevation.

muscles are stabilized and shaped, and hip contractures are prevented to maximize ambulatory potential. Most people who have a hip disarticulation amputation must rely on a wheelchair for mobility.

Upper extremity amputations are performed with the goal of preserving maximal functional length. The prosthesis is fitted early to ensure maximum function.

A *staged amputation* may be used when gangrene and infection exist. Initially, a guillotine amputation (eg, nonclosed residual limb) is performed to remove the necrotic and infected tissue. The wound is débrided and allowed to drain. Sepsis is treated with systemic antibiotics. In a few days,

after the infection has been controlled and the patient's condition has stabilized, a definitive amputation with skin closure is performed.

Complications

Complications that may occur with amputation include hemorrhage, infection, skin breakdown, phantom limb pain, and joint contracture. Because major blood vessels have been severed, massive bleeding may occur. Infection is a risk with all surgical procedures. The risk of infection increases with contaminated wounds after traumatic amputation. Skin irritation caused by the prosthesis may result in

Figure 69-17 Levels of amputation are determined by circulatory adequacy, type of prosthesis, function of the part, and muscle balance. **A**, Levels of amputation of upper extremity. **B**, Levels of amputation of lower extremity.

skin breakdown. **Phantom limb pain** is caused by the severing of peripheral nerves. Joint contracture is caused by positioning and a protective flexion withdrawal pattern associated with pain and muscle imbalance.

Medical Management

The objective of treatment is to achieve healing of the amputation wound, the result being a nontender residual limb with healthy skin for prosthetic use. Healing is enhanced by gentle handling of the residual limb, control of residual limb edema through rigid or soft compression dressings, and use of aseptic technique in wound care to avoid infection.

A closed rigid cast dressing or an elastic residual limb shrinker that covers the residual limb may be used to provide uniform compression, to support soft tissues, to control pain, and to prevent joint contractures. Immediately after surgery, a sterilized residual limb sock is applied to the residual limb. Padding is placed over pressure-sensitive areas.

For the patient with a lower extremity amputation, the cast may be equipped to attach a temporary prosthetic extension (pylon) and an artificial foot. This rigid dressing technique is used as a means of creating a socket for immediate postoperative prosthetic fitting. The length of the prosthesis is tailored to the individual patient. Early minimal weight bearing on the residual limb with a rigid cast dressing and a pylon attached produces little discomfort. The cast is changed in about 10 to 14 days. A fever, severe pain, or a loose-fitting cast may necessitate earlier replacement.

A removable rigid dressing may be placed over a soft dressing to control edema, to prevent joint flexion contracture, and to protect the residual limb from unintentional trauma during transfer activities. This rigid dressing is removed several days after surgery for wound inspection and is then replaced to control edema. The dressing facilitates residual limb shaping.

A soft dressing with or without compression may be used if there is significant wound drainage and frequent inspection of the residual limb is required. An immobilizing splint may be incorporated in the dressing. Residual limb wound hematomas are controlled with wound drainage devices to minimize infection.

Rehabilitation

The multidisciplinary rehabilitation team (patient, nurse, physician, social worker, physical therapist, occupational therapist, psychologist, prosthetist, vocational rehabilitation worker) helps the patient achieve the highest possible level of function and participation in life activities (Fig. 69-18). Prosthetic clinics and amputee support groups facilitate this rehabilitation process (Marzen-Groller & Bartman, 2005).

Patients who undergo amputation need support as they grieve the loss and change in body image. Their reactions can include anger, bitterness, and hostility. Psychological issues (eg, denial, withdrawal) may be influenced by the type of support the patient receives from the rehabilitation team and by how quickly ADLs and use of the prosthesis are learned. Knowing the full options and capabilities available with the various prosthetic devices can give the patient a sense of control over the resulting disability (Kelly & Dowling, 2008).

Patients who require amputation because of severe trauma are usually, but not always, young and healthy, heal

Figure 69-18 Many patients with amputations receive prostheses soon after surgery and begin learning how to use them with the help and support of the rehabilitation team, which includes nurses, physicians, physical therapists, and others.

rapidly, and are physically able to participate in a vigorous rehabilitation program. Because the amputation is the result of an injury, the patient needs psychological support in accepting the sudden change in body image and in dealing with the stresses of hospitalization, long-term rehabilitation, and modification of lifestyle.

Within the past decade, numerous U.S. soldiers have lost limbs because of ballistic injuries received while fighting in Iraq and Afghanistan. In order to best meet the complex needs of these young, previously healthy men and women, the U.S. Army instituted both a specialized treatment center for patients with amputations at Walter Reed Army Hospital in Washington, D.C., and a database registry to facilitate their long-term treatment and management. Treatment for these injured soldiers addresses not only their physical rehabilitation needs but also their emotional needs. Behavioral health services are considered key components to their therapy (Peake, 2005).

NURSING PROCESS

THE PATIENT UNDERGOING AN AMPUTATION

Assessment

Before surgery, the nurse must evaluate the neurovascular and functional status of the extremity through history and physical assessment. If the patient has experienced a traumatic amputation, the nurse assesses the function and condition of the residual limb. The nurse also assesses the circulatory status and function of the unaffected extremity. If infection or gangrene develops, the patient may have

associated enlarged lymph nodes, fever, and purulent drainage. A culture and sensitivity test is obtained to determine the appropriate antibiotic therapy.

The nurse evaluates the patient's nutritional status and develops a plan for nutritional care in consultation with a dietitian or metabolic support team, if indicated. A diet with adequate protein and vitamins is essential to promote wound healing.

Any concurrent health problems (eg, dehydration, anemia, cardiac insufficiency, chronic respiratory problems, diabetes mellitus) need to be identified and treated so that the patient is in the best possible condition to withstand the surgical procedure. The use of corticosteroids, anticoagulants, vasoconstrictors, or vasodilators may influence management and prolong or delay wound healing.

The nurse assesses the patient's psychological status. Evaluation of the patient's emotional reaction to amputation is important. Grief responses to permanent alterations in body image, function, and mobility are likely. Professional counseling can help the patient cope in the aftermath of amputation surgery.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain related to amputation
- Disturbed sensory perception: phantom limb pain related to amputation
- Impaired skin integrity related to surgical amputation
- Disturbed body image related to amputation of body part
- Grieving and/or risk for complicated grieving related to loss of body part and resulting disability
- Self-care deficit: feeding, bathing/hygiene, dressing/grooming, or toileting, related to loss of extremity
- Impaired physical mobility related to loss of extremity

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include the following:

- Postoperative hemorrhage
- Infection
- Skin breakdown

Planning and Goals

The major goals of the patient may include relief of pain, absence of altered sensory perceptions, wound healing, acceptance of altered body image, resolution of the grieving process, independence in self-care, restoration of physical mobility, and absence of complications.

Nursing Interventions

Relieving Pain

Pain may be incisional or may be caused by inflammation, infection, pressure on a bony prominence, or hematoma. Muscle spasms may add to the patient's discomfort. Surgical pain can be effectively controlled with opioid analgesics that may be accompanied with evacuation of a hematoma or accumulated fluid. Changing the patient's position or

placing a light sandbag on the residual limb to counteract the muscle spasm may improve the patient's level of comfort. Evaluation of the patient's pain and responses to interventions is an important component of pain management. The pain may be an expression of grief and alteration of body image.

Minimizing Altered Sensory Perceptions

A person who has had an amputation may begin to experience phantom limb pain soon after surgery or 2 to 3 months after amputation. It occurs more frequently in patients who have had AKAs. The patient describes pain or unusual sensations, such as numbness, tingling, or muscle cramps, as well as a feeling that the extremity is present, crushed, cramped, or twisted in an abnormal position. When a patient describes phantom pains or sensations, the nurse acknowledges these feelings as real and encourages the patient to verbalize when in pain so that effective treatment may be given. Although phantom sensations diminish over time for many patients, they do not occur in all patients with amputations (Ebrahimzadeh, Fattahi & Nejad, 2006).

The pathogenesis of the phantom limb phenomenon is unknown. Keeping the patient active helps decrease the occurrence of phantom limb pain. Early intensive rehabilitation and residual limb desensitization with kneading massage bring relief. Distraction techniques and activity are helpful. In addition to the nursing interventions, transcutaneous electrical nerve stimulation (TENS), ultrasound, or local anesthetics may provide relief for some patients. In addition, beta-blockers may relieve dull, burning discomfort; antiseizure medications control stabbing and cramping pain; and tricyclic antidepressants may not only alleviate phantom pain, they may also be prescribed to improve mood and coping ability.

Promoting Wound Healing

The residual limb must be handled gently. Whenever the dressing is changed, aseptic technique is required to prevent wound infection and possible osteomyelitis.

NURSING ALERT

If the cast or elastic dressing inadvertently comes off, the nurse must immediately wrap the residual limb with an elastic compression bandage. If this is not done, excessive edema will develop in a short time, resulting in a delay in rehabilitation. The nurse notifies the surgeon if a cast dressing comes off, so that another cast can be applied promptly.

Residual limb shaping is important for prosthesis fitting. The nurse instructs the patient and family to apply elastic wraps on the residual limb. Using ace wraps on the residual limb is discouraged because they may apply inconsistent pressure on the residual limb, causing problems with shaping it to fit a prosthetic. After the incision is healed, the patient is instructed how to care for the residual limb.

Enhancing Body Image

Amputation is a procedure that alters the patient's body image. The nurse who has established a trusting relationship

with the patient is better able to communicate acceptance of the patient who has experienced an amputation. The nurse encourages the patient to look at, feel, and care for the residual limb. It is important to identify the patient's strengths and resources to facilitate rehabilitation. The nurse helps the patient regain the previous level of independent functioning. The patient who is accepted as a whole person is more readily able to resume responsibility for self-care; self-concept improves, and body-image changes are accepted. Even with highly motivated patients, this process may take months.

Helping the Patient to Resolve Grieving

The loss of an extremity (or part of one) may come as a shock even if the patient was prepared preoperatively. The patient's behavior (eg, crying, withdrawal, apathy, anger) and expressed feelings (eg, depression, fear, helplessness) reveal how the patient is coping with the loss and working through the grieving process.

The nurse creates an accepting and supportive atmosphere in which the patient and family are encouraged to express and share their feelings and work through the grief process. The support from family and friends promotes the patient's acceptance of the loss. The nurse helps the patient deal with immediate needs and become oriented to realistic rehabilitation goals and future independent functioning. Mental health and support group referrals may be appropriate (Marzen-Groller & Bartman, 2005).

Promoting Independent Self-Care

Amputation of an extremity affects the patient's ability to provide adequate self-care. The patient is encouraged to be an active participant in self-care. The patient needs time to accomplish these tasks and must not be rushed. Practicing an activity with consistent, supportive supervision in a relaxed environment enables the patient to learn self-care skills. The patient and the nurse need to maintain positive attitudes and to minimize fatigue and frustration during the learning process.

Independence in dressing, toileting, and bathing depends on balance, transfer abilities, and physiologic tolerance of the activities. The nurse works with the physical therapist and occupational therapist to teach and supervise the patient in these self-care activities.

The patient with an upper extremity amputation has self-care deficits in feeding, bathing, and dressing. Assistance is provided only as needed; the nurse encourages the patient to learn to do these tasks, using assistive feeding and dressing aids when needed. The nurse, therapists, and prosthetist work with the patient to achieve maximum independence.

Helping the Patient to Achieve Physical Mobility

Proper positioning prevents the development of hip or knee joint contracture in the patient with a lower extremity amputation. Abduction, external rotation, and flexion of the lower extremity are avoided. The residual limb may be placed in an extended position or elevated for a brief period after surgery.

NURSING ALERT

The residual limb should not be placed on a pillow because a flexion contracture of the hip may result.

The nurse encourages the patient to turn from side to side and to assume a prone position, if possible, to stretch the flexor muscles and to prevent flexion contracture of the hip. The patient is encouraged not to sit for long periods of time to prevent flexion contracture. The legs should remain close together to prevent an abduction deformity. The nurse encourages the patient to use assistive devices to more readily perform self-care activities and to identify what home modifications, if any, should be made to perform these activities in the home environment.

Postoperative ROM exercises are started early because contracture deformities develop rapidly. ROM exercises include hip and knee exercises for patients with BKAs and hip exercises for patients with AKAs. It is important that the patient understand the importance of exercising the residual limb.

The upper extremities, trunk, and abdominal muscles are exercised and strengthened. The extensor muscles in the arm and the depressor muscles in the shoulder play an important part in crutch walking. The patient uses an overbed trapeze to change position and strengthen the biceps. The patient may flex and extend the arms while holding weights. Doing push-ups while seated strengthens the triceps muscles. Exercises (such as hyperextension of the residual limb), conducted under the supervision of the physical therapist, also aid in strengthening muscles as well as increasing circulation, reducing edema, and preventing atrophy.

Because a patient who has had an upper extremity amputated uses both shoulders to operate the prosthesis, the muscles of both shoulders are exercised. A patient with an above-the-elbow amputation or shoulder disarticulation is likely to develop a postural abnormality caused by loss of the weight of the amputated extremity. Postural exercises are helpful.

Strength and endurance are assessed, and activities are increased gradually to prevent fatigue. As the patient progresses to independent use of the wheelchair, use of ambulatory aids, or ambulation with a prosthesis, the nurse emphasizes safety considerations. Environmental barriers (eg, steps, inclines, doors, throw rugs, wet surfaces) are identified, and methods of managing them are implemented. It is important to anticipate, identify, and manage problems associated with the use of the mobility aids. Proper instructions in using assistive devices will help prevent these problems.

Amputation of the leg changes the center of gravity; therefore, the patient may need to practice position changes (eg, standing from sitting, standing on one foot). The patient is taught transfer techniques early and is reminded to maintain good posture when getting out of bed. A well-fitting shoe with a nonskid sole should be worn. During position changes, the patient should be guarded and stabilized with a transfer belt at the waist to prevent falling.

As soon as possible, the patient with a lower extremity amputation is assisted to stand between parallel bars to allow extension of the temporary prosthesis to the floor with minimal weight bearing. How soon after surgery the patient is allowed to bear full body weight on the prosthesis depends

on the patient's physical status and wound healing. As endurance increases and balance is achieved, ambulation is started with the use of parallel bars or crutches. The patient learns to use a normal gait, with the residual limb moving back and forth while walking with the crutches. To prevent a permanent flexion deformity from occurring, the residual limb should *not* be held up in a flexed position.

The patient with an upper extremity amputation is taught how to carry out ADLs with one arm. The patient is started on one-handed self-care activities as soon as possible. The use of a temporary prosthesis is encouraged. The patient who learns to use the prosthesis soon after the amputation is less dependent on one-handed self-care activities.

The patient with an upper extremity amputation may wear a cotton T-shirt to prevent contact between the skin and shoulder harness and to promote absorption of perspiration. The prosthetist advises about cleaning the washable portions of the harness. Periodically, the prosthesis is inspected for potential problems.

The residual limb must be conditioned and shaped into a conical form to permit accurate fit, maximum comfort, and function of the prosthetic device. Elastic bandages, an elastic residual limb shrinker, or an air splint is used to condition and shape the residual limb. The nurse teaches the patient or a member of the family the correct method of bandaging.

Bandaging supports the soft tissue and minimizes the formation of edema while the residual limb is in a dependent position. The bandage is applied in such a manner that the remaining muscles required to operate the prosthesis are as firm as possible. An improperly applied elastic bandage contributes to circulatory problems and a poorly shaped residual limb.

Effective preprosthetic care is important to ensure proper fitting of the prosthesis. The major problems that can delay prosthetic fitting during this period are (1) flexion deformities, (2) nonshrinkage of the residual limb, and (3) abduction deformities of the hip.

The physician usually prescribes activities to condition or "toughen" the residual limb in preparation for a prosthesis. The patient begins by pushing the residual limb into a soft pillow, then into a firmer pillow, and finally against a hard surface. The patient is taught to massage the residual limb to mobilize the surgical incision site, decrease tenderness, and improve vascularity. Massage is usually started once healing has occurred and is first performed by the physical therapist. Skin inspection and preventive care are taught.

The prosthesis socket is custom molded to the residual limb by the prosthetist. Prostheses are designed for specific activity levels and patient abilities. Types of prostheses include hydraulic, pneumatic, biofeedback-controlled, myoelectrically controlled, and synchronized prostheses. Adjustments of the prosthetic socket are made by the prosthetist to accommodate the residual limb changes that occur during the first 6 months to 1 year after surgery.

Some patients are not candidates for a prosthesis and are thus nonambulatory patients with amputations. If use of a prosthesis is not possible, the patient is instructed in the safe use of a wheelchair to achieve independence. A special wheelchair designed for patients who have had amputations is recommended. Because of the decreased weight in the

front, a regular wheelchair may tip backward when the patient sits in it. In wheelchairs designed for patients who have had amputations, the rear axle is set back about 5 cm (2 in) to compensate for the change in weight distribution.

Monitoring and Managing Potential Complications

After any surgery, efforts are made to reestablish homeostasis and to prevent complications related to surgery, anesthesia, and immobility. The nurse assesses body systems (eg, respiratory, hematological, gastrointestinal, genitourinary, skin) for problems associated with immobility (eg, atelectasis, pneumonia, DVT, PE, anorexia, constipation, urinary stasis, pressure ulcers).

Massive hemorrhage due to a loosened suture is the most threatening problem. The nurse monitors the patient for any signs or symptoms of bleeding and monitors the patient's vital signs and suction drainage.

NURSING ALERT

Immediate postoperative bleeding may develop slowly or may take the form of massive hemorrhage resulting from a loosened suture. A large tourniquet should be in plain sight at the patient's bedside so that, if severe bleeding occurs, it can be applied to the residual limb to control the hemorrhage. The nurse immediately notifies the surgeon in the event of excessive bleeding.

Infection is a common complication of amputation. Patients who have undergone traumatic amputation have contaminated wounds. The nurse administers antibiotics as prescribed. It is important to monitor the incision, dressing, and drainage for indications of infection (eg, change in color, odor, or consistency of drainage; increasing discomfort). The nurse also assesses for systemic indicators of infection (eg, elevated temperature, leukocytosis with an increase of more than 10% bands on the differential) and promptly reports indications of infection to the surgeon.

Skin breakdown may result from immobilization or from pressure from various sources. The prosthesis may cause pressure areas to develop. The nurse and the patient assess for breaks in the skin. Careful skin hygiene is essential to prevent skin irritation, infection, and breakdown. The healed residual limb is washed and dried (gently) at least twice daily. The skin is inspected for pressure areas, dermatitis, and blisters. If they are present, they must be treated before further skin breakdown occurs. Usually a residual limb sock is worn to absorb perspiration and to prevent direct contact between the skin and the prosthetic socket. The sock is changed daily and must fit smoothly to prevent irritation caused by wrinkles. The socket of the prosthesis is washed with a mild detergent, rinsed, and dried thoroughly with a clean cloth. It must be thoroughly dry before the prosthesis is applied.

Promoting Home and Community-Based Care

TEACHING THE PATIENT TO MANAGE SELF-CARE. Before the patient is discharged to the home or to a rehabilitation facility, the patient and family are encouraged to become active participants in care. They participate in care of the skin, residual limb, and prosthesis as appropriate. The patient

receives ongoing instructions and practice sessions to learn to transfer and to use mobility aids and other assistive devices safely. The nurse explains the signs and symptoms of complications that must be reported to the physician (Chart 69-6).

CONTINUING CARE IN THE HOME AND COMMUNITY. After the patient has achieved physiologic homeostasis and has demonstrated achievement of major health care goals, rehabilitation continues either in a rehabilitation facility or at home. Continued support and evaluation by the home care nurse are essential.

The patient’s home environment should be assessed prior to discharge. Modifications are made to ensure the patient’s continuing care, safety, and mobility. An overnight or weekend experience at home may be tried to identify problems that were not identified on the assessment visit. Physical therapy and occupational therapy may continue in the home or on an outpatient basis. Transportation to continuing health care appointments must be arranged. The social service department of the hospital or the home health agency may be of great assistance in securing personal assistance and transportation services.

During follow-up health visits, the nurse evaluates the patient’s physical and psychosocial adjustment. Periodic preventive health assessments are necessary. An elderly spouse may not be able to provide the assistance required if needed at home. Modifications in the plan of care are made on the basis of such findings. Often, the patient and family find involvement in a post-amputation support group to be of value; here they can share problems, solutions, and resources. Talking with those who have successfully dealt with

a similar problem may help the patient develop a satisfactory solution.

Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices, such as regular physical examinations and diagnostic screening tests. Accessible facilities for screening, health care, and exercise are identified. Patients are instructed about their importance and are referred to appropriate health care providers.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Experiences no pain
 - a. Appears relaxed
 - b. Verbalizes comfort
 - c. Uses measures to increase comfort
 - d. Participates in self-care and rehabilitative activities
2. Experiences no phantom limb pain
 - a. Reports diminished phantom sensations
 - b. Uses distraction techniques
 - c. Performs residual limb desensitization massage
3. Achieves wound healing
 - a. Controls residual limb edema
 - b. Exhibits healed, nontender, nonadherent scar
 - c. Demonstrates residual limb care

CHART
69-6

HOME CARE CHECKLIST
Amputation

At the completion of the home instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe approaches to controlling pain (eg, take analgesics as prescribed; use nonpharmacologic interventions).	✓	✓
• Report pain that is uncontrolled by analgesics and other pain management techniques.	✓	
• Describe care of residual limb and conditioning for prosthesis.	✓	✓
• Consume healthy diet to promote wound healing.	✓	
• Demonstrate ability to transfer.	✓	
• Use mobility and activity aids safely.	✓	
• Participate in rehabilitation program to regain functional independence.	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled pain; signs of local or systemic infection; residual limb skin breakdown).	✓	✓
• Identify professionals and community agencies to help with transition to home.	✓	✓
• Identify support group to facilitate rehabilitation.	✓	✓
• Describe effects of amputation on self-image.	✓	
• Acknowledge grieving as part of coping process.	✓	✓
• Identify modifications of home environment to promote safe environment and independence during rehabilitation.	✓	✓
• Identify the importance of keeping follow-up appointments and participating in health screening and health promotion activities, including exercises.	✓	✓

4. Demonstrates improved body image and effective coping
 - a. Acknowledges change in body image
 - b. Participates in self-care activities
 - c. Demonstrates increasing independence
 - d. Projects self as a whole person
 - e. Resumes role-related responsibilities
 - f. Reestablishes social contacts
 - g. Demonstrates confidence in abilities
5. Exhibits resolution of grieving
 - a. Expresses grief
 - b. Works through feelings with family and friends
 - c. Focuses on future functioning
 - d. Participates in support group
6. Achieves independent self-care
 - a. Asks for assistance when needed
 - b. Uses aids and assistive devices to facilitate self-care
 - c. Verbalizes satisfaction with abilities to perform ADLs
7. Achieves maximum independent mobility
 - a. Avoids positions contributing to contracture development
 - b. Demonstrates full active ROM
 - c. Maintains balance when sitting and transferring
 - d. Increases strength and endurance
 - e. Demonstrates safe transferring technique
 - f. Achieves functional use of prosthesis
 - g. Overcomes environmental barriers to mobility
 - h. Uses community services and resources as needed
8. Exhibits absence of complications of hemorrhage, infection, or skin breakdown
 - a. Does not experience excessive bleeding
 - b. Maintains normal blood values
 - c. Is free of local or systemic signs of infection
 - d. Repositions self frequently
 - e. Is free of pressure-related problems
 - f. Reports any skin discomfort and irritations promptly

Prevention of Injuries in Nursing Personnel

Nursing is consistently ranked among the top ten occupations that are most involved in occupation-related injuries and lost work days. The types of injuries that are most common include back, neck, shoulder, wrist, and knee injuries (de Castro, 2006). Most of these injuries have occurred during patient handling and movement activities. Traditional methods to prevent musculoskeletal injuries among nursing personnel during patient handling and moving have revolved around training sessions on proper body mechanics and “safe” lifting of patients and use of back belts, yet there is no research-based evidence that suggests that these methods reduce caregiver injuries (Nelson & Baptiste, 2006). The American Nurses Association (ANA) launched a “Handle

with Care” campaign aimed at reducing occupational musculoskeletal work-related injuries among nurses (de Castro, 2006). In particular, the ANA advocates include that:

- Hospitals, long-term care facilities, and other health care organizations should purchase patient handling equipment (eg, inflatable lateral-assist devices to transfer patients) and train nursing personnel in their appropriate use.
- Health care organizations should institute “no lift” policies for individual nursing personnel. Rather, patient lift teams should be organized.
- Health care organizations should devise methods to assess their patient care ergonomic risks and develop algorithms for patient handling and movement that include patient transfer and movement activities.

CRITICAL THINKING EXERCISES

1 You are a staff nurse in the emergency department, and a patient is brought in with an open tibia/fibula fracture. He is not in respiratory distress, with an SaO₂ of 99%, and is communicating appropriately with you, but complains of pain. What assessments will you gather first, second, and third on this patient? Explain your rationale for the priority order of your assessments.

EBP 2 You are the nurse manager of an orthopedic unit. In the past 3 months, four of the staff members have sustained back injuries when lifting or turning patients. What is your plan to prevent similar staff injuries in the future? Are there any evidence-based guidelines that you might follow to help you prevent recurrence of these injuries?

EBP 3 You are a staff nurse on an orthopedic unit and receive a patient from surgery who had ACL repair after sustaining a “knee injury.” Upon arrival to the unit, the patient appeared comfortable. His left leg was in a compression wrap and a belted brace. About 4 hours after arrival on the floor, he began to ask for pain medication. Morphine was administered as prescribed, yet 40 minutes after administration his pain level actually increased from 7 to 9 on the numeric pain scale. What assessment would you perform immediately on this patient? What should you do with the findings of the assessment? What actions do you anticipate you may initiate with this patient? What evidenced-based information supports your actions?

4 You are a home health nurse and are assigned a new patient to your caseload, a National Guard veteran who was released from duty after having amputations of both legs after stepping on a land mine. His right leg had a below-the-knee amputation and his left leg had an above-the-knee amputation 2 months ago. Identify this patient’s unique nursing, medical, physical therapy, occupational therapy, social, and emotional needs. Devise a nursing plan of care that addresses these needs.

unit 16

Other Acute Problems

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Multiple Trauma Resulting in Hemorrhage and Risk for Shock

Rescue personnel bring 19-year-old **Anna Woo** to the emergency department (ED) after a motorcycle crash. She has facial contusions and lacerations, a fractured sternum, three fractured ribs, a hemothorax, a dislocated hip, a fractured pelvis, and multiple minor lacerations. She is moaning but responds to her name. Initial findings include an unobstructed airway with absent breath sounds in the right basilar lung field, tachypnea with 32 shallow respirations per minute, and ABG values as follows: pH 7.29; pCO₂ 48; SaO₂ 90%; HCO₃⁻ 24. Blood pressure is 94/70; skin is cool and clammy; heart rate is 100; and peripheral pulses are intact. After a preliminary survey and placement of intravenous access lines, a chest tube is inserted. Immediately, 300 mL of bloody fluid drains into the collection chamber. Grossly bloody fluid continues to drain from the chest tube at a rate of 20 mL every 15 minutes.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
INEFFECTIVE BREATHING PATTERN —In- spiration and/or expiration that does not provide adequate ventilation	AIRWAY MANAGEMENT —Facilitation of patency of air passages	RESPIRATORY STATUS: AIRWAY PATENCY —Open, clear tracheo- bronchial passages for air exchange
IMPAIRED GAS EXCHANGE —Excess or deficit in oxygenation and/or carbon dioxide elimination at the alveolar–capillary membrane	RESPIRATORY MONITORING — Collection and analysis of patient data to ensure airway patency and adequate gas exchange	RESPIRATORY STATUS: VENTILATION — Movement of air in and out of the lungs
DEFICIENT FLUID VOLUME — Decreased intravascular, interstitial, and/or intracellular fluid	OXYGEN THERAPY —Administration of oxygen and monitoring of its effectiveness	RESPIRATORY STATUS: GAS EXCHANGE —Alveolar exchange of carbon dioxide and oxygen to main- tain arterial blood gas concentrations
DECREASED CARDIAC OUTPUT —Inad- equate blood pumped by the heart to meet metabolic demands of the body	ACID–BASE MANAGEMENT — Promotion of acid–base balance and prevention of complications re- sulting from acid–base imbalance	ELECTROLYTE AND ACID/BASE BALANCE —Balance of electrolytes and nonelectrolytes in the intracel- lular and extracellular compartments of the body
	HEMORRHAGE CONTROL —Reduction or elimination of rapid and exces- sive blood loss	CIRCULATION STATUS — Unobstructed, unidirectional blood flow at an appropriate pressure through large vessels of the systemic and pulmonary circuits
	IV INSERTION —Insertion of a needle into a peripheral or central vein for the purpose of administering fluids, blood, or medications	VITAL SIGNS —Extent to which tem- perature, pulse, respiration, and blood pressure are within normal range for the individual
	HYPOVOLEMIA MANAGEMENT —Expan- sion of intravascular fluid volume in a patient who is volume-depleted	CARDIAC PUMP EFFECTIVENESS —Ade- quacy of blood volume ejected from the left ventricle to support systolic perfusion pressure
	BLOOD PRODUCTS ADMINISTRATION — Administration of blood or blood products and monitoring of patient’s response	
	VITAL SIGNS MONITORING —Collection and analysis of cardiovascular, respi- ratory, and body temperature data to determine and prevent complications	
	SHOCK PREVENTION —Detecting and treating a patient at risk for impending shock	
	SHOCK MANAGEMENT —Facilitation of the delivery of oxygen and nutrients to systemic tissue with removal of cellular waste products in a patient with severely altered tissue perfusion

chapter 70

Management of Patients With Infectious Diseases

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Differentiate between colonization, infection, and disease.
- 2 Identify federal and local resources available to the nurse seeking information about infectious diseases.
- 3 Identify the benefits of vaccines recommended for health care workers.
- 4 Identify the reasons for Standard and Transmission-Based Precautions and discuss the elements of these standards.
- 5 Describe the concept of emerging infectious diseases and factors that led to the development of these diseases.
- 6 Use the nursing process as a framework for care of patients with sexually transmitted disease.
- 7 Describe home health care measures that reduce the risk of infection.
- 8 Use the nursing process as a framework for care of patients with infectious diseases.

GLOSSARY

- bacteremia:** laboratory-proven presence of bacteria in the bloodstream
- community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA):** a strain of MRSA infecting persons who have not been treated in a health care setting
- carrier:** person who has an organism without apparent signs and symptoms; one who is able to transmit an infection to others
- colonization:** microorganisms present in or on a host, without host interference or interaction and without eliciting symptoms in the host
- emerging infectious diseases:** human infectious diseases with incidence increased within the past two decades or potential increase in the near future
- fungemia:** a bloodstream infection caused by a fungal organism
- health care–associated infection (HAI):** an infection not present or incubating at the time of admission to the health care setting; this term is replacing the term “nosocomial infection,” which refers only to those infections acquired in a hospital

GLOSSARY (Continued)

- host:** an organism that provides living conditions to support a microorganism
- immune:** person with protection from a previous infection or immunization who resists reinfection when re-exposed to the same agent
- incubation period:** time between contact and onset of signs and symptoms
- infection:** condition in which the host interacts physiologically and immunologically with a microorganism
- infectious disease:** the consequences that result from invasion of the body by microorganisms that can produce harm to the body and potentially death
- latency:** time interval after primary infection when a microorganism lives within the host without producing clinical evidence
- methicillin-resistant *Staphylococcus aureus* (MRSA):** *Staphylococcus aureus* bacterium that is not susceptible to extended-penicillin antibiotic formulas, such as methicillin, oxacillin, or nafcillin; MRSA may occur in a health care or in a community setting
- normal flora:** persistent nonpathogenic organisms colonizing a host
- reservoir:** any person, plant, animal, substance, or location that provides living conditions for microorganisms and that enables further dispersal of the organism
- Standard Precautions:** strategy of assuming all patients may carry infectious agents and using appropriate barrier precautions for all health care worker–patient interactions
- susceptible:** not possessing immunity to a particular pathogen
- transient flora:** organisms that have been recently acquired and are likely to be shed in a relatively short period
- Transmission-Based Precautions:** precautions used in addition to Standard Precautions when contagious or epidemiologically significant organisms are recognized; the three types of Transmission-Based Precautions are Airborne, Droplet, and Contact Precautions
- vancomycin-resistant *Enterococcus* (VRE):** *Enterococcus* bacterium that is resistant to the antibiotic vancomycin
- vancomycin-resistant *Staphylococcus aureus* (VRSA):** *Staphylococcus aureus* bacterium that is not susceptible to vancomycin
- virulence:** degree of pathogenicity of an organism

An infectious disease is any disease caused by the growth of pathogenic microbes in the body. It may or may not be communicable (ie, contagious). Modern science has controlled, eradicated, or decreased the incidence of many infectious diseases. However, increases in other infections, such as those caused by antibiotic-resistant organisms and emerging infectious diseases, are of great and growing concern. Examples of these infectious diseases are presented in this chapter. Other infectious diseases are discussed in the appropriate chapters (for example, see Chapter 23 for information on tuberculosis [TB]). It is important to understand infectious causes and the treatment of contagious, serious, and common infections. Table 70-1 presents an overview of many infectious diseases, their causative organisms, mode of transmission, and usual **incubation periods** (time between contact and development of the first signs and symptoms).

The nurse plays an important role in infection control and prevention. Educating patients may decrease their risk of becoming infected or may decrease the sequelae of infection. Using appropriate barrier precautions, observing prudent hand hygiene, and ensuring aseptic care of intravenous

(IV) catheters and other invasive equipment also assists in reducing infections.

The Infectious Process

The Chain of Infection

A complete chain of events is necessary for infection to occur. Figure 70-1 illustrates the elements of the chain and identifies points where health care workers can intervene to interrupt the chain. Six elements are necessary for infection to occur. These essentials are (1) a causative organism, (2) a reservoir of available organisms, (3) a portal or mode of exit from the reservoir, (4) a mode of transmission from reservoir to host, (5) a susceptible host, and (6) a mode of entry to the host.

Causative Organism

The types of microorganisms that cause infections are bacteria, rickettsiae, viruses, protozoa, fungi, and helminths.

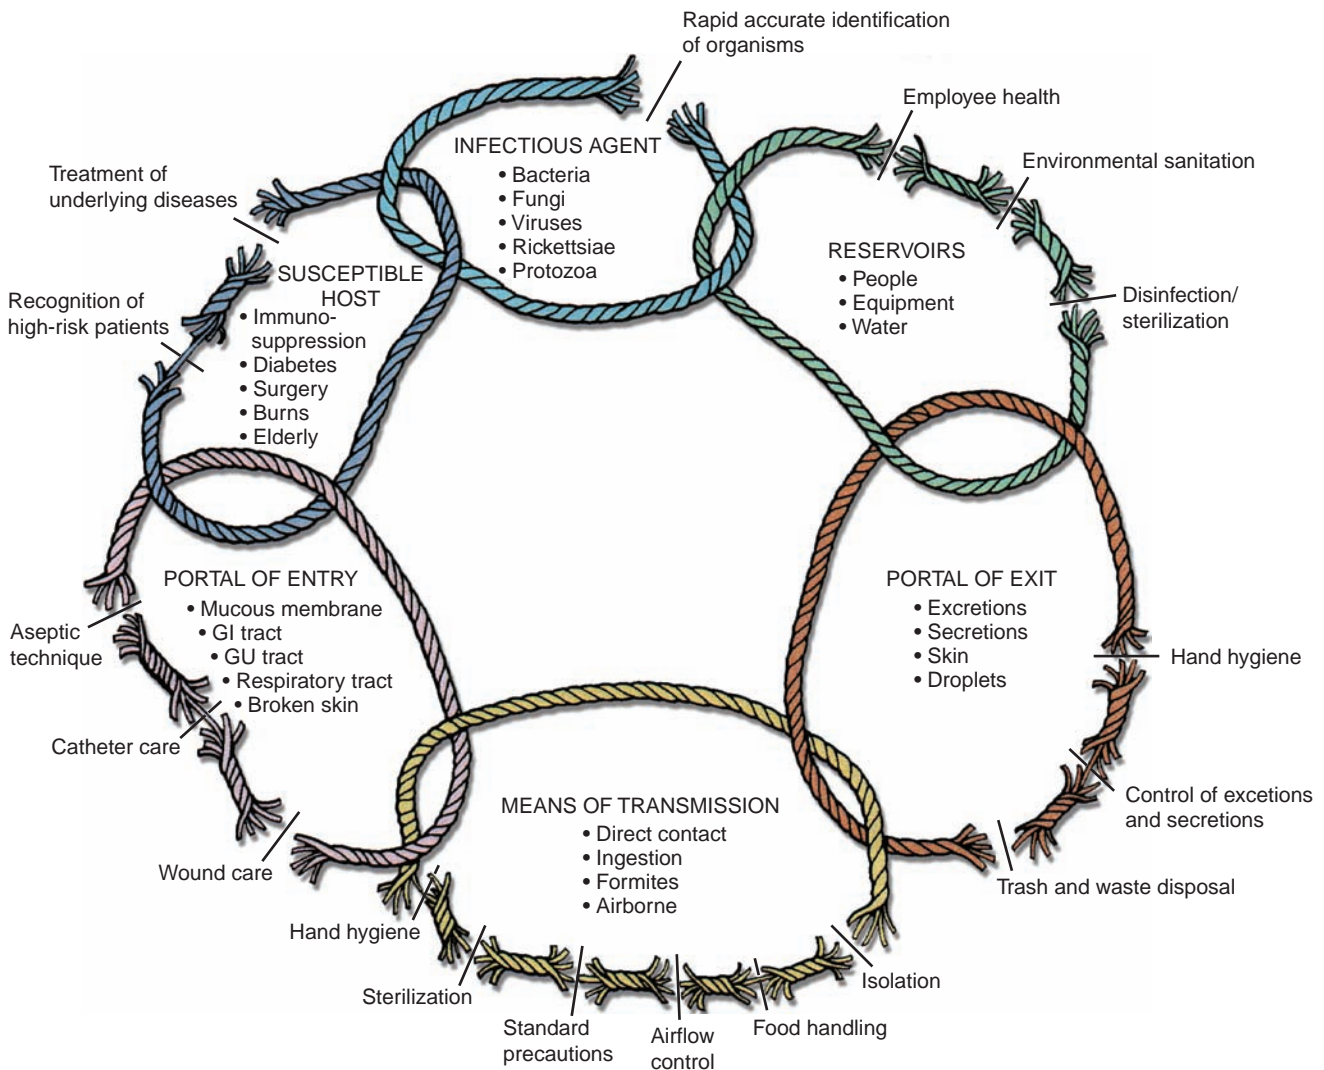

Figure 70-1 Health care workers' interventions used to break the chain of infection transmission.

Table 70-1 INFECTIOUS DISEASES, CAUSATIVE ORGANISMS, MODES OF TRANSMISSION, AND USUAL INCUBATION PERIODS

Disease or Condition	Organism	Usual Mode of Transmission	Usual Incubation Period (Infection to First Symptom)
Acquired immunodeficiency syndrome (AIDS)	Human immunodeficiency virus (HIV)	Sexual; percutaneous; perinatal	Median of 10 years
Amebiasis	<i>Entamoeba histolytica</i>	Contaminated water	2–4 weeks
Anthrax	<i>Bacillus anthracis</i>	Airborne or contact	2–60 days
Chancroid	<i>Haemophilus ducreyi</i>	Sexual	3–5 days
Chickenpox	Varicella zoster	Airborne or contact	About 14 days
Cholera	<i>Vibrio cholerae</i>	Ingestion of water contaminated with human waste	A few hours to 5 days
Cryptococcosis	<i>Cryptococcus neoformans</i>	Probably by inhalation	Unknown
Cryptosporidiosis	<i>Cryptosporidium</i> species	Ingestion of contaminated water; direct contact with carrier	Probably 1–12 days
Cytomegalovirus (CMV) infection	Cytomegalovirus	Transfusion and transplantation; sexual; perinatal	Highly variable: 3–8 weeks after transfusion, 3–12 weeks after delivery of newborn
Diarrheal disease (common causes)	<i>Campylobacter</i> species <i>Clostridium difficile</i>	Ingestion of contaminated food Fecal–oral	3–5 days Variable; in part related to the influence of antibiotics 12–36 hours
	<i>Salmonella</i> species <i>Shigella</i> species	Ingestion of contaminated food or drink Ingestion of contaminated food or drink; direct contact with carrier	1–3 days 1–3 days
	<i>Yersinia</i> species	Ingestion of contaminated food or drink; direct contact with carrier	
Ebola	Ebola virus	Contact with blood or body fluids	2–21 days
Gonorrhea	<i>Neisseria gonorrhoeae</i>	Sexual; perinatal	2–7 days
Hand, foot, and mouth disease	Coxsackievirus	Direct contact with nose and throat secretions and with feces of infected people	3–5 days
Hantavirus pulmonary syndrome (HPS)	Sin Nombre virus	Contact (direct or indirect) with rodents	Unclear
Foodborne hepatitis	Hepatitis A virus Hepatitis E virus	Ingestion of contaminated food or drink; direct contact with carrier Ingestion of contaminated food or drink; direct contact with carrier	15–50 days Unclear
Bloodborne hepatitis	Hepatitis B virus Hepatitis C virus Hepatitis D Hepatitis G	Sexual; perinatal; percutaneous Sexual; perinatal; percutaneous Sexual; perinatal; percutaneous Percutaneous	45–160 days 6–9 months Unclear Unclear
Herpangina	Coxsackievirus	Direct contact with nose and throat secretions and feces of infected people	3–5 days
Herpes simplex	Human herpesvirus 1 and 2	Contact with mucous membrane secretions	2–12 days
Histoplasmosis	<i>Histoplasma capsulatum</i>	Inhalation of airborne spores	5–18 days
Hookworm disease	<i>Necator americanus</i> ; <i>Ancylostoma duodenale</i>	Contact with soil contaminated with human feces	A few weeks to many months
Impetigo	<i>Staphylococcus aureus</i>	Contact with <i>S. aureus</i> carrier	4–10 days
Influenza	Influenza virus A, B, or C	Droplet spread	24–72 hours
Lassa fever	Lassa virus	Contact with animal droppings; direct contact with blood or body fluids	7–21 days
Legionnaires' disease	<i>Legionella pneumophila</i>	Airborne from water source	2–10 days
Listeriosis	<i>Listeria monocytogenes</i>	Foodborne; perinatal	Unclear; probably 3–70 days
Lyme disease	<i>Borrelia burgdorferi</i>	Tick bite	14–23 days
Lymphogranuloma venereum	<i>Chlamydia inguinale</i>	Sexual	Weeks to years
Malaria	<i>Plasmodium vivax</i> ; <i>Plasmodium malariae</i> ; <i>Plasmodium falciparum</i> ; <i>Plasmodium ovale</i>	Bite from <i>Anopheles</i> species mosquito	12–30 days
Marburg hemorrhagic fever	Marburg virus	Unknown route of transmission from animals to humans; person-to-person by droplets and direct contact	5–10 days
Meningococcal meningitis or bacteremia	<i>Neisseria meningitidis</i>	Contact with pharyngeal secretions; perhaps airborne	2–10 days
Mononucleosis	Epstein-Barr virus	Contact with pharyngeal secretions	4–6 weeks
Mycobacterial diseases (nontuberculosis <i>Mycobacterium</i> species)	<i>Mycobacterium avium</i> ; <i>Mycobacterium kansasii</i> ; <i>Mycobacterium fortuitum</i> ; <i>Mycobacterium goodii</i> ; other <i>Mycobacterium</i> species	Variable; probably contact with soil, water, or other environmental source; none is person-to-person transmissible	Variable
Mycoplasma pneumoniae pneumonia	<i>Mycoplasma pneumoniae</i>	Droplet inhalation	14–21 days

Continued

Table 70-1 INFECTIOUS DISEASES, CAUSATIVE ORGANISMS, MODES OF TRANSMISSION, AND USUAL INCUBATION PERIODS (Continued)

Disease or Condition	Organism	Usual Mode of Transmission	Usual Incubation Period (Infection to First Symptom)
Norovirus	<i>Norovirus</i>	Fecal–oral by food or water or by person-to-person spread	24–48 hours
Pediculosis	<i>Pediculus humanus capitis</i> (head louse); <i>Phthirus pubis</i> (crab louse)	Direct contact	1–2 weeks
Pertussis (whooping cough)	<i>Bordetella pertussis</i>	Contact with respiratory droplets	7–10 days
Pinworm disease	<i>Enterobius vermicularis</i>	Direct contact with egg-contaminated articles	4- to 6-week life cycle; often takes months of infection before recognition
<i>Pneumocystis jiroveci</i> pneumonia	<i>Pneumocystis jiroveci</i>	Unknown; not transmitted person-to-person	Infants: 1–2 months; adults: unclear
Pneumococcal pneumonia	<i>Streptococcus pneumoniae</i>	Droplet spread	Probably 1–3 days
Rabies	Rabies virus	Bite from rabid animal	2–8 weeks
Respiratory syncytial disease	Respiratory syncytial virus	Self-inoculation by mouth or nose after contact with infectious respiratory secretions	3–7 days
Ringworm	<i>Microsporum</i> species; <i>Trichophyton</i> species	Direct and indirect contact with lesions	4–10 days
Rocky mountain spotted fever	<i>Rickettsia rickettsii</i>	Bite from infected tick	3–14 days
Roseola infantum	Human herpes virus 6	Saliva	10–15 days
Rotavirus gastroenteritis	Rotavirus	Fecal–oral route	About 48 hours
Rubella	Rubella virus	Droplet spread; direct contact	14–21 days
Scabies	<i>Sarcoptes scabiei</i>	Direct skin contact	2–6 weeks
Severe acute respiratory syndrome (SARS)	SARS-associated coronavirus (SARS-CoV)	Droplet; direct contact; occasionally airborne	2–10 days
Smallpox	<i>Variola major</i>	Airborne and contact	7–14 days
Syphilis	<i>Treponema pallidum</i>	Sexual; perinatal	10 days to 10 weeks
Tetanus	<i>Clostridium tetani</i>	Puncture wound	4–21 days
Trichinosis	<i>Trichinella spiralis</i>	Ingestion of insufficiently cooked foods, especially pork and beef	10–14 days
Tuberculosis	<i>Mycobacterium tuberculosis</i>	Airborne	4–12 weeks to the formation of primary lesion
West Nile virus	West Nile virus	Bite of infected mosquitoes; from transfusions and transplants; perinatal	3–14 days

Reservoir

Reservoir is the term used for any person, plant, animal, substance, or location that provides nourishment for microorganisms and enables further dispersal of the organism. Infections may be prevented by eliminating the causative organisms from the reservoir.

Mode of Exit

The organism must have a mode of exit from a reservoir. An infected host must shed organisms to another or to the environment for transmission to occur. Organisms exit through the respiratory tract, the gastrointestinal tract, the genitourinary tract, or the blood.

Route of Transmission

A route of transmission is necessary to connect the infectious source with its new host. Organisms may be transmitted through sexual contact, skin-to-skin contact, percutaneous injection, or infectious particles carried in the air. A person who carries or transmits an organism but does not have apparent signs and symptoms of infection is called a **carrier**.

Specific organisms require specific routes of transmission for infection to occur. For example, *Mycobacterium tuberculosis* is almost always transmitted by the airborne route. Health care providers do not “carry” *M. tuberculosis* bacteria on their hands or clothing. In contrast, bacteria such as

Staphylococcus aureus are easily transmitted from patient to patient on the hands of health care providers.

When appropriate, the nurse should explain routes of disease transmission to patients. For example, a nurse may explain that sharing a room with a patient who is infected with human immunodeficiency virus (HIV) does not pose a risk because intimate contact (ie, sexual or parenteral) is necessary for transmission to occur.

Susceptible Host

For infection to occur, the **host** must be **susceptible** (not possessing immunity to a particular pathogen). Previous infection or vaccine administration may render the host **immune** (not susceptible) to further infection with an agent. Although exposure to potentially infectious microorganisms occurs essentially on a constant basis, people have elaborate immune systems that generally prevent infection from occurring. A person who is immunosuppressed has much greater susceptibility to infection than a healthy person.

Portal of Entry

A portal of entry is needed for the organism to gain access to the host. Again, specific organisms may require specific portals of entry for infection to occur. For example, airborne *M. tuberculosis* does not cause disease when it settles on the skin of an exposed host; the only entry route for *M. tuberculosis* is through the respiratory tract.

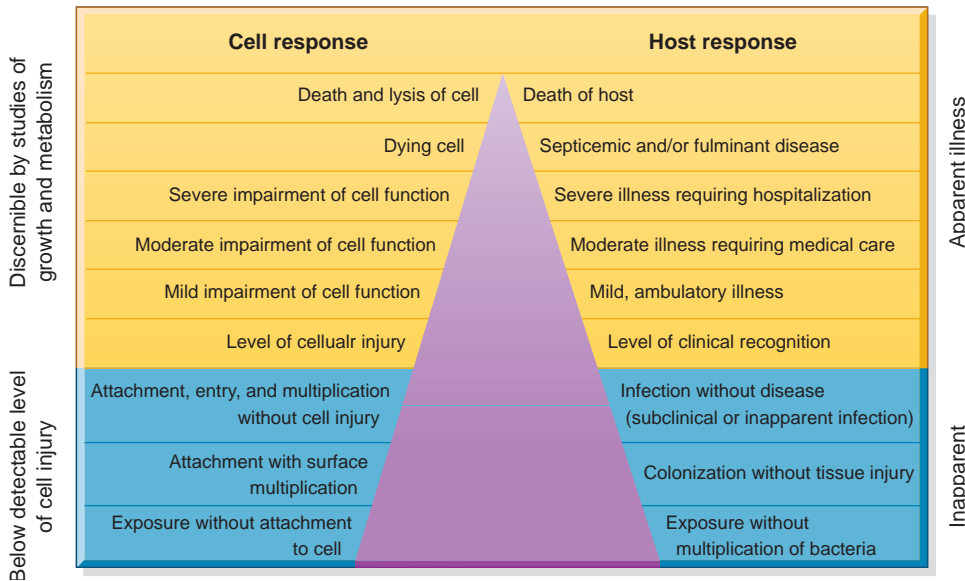

Figure 70-2 Biologic spectrum of response to bacterial infection at the cellular level (*left*) and of the intact host (*right*). Redrawn from Evans, A. S. & Brachman, P. S. (1998). *Bacterial infections in humans*. New York: Plenum.

Colonization, Infection, and Infectious Disease

Relatively few anatomic sites (eg, brain, blood, bone, heart, vascular system) are sterile. Bacteria found throughout the body usually provide beneficial **normal flora** to compete with potential pathogens, to facilitate digestion, or to work in other ways symbiotically with the host.

Colonization

The term **colonization** is used to describe microorganisms present without host interference or interaction. Organisms reported in microbiology test results often reflect colonization rather than infection. The patient's health care team must interpret microbiology test results accurately to ensure appropriate treatment.

Infection

Infection indicates a host interaction with an organism. A patient colonized with *S. aureus* may have staphylococci on the skin without any skin interruption or irritation. However, if the patient has an incision, *S. aureus* could enter the wound, resulting in an immune system reaction of local inflammation and migration of white cells to the site. Clinical evidence of redness, heat, and pain and laboratory evidence of white blood cells on the wound specimen smear suggest infection. In this situation, the host identifies the staphylococci as *foreign*. Infection is recognized by the host reaction (manifested by signs and symptoms) and by laboratory-based evidence of white blood cell reaction and microbiologic organism identification.

Infectious Disease

It is important to recognize the difference between infection and infectious disease. **Infectious disease** is the state in which the infected host displays a decline in wellness due to the infection. When the host interacts immunologically with an organism but remains symptom free, the definition of infectious disease has not been met. For example, when a person is first infected with *M. tuberculosis*, infection can be

detected by a positive tuberculin skin test, which demonstrates immunologic recognition. Most people who are infected with *M. tuberculosis* have latent infection, but few people (approximately 10%) actually become ill and demonstrate symptoms of TB (fever, weight loss, and advancing pneumonia). Figure 70-2 depicts response to bacterial infection at the cellular level and at the host level.

The primary source of information about most bacterial infections is the microbiology laboratory report, which should be viewed as a tool to be used along with clinical indicators to determine if a patient is colonized, infected, or diseased. Microbiology reports from clinical specimens usually show three components: the smear and stain, the culture and organism identification, and the antimicrobial susceptibility (ie, sensitivity). As a marker for the likelihood of infection, the smear and stain generally provide the most helpful information because they describe the mix of cells present at the anatomic site at the time of specimen collection. Culture and sensitivity results specify which organisms are recognized and which antibiotics actively affect the bacteria.

Infection Control and Prevention

The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) are the principal agencies involved in setting guidelines about infection prevention. In recent years, attention to **health care–associated infections (HAIs)** has grown with increased input from the Joint Commission, the Institute for Healthcare Improvement (IHI), and Medicare.

The impact of infectious diseases changes over time as microorganisms mutate, as human behavior patterns shift, or as therapeutic options change. The CDC provides timely recommendations about many of the situations that a nurse may face when caring for or teaching a patient with an infectious disease. The CDC routinely publishes recommendations, guidelines, and summaries. Through its Internet site and its weekly journal, the *Morbidity and Mortality Weekly Report (MMWR)*, the CDC reports significant cases,

outbreaks, environmental hazards, or other public health problems. Examples of important CDC guidelines and summaries are *Guidelines for Preventing the Transmission of Tuberculosis in Health Care Facilities* (2005g), *Updated US Public Health Service Guidelines for the Management of Occupation as Exposure to HIV and Recommendations for Post Exposure Prophylaxis* (2005e), *Sexually Transmitted Diseases Treatment Guidelines* (2006b), and *Recommended Immunization Schedules for Persons Aged 0 Through 18 years United States, 2009* (2009d).

This chapter summarizes several aspects of infectious diseases. However, the field of infection control and prevention changes rapidly. Health care workers should seek the most current information when they address patient care concerns or develop infection control policies. Table 70-2 presents an overview of selected CDC Web sites.

Preventing Infection in the Hospital

Isolation Precautions

Isolation precautions are guidelines created to prevent transmission of microorganisms in hospitals. The Hospital Infection Control Practices Advisory Committee (HIC-PAC) of the CDC recommends two tiers of isolation precautions. The first tier, called Standard Precautions, is designed for the care of *all* patients in the hospital and is the primary strategy for preventing HAIs. The second tier, called Transmission-Based Precautions, is designed for care of patients with known or suspected infectious diseases spread by airborne, droplet, or contact routes.

Standard Precautions

The premise of **Standard Precautions** is that all patients are colonized or infected with microorganisms, whether or not there are signs or symptoms, and that a uniform level of caution should be used in the care of all patients. The health care worker should use additional barriers in the form of personal protective equipment (PPE), including masks, eye protection, and cover gowns, depending on the degree of expected exposure to patient excretions or secretions. The

elements of Standard Precautions include hand hygiene, use of PPE, proper handling of patient care equipment and linen, environmental control, prevention of injury from sharps devices, and patients' room assignments within health care facilities. Hand hygiene, glove use, needlestick prevention, and avoidance of splash or spray of body fluids are discussed in the following sections. Chart 52-4 in Chapter 52 describes the Standard Precautions in detail.

Hand Hygiene. The most frequent cause of infection outbreaks in health care institutions is spread of microorganisms by the hands of health care workers. Hands should be washed or decontaminated frequently during patient care.

Chart 70-1 • Hand-Hygiene Methods

Hand Decontamination With Alcohol-Based Product

- After contact with body fluids, excretions, mucous membranes, nonintact skin, or wound dressings as long as hands are not visibly soiled
- After contact with a patient's intact skin (as after taking pulse or blood pressure or lifting a patient)
- In patient care, when moving from a contaminated body site to a clean body site
- After contact with inanimate objects in the patient's immediate vicinity
- Before caring for patients with severe neutropenia or other forms of severe immune suppression
- Before donning sterile gloves when inserting central catheters
- Before inserting urinary catheters or other devices that do not require a surgical procedure
- After removing gloves

Handwashing

- When hands are visibly dirty or contaminated with biologic material from patient care
- When health care workers do not tolerate waterless alcohol product

Chart 70-1 describes the recommended hand-hygiene methods.

When hands are visibly dirty or contaminated with biologic material from patient care, hands should be washed with soap and water. In intensive care units and other locations in which virulent or resistant organisms are likely to be present, antimicrobial agents (eg, chlorhexidine gluconate, iodophor, chloroxylenol, and triclosan) may be used. Effective handwashing requires at least 15 seconds of vigorous scrubbing, with special attention to the area around nail beds and between fingers, where there is a high bacterial load. Hands should be thoroughly rinsed after washing.

If hands are not visibly soiled, health care providers are strongly encouraged to use alcohol-based, waterless antiseptic agents (eg, Avagard or Endure) for routine hand decontamination. These solutions are superior to soap or antimicrobial handwashing agents in their speed of action and effectiveness against microorganisms. Because they are formulated with emollients, they are usually better tolerated than other agents, and because they can be used without sinks and towels, health care workers have been found to be more compliant with their use. Nurses working in home health care or other settings where they are relatively mobile should carry pocket-size containers of alcohol-based solutions (Rhinehart & McGoldrick, 2005).

Normal skin flora usually consist of coagulase-negative staphylococci or diphtheroids. In the health care setting, workers may temporarily carry other bacteria (ie, **transient flora**) such as *S. aureus*, *Pseudomonas aeruginosa*, or other organisms with increased pathogenic potential. Generally, transient flora are superficially attached and are shed with hand hygiene and skin regeneration.

Hand hygiene reduces the bacterial load and decreases the risk of transfer to other patients. The Joint Commission has included hand hygiene as one of the national patient safety goals and focuses on this behavior in all surveys of health care facilities. All health care settings should have mechanisms to evaluate compliance with hand hygiene by all personnel who care for patients.

When providing patient care, nurses should not wear artificial fingernails or nail extenders because they have been epidemiologically linked to several significant outbreaks of infections. Natural nails should be kept less than 0.25 inches (0.6 cm) long, and nail polish should be removed when chipped because it can support increased bacterial growth (CDC, 2002a).

Glove Use. Gloves provide an effective barrier for hands from the microflora associated with patient care. Gloves should be worn when a health care worker has contact with any patient secretions or excretions and must be discarded after each patient care contact. Because microbial organisms colonizing health care workers' hands can proliferate in the warm, moist environment provided by gloves, hands must be washed or disinfected after gloves are removed. As patient advocates, nurses have an important role in promoting hand hygiene and glove use by other hospital workers, such as laboratory personnel, technicians, and others who have contact with patients.

Compared with vinyl gloves, latex or nitrile gloves are preferred because they resist puncture better and provide

greater comfort and fit. Latex gloves have been improved to reduce the incidence of latex hypersensitivity, but some workers continue to experience local skin irritation or more severe reactions, including generalized dermatitis, conjunctivitis, asthma, angioedema, and anaphylaxis (see Chapter 53). The nurse who experiences irritation or an allergic reaction associated with exposure to latex should report symptoms to an occupational health specialist or a physician.

Needlestick Prevention. The most important aspect of reducing the risk of bloodborne infection is avoidance of percutaneous injury. Extreme care is essential in all situations in which needles, scalpels, and other sharp objects are handled. Used needles should not be recapped. Instead, they are placed directly into puncture-resistant containers near the place where they are used. If a situation dictates that a needle must be recapped, the nurse must use a mechanical device to hold the cap or use a one-handed approach to decrease the likelihood of skin puncture. Since 2001, the Occupational Safety and Health Administration (OSHA) has required use of needleless devices and other instruments designed to prevent injury from sharps when appropriate.

Avoidance of Splash and Spray. When the health care provider is involved in an activity in which body fluids may be sprayed or splashed, appropriate barriers must be used. If a splash to the face may occur, goggles and a face mask are warranted. If the health care worker is involved in a procedure in which clothing may be contaminated with biologic material, a cover gown should be worn.

Transmission-Based Precautions

Some microbes are so contagious or epidemiologically significant that precautions in addition to the Standard Precautions should be used when such organisms have been identified. The CDC recommends a second tier of precautions, called **Transmission-Based Precautions**. The isolation categories are Airborne, Droplet, and Contact Precautions (Siegel, Rhinehart, Jackson, et al., 2007).

Airborne Precautions are required for patients with presumed or proven pulmonary TB, chickenpox, or other airborne pathogen. Airborne Precautions would also be advised if a patient were infected with smallpox (eg, as a result of a bioterrorist attack). When hospitalized, patients should be in airborne infection isolation rooms (AIIR), engineered to provide negative air pressure, rapid turnover of air, and air either highly filtered or exhausted directly to the outside. Health care providers should wear an N-95 respirator (ie, protective mask) at all times while in the patient's room.

Droplet Precautions are used for organisms such as influenza or meningococcus that can be transmitted by close respiratory or mucous membrane contact with respiratory secretions. While taking care of a patient requiring Droplet Precautions, the nurse should wear a face mask, but because the risk of transmission is limited to close contact, the door may remain open.

Contact Precautions are used for organisms that are spread by skin-to-skin contact, such as antibiotic-resistant organisms or *Clostridium difficile*. Contact Precautions are designed to emphasize cautious technique and the use of barriers for organisms that have serious epidemiologic consequences or those easily transmitted by contact between health care

Chart 70-2 • Summary of Types of Precautions and Patients Requiring the Precautions**Standard Precautions**

Use Standard Precautions for the care of all patients.

Airborne Precautions

In addition to Standard Precautions, use Airborne Precautions for patients known or suspected to have serious illnesses transmitted by airborne droplet nuclei. Examples of such illnesses include the following:

- Measles
- Varicella (including disseminated zoster)*
- Tuberculosis

Droplet Precautions

In addition to Standard Precautions, use Droplet Precautions for patients known or suspected to have serious illnesses transmitted by large particle droplets. Examples of such illnesses include:

- Invasive *Haemophilus influenzae* type b disease, including meningitis, pneumonia, epiglottitis, and sepsis
- Invasive *Neisseria meningitidis* disease, including meningitis, pneumonia, and sepsis
- Other serious bacterial respiratory infections spread by droplet transmission, including:
 - Diphtheria (pharyngeal)
 - Primary atypical pneumonia (*Mycoplasma pneumoniae*)
 - Pertussis
 - Pneumonic plague
 - Streptococcal (group A) pharyngitis, pneumonia, or scarlet fever in infants and young children
- Serious viral infections spread by droplet transmission, including:
 - Adenovirus*
 - Influenza
 - Mumps
 - Parvovirus B19
 - Rubella

Contact Precautions

In addition to Standard Precautions, use Contact Precautions for patients known or suspected to have serious illnesses easily transmitted by direct patient contact or by contact with items in the patient's environment. Examples of such illnesses include:

- Gastrointestinal, respiratory, skin, or wound infections or colonization with multidrug-resistant bacteria judged by the infection control program, based on current state, regional, or national recommendations, to be of special clinical and epidemiologic significance
- Enteric infections with a low infectious dose or prolonged environmental survival, including:
 - Clostridium difficile*
 - For diapered or incontinent patients: enterohemorrhagic *Escherichia coli* O157:H7, *Shigella* species, hepatitis A, or rotavirus
- Respiratory syncytial virus, parainfluenza virus, or enteroviral infections in infants and young children
- Skin infections that are highly contagious or that may occur on dry skin, including:
 - Diphtheria (cutaneous)
 - Herpes simplex virus (neonatal or mucocutaneous)
 - Impetigo
 - Major (noncontained) abscesses, cellulitis, or pressure ulcers
 - Pediculosis
 - Scabies
 - Staphylococcal furunculosis in infants and young children
 - Zoster (disseminated or in the immunocompromised host)*
- Viral and hemorrhagic conjunctivitis
- Viral hemorrhagic infections (Ebola, Lassa, or Marburg)

*Certain infections require more than one type of precaution. From Centers for Disease Control and Prevention, Atlanta, GA, 2007.

worker and patient. When possible, the patient requiring contact isolation is placed in a private room to facilitate hand hygiene and decreased environmental contamination. Masks are not needed, and doors do not need to be closed (Chart 70-2).

Specific Organisms with Health Care–Associated Infection Potential**Clostridium Difficile**

This spore-forming bacterium has significant HAI potential. A more virulent strain has affected health care facilities throughout North America in the past several years, and rates of *C. difficile* infection increased significantly in the United States since 2000 (McDonald, 2007). Infection is usually preceded by antibiotics that disrupt normal intestinal flora and allow the antibiotic-resistant *C. difficile* spores to proliferate within the intestine. The organism causes pathology by releasing toxins into the lumen of the bowel. In pseudomembranous colitis, the most extreme form of *C. difficile* infection, debris from the injured lumen of the bowel and from white

blood cells, accumulates in the form of pseudomembranes or studded areas of the colon. The destruction of such a large anatomic area can produce profound sepsis.

Because antibiotics are used so extensively in health care settings, many patients are at risk for infection with *C. difficile*. The potential for health care–associated acquisition is increased because the spore is relatively resistant to disinfectants and can be spread on the hands of health care providers after contact with equipment previously contaminated with *C. difficile*. Control is best achieved by using Contact Precautions for infected patients, with use of gowns and gloves for all patient contact. Because the spores are resistant to alcohol, waterless hand products are not as effective as handwashing with soap and water for use in hand hygiene. Bleach-based solutions and cleaning products are preferred over other hospital disinfectants for environmental cleaning. Frequently touched equipment (such as the overbed table and side rails) should be cleaned daily and whenever visibly soiled. IV poles and other peripheral items should be cleaned when the patient is discharged.

Methicillin-Resistant *Staphylococcus Aureus*

Methicillin-resistant *Staphylococcus aureus* (MRSA), a common human pathogen, refers to *S. aureus* that is resistant to methicillin or its comparable pharmaceutical agents, oxacillin and nafcillin. Soon after penicillin was discovered in the 1940s, *S. aureus* became all but universally penicillin resistant. Alternative therapies in the form of cephalosporins and synthetic penicillin solutions such as methicillin were introduced. However, since the late 1970s, MRSA became increasingly more prevalent, and transmission within hospitals and nursing homes is well documented. In the past 10 years, MRSA has also been found in otherwise healthy people who have not been in health care settings (CDC, 2006a).

Health Care–Associated MRSA. Health care providers transmit MRSA to patients easily because *S. aureus* has an affinity for skin colonization. The patient who is colonized with MRSA has an increased probability of developing health care–associated MRSA (HA-MRSA), especially when invasive procedures, such as IV therapy, respiratory therapy, or surgery are performed. The colonized patient also serves as a reservoir of MRSA that can be transmitted to others. HA-MRSA may persist as normal flora in the patient for an extended time. From the early 1990s to 2003, the proportion of MRSA in *S. aureus* samples grew from approximately 20% to approximately 60% (CDC, 2006a).

Community-Associated MRSA. MRSA is not limited to health care facilities, and in recent years there has been a significant increase in the incidence of MRSA infections in children, members of sports teams, prison inmates, and in other people who have no apparent health care exposure. These **community-associated MRSA (CA-MRSA)** infections are typically caused by strains of *S. aureus* that are molecularly distinct from HA-MRSA. The CA-MRSA strains typically produce more toxins than HA-MRSA, and localized skin symptoms can lead to necrotizing fasciitis or bacteremia (Weber, 2005). Often, skin symptoms are initially mistaken for spider or bug bites. CA-MRSA infections have resulted in serious skin and soft tissue infections, pneumonia, and, in rare cases, death. Once introduced into a health care facility, the virulent CA-MRSA strains can be transmitted to other patients in a manner typically associated with HA-MRSA (Gonzalez, Rueda, Shelburne, et al., 2006).

Control of MRSA in Health Care Facilities. The CDC recommends Contact Precautions for patients with MRSA colonization or infection. In recent years, there has been a growing debate about the benefits of active surveillance cultures to determine unrecognized carriers. In active surveillance, asymptomatic patients are cultured routinely (on admission or on a regular basis) to determine unrecognized carriers. Although the epidemiologic evidence does not clearly indicate whether this strategy reduces patient risk, a growing number of states have mandated this approach (Milstone & Perl, 2008). Nurses who participate in active surveillance programs must be prepared to educate patients and their families about the definitions of colonization and infection and the reason for the vigorous isolation efforts.

Vancomycin (Vancocin) and linezolid (Zyvox) are typically the preferred treatments for serious MRSA infection. However, there is concern that MRSA will eventually be-

come resistant to even these medications because they are used so commonly. Since 2002, a very small but disturbing number of patients have been diagnosed with *S. aureus* infections that are completely resistant to vancomycin (ie, **vancomycin-resistant *Staphylococcus aureus* [VRSA]**). Researchers have also noted decreased efficacy of vancomycin both in the laboratory and in clinical settings (Wang, Hindler, Ward, et al., 2006). The threat of VRSA is considered a very serious public health concern because of the commonality and pathogenicity of *S. aureus*. Without effective antibiotics, many patients with *S. aureus* infections would have a poor outcome (CDC, 2002b). Control of MRSA is an important goal, and it may also make the emergence of VRSA strains less likely.

Vancomycin-Resistant *Enterococcus*

Vancomycin-resistant *Enterococcus* (VRE) is the second most frequently isolated source of HAIs in the United States. This gram-positive bacterium, which is part of the normal flora of the gastrointestinal tract, can produce significant disease when it infects blood, wounds, or the urinary tract.

Enterococcus has several traits that make it an easily transmittable HAI organism. It is a normal part of the gastrointestinal flora of the host; it is bile resistant and able to withstand harsh anatomic sites, such as the intestine; and it persists well on the hands of health care providers and on environmental objects.

As a relatively resistant organism at baseline, therapy for *Enterococcus* is limited to penicillin formulations (eg, ampicillin), vancomycin in combination with an aminoglycoside (eg, gentamicin), or linezolid (Zyvox). Between 1994 and 2003, the CDC recorded an increase of more than 62% in the number of cases of VRE infections in patients in intensive care units (CDC, 2004b). This rapid increase has serious implications. Because many strains of VRE are resistant to all other antimicrobial therapies, clinicians are left with few choices for effective therapy. Equally important, VRE colonization and infection may serve as a reservoir of vancomycin-resistant coded genes that may be transferred to the more virulent *S. aureus* (CDC, 2002b).

Multidrug-Resistant Gram-Negative Organisms

During the past several decades, the incidence of infections caused by multidrug-resistant gram-negative organisms has also increased significantly. Extensive use of antibiotics induces resistance. The bacteria that most commonly develop resistance include *P. aeruginosa* (resistant to fluoroquinolone antibiotics and/or carbapenems), *Acinetobacter* species (resistant to many antibiotics, including carbapenems), and both *Klebsiella pneumoniae* and *Escherichia coli* (resistant to extended-spectrum beta-lactam antibiotics). These pathogens are also associated with outbreaks in health care facilities. Transmission has been associated with contamination of equipment and with transfer via the hands of health care workers (CDC, 2002b).

Preventing Health Care-Associated Bloodstream Infections (Bacteremia and Fungemia)

Reducing the risk of health care–associated bloodstream infections requires preventive activities in addition to the Standard Precautions. If a health care–associated

Chart 70-3 • Conditions That Suggest the Presence of Health Care–Associated Vascular Access Device–Related Bacteremia or Fungemia

- The patient has catheter in place, appears septic, but has no obvious reason to suggest predisposition to sepsis.
- There is no infection at another body site to indicate probable source of sepsis.
- The site of vascular line insertion is red, swollen, or draining (especially purulent drainage).
- The patient has a central vascular line in place at the onset of sepsis.
- The bloodstream infection is caused by *Candida* species or by common skin organisms such as coagulase-negative staphylococci, *Bacillus* species, or *Corynebacterium* species.
- The patient remains septic after appropriate therapy without removal of the vascular access device.

bloodstream infection occurs, early diagnosis is important to prevent complications, such as endocarditis and brain abscess. Mortality rates associated with infection by some organisms are estimated to average 18%. The estimated cost attributed to catheter-related bloodstream infections ranges from \$12,000 to \$54,000 per case (Pronovost, Needham, Berenholtz, et al., 2006).

Bacteremia is defined as the laboratory-confirmed presence of bacteria in the bloodstream. **Fungemia** is a bloodstream infection caused by a fungal organism. Any vascular access device (VAD) can serve as the source for a bloodstream infection. Most hospitalized patients receive VADs, and increasingly, long-term central catheters are used to provide IV therapy to outpatients in clinic or home settings. In all instances, the nurse must use appropriate care to reduce the risk of bacteremia and to be alert for signs of bacteremia. Chart 70-3 identifies conditions that suggest the presence of health care–associated VAD-related bacteremia or fungemia.

Hand hygiene and strict attention to aseptic technique are essential during the insertion of all VADs. Health care personnel who insert central catheters should use surgical technique, including sterile gloves, sterile gowns with long sleeves, masks, and a large drape over the patient.

Disinfecting Skin

The patient's own flora, traversing the exterior of a peripherally inserted catheter or contaminating the central catheter hub, is the most common bacterial source of catheter-related bacteremia (CDC, 2002b). Rarely, IV fluid itself can become contaminated and serve as a source of infection. The preferred solution for disinfection of the insertion site is chlorhexidine gluconate (CHG, Hibiclens). Alternative solutions are povidone-iodine (Betadine) or alcohol.

There is no apparent difference in risk or benefit when comparing transparent polyurethane dressings and gauze dressings. However, if blood is oozing from the catheter insertion site, a gauze dressing should be used. Most importantly, the dressing should be applied using aseptic technique and should be sealed along its entire perimeter. A highly absorbent CHG-impregnated dressing (Biopatch

Antimicrobial Dressing), which releases disinfectant for up to 7 days, may be used to reduce risk in patients older than 2 months of age (Marschall, Mermel, Classen, et al., 2008).

Changing Infusion Sets, Caps, and Solutions

Infusion sets and stopcock caps should be changed no more frequently than every 3 days, unless an infusion set is used for the delivery of blood or lipid solutions. Infusion sets and tubing for blood, blood products, or lipid emulsions should be changed within 24 hours of initiating the infusion. Blood infusions should finish within 4 hours of hanging the blood; lipid solutions should be completed within 24 hours of hanging. There are no guidelines for the appropriate intervals for the hang time of other solutions. Injection ports should be cleaned with 70% alcohol or iodophor before accessing the system (CDC, 2002b).

Preventing Infection in the Community

The CDC and state and local public health departments share responsibility for prevention and control of infection in the community. Methods of infection prevention include sanitation techniques (eg, water purification, disposal of sewage and other potentially infectious materials), regulated health practices (eg, the handling, storage, packaging, and preparation of food by institutions), and immunization programs. In the United States, immunization programs have markedly decreased the incidence of infectious diseases.

Vaccination Programs

The goal of vaccination programs is to use wide-scale efforts to prevent specific infectious diseases from occurring in a population. Public health decisions about vaccination efforts are complex. Risks and benefits for the person and the community must be evaluated in terms of morbidity, mortality, and financial cost and benefit. The most successful vaccine programs have been ones for the prevention of smallpox, measles, mumps, rubella, polio, diphtheria, pertussis, and tetanus. Table 70-3 demonstrates this success.

More than 25 vaccines are currently licensed in the United States. Vaccines are suspensions of antigen preparations, intended to produce a human immune response to protect the host from future encounters with the organism. Because no vaccine is completely safe for all recipients, contraindications on package inserts of a vaccine must be heeded. These guidelines provide details about studied experiences with allergy and other complications and provide crucial information about refrigeration, storage, dosage, and administration. The most common adverse effects are allergic reaction to the antigen or carrier solution and the occurrence of the actual disease (often in modified form) when live vaccine is used.

The standard recommended immunization schedules for adults as developed by the CDC can be found at the CDC Web site (2009b). The schedule is revised as epidemiologic evidence warrants; nurses should consult the CDC to determine the most recent schedule. Variations to the recommended immunization schedule should be made on a case-by-case basis, depending on the patient's risk factors. The recommended vaccines for adults are designed to protect those with underlying diseases that increase infection risk, those with potential for occupational exposure, and those

Table 70-3 IMPACT OF VACCINES IN THE TWENTIETH AND TWENTY-FIRST CENTURIES

Disease	20th-Century Annual Morbidity	2006 Total	% Decrease
Smallpox	48,164	0	100
Diphtheria	175,885	0	100
Pertussis	147,271	15,632	89
Tetanus	1314	41	97
Polio (paralytic)	16,316	0	100
Measles	503,282	55	>99.9
Mumps	152,209	6,584	96
Rubella	47,745	11	>99.9
Congenital rubella	823	1	88.8
<i>Haemophilus influenzae</i> (<5 years)	20,000 (EST)	208 (serotype b or unknown)	99

Centers for Disease Control and Prevention. (2008). Atkinson, W., Hamborsky, J., McIntyre, L., et al. (Eds.). *Epidemiology and prevention of vaccine-preventable diseases* (10th ed. 2nd printing). Washington DC: Public Health Foundation.

who may be exposed to infectious agents during travel. Immunosuppressed adults (including those who have had a splenectomy) should be vaccinated for pneumococcus (*Streptococcus pneumoniae*) and meningococcus (*Neisseria meningitidis*). Health care workers should be immune to measles, mumps, rubella, pertussis, tetanus, hepatitis B, and varicella. An annual influenza vaccine is recommended for people with chronic conditions such as immune suppression, asthma, and cardiac or respiratory diseases, as well as for all health care workers and for people 65 years of age and older.

The CDC (2009a) gives information about individual vaccines and vaccine-preventable diseases. It also provides a 24-hour telephone hotline (see Resources below) for routine pediatric or adult vaccine advice. Advice about optimal vaccinations for travelers is also available at the CDC (2006d) Web site and by phone (see Resources).

The incidence of vaccine-preventable diseases, such as measles, mumps, rubella, and diphtheria, is affected by immigration from developing countries. Vaccine campaigns in developing countries are often financially and logistically constrained, and immigrants from such areas may be more likely than U.S. residents to be unprotected. Individual risk and epidemic risk are reduced when vaccination campaigns reach all communities, including those with a high proportion of immigrants.

Common Vaccines

Measles, Mumps, and Rubella Vaccine. Since the measles, mumps, and rubella (MMR) vaccines were licensed, endemic rubella has been eliminated in the United States (CDC, 2005a), and mumps and rubella have decreased by more than 99%. To maintain this effective public health strategy, routine MMR vaccination should be administered to children at 12 to 15 months of age, with repeat dosing at 4 to 6 years of age (CDC, 2007a).

Patients should be advised that fever, transient lymphadenopathy, or hypersensitivity reaction might occur following an MMR vaccination. The risk of side effects is greater in vaccine recipients who have not previously received the vaccine than in those who have received repeat doses. Antipyretics may be used to decrease the risk of fever.

Varicella (Chickenpox) Vaccine and Zoster (Shingles) Vaccine. Varicella zoster is the virus that causes chicken-

pox and herpes zoster. In its natural state, the varicella virus often attacks children, causing disseminated disease in the form of chickenpox. Although the incidence of varicella is lower in adults, the severity of chickenpox and possible sequelae, including death, is substantially greater (CDC, 2007a). Transmission occurs by the airborne and contact routes. With rare exception, varicella infects a person only once. The incubation period is about 2 weeks (range, 10 to 21 days). During a prodrome of general malaise (often noticed about 2 days before the rash develops), the newly infected host is capable of transmitting the virus to other susceptible contacts. Typically, the vesicular, pustular rash spreads rapidly from few too many lesions in a matter of hours. New lesions continue to form for 2 to 3 days and appear at different stages throughout this time. By the fourth symptomatic day, the lesions begin to dry, and new lesions usually do not develop. Fever is common during the 4 to 6 days of rash progression. When the lesions have crusted, the patient is no longer contagious.

Between 1995, when the varicella vaccine was first licensed in the United States, and 2004, the incidence of chickenpox decreased by 83% to 93%. The vaccine is effective in preventing chickenpox in approximately 70% to 90% of people who receive vaccinations, and it is 90% to 100% effective in preventing severe varicella (CDC, 2007a). The vaccine should not be given to those who have depressed immune function, are pregnant, have received blood products in the past 6 months, or have demonstrated allergy to varicella vaccine.

Herpes zoster, also known as shingles, is a painful, localized rash caused by recurrent varicella. Vesicles are restricted to areas supplied by single associated nerve groups. Varicella may be transmitted from the rash of those with shingles to people who are susceptible to varicella; the new varicella infections are manifested as chickenpox. It is estimated that more than 50% of unvaccinated people who live to at least 85 years of age will develop shingles.

In 2006, the Food and Drug Administration approved Zostavax, a vaccine to reduce the risk of shingles. The vaccine is recommended for people older than 60 years of age because it reduces the risk of shingles by approximately 50% in those people (CDC, 2007a).

Influenza Vaccine. Influenza is an acute viral respiratory disease that predictably and periodically causes worldwide epidemics known as pandemics. Epidemics occur every 2 to 3 years, with a highly variable degree of severity. An estimated 36,000 deaths per year are attributed to influenza or its sequelae (ie, pneumonia, cardiopulmonary collapse). Elderly people are more susceptible to influenza, and the incidence of the disease in the United States is increasing as the proportion of the elderly increases (CDC, 2007a).

Each year a new vaccine is composed of the three virus strains (two type A influenza strains and one type B influenza strain) considered most likely to occur in the coming season. If the correct influenza agents have been included in that year's vaccine, the vaccine offers approximately 70% to 90% protection for healthy children and adults younger than 65 years of age. Although less effective in preventing disease in the elderly, it decreases the severity of illness in those who become infected. In extended care facilities, the vaccine is approximately 80% effective in preventing death and 50% to 60% effective in preventing hospitalization (CDC, 2007a). The vaccine is administered as an injection with inactivated virus or as a nasal spray with live attenuated virus.

The Advisory Committee for Immunization Practices of the Public Health Service recommends annual influenza vaccinations for the following groups: people older than 50 years of age, children 6 to 59 months of age, pregnant women, residents of extended care facilities, and those with chronic medical diseases or disabilities. In addition, health care providers and household members of those in high-risk groups should receive the vaccine to reduce the risk of transmission to people vulnerable to influenza sequelae. Vaccine campaigns in health care workers and patients should be intensified when there is evidence of community influenza.

Reporting Problems With Vaccines

Nurses should ask parents or adult vaccine recipients to provide information about any problems encountered after vaccination. As mandated by law, a Vaccine Adverse Event Reporting System (VAERS) form must be completed with the following information: type of vaccine received, timing of vaccination, onset of the adverse event, current illnesses or medication, history of adverse events after vaccination, and demographic information about the recipient. Forms are obtained by telephone or via the Internet (see Resources section) and can be submitted online.

Contraindications to Vaccines

Patients who have developed encephalopathy within 7 days of a previous diphtheria, tetanus, and pertussis dose and those who have developed anaphylaxis or other moderate or severe sequelae after a previous dose should not receive further doses. Diphtheria, tetanus, and acellular pertussis (DTap) is often deferred for the child who previously developed a fever higher than 40.5°C (105°F) within 48 hours of vaccination or who had a seizure or developed a shocklike state within 3 days of previous vaccination. Some live vaccines (eg, varicella, MMR, yellow fever) are contraindicated for people who are severely immunosuppressed or who are pregnant. All decisions about vaccination should be made by the patient's primary health care provider after careful review of vaccine-specific contraindications.

Planning for an Influenza Pandemic

A pandemic is a global outbreak of a disease. For example, influenza caused three pandemics in the 20th century. In the United States, the pandemic influenza caused more than 500,000 deaths in the 1918 "Spanish flu" pandemic, about 70,000 deaths in 1957 in the "Asian flu" pandemic, and about 34,000 deaths in 1968 in the "Hong Kong flu" pandemic. In June 2009, the WHO announced that a novel influenza virus, H1N1 had reached pandemic proportion. At the time of this printing, the extent of the H1N1 pandemic cannot be characterized, but its rapid dissemination worldwide with sustained human to human transmission in many locations was well recognized.

Subtypes of influenza viruses have pandemic potential because they constantly change within animals and secondarily within humans. As a result of these changes, essentially new viruses can "emerge" and can expose entire populations who are immunologically unprotected.

Influenza pandemics are likely to be more catastrophic than other anticipated public health problems because they last longer than other emergency events, they often occur in "waves," they deplete the available health care workforce, and they reduce the supply of medical equipment because of their widespread nature. The frequency and severity of pandemics cannot be accurately predicted, but models suggest that a medium-intensity pandemic could cause more than 200,000 deaths in the United States and quickly overwhelm the existing health care infrastructure. The CDC encourages all health care institutions to have a pandemic plan and to test the components of the plan regularly. A tool to help estimate the number of hospitalizations that will occur, the need for intensive care unit beds, and the need for ventilators can be found at <http://www.cdc.gov/flu/fluurge.htm>.

Avian Influenza Pandemic

Avian influenza (bird flu) is an infection caused by influenza viruses that chiefly infect birds and poultry. The H5N1 strain (named for the characteristics of the viral surface proteins hemagglutinin and neuraminidase) is of particular concern. It has caused a number of outbreaks in poultry since 2003, and the problem is ongoing; flocks of migratory birds have rapidly disseminated the virus throughout much of the world. Although many avian influenza viruses are natural and nonpathogenic in birds, H5N1 is unusual because of its high mortality rate in birds and because it has shown a limited ability to be transmitted from a bird source to mammals, including humans. The human mortality rate from H5N1 avian influenza has been more than 60% (WHO, 2008a). The majority of human cases of H5N1 are attributed to direct contact with poultry, but there are rare instances that suggest occasional human-to-human transmission.

Scientists are especially concerned that avian influenza H5N1 may change, either through mutation or reassortment, to become easily transmitted from human to human. If H5N1 were easily transmissible to humans, it would be likely to cause a severe pandemic because the human population has no immunity to the virus and because development of an appropriate vaccine would take too long to effectively stop the pandemic (U.S. Department of Health and Human Services [USDHHS], 2008).

The symptoms associated with H5N1 avian influenza in humans have ranged from the symptoms typically seen with seasonal influenza (cough, fever, and muscle aches) to severe pneumonia and multiorgan failure. Influenza antiviral therapy (ie, oseltamivir [Tamiflu] and zanamivir [Relenza]) is stockpiled as part of a national strategy, with hopes that they would be effective in treating humans infected with the pandemic strain of H5N1. Simple infection control strategies using careful hand hygiene and masks will be especially important in an avian influenza pandemic. Health departments throughout the country are also planning how to implement isolation programs to keep symptomatic people away from schools and work places (USDHHS, 2008).

Home-Based Care of the Patient With an Infectious Disease

The nurse who cares for the patient with an infectious disease in the home should provide information about infection risk prevention to the patient, the family, and the caregiver (Chart 70-4). Recognizing that a health history may not identify all active or latent infections, the caregiver should carefully follow Standard Precautions in the home. The nurse should establish a work environment that facilitates hand hygiene and aseptic technique.

Family caregivers should receive an annual influenza vaccine. This is especially true if the caregiver or the patient is older than 50 years of age, has underlying cardiac or pulmonary disease, or has underlying immunosuppression.

Patients requiring home care are often people with immunosuppression from underlying conditions, such as HIV infection or cancer, or those who have treatment-induced immunosuppression, as occurs with many antineoplastic agents. Careful assessment for signs of infection is important.

Reducing Risk to the Patient

Equipment Care

All caregivers must pay careful attention to disinfection and aseptic technique while using medical equipment. Catheter-related sepsis should be suspected in a patient who has un-

explained fever, redness, swelling, and drainage around a vascular catheter insertion site. Indwelling urinary catheters should be discontinued whenever possible, because each day of use increases the risk of infection. The nurse should promptly report signs of urinary tract infection or of generalized sepsis to the patient's physician.

Patient Teaching

When assessing the risk of the immunosuppressed patient in the home environment for infection, it is important to realize that intrinsic colonizing bacteria and latent viral infections present a greater risk than do extrinsic environmental contaminants. The nurse should reassure the patient and family that their home needs to be clean but not sterile. Common-sense approaches to cleanliness and risk reduction are helpful.

For patients with neutropenia or T-cell dysfunction (eg, patients with acquired immunodeficiency syndrome [AIDS]), it is wise to restrict visits of people with potentially contagious illnesses. The patient who is severely neutropenic should not eat uncooked fruits and vegetables. The immunosuppressed patient is vulnerable to acquiring bacterial infection with enteric pathogens from food; therefore, family members should be reminded about the need to follow recommendations for hygiene and safe cooking times and temperatures.

Reducing Risk to Household Members

Establishing reasonable barriers to infection transmission in the household is an important part of home care. The route of transmission of the organism in question must first be determined. The nurse can then teach household members strategies to reduce their risk of becoming infected. If the patient has active pulmonary TB, the public health department should be contacted to provide screening and treatment for family members. If the patient has shingles (herpes zoster), family members who have had varicella vaccine or who have previously had chickenpox are considered immune and need no precautions. However, if a family member is immunosuppressed or otherwise susceptible to varicella, maintaining physical separation may be an important strategy during the time when the patient has draining

CHART
70-4

HOME CARE CHECKLIST

Prevention of Infection in the Home Care Setting

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate aseptic technique in the care of technical equipment such as intravenous catheter and indwelling urinary catheter.	✓	✓
• Demonstrate thorough hand hygiene after patient care. (Use alcohol-based disinfectant <i>or</i> handwashing.)	✓	✓
• Complies with antibiotic regimen (patient) or with completion of vaccination series (patient and caregiver).	✓	✓
• State the rationale for thoroughly cooking all foods and storing meat products separate from other food groups.	✓	✓
• Use separate eating utensils and towels.	✓	✓
• Avoid contact with someone who has a known infectious disease.	✓	✓

lesions. When the patient is infected with *Shigella*, *Salmonella*, *C. difficile*, hepatitis A, or other enteric organisms, the family should be reassured that common household disinfectants are effective in controlling environmental contamination.

Family members who assist in the care of a patient with a bloodborne infection such as HIV or hepatitis C can prevent transmission by carefully handling any sharp objects that are contaminated with blood. Family teaching may include discussion about the need for caution when shaving the patient; performing dressing changes; or administering any IV, intramuscular, or subcutaneous medication. To collect and dispose of used needles, syringes, and vascular access equipment, the family should use containers designed for sharps disposal. With the exception of TB, the opportunistic infections associated with AIDS do not usually pose a risk to the healthy family member. Family members should be reassured that dishes are safe to use after being washed with hot water and that linens and clothing are safe to use after being washed in a hot-water cycle.

Nursing Management

Assessment

The health history and physical examination and the use of diagnostic tests are important for determining the presence of infection and infectious diseases. Symptoms of infectious diseases vary significantly between and within diseases. For some infections, visible symptoms such as rash, redness, or swelling provide early warnings of infection. In other infections, such as TB and HIV, asymptomatic latency is prolonged, and infection must be determined through diagnostic procedures.

The history is obtained to establish the likelihood and probable source of infection as well as the degree of associated pathology and symptoms. The patient's previous medical record is reviewed when possible. In obtaining a health history, the following questions may be asked:

- Does the patient have a history of previous or recurrent infections?
- Has there been fever? How high has the patient's temperature been? Is the temperature constant, or does it rise and fall? Has fever been associated with chills? Has the patient taken any medication to relieve fever?
- Is there cough? Is the cough chronic or acute? Is it associated with shortness of breath? Does the cough produce sputum? Is the sputum bloody? Has the patient had a tuberculin skin test (TST) recently? If so, what were the results? Has the patient been given isoniazid (INH) prophylaxis for TB infection? Has the patient been treated for TB in the past?
- Is there pain? Where is the pain? What is the nature of the pain? Does the patient have a sore throat, headache, myalgias, or arthralgias? Is there pain on urination or other activity?
- Is there edema? Is there drainage associated with the edema? Is the edematous area warm to touch?
- Is there a draining lesion? Is the drainage associated with trauma or a previous procedure? Is the drainage purulent or clear?
- Does the patient have diarrhea, vomiting, or abdominal pain?

- Is there a rash? What is the nature of the rash—is it flat, raised, red, crusted, purulent, or lacelike? Has the patient taken medications that could induce rash? Has there been exposure to another person who has an identified infectious disease or rash?
- What is the patient's vaccination history?
- Has there been an insect or animal bite? Has there been an animal scratch or other exposure to pets, farm animals, or experimental animals?
- What medications are used? Have antibiotics been taken recently or long term? Is the patient being treated with corticosteroids, immunosuppressive agents, or chemotherapy?
- Has the patient been treated in the past for other infectious diseases? Has the patient been hospitalized for infectious diseases?
- If sexual history is pertinent, has there been sexual exposure to another person with a known sexually transmitted disease (STD)? Has the patient been treated for STDs in the past? Is the patient pregnant, or has she recently been pregnant? Has the patient been tested for HIV?
- Has the patient traveled abroad, including developing countries? What was the immunization or antimicrobial prophylaxis used for protection while traveling?
- What is the patient's occupation? What are the patient's recreational activities? Hobbies?

Because infection may occur in any body system, physical examination may reveal signs of infection at any body site. Generalized signs of chronic infection may include significant weight loss or pallor associated with anemia of chronic diseases. Acute infection may manifest with fever, chills, lymphadenopathy, or rash. Localized signs vary by source of infection. Purulent drainage, pain, edema, and redness are strongly associated with localized infection. Cough and shortness of breath may be caused by influenza, pneumonia, or TB, as well as many noninfectious causes.

Nursing Interventions

Preventing Infection Transmission

Preventing the spread of infection requires an understanding of the usual routes of transmission of the organism. The hospitalized patient may pose a contagious risk to others if the disease is easily spread (such as *C. difficile*) or is spread through an airborne route (such as TB). In these situations, strict adherence to isolation measures is important in reducing the opportunity for spread. Preventing transmission of organisms from patient to patient requires participation of the health care team. Transmission of organisms on the hands and gloves of health care workers remains a common source of cross-infection in the hospital or clinic setting.

Nurses serve an important role in preventing the transfer of organisms in two ways. First, as the health professionals who spend the most time with patients, nurses have a greater opportunity for spreading organisms. It is imperative that nurses disinfect their hands before and after contact with patients and after performing a potentially hand-contaminating activity. Hands must be disinfected each time gloves are removed. For example, the nurse who has performed endotracheal suctioning should remove the gloves, wash the hands,

and put on a new pair of gloves before performing wound care on the same patient. Second, nurses can reduce hand-to-hand spread of organisms by serving as patient advocates. To the degree feasible, the nurse should observe the hand-hygiene activities of other professionals and discuss with them any lapses in technique that are observed.

Teaching About the Infectious Process

Interruption of transmission requires diagnosis and patient compliance with the treatment regimen. The nurse's role is to educate the patient and, in some situations, to report the case to public health officials for contact tracing and verification of follow-up.

The nurse must stress the importance of immunization to parents of young children and to others for whom vaccines are recommended, such as patients who are elderly, are immunosuppressed, or have chronic illnesses or disabilities. Nurses should recognize their personal responsibility to receive the hepatitis B vaccine and an annual influenza vaccine to reduce potential transmission to themselves and vulnerable patient groups.

Infectious diseases often seem mysterious and frequently are socially stigmatizing. Patient teaching efforts require empathy and sensitivity. For example, in the past, TB was a stigmatizing disease. The nurse may need to provide basic information to the patient who needs INH prophylaxis to promote understanding and allay anxiety that the patient may feel.

Controlling Fever and Accompanying Discomforts

Fever must always be investigated to determine whether infection is the source. Evidence indicates that fever, mediated by the hypothalamus, may potentiate beneficial functions in the syndrome of reactions known as *acute-phase reaction*. These reactions include changes in liver protein synthesis; alterations in serum metals, such as iron; and increased production of certain classes of white blood cells and other cells of the immune system. Most fevers are physiologically controlled so that the temperature remains below 41°C (105.8°F). However, severe fever, as occurs with meningococcal meningitis, may cause heat stroke and other complications. Even milder fevers accompanied by fatigue, chills, and diaphoresis are often uncomfortable for the patient. Whether fever is treated or untreated, adequate fluid intake is important during febrile episodes.

NURSING ALERT

Because fever offers clues about infection severity and the success of antibiotic therapy, outpatients with fever should be taught to obtain accurate temperature readings. Frequently, family caregivers know that a patient has warm skin but do not disturb the patient by taking a temperature reading. Body temperature information can be very helpful in adjusting therapy or in reevaluating a preliminary diagnosis.

Monitoring and Managing Potential Complications

The patient with a rapidly progressive infectious disease should have vital signs and level of consciousness closely

monitored. X-ray findings and microbiologic, immunologic, hematologic, cytologic, and parasitologic laboratory values must be interpreted in the context of other clinical findings to assess the course of the infectious disease.

Antibiotic therapy is frequently complex, and modifications are necessary because of sensitivity test results and disease progression. To ensure therapeutic blood levels rapidly, antibiotic therapy should be initiated as soon as it is prescribed rather than waiting until routine medication scheduling times. The Plan of Nursing Care in Chart 70-5 describes nursing interventions for specific complications of infection.

Diarrheal Diseases

Diarrheal diseases, which are especially prevalent in the developing world, cause significant morbidity and mortality. It is estimated that diarrheal diseases kill more than 6,000 children per day in Asia, Africa, and Latin America. The most important cause of death associated with these diseases is dehydration, and the most important treatment that decreases death rates is rehydration therapy (Guerrant & Steiner, 2005).

In the United States, the epidemiology of diarrheal diseases is changing constantly. Water disinfection, pasteurization, and appropriate food packaging have decreased the incidence of diseases such as typhoid and cholera. However, importation of foreign foods, environmental and ecological changes, and changes in diagnostic test modalities have led to recognition of important new trends and outbreaks.

Transmission

The portal of entry of all diarrheal pathogens is oral ingestion. Although food is far from sterile, the high acidity of the stomach and the antibody-producing cells of the small bowel generally serve to decrease the potential of pathogens. Infection can occur when the infectious dose is high enough or if the food neutralizes the acidic environment. Decreased gastric acidity with disruption of normal bowel flora (as occurs after surgery), use of antimicrobial agents, and the immune dysfunction of AIDS all decrease intestinal defenses.

Causes

There are many bacterial, viral, and parasitic causes of diarrheal diseases. Common causes of bacterial infection include *E. coli* and *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia* species. The most significant viral causes of diarrhea are *Rotavirus*, which commonly results in diarrhea in young children, and *Calicivirus* (often called *Norovirus*), a virus associated with outbreaks in long-term care facilities and cruise ships. Parasitic infections of importance include *Giardia* and *Cryptosporidium* species and *Entamoeba histolytica*.

Campylobacter Infections

Campylobacter species are the most frequent cause of diarrheal disease worldwide. The bacterium, which is abundant in animal foods, is especially common in poultry but can also be found in beef and pork. Direct person-to-person transmission appears to be less common than it is for other enteric pathogens, such as *Shigella*. Guillain-Barré syndrome, a serious neurologic disorder characterized by

CHART
70-5

PLAN OF NURSING CARE
Care of the Patient With an Infectious Disease

NURSING DIAGNOSIS: Risk for infection transmission
GOAL: Prevention of transmission of infectious agents

Nursing Interventions

1. Prevent patient-to-patient infection spread.
 - a. Provide isolation according to CDC guidelines and Standard Precautions.
 - b. Ensure that patients with airborne infections remain in private rooms during hospital stay. If they must leave their rooms, arrangements should be made to decrease the likelihood of contact with other patients. Rooms should be ventilated according to CDC criteria. Personal protective equipment in the form of N95 respirators should be worn as indicated.

The N95 respirator is the minimal level of personal protection for tuberculosis control. The “N” indicates the filter resistance to oil aerosols; and the “95” indicates that the respirator has 95% effectiveness in filtering test particles.

In any care setting where patients may have increased risk for the sequelae of influenza, annual influenza vaccination should be encouraged for personnel and patients.
 - c. Ensure that patients with highly transmissible, nonairborne organisms such as *Clostridium difficile* and *Shigella* species are physically separated from other patients if hygiene or institutional policy dictates.
2. Prevent health care workers’ transfer of organisms from patient to patient.
 - a. Perform hand hygiene (by hand washing or by use of alcohol-based solution) consistently and thoroughly, disinfecting hands before and after each patient contact, and after procedures that offer contamination risk while caring for an individual patient.
 - b. Use gloves when handling any body fluid from any patient. Change gloves between patient care activities, and disinfect hands after gloves are removed.

Rationale

1. Organisms that are spread through an airborne route or are very contagious through direct contact can be transmitted in a health care setting.
 - a. CDC isolation strategies are developed to reduce the likelihood of transmission from patient to patient.
 - b. Engineering controls are important in the prevention of airborne diseases. Influenza vaccine safely reduces risk of illness associated with this highly communicable, and frequently virulent, condition.
 - c. Increased prevention strategies are needed when the organism has high epidemic potential.
2. Transfer of organisms on the hands of health care workers is a common route of transmission. Hospital organisms colonizing the hands of health care workers may be virulent.
 - a. Hand hygiene is important in reducing transient flora on outer epidermal layers of skin. Alcohol-based hand disinfectants are effective methods to reduce transient flora.
 - b. Gloves provide effective barrier protection. Gloves quickly become contaminated and then become a potential vehicle for the transfer of organisms between patients. Microflora on hands are likely to proliferate while gloves are worn.

Expected Outcomes

- No evidence of patient-to-patient transmission of infection
- No evidence of transmission via health care workers
- No occupationally acquired infections in nurses and other health care workers
- No evidence of transmission due to contaminated equipment
- Absence of bacteremia, septicemia, and sepsis
- Absence of urinary tract infections
- Absence of pneumonia

CHART
70-5

PLAN OF NURSING CARE

Care of the Patient With an Infectious Disease (Continued)

Nursing Interventions

3. Monitor intake and output and serum electrolyte levels.
4. Replace fluids as needed. If the patient can tolerate oral fluids, offer fluids every 2–4 hours. Administer intravenous fluids as prescribed.

Abscess Formation

1. Assess vascular access sites, wound sites, pressure ulcers, and other appropriate sites for apparent collections of purulent material.
2. Assess the patient who has had abdominal surgery or trauma to abdominal area for localized signs of intra-abdominal abscess. These signs include:
 - a. Low-grade fever
 - b. Elevated peripheral white blood cell count
 - c. Localized pain
 - d. Abdominal tenderness
 - e. Visible or palpable mass
 - f. Postoperative diarrhea
 - g. GI bleeding
3. Assess patient who has had percutaneous abscess drainage to determine whether drainage has been successful. Be alert for all of the above signs and symptoms.
4. Administer antibiotics as prescribed.

Endocarditis Prevention

1. Teach patients with the following conditions about the importance of antibiotic prophylaxis for events and procedures that may introduce the risk of endocarditis:
 - a. Valvular disease
 - b. Congenital heart disease
 - c. Intracardiac prosthesis
 - d. Previous endocarditis

Management

1. Obtain blood cultures as prescribed; carefully record results. Note persistent bloodstream infections with a particular organism.
2. Obtain a detailed history about the duration of fever in the absence of well-recognized cause.

Rationale

3. Dehydration produces a deficit in some electrolytes. Decreased urine production may indicate hypovolemia and decreased renal perfusion.
4. When possible, oral hydration is preferable because the patient can select the beverage, control the rate and interval of replacement, and care for self at home. Additionally, the risks associated with vascular devices are avoided. If intravenous fluid is required, intravenous solutions are selected to facilitate intestinal reabsorption of fluid and electrolytes.

1. Collections of purulent material often require drainage before antimicrobial therapy is effective.
2. Intra-abdominal abscess formation is most common following traumatic or surgical disruption of the GI tract. Signs are often initially subtle.
3. After percutaneous drainage, recurrent or persistent signs of abscess may indicate the need for surgical treatment.
4. Antibiotics, along with drainage, are the most important elements of intra-abdominal abscess management.

1. Patients with underlying valvular disease and other cardiac abnormalities are at increased risk for “seeding” of the cardiac valves during procedures that can cause bacteremia.
1. A definitive diagnosis of endocarditis requires blood culture confirmation.
2. Endocarditis should be suspected in patients who report an unexplained fever of more than 1 week’s duration

Expected Outcomes

- Absence of abscess
- Takes antibiotics as prescribed

- Informs health care professionals of cardiac conditions that require antibiotic prophylaxis before invasive procedures
- Takes prophylactic antibiotics as prescribed

- Endocarditis is diagnosed, treated, and cured

CHART
70-5

PLAN OF NURSING CARE

Care of the Patient With an Infectious Disease (Continued)

Nursing Interventions

- Administer intravenous antibiotic therapy at prescribed time schedule.

Rationale

- Intravenous therapy is usually required for cure. The goal of therapy is complete eradication of all organisms. Careful adherence to following the scheduled administration is therefore essential.

Expected Outcomes

Infectious Disease-Related Cancers and Infertility

These potential complications of infectious diseases are prevented by primary avoidance of infection. Management of them is directed toward treating each of them as a noninfectious entity. For example, the management of cancer secondary to hepatitis B is handled as an oncology issue, not as an infectious disease issue.

temporary paralysis, is a complication of approximately 1 of 1000 cases of *Campylobacter* infection.

Cooking and storing food at appropriate temperatures protects against *Campylobacter*. It is important that kitchen utensils used in meat preparation be kept away from other food to prevent *Campylobacter* transmission.

After a person is infected, the bacterium directly attacks the lumen of the intestine and may cause disease through enterotoxin release. Symptoms can range from mild abdominal cramping and minimal diarrhea to severe disease with profuse watery bloody diarrhea and debilitating abdominal cramping. Antimicrobial therapy is recommended only for patients who are seriously ill (CDC, 2005d).

Salmonella Infection

Salmonella is a gram-negative bacillus with many species, including the very pathogenic *Salmonella typhi* (ie, typhoid fever). Of the nontyphi species, most organisms are prevalent in animal food sources. *Salmonella* species contaminate over 30% of commercially available chicken products and are frequently found in eggs (intact and with broken shells), in turkeys, and occasionally in beef (U.S. Department of Agriculture [USDA], 2008). Most of the deaths caused by *Salmonella* enteritis occur in elderly nursing home residents because of their weakened immune systems (CDC, 2005d).

Variable symptoms are associated with *Salmonella* species infection, including an asymptomatic carrier state, gastroenteritis, and systemic infection. Diarrhea with gastroenteritis is common. Disseminated disease and bacteremia, sometimes accompanied by diarrhea, occur less often.

The person with *Salmonella*-caused diarrhea can on rare occasions be a source for transmission to others. The importance of good hygiene should be emphasized, and health care workers should use special care when handling bedpans, stool specimens, or other objects that may be contaminated with feces. Hand hygiene is imperative after any contact with a person with *Salmonella* diarrhea. Although patients with systemic salmonellosis require antimicrobial therapy, those with gastroenteritis only are not usually treated, because antibiotic use may increase the period of time that the patient carries the bacteria while not improving the clinical outcome.

Shigella Infection

The *Shigella* species is a gram-negative organism that invades the lumen of the intestine and causes disease and severe watery (possibly bloody) diarrhea. *Shigella* species are spread through the fecal-oral route, with easy transmission from one person to another. *Shigella* exhibits high levels of **virulence** (degree of pathogenicity of an organism); infection with a very small number of organisms can cause disease. Because transmission occurs easily with improper hygiene, it is not surprising that *Shigella* organisms disproportionately affect pediatric populations. Disease in the very young may infrequently be complicated by pulmonary or neurologic symptoms.

Antimicrobial therapy should be instituted early. Frequently, initial therapy choices must be altered when final microbiologic testing reveals the organism's sensitivity.

Escherichia coli

E. coli is the most common aerobic organism colonizing the large bowel. When *E. coli* bacteria are cultured from fecal specimens, the results usually reflect normal flora. However, certain strains of *E. coli* with increased virulence have been responsible for significant outbreaks of diarrheal disease in recent years. These stronger pathologic strains are subgrouped as enterotoxigenic *E. coli* (ETEC) because of their production of enterotoxins. ETEC strains often cause cholera-like disease, with rapid, severe dehydration and an increased risk of death.

Several outbreaks of an *E. coli* species, 0157:H7, have been linked to the ingestion of undercooked beef and to vegetables that have been contaminated by animal waste water. This bacterium lives in the intestines of cattle and can be introduced into meat at the time of slaughter. Prevention of disease from *E. coli* 0157:H7 is aimed at teaching the public to cook ground beef thoroughly (ie, until the meat is no longer pink and the juices run clear). During an important outbreak of *E. coli* 0157:H7 that resulted from contaminated spinach in 2006, spinach from an implicated packager was recalled. Consumers were advised to boil or fry fresh spinach if there was a concern that it might be from the contaminated area (CDC, 2006c).

Calicivirus (Norwalk-like Virus; Norovirus)

Calicivirus, which is often referred to as the Norwalk-like virus or the *Norovirus*, is a very common cause of foodborne illness. This agent has been associated with important diarrheal outbreaks in long-term care facilities, hospitals, and cruise ships. Onset of illness is usually acute, with vomiting and watery diarrhea that generally last for approximately 2 days. Dehydration is the most common complication.

Calicivirus is transmitted easily from person to person by direct contact and by ingesting contaminated food. Waterborne outbreaks have been associated with sewage-contaminated wells and contaminated swimming pools. Although people with *Calicivirus* infection typically recover within 2 to 3 days, they may continue to transmit the virus to others for approximately 2 more weeks.

Caliciviruses can withstand environmental extremes of heat or cold and are resistant to chemical disinfection, which are significant reasons for their epidemic potential. Control of *Calicivirus* in health care facilities requires a coordinated program with decisions about isolation, environmental disinfection, diagnosis, and coordination with public health officials. Contact Precautions should be used when caring for patients with incontinence and during outbreaks of the virus. Workers should wear masks if they are cleaning heavily soiled areas or caring for a patient who is actively vomiting. No Environmental Protection Agency (EPA)-approved disinfectants have specific claims about effectiveness for *Calicivirus*. Therefore, the CDC recommends that surface disinfection be accomplished with a freshly prepared solution of 1 part bleach to 50 parts water or with the peroxygen compound Virkon-S, which has been approved for feline *Calicivirus* and may be similarly effective for human viruses (CDC, 2005d).

Giardia Lamblia

Transmission of the protozoan *Giardia lamblia* occurs when food or drink is contaminated with viable cysts of the organism. People often become infected while traveling to endemic areas or by drinking contaminated water from mountain streams within the United States. The organism can be transmitted by close contact, such as occurs in day care settings. Transmission by sexual contact has also been documented.

Frequently, the infection goes unnoticed. Infection is often recognized more easily in children than in adults. In extreme cases, the patient may experience abdominal pain and chronic diarrhea, usually described as containing mucus and fat but not blood. Microscopic examination of stool specimens reveals the trophozoite or cyst stages of the parasitic life cycle.

Metronidazole (Flagyl) is commonly used to treat *Giardia*, but success rates for this and alternative therapies are inconsistent. Patients with *Giardia* infections should be instructed that the organism can be easily transmitted in family or group settings. Personal hygiene measures should be reinforced, and those who travel or camp where water is not treated and filtered should be advised to avoid local water supplies unless water is purified before drinking or using it in cooking.

Vibrio Cholerae

Although reported cases of cholera have been rare in the United States in recent decades, no discussion of infectious

diarrhea is complete without mention of this very serious infectious disease. Historically, epidemics of cholera have influenced all aspects of life—from medical to political—and infection rates have been significant enough to destroy governments and armies. Cholera is always a concern when wars or natural disasters result in inadequately processed waste water. *Vibrio cholerae* also may be found naturally in brackish rivers and coastal waters.

V. cholerae is a gram-negative organism with several different serotypes. The type usually associated with epidemics is toxigenic *V. cholerae* 01. The organism is transmitted by contaminated food or water. Most recent cases in the United States have been from contaminated shellfish found in the Gulf of Mexico or from contaminated shellfish brought into the United States by visitors. However, even though the incidence in other *Vibrio* species increased in the aftermath of Hurricane Katrina, in 2005, there were no cases of toxigenic *V. cholerae* 01 reported (CDC, 2005f).

Cholera causes disease with a very rapid onset of copious diarrhea in which up to 1 L of fluid per hour can be lost. Dehydration, with subsequent cardiopulmonary collapse, may cause rapid progression from onset of signs and symptoms to death. Rehydration efforts should be vigorous and sustained. If oral rehydration cannot be accomplished, the patient needs IV therapy.

In the United States, cholera should be suspected in patients who have watery diarrhea after eating shellfish harvested from the Gulf of Mexico. Confirmation of the causative organism can be made by stool culture. It is imperative that all cases are reported to local and state public health authorities. People traveling to areas where cholera occurs regularly should remember the simple rule of thumb: “boil it, cook it, peel it, or forget it.”

NURSING PROCESS

THE PATIENT WITH INFECTIOUS DIARRHEA

Assessment

The most important element of assessment in the patient with diarrhea is to determine hydration status. The goal of rehydration is to correct the dehydration. Assessment includes evaluation for thirst, dryness of oral mucous membranes, sunken eyes, a weakened pulse, and loss of skin turgor. Careful observation for these signs is especially important in cases of rapidly dehydrating diseases (most notably cholera) and in younger children.

Intake and output measurements are crucial in determining fluid balance. Liquid stool should be measured and recorded, along with the frequency of stools. It is important to note the consistency and appearance of stool as key indicators of the type and severity of the diarrheal disease. The presence of mucus or blood should also be documented.

When conducting a health history, the nurse asks if the patient has recently traveled, if the patient is being treated with antibiotics, if the patient has been in contact with anyone who has recently had diarrheal disease, and what the patient has recently eaten. Frequently, patients attribute the most recent meal eaten as the cause of symptoms. However, the incubation period for most diarrheal conditions is

longer than the time interval between meals, and the nurse needs to get detailed information about the meal preceding the illness and about all food intake in the previous 3 to 4 days. When eliciting this kind of history, it is helpful to ask the patient to list every food tasted. The nurse also asks the patient if he or she is employed in a food preparation service, because the local public health departments should be notified about any person with infectious diarrhea who works in the food industry.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Deficient fluid volume related to fluid lost through diarrhea
- Deficient knowledge about the infection and the risk of transmission to others

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include the following:

- Bacteremia
- Hypovolemic shock

Planning and Goals

The most important goals are maintenance of fluid and electrolyte balance, increased knowledge about the disease and risk of transmission, and absence of complications.

Nursing Interventions

Correcting Dehydration Associated With Diarrhea

The patient is assessed to determine the degree of dehydration and the amount and route of rehydration needed. Oral rehydration therapy is a strategy used to reduce the severe complications of diarrheal disease regardless of causative agent. It is inexpensive and effective for most patients, but it is often underused because of cultural beliefs discouraging oral intake during episodes of diarrhea. The World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF) recommend an oral rehydration solution (ORS) for the treatment of children and adults with dehydration and electrolyte imbalance associated with cholera and other forms of diarrheal disease. It contains (in millimoles per liter) sodium, 90; potassium, 20; chloride, 80; citrate, 10; and glucose, 111.

MILD DEHYDRATION. The patient exhibits dry oral mucous membranes of the mouth and increased thirst. The rehydration goal at this level of dehydration is to deliver about 50 mL of ORS per 1 kg of weight over a 4-hour interval.

MODERATE DEHYDRATION. Common findings are sunken eyes, loss of skin turgor, increased thirst, and dry oral mucous membranes. The rehydration goal at this level of dehydration is to deliver about 100 mL/kg of ORS over 4 hours.

SEVERE DEHYDRATION. The patient with severe dehydration shows signs of shock (ie, rapid thready pulse, cyanosis, cold extremities, rapid breathing, lethargy, or coma) and should receive IV replacement until hemodynamic and

mental status return to normal. When improvement is evident, the patient can be treated with ORS.

Administering Rehydration Therapy

Because diarrheal episodes are often accompanied by vomiting, rehydration and refeeding can be difficult. Oral rehydration therapy should be delivered frequently in small amounts. When patients are persistently vomiting, they often require frequent administration of fluids by spoonfuls. IV therapy is necessary for the patient who is severely dehydrated or in shock.

It is important for children and adults with acute diarrheal symptoms to maintain caloric intake. As soon as dehydration has been corrected, an age-appropriate, unrestricted diet is allowed. Recommended foods include starches, cereals, yogurt, fruits, and vegetables. Foods that are high in simple sugars, such as undiluted apple juice or gelatin, should be avoided.

NURSING ALERT

Sports drinks do not replace fluid losses correctly and should not be used.

Increasing Knowledge and Preventing Spread of Infection

Public health nurses, school nurses, and others who are involved in patient teaching should emphasize principles of safe food preparation, with special attention to meat preparation and cooking. Ground beef should be cooked until no longer pink, and all meat should be maintained at temperatures below 40°F or above 140°F. In planning events for groups of people, adequate provision for storage and reheating to temperature thresholds is important. When preparing food, it is important to use different surfaces, knives, and other equipment for meat and nonmeat items.

Diarrheal diseases discussed in this section must be reported to local or state health departments. The goal of reporting is to provide information for determining incidence trends and promptly identifying any restaurants or other food preparation establishments that have served contaminated food.

The need for rehydration and refeeding should be taught to parents of children with diarrheal disease. Beliefs about illness and food patterns may have a traditional or cultural basis, and any teaching of health facts requires cultural sensitivity.

In both homes and health care delivery settings, good hygiene and principles of Standard Precautions should be emphasized.

Monitoring and Managing Potential Complications

BACTEREMIA. *E. coli*, *Salmonella*, and *Shigella* are organisms that can enter the bloodstream and disseminate to other organs. Blood cultures are necessary in the acutely febrile patient with diarrhea. If initial smear results reveal gram-negative organisms, antibiotic therapy is instituted.

HYPOVOLEMIC SHOCK. Shock associated with diarrheal diseases demands accurate intake and output assessment and vigorous fluid replacement. In rare instances, patients

with severe fluid imbalance require intensive care nursing support with aggressive hemodynamic monitoring. For further information, see Chapter 15.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Attains fluid balance
 - a. Output approximates intake
 - b. Mucous membranes appear moist
 - c. Skin turgor is normal
 - d. Adequate amounts of fluids and calories ingested
 - e. Absence of vomiting
 - f. Stools are of normal color and consistency
2. Acquires knowledge and understanding about infectious diarrhea and transmission potential
 - a. Takes proper precautions to prevent spread of infection to others
 - b. Describes principles and techniques of safe food storage, preparation, and cooking
3. Absence of complications
 - a. Temperature is within normal range
 - b. Blood culture reports are negative
 - c. Fluid balance is achieved

Sexually Transmitted Diseases

An STD (also known as a sexually transmitted infection [STI]) is a disease acquired through sexual contact with an infected person. Table 70-4 identifies diseases that can be classified as STDs. Infections caused by organisms not generally considered STDs can also be transmitted during sexual contact; for example, *G. lamblia*, usually associated with contaminated water, can be transmitted through sexual exposure.

STDs are the most common infectious diseases in the United States and are epidemic in most parts of the world. Portals of entry of STD-causing microorganisms and sites of

infection include the skin and mucosal linings of the urethra, cervix, vagina, rectum, and oropharynx.

Approximately 19 million Americans become infected with STDs annually. STDs have severe health consequences. In addition, they represent a financial burden estimated to be as high as \$15.3 billion per year (CDC, 2009e). To determine the most effective methods for communicating information about STDs to people between 25 and 45 years of age (those who are most at risk for STDs), the CDC sought the help of focus groups. These groups proposed that using straightforward language and personal testimonials, developing materials for targeted audiences (eg, people who want information about protecting themselves), and conducting presentations in trusted establishments (eg, churches, health care facilities) might be effective. These suggestions could serve as a resource to all health care personnel who specialize in the prevention of STDs (CDC, 2004c).

Education about prevention of STDs includes information about risk factors and behaviors that can lead to infection. Included in this education is information about the relative value of condoms in reducing risk of infection. The use of condoms to provide a protective barrier from transmission of STD-related organisms has been broadly promoted, especially since the recognition of HIV/AIDS. At first referred to as a method to ensure *safe sex*, the use of condoms has been shown to reduce but not eliminate the risk of transmission of HIV and other STDs. Thus, the term *safer sex* more appropriately connotes the public health message to be used when promoting the use of condoms.

STDs provide a unique set of challenges for nurses, physicians, and public health officials. Because of perceived stigma and possible threat to emotional relationships, people with symptoms of STDs are often reluctant to seek health care in a timely fashion. STDs may progress without symptoms and a delay in diagnosis and treatment is potentially harmful because the risk of complications for the infected person and the risk of transmission to others increase over time.

Infection with one STD suggests the possibility of infection with other diseases as well. After one STD is identified, diagnostic evaluation for others should be conducted. The possibility of HIV infection should be pursued when any STD is diagnosed.

Table 70-4 CONDITIONS CLASSIFIED AS SEXUALLY TRANSMITTED DISEASES (STDs) AND THEIR ROUTES OF TRANSMISSION

Disease	Route(s) of Transmission
Chancroid, <i>Lymphogranuloma venereum</i> , and <i>Granuloma inguinale</i>	Sexual
Chlamydia	Sexual
Cytomegalovirus (CMV)	Sexual, less intimate contact
Gonorrhea	Sexual, perinatal
Hepatitis B (HBV)	Sexual, percutaneous, perinatal
Hepatitis C (HCV)	Percutaneous, probably sexual, probably perinatal
Herpes simplex	Sexual
HIV infection/AIDS	Sexual, percutaneous, perinatal
Human papillomavirus (HPV)	Sexual
Syphilis	Sexual, perinatal

HUMAN IMMUNODEFICIENCY VIRUS

HIV is the causative agent of AIDS. The definition of AIDS, as determined by the CDC, sets a point in the continuum of HIV pathogenesis in which the host has clinically demonstrated profound immune dysfunction. Since 1993, the AIDS definition has also included a CD4-positive (CD4+) cell count of less than 200 cells/mm³ as a threshold criterion. CD4+ cells are a subset of lymphocytes and one of the targets of HIV infection. Many opportunistic infections and neoplasms occur with severe immunosuppression.

HIV is transmitted through sexual contact or percutaneous injection of contaminated blood or from infected mother to fetus. Most people infected by the percutaneous route are IV or injecting drug users who share contaminated

needles, but transmission is also remotely possible through contaminated blood transfusion. Since 1985, all blood transfusions have been screened, and transfusion-related transmission of HIV is now extremely unlikely. Additional information about HIV is provided in Chapter 52.

Risk to Health Care Workers

Health care workers can be infected through the percutaneous route if needlestick or other injury from a sharp object introduces contaminated blood. Prospective studies of this risk demonstrate that less than 1% of occupational exposures in which the source patient is infected with HIV lead to transmission (CDC, 2005e). Despite the rarity of transmission, health care workers are advised to use extreme care to avoid needlestick or mucous membrane exposure to blood from all patients.

In health care facilities, employers are required to provide devices designed to reduce the risk of needlestick and other injuries. Health care workers should understand the need to report a needlestick or other percutaneous exposure immediately. Since 1996, the CDC has recommended post-exposure prophylaxis (PEP) for significant occupational exposures to HIV (further discussion of PEP is provided in Chapter 52). Counseling about the advisability of prophylaxis, appropriate combination of drugs, and dosing is made on a case-by-case basis.

SYPHILIS

Syphilis is an acute and chronic infectious disease caused by the spirochete *Treponema pallidum*. It is acquired through sexual contact or may be congenital in origin.

Stages of Syphilis

In the untreated person, the course of syphilis can be divided into three stages: primary, secondary, and tertiary. These stages reflect the time from infection and the clinical manifestations observed in that period and are the basis for treatment decisions.

Primary syphilis occurs 2 to 3 weeks after initial inoculation with the organism. A painless lesion at the site of infection is called a *chancre*. Untreated, these lesions usually resolve spontaneously within about 2 months.

Secondary syphilis occurs when the hematogenous spread of organisms from the original chancre leads to generalized infection. The rash of secondary syphilis occurs about 2 to 8 weeks after the chancre and involves the trunk and the extremities, including the palms of the hands and the soles of the feet. Transmission of the organism can occur through contact with these lesions. Generalized signs of infection may include lymphadenopathy, arthritis, meningitis, hair loss, fever, malaise, and weight loss.

After the secondary stage, there is a period of **latency**, when the infected person has no signs or symptoms of syphilis. Latency can be interrupted by a recurrence of secondary syphilis symptoms.

Tertiary syphilis is the final stage in the natural history of the disease. It is estimated that between 20% and 40% of those infected do not exhibit signs and symptoms in this final stage. Tertiary syphilis presents as a slowly progressive

inflammatory disease with the potential to affect multiple organs. The most common manifestations at this level are aortitis and neurosyphilis, as evidenced by dementia, psychosis, paresis, stroke, or meningitis.

Assessment and Diagnostic Findings

Because syphilis shares symptoms with many diseases, clinical history and laboratory evaluation are important. The conclusive diagnosis of syphilis can be made by direct identification of the spirochete obtained from the chancre lesions of primary syphilis. Serologic tests used in the diagnosis of secondary and tertiary syphilis require clinical correlation in interpretation. The serologic tests are summarized as follows:

- *Nontreponemal* or *reagin* tests, such as the Venereal Disease Research Laboratory (VDRL) or the rapid plasma reagin circle card test (RPR-CT), are generally used for screening and diagnosis. After adequate therapy, the test result is expected to decrease quantitatively until it is read as negative, usually about 2 years after therapy is completed.
- *Treponemal* tests, such as the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhemagglutination test (MHA-TP), are used to verify that the screening test did not represent a false-positive result. Positive results usually are positive for life and therefore are not appropriate to determine therapeutic effectiveness.

Medical Management

Treatment of all stages of syphilis is administration of antibiotics. Penicillin G benzathine is the medication of choice for early syphilis or early latent syphilis of less than 1 year's duration. It is administered by intramuscular injection at a single session. Patients with late latent or latent syphilis of unknown duration should receive three injections at 1-week intervals. Patients who are allergic to penicillin are usually treated with doxycycline (Adoxa). The patient treated with penicillin is monitored for 30 minutes after the injection to observe for a possible allergic reaction.

Treatment guidelines established by the CDC are updated on a regular basis. Recommendations provide special guidelines for treatment in the setting of pregnancy, allergy, HIV infection, pediatric infection, congenital infection, and neurosyphilis (CDC, 2006b).

Nursing Management

Syphilis is a reportable communicable disease. In any health care facility, a mechanism must be in place to ensure that all diagnosed patients are reported to the state or local public health department to ensure community follow-up. The public health department is responsible for identification of sexual contacts, contact notification, and contact screening.

Lesions of primary and secondary syphilis may be highly infective. Gloves are worn when direct contact with lesions is likely, and hand hygiene is performed after gloves are removed. Isolation in a private room is not required (Chart 70-6).

CHART
70-6

PATIENT EDUCATION Preventing the Spread of Syphilis

- If multiple penicillin injections are required, complete the full course of therapy.
- Refrain from sexual contact with previous or current partners until the partners have been treated.
- If you have primary or secondary syphilis, be aware that with proper treatment, skin lesions and other sequelae of infection will improve, and serology eventually will reflect cure.
- Condoms significantly reduce the risk of transmission of syphilis and other sexually transmitted diseases.
- Having multiple sexual partners increases the risk of acquiring syphilis and other sexually transmitted diseases.

CHLAMYDIA TRACHOMATIS AND NEISSERIA GONORRHOEAE INFECTIONS

Chlamydia trachomatis and *Neisseria gonorrhoeae* are the most commonly reported infectious diseases in the United States. Coinfection with *C. trachomatis* often occurs in patients infected with *N. gonorrhoeae*. The greatest risk of *C. trachomatis* infection occurs in young women between 15 and 19 years of age (CDC, 2007b).

Clinical Manifestations

Women

Both *C. trachomatis* and *N. gonorrhoeae* infections frequently do not cause symptoms in women. When symptoms are present, mucopurulent cervicitis with exudates in the endocervical canal is the most frequent finding. Women with gonorrhea can also present with symptoms of urinary tract infection or vaginitis.

Men

Although men are more likely than women to have symptoms when infected, infection with *N. gonorrhoeae* or *C. trachomatis* can be asymptomatic. When symptoms are present, they may include burning during urination and penile discharge. Patients with *N. gonorrhoeae* infection may also report painful, swollen testicles.

Complications

In women, pelvic inflammatory disease (PID), ectopic pregnancy, endometritis, and infertility are possible complications of either *N. gonorrhoeae* or *C. trachomatis* infection. In men, epididymitis, a painful disease that may lead to infertility, may result from infection with either bacterium. In people of either gender, arthritis or bloodstream infection may be caused by *N. gonorrhoeae*.

Assessment and Diagnostic Findings

The patient is assessed for fever, discharge (urethral, vaginal, or rectal), and signs of arthritis. Diagnostic methods used in *N. gonorrhoeae* infection include Gram stain (appropriate only for male urethral samples), culture, and nucleic acid amplification tests (NAATs). Gram stain and the direct fluorescent antibody test can be used in chlamydia. NAATs are

also available for *C. trachomatis* but demand strict attention to laboratory procedures to ensure test reliability. In the female patient, samples are obtained from the endocervix, anal canal, and pharynx. In the male patient, specimens are obtained from the urethra, anal canal, and pharynx. Because *N. gonorrhoeae* organisms are susceptible to environmental changes, specimens for culture must be delivered to the laboratory immediately after they are obtained.

Because as many as 70% of chlamydial infections are asymptomatic, the CDC recommends annual *Chlamydia* testing for all pregnant women, sexually active women younger than 25 years of age, and older women with a new sexual partner or multiple partners (CDC, 2006b).

Medical Management

Because patients are often coinfecting with both gonorrhea and chlamydia, the CDC recommends dual therapy even if only gonorrhea has been laboratory proven. The CDC-recommended treatment for chlamydia is either doxycycline or azithromycin (Zithromax) and one of the following for gonorrhea: ceftriaxone (Rocephin), cefixime (Suprax), or ciprofloxacin (Cipro). These antibiotics are not recommended during pregnancy. CDC guidelines should be used to determine alternative therapy for the patient who is pregnant or allergic or who has a complicated chlamydial infection.

Patients with uncomplicated gonorrhea who are treated with CDC-recommended therapy do not routinely need to return for a proof-of-cure visit. If the patient reports a new episode of symptoms or tests are positive for gonorrhea again, the most likely explanation is reinfection rather than treatment failure. Serologic testing for syphilis and HIV should be offered to patients with gonorrhea or chlamydia, because any STD increases the risk of other STD infections.

Nursing Management

Gonorrhea and chlamydia are reportable communicable diseases. In any health care facility, a mechanism should be in place to ensure that all diagnosed patients are reported to the local public health department to ensure follow-up of the patient. The public health department also is responsible for interviewing the patient to identify sexual contacts, so that contact notification and screening can be initiated.

The target group for preventive patient teaching about gonorrhea and chlamydia is the adolescent and young adult population. Along with reinforcing the importance of abstinence, when appropriate, education should address postponing the age of initial sexual exposure, limiting the number of sexual partners, and using condoms for barrier protection. Young women and pregnant women should also be instructed about the importance of routine screening for chlamydia.

NURSING PROCESS

THE PATIENT WITH A SEXUALLY TRANSMITTED DISEASE

Assessment

The patient should be asked to describe the onset and progression of symptoms and to characterize any lesions

by location and by describing drainage, if present. Brief explanations of why the information is needed are often helpful. Clarification of terms may be necessary if either the patient or nurse uses words that are unfamiliar to the other.

Protecting confidentiality is important when discussing sexual issues. When a detailed sexual history is necessary, it is important to respect the patient's right to privacy. When obtaining a sexual history, the CDC recommends the following systematic interview of key areas, the five Ps: *partners, prevention of pregnancy, protection from STDs, practices, past history of STDs* (CDC, 2006b).

Asking specific information about sexual contacts usually should be done only when the nurse is part of a team that will conduct partner notification. The nurse should describe to the patient the public health notification process and resources that are available to assist sexual partners or infants and children.

During the physical examination, the examiner looks for rashes, lesions, drainage, discharge, or swelling. Inguinal nodes are palpated to elicit tenderness and to assess swelling. Women are examined for abdominal or uterine tenderness. The mouth and throat are examined for signs of inflammation or exudate. The nurse wears gloves while examining the mucous membranes, and gloves are changed and replaced after vaginal or rectal examination.

Diagnosis

Nursing Diagnoses

Based on assessment data, the patient's major nursing diagnoses may include the following:

- Deficient knowledge about the disease and risk for spread of infection and reinfection
- Anxiety related to anticipated stigmatization and to prognosis and complications
- Noncompliance with treatment

Collaborative Problems/Potential Complications

Based on assessment data, potential complications that may develop include the following:

- Increased risk for ectopic pregnancy
- Infertility
- Transmission of infection to fetus, resulting in congenital abnormalities and other outcomes
- Neurosyphilis
- Gonococcal meningitis
- Gonococcal arthritis
- Syphilitic aortitis
- HIV-related complications

Planning and Goals

Major goals are increased patient understanding of the natural history and treatment of the infection, reduction in anxiety, increased compliance with therapeutic and preventive goals, and absence of complications.

Nursing Interventions

Increasing Knowledge and Preventing Spread of Disease

Education about STDs and prevention of the spread to others is often accomplished simultaneously. The infected patient should be told what the causative organism is and

should receive an explanation of the usual course of the infection (including the interval of potential communicability to others) and possible complications. The nurse should stress the importance of following therapy as prescribed and the need to report any side effects or symptom progression.

Discussion should emphasize that the same behaviors that led to infection with one STD increase the risk for any other STD, including HIV. Methods used to contact sexual partners should be discussed. The patient should understand that until the partner has been treated, continued sexual exposure to the same person may lead to reinfection. The relative value of condoms in reducing the risk for infection with STDs should be addressed. When appropriate, the patient should be encouraged to discuss any reasons for resistance to condom use to promote thoughtful decision making about this preventive method.

Reducing Anxiety

When appropriate, the patient is encouraged to discuss anxieties and fear associated with the diagnosis, treatment, or prognosis. By individualizing teaching efforts, factual information applied to specific needs may offer reassurance. Patients may need help in planning discussion with partners. If the patient is especially apprehensive about this aspect, referral to a social worker or other specialist may be appropriate. For example, such support is especially important when the patient has newly diagnosed HIV infection. Patients with HIV may benefit from programs that combine support, education, counseling, and therapeutic goals. Such programs are designed to offer coordinated care throughout the course of disease progression.

Increasing Compliance

In group settings (eg, an outpatient obstetric setting) or in a one-to-one setting, open discussion about STD information facilitates patient teaching. Discomfort can be reduced by factual explanation of causes, consequences, treatments, prevention, and responsibilities. Because most communities have expanded STD prevention resources, referrals to appropriate agencies can complement individual educational efforts and ensure that later questions or uncertainties can be addressed by experts. Patients can obtain more information by accessing the CDC Web site (2009c).

Monitoring and Managing Potential Complications

INFERTILITY AND INCREASED RISK OF ECTOPIC PREGNANCY. STDs may lead to PID and, with it, increased risk of ectopic pregnancy and infertility. For additional information, see Chapters 46 and 47.

CONGENITAL INFECTIONS. All STDs can be transmitted to infants in utero or at the time of birth. Complications of congenital infection can range from localized infection (eg, throat infection with *N. gonorrhoeae*), to congenital abnormalities (eg, stunting of growth or deafness from congenital syphilis), to life-threatening disease (eg, congenital herpes simplex virus).

NEUROSYPHILIS, GONOCOCCAL MENINGITIS, GONOCOCCAL ARTHRITIS, AND SYPHILITIC AORTITIS. STDs can cause disseminated infection. The central nervous system may be infected, as seen in cases of neurosyphilis or gonococcal

meningitis. Gonorrhea that infects the skeletal system may result in gonococcal arthritis. Syphilis can infect the cardiovascular system by forming vegetative lesions on the mitral or aortic valves.

HUMAN IMMUNODEFICIENCY VIRUS-RELATED COMPLICATIONS. HIV infection leads to the profound immunosuppression characteristic of AIDS. Complications of HIV infection include many opportunistic infections, including those due to *Pneumocystis jiroveci*, *Cryptococcus neoformans*, cytomegalovirus, and *Mycobacterium avium* (see Chapter 52).

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Exhibits knowledge about STDs and their transmission
2. Demonstrates a less anxious demeanor
 - a. Discusses anxieties and goals for treatment
 - b. Inspects self for lesions, rashes, and discharge
 - c. Accepts support, education, and counseling when indicated
 - d. Assists with sharing information about infection with sexual partners
 - e. Discusses risk-reduction behaviors and safer sex practices
3. Complies with treatment
4. Achieves effective treatment
5. Reports for follow-up examinations if necessary
6. Absence of complications

Emerging Infectious Diseases

As defined by the CDC, **emerging infectious diseases** are human diseases of infectious origin that have increased within the past two decades or that are likely to increase in the near future. Examples of emerging infectious diseases presented here include West Nile virus, Legionnaires' disease, pertussis, hantavirus pulmonary syndrome, and viral hemorrhagic fevers. Some multiple resistant strains of common bacteria such as CA-MRSA and gram-negative organisms that are resistant to extended-spectrum beta-lactam antibiotics or carbapenem-based antibiotics are also often considered causes of emerging diseases. This is especially true of CA-MRSA, because its presentation in people without underlying disease and its aggressive nature in skin and soft tissue infections are different from those seen with HA-MRSA. Table 70-1 provides an overview of infectious diseases, including emerging infectious diseases.

Many factors contribute to newly emerging or re-emerging infectious diseases. These include travel, globalization of food supply and central processing of food, population growth, increased urban crowding, population movements (eg, those that result from war, famine, or man-made or natural disasters), ecologic changes, human behavior (eg, risky sexual behavior, IV/injection drug use), antimicrobial resistance, and breakdown in public health measures.

These diseases are important from an epidemiologic standpoint because their incidence has not yet stabilized. When the pattern of disease in a community is not well understood in the medical-scientific community, patients, families, and others in the community often become alarmed about these diseases. During times of increased concern about bioterrorism, whether triggered by actual events or by hoaxes, nurses have responsibility to rationally separate facts from fears. In discussions with patients and other caregivers, it is important to keep the focus on what is known and to clarify the plan for diagnosis, treatment, and containment.

WEST NILE VIRUS

The West Nile virus was first recognized in the 1930s in Africa and was first seen in humans in the United States in 1999. Although most human infections are mild or asymptomatic, a range of presentations is possible. Approximately 20% of infected people have a mild disease called West Nile fever. These patients usually experience headache, fever, and a persistent fatigue that may continue for several months. In these patients, fewer than 1 in 150 infections develop into more serious disease, which is characterized by severe neuroinvasive illness, meningitis, encephalitis, and paralysis or poliomyelitis. The mortality rate for people with the milder West Nile fever and meningitis is less than 1%, but this rate increases to approximately 20% for those with encephalitis and as high as 50% for those with paralysis (Sejvar, 2007). Although age-related factors do not appear to affect a person's chances of acquiring West Nile virus, the risk of neuroinvasive disease is greater in those older than 64 years of age (Hayes, Komar, Nasci, et al., 2005).

The incubation period (ie, from mosquito bite to onset of symptoms) is between 3 and 14 days. Currently, there is no treatment for West Nile virus infection. Medical and nursing management consists of fluid replacement, airway management, and supportive nursing care when meningitis or symptoms are present.

Birds are the natural reservoir for the virus, and since 1999, the population of infected birds in the eastern United States has increased steadily. Mosquitoes become infected when feeding on birds and can transmit the virus to animals and humans. Although human-to-human transmission of West Nile virus is very rare, transmission has occurred as the result of occupational exposure in laboratory workers, infant exposure transplacentally and from breastfeeding, and blood transfusion or organ transplant from infected donors (CDC, 2004a).

LEGIONNAIRES' DISEASE

Legionnaires' disease is a multisystem illness that usually includes pneumonia and is caused by the gram-negative bacterium *Legionella pneumophila*. Named after an outbreak among people attending a convention of the American Legion in 1976, its potential to cause outbreaks has been demonstrated repeatedly in hospitals and other settings. It continues to be considered an emerging infectious disease because there are new patterns in recent years. There has been an approximate 70% increase in new cases since 2003 compared with earlier time periods, and a disproportionate increase in the eastern United States (Neil & Berkeman, 2008).

Legionella organisms are found in many man-made and naturally occurring water sources. Although the organisms may initially be introduced to the plumbing system in low numbers, growth is enhanced by water storage, sediment, temperatures ranging from 25°C to 42°C (77°F to 107°F), and certain amoebae frequently present in water that can support intracellular growth of legionellae. As incidence appears to increase in the summer and autumn months, vacation-related exposure to hotel or cruise ship plumbing and air conditioning systems, whirlpool spas, and decorative fountains may be the causative risk.

Pathophysiology

L. pneumophila is transmitted by the aerosolized route from an environmental source to a person's respiratory tract. It is not transmitted from person to person. In hospitals, patients may be exposed to aerosols created by cooling towers, water exposure from in-room plumbing, and respiratory therapy equipment. Because underlying medical conditions can increase host susceptibility and subsequent severity of disease and because hospital plumbing systems are often very complex, outbreaks occur in hospitals more frequently than at other centers within the community. The mortality rate for Legionnaires' disease may be as high as 40% in some populations (CDC, 2008a).

Risk Factors

Risk factors for *Legionella* infection include diseases that lead to severe immunosuppression, such as AIDS, hematologic malignancy, end-stage renal disease, or use of immunosuppressive agents. Other factors associated with increased risk include diabetes, smoking, exposure to whirlpool spas, and recent travel.

Clinical Manifestations

The lungs are the principal organs of infection; however, other organs may also be involved. The incubation period ranges from 2 to 10 days. Early symptoms may include malaise, myalgias, headache, and dry cough. The patient develops increasing pulmonary symptoms, including productive cough, dyspnea, and chest pain. Patients are usually febrile, and body

temperatures may reach or exceed 39.4°C (103°F). Diarrhea and other gastrointestinal symptoms are common. In severe cases, multiorgan involvement and failure may follow.

Assessment and Diagnostic Findings

The diagnostic approach generally involves accumulation of information obtained from the history, physical examination, x-rays, laboratory findings, and assessment of therapeutic effectiveness. Chest x-ray abnormalities may vary in severity and in location within the lungs. Laboratory tests available for the diagnosis of *Legionella* include culture or tests that detect either antigen or antibody. The most frequently used test is the urinary antigen. The greatest limitation of the test is that it detects only one subgroup of one of the several species of *Legionella*. The CDC recommends using multiple tests when Legionnaires' disease is suspected because none of the tests is completely accurate.

Medical Management

The antibiotics of choice are azithromycin or a fluoroquinolone such as moxifloxacin (Avelox) (Mandell, Wunderink, Anzueto, et al., 2007). The antibiotic doxycycline may also be used.

Nursing Management

The nursing management described for the patient with any pneumonia (see Chapter 23) should form the basis of care for the patient with *Legionella* pneumonia. Isolation is not required because *Legionella* is not transmitted between humans. When the patient has acquired the infection in a health care facility, water cultures should be performed to determine if the water supply is contaminated.

PERTUSSIS

Pertussis, also known as whooping cough, a common childhood disease in the prevaccine era, is an example of a disease that has reemerged. Incidence rates declined until the 1980s, when rates for all age groups began to increase steadily for the next two decades. In the short period from 2001 to 2003, the incidence of cases in adolescents and adults more than doubled compared with the period from 1990 to 1993 (CDC, 2008b) (Fig. 70-3).

Figure 70-3 Graph showing increased incidence of pertussis in the United States, 1980–2005. From Centers of Disease Control and Prevention. (2007). *Epidemiology and prevention of vaccine preventable diseases broadcasts: Slide sets*. (10th ed.). Available at: www.cdc.gov/vaccines/ed/epivac07/epivac07-slides.htm

Pertussis is highly contagious, and patients usually present to health care professionals with a sudden (paroxysmal) cough that is accompanied by a characteristic whoop, a high-pitched noise heard when inhaling. Whooping cough is caused by the bacterium *Bordetella pertussis*.

Pathophysiology

B. pertussis is transmitted by droplets. The bacteria easily attach to pharyngeal epithelial cells, where they release a number of antigens, toxins, and other substances that trigger the immune system. Because most of the disease manifestations are caused by this immune reaction, patients are usually contagious only early in the disease (when the bacteria are still present) and not during the protracted period of cough (when the immune reaction is causing the pathology).

Clinical Manifestations

Pertussis causes a range of respiratory symptoms, with cough being the most frequent. It is generally most severe for infants who have not yet been vaccinated. Pneumonia is the most common consequence of infection, but the disease can also lead to seizures, encephalopathy, and rarely death. People who have been vaccinated seldom have severe disease.

Assessment and Diagnostic Findings

Most diagnoses of pertussis are made, at least initially, without laboratory confirmation. The clinical case definition, unless there is a preexisting condition to explain the symptoms, is a new cough lasting at least 2 weeks with inspiratory whoop or vomiting after cough. Laboratory confirmation can be made by clinical culture or by polymerase chain reaction (PCR) assay for *B. pertussis*. Serologic testing, although less reliable, can also strengthen the diagnostic suspicion. The best source for a culture is a nasopharyngeal specimen.

Medical Management

The antibiotics of choice are azithromycin, erythromycin (Erythrocin), or clarithromycin (Biaxin). The antibiotic trimethoprim sulfate (Bactrim) may also be used (Mandell, et al., 2007). Close contacts of a patient with proven or suspected pertussis should receive prophylaxis with one of these agents to reduce the risk of disease.

Nursing Management

Hospitalized patients with pertussis should be isolated in Droplet Precautions until they have received 5 days of appropriate therapy. Household members should receive antimicrobial prophylaxis and should be advised to report any symptoms of an upper respiratory infection.

HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome is caused by a member of the Hantavirus family of viruses. In the United States, the Sin Nombre hantavirus causes severe cardiopulmonary illness, with a case mortality rate of approximately 50%. It occurs most frequently in the western United States, but the rodents known to carry the virus are found throughout the country (Vaheri & Calisher, 2002).

The diagnosis of hantavirus pulmonary syndrome should be suspected in patients who live in rural areas; who may have had exposure to rodents; and who report fever, aching muscles, and nausea. Thrombocytopenia and hemoconcentration are also common.

No specific treatment for hantavirus pulmonary syndrome has been approved. Early identification, assessment, and maintenance of respiratory status are the most important aspects of care for patients with the disease. Intake and output should be monitored closely because overhydration is possible, with resultant cardiopulmonary compromise.

Prevention requires strategies to reduce human contact with rodents and their droppings. Public health programs and clinics in rural areas should regularly teach people to eliminate rodent food sources that are in areas close to humans. Openings in walls or cabinets should be sealed. Traps should be used in areas such as sheds and barns in which humans work and rodents may enter. Gloves should be worn when removing an animal from a trap, and the trap should be disinfected with a 1:10 bleach solution. People entering such areas should be taught to avoid stirring up dust or breathing potentially contaminated dust. Brooms and vacuum cleaners should be used with caution; areas that may emit dust while being cleaned should be first dampened with a bleach solution to reduce viral contaminants and the potential for dust dispersion.

VIRAL HEMORRHAGIC FEVERS

Viral hemorrhagic fevers are a group of illnesses caused by several families of viruses (the arenaviruses, filoviruses, bunyaviruses, and flaviviruses). These viruses cause a syndrome characterized by multisystem involvement, resulting in a damaged vascular system. Although most cases of hemorrhagic fever are severe, some cases are less acute. The viruses as a whole can be found throughout the world; however, each virus usually causes disease only in its own limited geographic area.

The Ebola and Marburg viruses, both belonging to the filovirus family, are the best-known viral hemorrhagic fever viruses. Since the 1960s, they have been the source of an irregular pattern of sporadic outbreaks. The clinical course differs among patients but often includes fever, hemorrhage, vomiting, diarrhea, cough, and jaundice. Symptoms usually occur rapidly, and the course of the illness often progresses rapidly to profound hemorrhage, organ destruction, and shock. The mortality rate ranges from 25% to 80%. When patients survive, the recovery period is often prolonged, and weakness, malaise, and cachexia are common (Heymann, 2004).

Nonhuman animals or insects appear to be the natural reservoirs of the viruses. Humans usually become infected when exposed to the natural reservoir (eg, after exposure to an unrecognized host or an insect bite). However, human-to-human transmission occurs occasionally; it involves close contact and usually occurs via the bloodborne route after exposure to blood or other body fluid. Percutaneous exposure requires only a very low inoculum of contaminated blood for transmission to occur. Mucous membrane exposure is another method of transmission. Although airborne transmission does not appear to be likely, the possibility has not been entirely eliminated.

A diagnosis of Ebola or Marburg should be considered in a patient who has a febrile, hemorrhagic illness after traveling to Asia or Africa or who has handled animals or animal carcasses from those parts of the world. The CDC should be contacted immediately when Ebola and Marburg viruses are suspected because hospital and local public health laboratories would not be able to confirm a diagnosis. Because no cases of Ebola or Marburg have been diagnosed in the United States to date, more likely diagnoses should also be considered whenever one of these diseases is a diagnostic possibility.

All health care workers who are involved in caring for patients with filoviruses must adhere to strict infection control measures. Systems must be set up to have objective observers ensure that each worker wears complete protective equipment in the form of cap, goggles, mask, gown, gloves, and shoe covers.

Treatment is largely supportive maintenance of the circulatory system and respiratory systems. It is likely that the infected patient will need ventilator and dialysis support during the acute phases of illness (CDC, 2005b). Supportive care for a patient with such a devastating disease requires psychological support for the patient and family. The patient, family, health care workers, and others in the community need substantial, coordinated education about the known elements and approach. Intervention may be required from those trained to provide psychological support for national emergencies or crises.

Travel and Immigration

Travel, trade, migration, and wars have led to many epidemics throughout history. The potential for epidemics is greatest when travelers and immigrants introduce microorganisms to which the host population has little or no immunity. Examples of important epidemics in the Western Hemisphere have included yellow fever, malaria, hookworm, leprosy, smallpox, measles, mumps, and syphilis. The HIV epidemic demonstrates the way that travel and immigration allow a disease to spread undetected worldwide. The 2003 severe acute respiratory syndrome (SARS) outbreak demonstrates how global travel contributes to a rapidly occurring epidemic involving an unrecognized pathogen.

In the United States, an infrastructure with enforced vaccination, clean water, and insect and rodent control decreases the risk that epidemics will progress even when travel may introduce exotic microorganisms. However, the recent experience with West Nile virus has reinforced knowledge that insect transmission can lead to significant human outbreaks. Thus, the concern grows that vector-borne diseases such as dengue and malaria may increase in the United States as mosquitoes can transmit disease locally when a reservoir of infected humans is established. The CDC maintains an active surveillance system to monitor and halt the incidence of many diseases prospectively.

Immigration and Acquired Immunodeficiency Disease Syndrome

The fact that AIDS reached pandemic proportions less than a decade after its recognition attests to the efficiency of world travel in spreading disease. Such rapid transmission

rates are especially dramatic because HIV essentially requires intimate contact between two people through sexual activity or sharing blood through needles.

HIV/AIDS is now an international health disaster. Since the start of the epidemic, more than 67 million people have become infected with HIV and more than 27 million have died of AIDS. Control of the epidemic anywhere in the world requires control everywhere. More than 95% of the current burden is felt in economically depressed countries, which means that the control of the disease, using anti-retroviral therapy and public health education, requires investment from nations, corporations, and people throughout the world, especially the wealthy nations (UNAIDS, 2008).

Immigration and Tuberculosis

Although there are substantive efforts to eliminate TB in the United States, TB remains a growing epidemic in developing nations. Approximately one third of the world's population is currently infected with TB. Between 5% and 10% of those infected eventually develop disease; therefore, approximately 9 million people per year become ill with TB (WHO, 2008b). Immigration has always been an important influence in the dynamic epidemiology of TB in the United States. In 2007, the incidence of TB in the United States was 9.7 times greater in foreign-born people than in native-born people (CDC, 2008b).

The association between immigration and transmission risk is greatest in urban areas because these locations are frequently heavily populated and frequently visited by foreign-born people. These locales are also often the epicenter of the HIV epidemic. Because HIV infection depletes T cells, which are necessary for TB protection, the geographic closeness of these two microorganisms potentiates increased rates of both infections.

A positive tuberculin skin test (TST) establishes that TB infection has occurred at some time in a person's life but does not provide information about current infectivity. The reliability of TST interpretation is decreased among foreign-born people because the bacille Calmette-Guérin (BCG) vaccine is used in many countries. After receiving BCG, people often have some degree of TST reactivity for a prolonged time.

Immigration and Vector-Borne Diseases

Malaria and dengue are diseases that cause significant morbidity and mortality throughout the developing world. These diseases may be "imported" to the United States via travel, immigration, or commerce. They are caused by microorganisms that can be spread to humans by mosquitoes in the United States that thrive in tropical zones and breed in stagnant water sources. Although malaria was eradicated in the United States in the 1950s, limited local outbreaks have occurred regularly when mosquitoes acquire the bacteria from a person recently traveling from an area in which malaria is endemic and transmit it to a small number of people. Similarly, an increase of dengue virus in the Caribbean has caused concern that outbreaks may occur in the United States.

CRITICAL THINKING EXERCISES

1 Several elderly patients in your community have developed skin infections caused by MRSA. What should nurses in different roles in the community do to reduce the risk of new infections and to reduce people's anxiety? What strategies are used to control MRSA in health care facilities?

2 Several patients in your long-term care facility have developed fever and diarrhea. What steps should be taken to reduce the risk of further outbreaks?

EBP 3 Audits of hand hygiene in your health care facility demonstrate poor compliance with recommended methods of hand hygiene. What methods of hand hygiene should be used? What strategies should be used to improve compliance and to sustain appropriate behavior once acceptable rates are achieved? What is the evidence base for these practices?

chapter 71

Emergency Nursing

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe emergency care as a collaborative, holistic approach that includes the patient, the family, and significant others.
- 2 Discuss priority emergency measures instituted for the patient with an emergency condition.
- 3 Describe the emergency management of patients with intra-abdominal injuries.
- 4 Identify the priorities of care for the patient with multiple injuries.
- 5 Compare and contrast the emergency management of patients with heat stroke, frostbite, and hypothermia.
- 6 Specify the similarities and differences of the emergency management of patients with swallowed or inhaled poisons, skin contamination, and food poisoning.
- 7 Discuss the emergency management of patients with drug overdose and with acute alcohol intoxication.
- 8 Describe the significance of crisis intervention in the care of rape victims.
- 9 Differentiate between the emergency care of patients who are overactive, those who are violent, those who are depressed, and those who are suicidal.

GLOSSARY

antivenin: antitoxin manufactured from venom of poisonous snakes to assist the patient's immune system response to an envenomation

carboxyhemoglobin: hemoglobin that is bound to carbon monoxide and therefore is unable to bind with oxygen, resulting in hypoxemia

corrosive poison: alkaline or acidic agent; causes tissue destruction after contact

cricothyroidotomy: surgical opening of the cricothyroid membrane to obtain an airway that is maintained with a tracheostomy or endotracheal tube

diagnostic peritoneal lavage: instillation of lactated Ringer's or normal saline solution into the abdominal cavity to detect red blood cells, white blood cells, bile, bacteria, amylase, or gastrointestinal contents indicative of abdominal injury

emergent: triage category signifying potentially life-threatening injuries or illnesses requiring immediate treatment

envenomation: injection of a poisonous material by sting, spine, bite, or other means

fasciotomy: surgical incision of the extremity to the level of the fascia to relieve pressure and restore neurovascular function to the extremity

Hare traction: portable in-line traction applied to the lower extremity to manage femur or hip fractures or dislocations

minor: triage category signifying non-life-threatening injuries or illnesses that can be routinely managed in a clinic or physician's office or that require no medical care

nonurgent: triage category signifying episodic or minor injury or illness in which treatment may be delayed several hours or longer without increased morbidity

resuscitation: triage category signifying life-threatening injuries or illnesses requiring immediate intervention

triage: process of assessing patients to determine management priorities

urgent: triage category signifying serious illness or injury that is not immediately life-threatening

The term *emergency management* traditionally refers to care given to patients with urgent and critical needs. However, because many people lack access to health care, the emergency department (ED) is increasingly used for nonurgent problems. Therefore, the philosophy of emergency management has broadened to include the concept that an emergency is whatever the patient or the family considers it to be.

Large numbers of people seek emergency care for serious life-threatening conditions, such as cardiac dysrhythmias, acute coronary syndrome (ACS), acute heart failure, pulmonary edema, and stroke. Priorities for managing these cardiac and other conditions are discussed in Chapters 27, 28, 30, and 62. Emergency management of trauma and conditions not found elsewhere in this book are discussed in this chapter. It is assumed that care and treatment are provided under the direction of a physician or emergency nurse practitioner. Facts about ED visits in the United States are presented in Chart 71-1.

SCOPE AND PRACTICE OF EMERGENCY NURSING

The emergency nurse has had specialized education, training, experience, and expertise in assessing and identifying patients' health care problems in crisis situations. In addition, the emergency nurse establishes priorities, monitors and continuously assesses acutely ill and injured patients, supports and attends to families, supervises allied health personnel, and teaches patients and families within a time-limited, high-pressured care environment. Nursing interventions are accomplished interdependently, in consultation with or under the direction of a physician or nurse practitioner. The roles of nursing and medicine are complementary in an emergency situation. Appropriate nursing and medical interventions are anticipated based on assessment data. The emergency health care staff members work as a team in performing the highly technical, hands-on skills required to care for patients in emergency situations.

The nursing process provides a logical framework for problem solving in this environment. Patients in the ED have a wide variety of actual or potential problems, and their condition may change. Therefore, nursing assessment must be continuous, and nursing diagnoses change with the patient's condition. Although a patient may have several diagnoses at a given time, the focus is on the most life-threatening ones; often, both independent and interdependent nursing interventions are required.

Issues in Emergency Nursing Care

Emergency nursing is demanding because of the diversity of conditions and situations that present unique challenges. These challenges include legal issues, occupational health and safety risks for ED staff, and the challenge of providing holistic care in the context of a fast-paced, technology-driven environment in which serious illness and death are encountered on a daily basis. Another dimension of emergency nursing is nursing in disasters. With the increasing use of weapons of terror and mass destruction, the emergency nurse must recognize and treat patients exposed to biologic and other weapons and anticipate nursing care in the event of a mass casualty incident (see Chapter 72).

Chart 71-1 • Facts About Emergency Department Visits

In 2005, there were 115.3 million visits to emergency departments (EDs), a 31% increase from 1995. This was accompanied by a 10% decrease in the number of EDs and an increased utilization by 7%.

- The highest rate of ED visits in people 65 years of age and older were from long-term care facilities.
- More than 15.5% of patients arrived at the ED by ambulance.
- Patients with Medicaid used EDs more often than patients with private health insurance, Medicare, or self-pay.
- Injuries accounted for 41.9% of all ED visits.
- The leading causes of injuries, including falls and motor vehicle crashes, accounted for 31% of injury-related ED visits. For those injured, 36.9% were transported to designated trauma centers.
- The average ED waiting time before being seen by a health care provider for definitive treatment was 2.4 hours, with 7 of 10 patients spending less than 4 hours in the ED.

Documentation of Consent and Privacy

Consent to examine and treat the patient is part of the ED record. The patient must consent to invasive procedures (eg, angiography, lumbar puncture) unless he or she is unconscious or in critical condition and unable to make decisions. If the patient is unconscious and brought to the ED without family or friends, this fact must be documented. Monitoring of the patient's condition, as well as all instituted treatments and the times at which they were performed, must be documented. After treatment, a notation is made on the record about the patient's condition, response to the treatment, and condition at discharge or transfer and about instructions given to the patient and family for follow-up care.

The patient is also provided with a statement of the privacy policy of the health care agency, according to federal law. Patients involved in violent events are often provided with an alias, and access to the medical record, both paper and electronic, is limited to protect the privacy of the patient. A patient may also request extra privacy by limiting access to his or her room and by choosing not to receive phone calls, mail, flowers, other gifts, or certain visitors. These practices relate to the federally mandated privacy policy stipulated in the Health Insurance Portability and Accountability Act (HIPAA).

Limiting Exposure to Health Risks

Because of the increasing numbers of people infected with hepatitis B and C, with human immunodeficiency virus (HIV), and other infectious diseases, health care providers are at an increased risk for exposure to communicable diseases through blood, respiratory droplets, or other body fluids. This risk is further compounded in

the ED because of the common use of invasive treatments in patients who may have a wide range of conditions and who frequently cannot provide a comprehensive medical history. All emergency health care providers must adhere strictly to standard precautions for minimizing exposure.

The reemergence of tuberculosis as a major health problem is complicated by multi-drug-resistant tuberculosis and by tuberculosis concomitant with HIV infection. Early identification and adherence to transmission-based precautions for patients who are potentially infectious are crucial. Nurses in the ED are usually fitted with personal high-efficiency particulate air (HEPA) filter masks to use when treating patients with airborne diseases.

The potential for exposure to highly contagious organisms, hazardous chemicals or gases, and radiation related to acts of terrorism or natural or manmade disasters presents additional risks to ED staff (see Chapter 72 for information about decontamination procedures).

Violence in the Emergency Department

Not only do ED staff members encounter patients who may be violent because of the effects of substance abuse, injury, or other emergencies, but they may also encounter other violent situations. Frequently, patients and families waiting for assistance are emotionally volatile. Often, waiting rooms are the sites where feelings of dissatisfaction, fear, and anger are channeled violently. Some EDs assign security officers to the area and have installed silent alarm systems or metal detectors to identify weapons in order to protect patients, families, and staff. Safety is the first priority.

It is not unusual for a patient or family member to come to the ED armed. To avoid angry confrontations, members of gangs and feuding families need to be separated in the ED, in the waiting room, and later in the inpatient nursing unit. Nurses and other personnel must be prepared to deal with these circumstances. The ED should be locked against entry if security is questionable.

Patients from prison and those who are under guard need to be handcuffed to the bed and appropriately assessed to ensure the safety of hospital staff and other patients. The following precautions are taken:

- The hand or ankle restraint (handcuff) is never released.
- A guard is always present in the room.
- The patient is placed face down on the stretcher to avoid injury from head-butting, spitting, or biting.
- Restraints are used on any violent patient as needed.
- Medication is administered as necessary to control violent behavior until definitive treatment can be obtained.

In the case of gunfire in the ED, self-protection is a priority. There is no advantage to protecting others if medical caregivers are injured. Security officers and police must gain control of the situation first, and then care is provided to the injured.

Providing Holistic Care

Patients and families experiencing sudden injury or illness are often overwhelmed by anxiety because they have not had time to adapt to the crisis. They experience real and

terrifying fear of death, mutilation, immobilization, and other assaults on their personal identity and body integrity. When confronted with trauma, severe disfigurement, severe illness, or sudden death, the family experiences several stages of crisis. The stages begin with anxiety and progress through denial, remorse and guilt, anger, grief, and reconciliation. The initial goal for the patient and family is anxiety reduction, a prerequisite to effective and appropriate coping. During this stressful time, safety is of prime importance. Close observation and preplanning are essential and security personnel are stationed nearby in the event that a patient or family member responds to stress with physical violence.

Assessment of the patient and family's psychological function includes evaluating emotional expression, degree of anxiety, and cognitive functioning. Possible nursing diagnoses include:

- General anxiety or death anxiety related to uncertain potential outcomes of the illness or trauma
- Ineffective coping related to acute situational crisis

Possible nursing diagnoses for the family include:

- Grieving
- Interrupted family processes
- Compromised or disabled family coping related to acute situational crises

Patient-Focused Interventions

Clinicians caring for the patient should act confidently and competently to relieve anxiety and promote a sense of security. Explanations should be given that the patient can understand. Human contact and reassuring words reduce the panic of the severely injured or ill person and aid in dispelling fear of the unknown.

The unconscious patient should be treated as if conscious; that is, the patient should be touched, called by name, and given an explanation of every procedure that is performed. As the patient regains consciousness, the nurse should orient the patient by stating his or her name, the date, and the location. This basic information should be provided repeatedly, as needed, in a reassuring way.

Family-Focused Interventions

The family is kept informed about where the patient is, how he or she is doing, and the care that is being given. Allowing family members to stay with the patient, when possible, also helps allay their anxieties. In many facilities, family presence during resuscitation is permitted to assist the family to cope through this difficult time. Many family members respond very well to this approach, and it provides some answers to the question "Was everything done?" (Walker, 2008). Additional interventions are based on the assessment of the stage of crisis that the family is experiencing. Measures to help family members cope with sudden death are presented in Chart 71-2.

Anxiety and Denial. During these crises, family members are encouraged to recognize and talk about their feelings of anxiety. Asking questions is encouraged. Honest answers given at the level of the family's understanding must be provided. Although denial is an ego-defense mechanism that protects one from recognizing

Chart 71-2 • Helping Family Members Cope With Sudden Death

- Take the family to a private place.
- Talk to the family together, so that they can grieve together.
- Reassure the family that everything possible was done; inform them of the treatment rendered.
- Avoid using euphemisms such as “passed on.” Show the family that you care by touching, offering coffee, water, and the services of a chaplain.
- Encourage family members to support each other and to express emotions freely (grief, loss, anger, helplessness, tears, disbelief).
- Avoid giving sedation to family members; this may mask or delay the grieving process, which is necessary to achieve emotional equilibrium and to prevent prolonged depression.
- Encourage the family to view the body if they wish; this action helps to integrate the loss. Cover disfigured and injured areas before the family sees the body. Go with the family to see the body. Show acceptance by touching the body to give the family “permission” to touch.
- Spend time with the family, listening to them and identifying any needs that they may have for which the nursing staff can be helpful.
- Allow family members to talk about the deceased and what he or she meant to them; this permits ventilation of feelings of loss. Encourage the family to talk about events preceding admission to the emergency department. Do not challenge initial feelings of anger or denial.
- Avoid volunteering unnecessary information (eg, the patient was drinking).

painful and disturbing aspects of reality, prolonged denial is not encouraged or supported. The family must be prepared for the reality of what has happened and what may come.

Remorse and Guilt. Expressions of remorse and guilt are common, with family members accusing themselves (or each other) of negligence or minor omissions. Family members are urged to verbalize their feelings to help them cope appropriately.

Anger. Expressions of anger, common in crisis situations, are a way of handling anxiety and fear. Anger is frequently directed by the family at the patient, but it is also often expressed toward the physician, the nurse, or admitting personnel. The therapeutic approach is to allow the anger to be expressed and to assist the family members to identify their feelings of frustration.

Grief. Grief is a complex emotional response to anticipated or actual loss. The key nursing intervention is to help family members work through their grief and to support their coping mechanisms, letting them know that it is normal and acceptable for them to cry, feel pain, and express loss. The hospital chaplain and social services staff serve as invaluable members of the team when assisting families to work through their grief.

Caring for Emergency Personnel

Concerted efforts have been made to focus on the needs of the ED staff, especially after serious and stressful events (Emergency Nurses Association [ENA], 2007). Events can range from a local trauma case involving children; to treating someone known to the emergency worker, such as a colleague or family member; to a more complex natural disaster or multicasualty situation. It is important to remember that all staff members may not necessarily respond in the same way; an event that is stressful for one person may not be as stressful for another. In addition, because stress is a daily occurrence in the ED, the staff may not recognize the personal effect of any one event. The availability of nonjudgmental counseling is essential to promoting a healthy staff. After serious events, critical incident stress debriefing necessary to critique individual and group performance. In addition, personal and group stress debriefing is also essential.

Emergency Nursing and the Continuum of Care

A key principle underlying emergency care is that the patient is rapidly assessed, treated, and referred to the appropriate setting for ongoing care. This makes the ED a temporary point on the continuum of care. Most patients who receive emergency care are discharged directly from the ED to their homes, and emergency nurses must plan and facilitate the patient's safe discharge and follow-up care in the home and the community.

Discharge Planning

Before discharge, verbal and written instructions for continuing care are given to the patient and the family or significant others. Many EDs have preprinted standard instruction sheets for the more common conditions, which can then be individualized. Discharge instructions should be available in a variety of languages. A language interpreter should be used as necessary to provide both written and verbal instructions.

Instructions should include information about prescribed medications, treatments, diet, activity, and when to contact a health care provider or schedule follow-up appointments. It is imperative that instructions are written legibly, use simple language, and are clear in their teaching. When providing discharge instructions, the nurse also considers any special needs the patient may have related to hearing or visual impairments. Alternate formats of instruction (eg, large print, Braille, audiotape) should be available to meet the needs of patients with hearing or visual impairments.

Community Services

Before discharge, some patients require the services of a social worker to help them meet continuing health care needs. Home care resources may be contacted before discharge to arrange services. This is particularly important for patients who are elderly or disabled and who need assistance. Identifying continuing health care needs and making arrangements for meeting these needs can prevent return visits to the ED or readmission to the hospital.

For patients who are returning to long-term care facilities and for those who already rely on community agencies for continuing health care, communication about the patient's condition and any changes in health care needs that have occurred must be provided to the appropriate facilities or agencies. This communication is essential to promote continuity of care and to ensure ongoing care to meet the patient's changing health care needs.

Gerontologic Considerations

The ED is a common point of entry into the health care system for patients 65 years and older. In fact, patients in this age group account for more than 41% of the admissions to the hospital from the ED. Of the 115 million ED visits in the United States in 2005, 2.2 million of these were patients from long-term care facilities (National Hospital Ambulatory Medical Care Survey, 2005) (see Chart 71-1). Elderly patients typically arrive with one or more presenting conditions. Nonspecific symptoms, such as weakness and fatigue, episodes of falling, incontinence, and change in mental status, may be manifestations of acute, potentially life-threatening illness in the elderly person. Emergencies in this age group may be more difficult to manage because elderly patients may have an atypical presentation, an altered response to treatment, a greater risk of developing complications, or a combination of these factors.

The elderly patient may perceive the emergency as a crisis signaling the end of an independent lifestyle or even resulting in death. The nurse should give attention to the patient's feelings of anxiety and fear.

The older patient may have limited sources of social and financial support during these times of crises. The nurse should assess the psychosocial resources of the patient (and of the caregiver, if necessary) and anticipate discharge needs. Referrals for support services (eg, to the social service department or a gerontologic nurse specialist) may be necessary.

PRINCIPLES OF EMERGENCY CARE

By definition, emergency care is care that must be rendered without delay. In an ED, several patients with diverse health problems—some life-threatening, some not—may present to the ED simultaneously. One of the first principles of emergency care is triage.

Triage

The word **triage** comes from the French word *trier*, meaning “to sort.” In the daily routine of the ED, triage is used to sort patients into groups based on the severity of their health problems and the immediacy with which these problems must be treated.

A basic and widely used triage system that has been in use for many years has three categories: emergent, urgent, and nonurgent (Berner, 2005). **Emergent** patients have the highest priority—their conditions are life-threatening and they must be seen immediately. **Urgent** patients have serious health problems but not immediately life-threatening ones; they must be seen within 1 hour. **Nonurgent** patients have

episodic illnesses that can be addressed within 24 hours without increased morbidity (Berner, 2005). A fourth category that is increasingly used is “fast-track.” These patients require simple first aid or basic primary care and may be treated in the ED or safely referred to a clinic or physician's office.

A more refined comprehensive triage system, which recognizes that EDs are used for both emergency and routine health care, has been implemented. This system has five levels: resuscitation, emergent, urgent, nonurgent, and minor (Tanabe, Gimbel, Yarnold, et al., 2004). The increased number of triage levels assists the triage nurse to more precisely determine the needs of the patient and the urgency for treatment. This five-level triage system is currently used throughout the United States, Australia, the United Kingdom, and Canada.

In the five-level system, patients in the emergent category identified in the previously used three-level system have been divided into two distinct groupings, resuscitation and emergent. Patients in the **resuscitation** category need treatment immediately to prevent death. Patients in the emergent category may deteriorate rapidly and develop a major life-threatening situation or require time-sensitive treatment. Patients in the urgent category have non-life-threatening conditions but require two or more resources (defined below) to provide their care. If these patients' vital signs deviate significantly from their baseline, they may require “up-triaging” to the emergent category. Patients in the nonurgent category have non-life-threatening conditions and likely need only one resource to provide for their needs. Patients in the **minor** category have no life-threatening conditions and likely require no resources to provide their evaluation and management.

Resources include imaging studies, medications administered by intravenous (IV) or intramuscular (IM) routes, and invasive procedures. Insertion of an indwelling catheter is an example of a one-resource procedure. Use of moderate sedation is a two-resource procedure because it requires frequent monitoring and IV medications.

Triage is an advanced skill. Emergency nurses spend many hours learning to classify different illnesses and injuries to ensure that patients most in need of care do not needlessly wait. Protocols may be followed to initiate laboratory or x-ray studies while the patient is in the triage area. Collaborative protocols are developed and used by the triage nurse based on his or her level of experience. Nurses in the triage area collect additional crucial baseline data: full vital signs including pain assessment, history of the current event and past medical history, neurologic assessment findings, weight, allergies (especially to latex and medications), domestic violence screening, and necessary diagnostic data. Some facilities collect these data in a computerized system, which helps guide the nurse through assessment and documentation. The following questions reflect the minimum information that should be obtained from the patient or from the person who accompanied the patient to the ED and then are documented.

- What were the circumstances, precipitating events, location, and time of the injury or illness?
- When did the symptoms appear?
- Was the patient unconscious after the injury or onset of illness?

- How did the patient get to the ED?
- What was the health status of the patient before the injury or illness?
- Is there a history of medical illness or previous surgeries? A history of admissions to the hospital?
- Is the patient currently taking any medications, especially hormones, insulin, digitalis, or anticoagulants? Is the patient using any complementary or alternative therapies such as herbology, naturopathy, reiki, massage, or acupuncture?
- Does the patient have any allergies, especially to latex, medications, eggs, or nuts?
- Does the patient smoke or use recreational drugs? How frequently? What type? When was the last time they were used?
- Does the patient have any fears? Does the patient feel that he or she is in danger or in an unsafe situation?
- When was the last meal eaten? (This is important if general anesthesia is to be given or if the patient is unconscious.)
- When was the last menstrual period?
- Is the patient under a physician's care? What are the name and contact information for the physician?
- What was the date of the patient's most recent tetanus immunization?

In addition to the collection of initial vital signs and medical history, triage consists of providing basic first aid, which may include application of ice, bleeding control, and basic wound care, as well as initiating protocol-based orders (eg, x-rays, administering antipyretics or mild analgesics, obtaining an electrocardiogram [ECG] or urinalysis, removing sutures). The triage nurse also is responsible for and monitors the waiting area, maintains a safe environment, reassesses waiting patients, and is the initial liaison to the families of patients.

Routine ED triage protocols differ significantly from the triage protocols used in disasters and mass casualty incidents (field triage). Routine triage directs all available resources to the patients who are most critically ill, regardless of potential outcome. In field triage (or hospital triage during a disaster), scarce resources must be used to benefit the most people possible. This distinction affects triage decisions (see Chapter 72).

Assess and Intervene

For the patient assigned to a resuscitation, emergent, or urgent triage category, stabilization, provision of critical treatments, and prompt transfer to the appropriate setting (intensive care unit, operating room, general care unit) are the priorities of emergency care. Although treatment is initiated in the ED, ongoing definitive treatment of the underlying problem is provided in other settings, and the sooner the patient is stabilized and moved to that area, the better the outcome.

A systematic approach to effectively establishing and treating health priorities is the primary survey/secondary survey approach. The primary survey focuses on stabilizing life-threatening conditions. The ED staff work collaboratively and follow the ABCD (**a**irway, **b**reathing, **c**irculation, **d**isability) method:

- Establish a patent airway.
- Provide adequate ventilation, employing resuscitation measures when necessary. (Trauma patients must have the cervical spine protected and chest injuries assessed first, immediately after the airway is established.)
- Evaluate and restore cardiac output by controlling hemorrhage, preventing and treating shock, and maintaining or restoring effective circulation. This includes the prevention and management of hypothermia. In addition, peripheral pulses are examined, and any immediate closed reductions of fractures or dislocations are performed if an extremity is pulseless.
- Determine neurologic disability by assessing neurologic function using the Glasgow Coma Scale and a motor and sensory evaluation of the spine (see Chapter 60).

After these priorities have been addressed, the ED team proceeds with the secondary survey. This includes the following:

- A complete health history and head-to-toe assessment (includes a reassessment of airway and breathing parameters)
- Diagnostic and laboratory testing
- Insertion or application of monitoring devices such as ECG electrodes, arterial lines, or urinary catheters
- Splinting of suspected fractures
- Cleansing, closure, and dressing of wounds
- Performance of other necessary interventions based on the patient's condition

Once the patient has been assessed, stabilized, and tested, appropriate medical and nursing diagnoses are formulated, initial important treatment is started, and plans for the proper disposition of the patient are made. Many emergent and urgent conditions and priority emergency interventions are discussed in detail in the remaining sections of this chapter.

In addition to the management of the illness or injury, the ED nurse must also focus on providing comfort and emotional support to the patient and family. Included in this is pain management. Effective pain management must be instituted early and should include rapid-acting agents that result in minimal sedation so that the patient can continue to interact with the staff for continued assessment. Moderate sedation can help facilitate short procedures in the ED; the patient will not remember the procedure later. The patient is closely monitored during the procedure and then rapidly awakens when it is complete (see Chapter 19).

It is essential that family crisis intervention services are available for families of ED patients. Even if a patient's condition is not emergent, the situation may be perceived as such by the family. Every family needs attention and support. The chaplain and social worker may be available to assist with interventions.

AIRWAY OBSTRUCTION

Acute upper airway obstruction is a life-threatening medical emergency.

Pathophysiology

The airway may be partially or completely occluded. Partial obstruction of the airway can lead to progressive hypoxia, hypercarbia, and respiratory and cardiac arrest. If the airway is completely obstructed, permanent brain injury or death will occur within 3 to 5 minutes secondary to hypoxia. Air movement is absent in the presence of complete airway obstruction. Oxygen saturation of the blood decreases rapidly because obstruction of the airway prevents entry of air into the lungs. Oxygen deficit occurs in the brain, resulting in unconsciousness, with death following rapidly.

Upper airway obstruction has a number of causes, including aspiration of foreign bodies, anaphylaxis, viral or bacterial infection, trauma, and inhalation or chemical burns. For elderly patients, especially those in extended-care facilities, sedatives and hypnotic medications, diseases affecting motor coordination (eg, Parkinson's disease), and mental dysfunction (eg, dementia, mental retardation) are risk factors for asphyxiation by food. In adults, aspiration of a bolus of meat is the most common cause of airway obstruction. Peritonsillar abscesses, epiglottitis, and other acute infectious processes of the posterior pharynx can also result in airway obstruction (Marx, 2006).

Clinical Manifestations

Typically, a person with a foreign body airway obstruction cannot speak, breathe, or cough. The patient may clutch the neck between the thumb and fingers (ie, universal distress signal). Other common signs and symptoms include choking, apprehensive appearance, refusing to lie flat, inspiratory and expiratory stridor, labored breathing, use of accessory muscles (suprasternal and intercostal retraction), flaring nostrils, increasing anxiety, restlessness, and confusion. Cyanosis and loss of consciousness develop as hypoxia worsens. Cyanosis and loss of consciousness are late signs. Action must be taken before these manifestations develop, if possible, or immediately if the patient has already exhibited these signs.

Assessment and Diagnostic Findings

Assessment of the patient who has a foreign object occluding the airway may involve simply asking the person whether he or she is choking and requires help. If the person is unconscious, inspection of the oropharynx may reveal the offending object. X-rays, laryngoscopy, or bronchoscopy also may be performed.

Management

If the patient can breathe and cough spontaneously, a partial obstruction should be suspected. The victim is encouraged to cough forcefully and to persist with spontaneous coughing and breathing efforts as long as good air exchange exists. There may be some wheezing between coughs. If the patient demonstrates a weak, ineffective cough, high-pitched noise while inhaling, increased respiratory difficulty, or cyanosis, the patient should be managed as if there were complete airway obstruction.

After the obstruction is removed, rescue breathing is initiated. If the patient has no pulse, cardiac compressions are instituted. These measures provide oxygen to the brain, heart, and other vital organs until definitive medical treat-

ment can restore and support normal heart and ventilatory activity.

Establishing an Airway

Establishing an airway may be as simple as repositioning the patient's head to prevent the tongue from obstructing the pharynx. Alternatively, other maneuvers, such as abdominal thrusts, the head-tilt–chin-lift maneuver, the jaw-thrust maneuver, or insertion of specialized equipment, may be needed to open the airway, remove a foreign body, or maintain the airway. In all maneuvers, the cervical spine must be protected from injury. After these maneuvers are performed, the patient is assessed for breathing by watching for chest movement and listening and feeling for air movement. In such a case, nursing diagnoses would include ineffective airway clearance related to obstruction of the airway by the tongue, an object, or fluids (blood, saliva) and ineffective breathing pattern related to airway obstruction or injury.

Abdominal Thrusts

The terms *subdiaphragmatic abdominal thrusts*, *abdominal thrusts*, and *Heimlich maneuver* are used interchangeably. This maneuver causes elevation of the diaphragm, forcing air from the lungs to create an artificial cough that can move and expel an obstructing foreign body from the airway. Chart 71-3 describes how to manage a foreign body obstruction using abdominal or chest thrusts.

Head-Tilt–Chin-Lift Maneuver

The patient is placed supine on a firm, flat surface. If the patient is lying face down, the body is turned as a unit so that the head, shoulders, and torso move simultaneously with no twisting (ie, logroll). Next, the airway is opened using either the head-tilt–chin-lift maneuver or the jaw-thrust maneuver. In the head-tilt–chin-lift maneuver, one hand is placed on the victim's forehead, and firm backward pressure is applied with the palm to tilt the head back. The fingers of the other hand are placed under the bony part of the lower jaw near the chin and lifted up. The chin and the teeth are brought forward almost to occlusion to support the jaw.

NURSING ALERT

The head-tilt–chin-lift maneuver, which helps tilt the head back, should be used only if it is determined that the patient's cervical spine is not injured.

Jaw-Thrust Maneuver

After one hand is placed on each side of the patient's jaw, the angles of the patient's lower jaw are grasped and lifted, displacing the mandible forward. This is a safe approach to opening the airway of a patient with suspected spinal cord injury because it can be accomplished without extending the neck.

Oropharyngeal Airway Insertion

An oropharyngeal airway is a semicircular tube or tubelike plastic device that is inserted over the back of the tongue into the lower posterior pharynx in a patient who is breathing spontaneously but who is unconscious (Chart 71-4). This type of airway prevents the tongue from falling back

Chart 71-3 • Managing a Foreign Body Airway Obstruction**Assess for Indications of Airway Obstruction**

- Person may clutch the neck between thumb and fingers
- Weak, ineffective cough; high-pitched noises on inspiration
- Increased respiratory distress
- Inability to speak, breathe, or cough
- Collapse

Heimlich Maneuver (Subdiaphragmatic Abdominal Thrusts)**For Standing or Sitting Conscious Patient**

Stand behind the patient, wrap your arms around the patient's waist, and proceed as follows:

1. Make a fist with one hand, placing the thumb side of the fist against the patient's abdomen, in the midline slightly above the umbilicus and well below the xiphoid process. Grasp the fist with the other hand.
2. Press your fist into the patient's abdomen with a quick inward and upward thrust. Each new thrust should be a separate and distinct maneuver. All thrusts should be in rapid sequence.

For Patient Lying Down (Unconscious)

1. Position patient on the back.
2. Kneel astride the patient's thighs, facing the head.
3. Place the heel of one hand against the patient's abdomen, in the midline slightly above the umbilicus and well below the tip of the xiphoid; place the second hand directly on top of the first.
4. Press into the abdomen with a quick upward thrust. All thrusts should be in rapid sequence.

Finger Sweep

1. Open the adult patient's mouth by grasping both the tongue and lower jaw between the thumb and fingers and lifting the mandible (tongue-jaw lift). This maneuver is to be used *only in the unconscious adult patient*. This action

draws the tongue away from the back of the throat and away from the foreign body that may be lodged there.

2. If a foreign body is visible in the mouth, insert the index finger of the other hand down along the inside of the cheek and scrape across the back of the throat.
3. Use a hooking action to dislodge the foreign body and maneuver it into the mouth for removal. Care is used to avoid forcing the object deeper into the throat.

Chest Thrusts With Conscious Patient Standing or Sitting

This technique is to be used *only in the patient in advanced stages of pregnancy or in the markedly obese person*.

1. Stand behind the patient with your arms under the patient's axillae to encircle the patient's chest.
2. Place the thumb side of your fist on the middle of the patient's sternum, taking care to avoid the xiphoid process and the margins of the rib cage.
3. Grasp your fist with the other hand and perform backward thrusts until the foreign body is expelled or the patient becomes unconscious. Each thrust should be administered with the intent of relieving the obstruction. All thrusts should be in rapid sequence.

Chest Thrust With Patient Lying (Unconscious)

This maneuver is *used only in the patient in advanced stages of pregnancy or when the rescuer cannot apply the Heimlich maneuver effectively to the unconscious, markedly obese person*.

1. Place the patient on the back and kneel close to the side of the patient's body.
2. Place the heel of your hand on the lower half of the sternum.
3. Deliver each chest thrust slowly and distinctly with the intent of relieving the obstruction.

against the posterior pharynx and obstructing the airway. It also allows health care providers to suction secretions.

Endotracheal Intubation

The purpose of endotracheal intubation is to establish and maintain the airway in patients with respiratory insufficiency or hypoxia. Endotracheal intubation is indicated to establish an airway for a patient who cannot be adequately ventilated with an oropharyngeal airway, bypass an upper airway obstruction, prevent aspiration, permit connection of the patient to a resuscitation bag or mechanical ventilator, or facilitate the removal of tracheobronchial secretions (Fig. 71-1). Because the procedure requires skill, endotracheal intubation is performed only by those who have had extensive training. These may include physicians, nurse anesthetists, respiratory therapists, flight nurses, and nurse practitioners. However, the emergency nurse is commonly called on to assist with intubation.

Rapid sequence intubation may be indicated, which provides management of the patient in a situation similar to that in the operating room. Medications used to facilitate

rapid sequence intubation include a sedative, an analgesic, and a neuromuscular blockade agent; these are usually administered by the practitioner performing the intubation.

Intubation With a Combitube or Laryngeal Mask Airway

If the patient is not hospitalized and cannot be intubated in the field, emergency medical personnel may insert a Combitube, which rapidly provides pharyngeal ventilation. When the tube is inserted into the trachea, it functions like an endotracheal tube (Fig. 71-2).

The two balloons that surround the tube are inflated after the tube is inserted. One balloon is large (100 mL) and occludes the oropharynx. This permits ventilation by forcing air through the larynx. The smaller balloon is inflated with 15 mL of air and is supposed to anchor the device in the esophagus at a site distal to the glottis; however, it can occlude the trachea if it is inadvertently placed there. Breath sounds are auscultated after balloon inflation to make sure that the oropharyngeal balloon (or cuff) does not obstruct the glottis. The patient can be ventilated through either one of the two ports (eg, tracheal or esophageal) of

Chart 71-4 • Inserting an Oropharyngeal Airway

1. Measure the oral airway alongside the head. The airway should reach from lip to ear.
2. Extend the patient's head by placing one hand under the bony chin (*only if the cervical spine is uninjured*). With the other hand, tilt the head backward by applying pressure to the forehead while simultaneously lifting the chin forward.
3. Open the patient's mouth.
4. **(A)** Insert the oropharyngeal airway with the tip facing up toward the roof of the mouth until it passes the uvula. **(B)** Rotate the tip 180 degrees so that the tip is pointed down toward the pharynx. This displaces the tongue anteriorly, and the patient then breathes through and around the airway.
5. The distal end of the oropharyngeal airway is in the hypopharynx, and the flange is approximately at the patient's lips. Make sure that the tongue has not been pushed into the airway.

the tube, depending on whether the tube is placed in the trachea or esophagus.

If it is difficult to establish an airway, a laryngeal mask airway (LMA) may be inserted as an interim airway device. The design of the LMA provides a “mask” in the subglottic airway with a cuff inflated within the esophagus. It allows easy insertion for rapid airway control until a more definitive airway can be placed. Some LMAs also permit removal of secretions from the esophagus (see Chapter 19).

Cricothyroidotomy (Cricothyroid Membrane Puncture)

Cricothyroidotomy is the opening of the cricothyroid membrane to establish an airway. This procedure is used in emergency situations in which endotracheal intubation is

either not possible or contraindicated, as in airway obstruction from extensive maxillofacial trauma, cervical spine injuries, laryngospasm, laryngeal edema (after an allergic reaction or extubation), hemorrhage into neck tissue, or obstruction of the larynx. A cricothyroidotomy is replaced with a formal tracheostomy when the patient is able to tolerate this procedure.

Maintaining Ventilation

Only a few conditions, such as an obstructed airway or a sucking wound of the chest, take precedence over the immediate control of hemorrhage. After the airway is determined to be unobstructed, the nurse must ensure that ventilation is adequate by checking for equal bilateral breath sounds. Satisfactory management of ventilations may prevent hypoxia and hypercapnia. The nurse must quickly assess for absent or diminished breath sounds, open chest wounds, and difficulty delivering artificial breaths for the patient. The nurse should monitor pulse oximetry, capnography, and arterial blood gases if the patient requires airway or ventilatory assistance. A tension pneumothorax can mimic hypovolemia, so ventilatory assessment precedes assessment for hemorrhage. A pneumothorax (both simple and tension) or sucking (open) chest wound is managed with a chest tube; immediate relief of increasing positive intrathoracic pressure and maintenance of adequate ventilation should occur immediately.

Figure 71-1 Endotracheal intubation in a patient without a cervical spine injury. **A**, The primary glottic landmarks for tracheal intubation as visualized with proper placement of the laryngoscope. **B**, Positioning the endotracheal tube.

HEMORRHAGE

Stopping bleeding is essential to the care and survival of patients in an emergency or disaster situation. Hemorrhage that results in the reduction of circulating blood

Figure 71-2 A, Combitube in esophageal position. B, Combitube tracheal position.

volume is a primary cause of shock. Minor bleeding, which is usually venous, generally stops spontaneously unless the patient has a bleeding disorder or has been taking anticoagulants.

The patient is assessed for signs and symptoms of shock: cool, moist skin (resulting from poor peripheral perfusion), decreasing blood pressure, increasing heart rate, delayed capillary refill, and decreasing urine volume (see Chapter 15). The goals of emergency management are to control the bleeding, maintain adequate circulating blood volume for tissue oxygenation, and prevent shock. Patients who hemorrhage are at risk for cardiac arrest caused by hypovolemia with secondary anoxia. Nursing interventions are carried out collaboratively with other members of the emergency health care team.

Management

Fluid Replacement

Whenever a patient is hemorrhaging—whether externally or internally—a loss of circulating blood results in a fluid volume deficit and decreased cardiac output. Therefore, fluid replacement is imperative to maintain circulation. Typically, two large-gauge IV catheters are inserted to provide a means for fluid and blood replacement, and blood samples are obtained for analysis, typing, and cross-matching. Replacement fluids are administered as prescribed, depending on clinical estimates of the type and volume of fluid lost. Replacement fluids may include isotonic electrolyte solutions (eg, lactated Ringer's, normal saline), colloids, and blood component therapy.

Packed red blood cells are infused when there is massive blood loss, which may also necessitate transfusion of other blood components, including platelets and clotting factors. (See Chapter 33 for full discussion of blood component therapy indications and treatment.)

NURSING ALERT

The infusion rate is determined by the severity of the blood loss and the clinical evidence of hypovolemia. If massive blood replacement is necessary, the blood must be warmed in a commercial blood warmer, because administration of large amounts of blood that has been refrigerated has a core cooling effect that may lead to cardiac arrest and coagulopathy.

Control of External Hemorrhage

If a patient is hemorrhaging externally (eg, from a wound), a rapid physical assessment is performed as the patient's clothing is cut away in an attempt to identify the area of hemorrhage. Direct, firm pressure is applied over the bleeding area or the involved artery at a site that is proximal to the wound (Fig. 71-3). Most bleeding can be stopped or at least controlled by application of direct pressure. Otherwise, unchecked arterial bleeding results in death. A firm pressure dressing is applied, and the injured part is elevated to stop venous and capillary bleeding if possible. If the injured area is an extremity, the extremity is immobilized to control blood loss.

A tourniquet is applied to an extremity only as a *last resort* when the external hemorrhage cannot be controlled in any other way and immediate surgery is not feasible. Care must be taken when applying a tourniquet because of the risk of loss of the extremity. The tourniquet is applied just proximal to the wound and tied tightly enough to control arterial blood flow. The patient is tagged with a skin-marking pencil or on adhesive tape on the forehead with a "T," stating the location of the tourniquet and the time applied (Lakstein, Blumenfeld, Sokolov, et al., 2003). If there is no arterial bleeding, the tourniquet is removed and a pressure dressing is applied. If the patient has suffered a traumatic amputation with uncontrollable hemorrhage, the tourniquet remains in place until the patient is in the operating room.

Figure 71-3 Pressure points for control of hemorrhage.

Control of Internal Bleeding

If the patient shows no external signs of bleeding but exhibits tachycardia, falling blood pressure, thirst, apprehension, cool and moist skin, or delayed capillary refill, internal hemorrhage is suspected. Typically, packed red blood cells are administered at a rapid rate, and the patient is prepared for more definitive treatment (eg, surgery, pharmacologic therapy). In addition, arterial blood gas specimens are obtained to evaluate pulmonary function and tissue perfusion and to establish baseline hemodynamic parameters, which are then used as an index for determining the amount of fluid replacement the patient can tolerate and the response to therapy. The patient is maintained in the supine position and monitored closely until hemodynamic or circulatory parameters improve, or until he or she is transported to the operating room or intensive care unit.

HYPOVOLEMIC SHOCK

Shock is a condition in which there is loss of effective circulating blood volume. Inadequate organ and tissue perfusion follows, ultimately resulting in cellular metabolic derangements. In any emergency situation, the onset of shock should be anticipated by assessing all injured people immediately. The underlying cause of shock (hypovolemic,

cardiogenic, neurogenic, anaphylactic or septic) must be determined. Of these, hypovolemia is the most common cause (see Chapter 15 for further discussion of management of hypovolemic shock).

WOUNDS

Wounds involving injury to soft tissues can vary from minor tears to severe crushing injuries. The types of wounds that may occur are defined in Chart 71-5. The primary goal of treatment is to restore the physical integrity and function of the injured tissue while minimizing scarring and preventing infection. Proper documentation of the characteristics of the wound, using precise descriptions and correct terminology, is essential. Such information may be needed in the future for forensic evidence. Photographs are helpful because they provide an accurate, visible depiction of the wound. Photographs also become important for exigent wounds (ie, wounds that will eventually heal). Patients involved in domestic violence or trauma may need the photographs later to visually describe the extent of injury.

Determining *when* and *how* the wound occurred is important because a treatment delay increases infection risk. Using aseptic technique, the clinician inspects the wound to determine the extent of damage to underlying structures

Chart 71-5 • Definition of Terms: Wounds

Laceration: skin tear with irregular edges and vein bridging
Avulsion: tearing away of tissue from supporting structures
Abrasion: denuded skin
Ecchymosis/contusion: blood trapped under the surface of the skin
Hematoma: tumorlike mass of blood trapped under the skin
Stab: incision of the skin with well-defined edges, usually caused by a sharp instrument; a stab wound is typically deeper than long
Cut: incision of the skin with well-defined edges, usually longer than deep
Patterned: wound representing the outline of the object (eg, steering wheel) causing the wound

or the presence of a foreign body. Sensory, motor, and vascular function is evaluated for changes that might indicate complications.

Management**Wound Cleansing**

Hair around the wound may be clipped (only as directed) if it is anticipated that the hair will interfere with wound closure. Typically, the area around the wound is cleansed with normal saline solution or a polymer agent (eg, Shur-Clens). Antibacterial agents, such as povidone-iodine (Betadine) or hydrogen peroxide, should not be allowed to get deep into the wound without thorough rinsing. These agents are used only for the initial cleansing because they injure exposed and healthy tissue, resulting in further tissue damage.

If indicated, the area is infiltrated with a local intradermal anesthetic through the wound margins or by regional block. Patients with soft tissue injuries usually have localized pain at the site of injury. The nurse then assists with cleaning and debriding the wound. The wound is irrigated gently and copiously with sterile isotonic saline solution to remove surface dirt. Devitalized tissue and foreign matter are removed because they impede healing and may promote infection. Any small bleeding vessels are clamped, tied, or cauterized. After wound treatment, a nonadherent dressing is applied to protect the wound and to serve as a splint and as a reminder to the patient that the area is injured.

Primary Closure

The decision to suture a wound depends on the nature of the wound, the time since the injury was sustained, the degree of contamination, and the vascularity of tissues. If primary closure is indicated, the wound is sutured or stapled, usually by the physician, with the patient receiving either local anesthesia or moderate sedation (see Chapter 19). Wound closure begins when subcutaneous fat is brought together loosely with a few sutures to close off the dead space. The subcuticular layer is then closed, and finally the epidermis is closed. Sutures are placed near the wound edge, with the skin edges leveled carefully to promote optimal healing. Instead of sutures, sterile strips of reinforced micro-porous tape or a bonding agent (skin glue) may be used to close clean, superficial wounds.

Delayed Primary Closure

Delayed primary closure may be indicated if tissue has been lost or there is a high potential for infection. A thin layer of gauze (to ensure drainage and prevent pooling of exudate), covered by an occlusive dressing, may be used. The wound is splinted in a functional position to prevent motion and decrease the possibility of contracture.

If there are no signs of suppuration (formation of purulent drainage), the wound may be sutured (with the patient receiving a local anesthetic). Use of antibiotics to prevent infection depends on factors such as how the injury occurred, the age of the wound, and the risk of contamination. The site is immobilized and elevated to limit accumulation of fluid in the interstitial spaces of the wound.

Tetanus prophylaxis is administered as prescribed, based on the condition of the wound and the patient's immunization status. If the patient's last tetanus booster was administered more than 5 years ago, or if the patient's immunization status is unknown, a tetanus booster must be given (American College of Surgeons [ACS], 2008). The patient is instructed about signs and symptoms of infection and is instructed to contact the health care provider or clinic if there is sudden or persistent pain, fever or chills, bleeding, rapid swelling, foul odor, drainage, or redness surrounding the wound.

TRAUMA

Trauma (an unintentional or intentional wound or injury inflicted on the body from a mechanism against which the body cannot protect itself) is the fourth leading cause of death in the United States. Trauma is the leading cause of death in children and in adults younger than 44 years of age. The incidence is increasing in adults older than 44 years of age. Alcohol and drug abuse are often implicated as factors in both blunt and penetrating trauma (McQuillan, VonReuden, Hartsock, et al., 2008).

Collection of Forensic Evidence

In assessing and managing any patient with an emergency condition, but especially the patient experiencing trauma, meticulous documentation is essential. Included in documentation are descriptions of all wounds, mechanism of injury, time of events, and collection of evidence. In trauma care, the nurse must be exceedingly careful with all potential evidence, handling and documenting it properly.

The basics of care management for patients with traumatic injury include an understanding that trauma in any patient (living or dead) has potential legal or forensic implications if criminal activity is suspected. Hence, proper management from both a medical and forensic perspective is essential.

When clothing is removed from the patient who has experienced trauma, the nurse must be careful not to cut through or disrupt any tears, holes, blood stains, or dirt present on the clothing if criminal activity is suspected. Each piece of clothing should be placed in an individual paper bag. If the clothing is wet, it should be hung to dry. Clothing should not be given to families. Valuables should be inventoried and either

placed in the hospital safe or it should be clearly documented to which family member they were given. If a police officer is present to collect clothing or any other items from the patient, each item is labeled. The transfer of custody to the officer, the officer's name, the date, and the time are documented.

If suicide or homicide is suspected in a deceased trauma patient, the medical examiner examines the body on site or has the body moved to the coroner's office for autopsy. All tubes and lines must remain in place. The patient's hands must be covered with paper bags to protect evidence on the hands or under the fingernails. In the surviving patient, tissue specimens may be swabbed from the hands and nails as potential evidence. Photographs of wounds or clothing are essential and should include a reference ruler in one photo and one without the ruler.

Documentation should also include any statements made by the patient in the patient's own words and surrounded by quotation marks. A chain of evidence is essential. If the patient's case is reviewed in a court of law in the future, clear documentation assists the judicial process and helps to identify the activities that occurred in the ED.

Injury Prevention

Any discussion of trauma management must address injury prevention. A component of the emergency nurse's daily role is to provide injury prevention information to every patient with whom there is contact, including patients admitted for reasons other than injury. The only way to reduce the incidence of trauma is through prevention.

There are three components of injury prevention. The first is education. Providing information and materials to help prevent violence and to maintain safety at home and in vehicles is important. Involvement in local injury prevention organizations, nursing organizations, and health fairs promotes wellness and safety. In practice, nursing and other health care professionals should avoid using the word "accident," because trauma events are *preventable* and should be viewed as such rather than as "fate" or "happenstance." Responsibility and accountability must be assigned to traumatic incidents, particularly because of the high rate of trauma recidivism (repeated trauma). People who are at risk for trauma and trauma recidivism should be identified and provided with education and counseling directed toward altering risky behaviors and preventing further trauma (ENA, 2007).

The second component of injury prevention is legislation. Nurses should be actively involved in safety legislation at the local, state, and federal levels. Such legislation is meant to provide universal safety measures, not to infringe on rights.

The third component is automatic protection. Airbags and automotive design are included in this category. These mechanisms provide for safety without requiring personal intervention.

Multiple Trauma

Multiple trauma is caused by a single catastrophic event that causes life-threatening injuries to at least two distinct organs or organ systems. Patients with single-system trauma still re-

ceive full assessment, because even single-system injuries can be life-threatening or more severe than they initially appear. Mortality in patients with multiple trauma is related to the severity of the injuries and the number of systems and organs involved. Immediately after injury, the body is hypermetabolic, hypercoagulable, and severely stressed.

Care of the patient with multiple injuries requires a team approach, with one person responsible for coordinating the treatment. The nursing staff assumes responsibility for assessing and monitoring the patient, ensuring airway and IV access, administering prescribed medications, collecting laboratory specimens, and documenting activities and the patient's subsequent responses.

Assessment and Diagnostic Findings

Evidence of trauma may be sparse or absent. Patients with multiple trauma should be assumed to have a spinal cord injury until it is proven otherwise. The injury regarded as the least significant in appearance may be the most lethal. For example, the pelvic fracture not identified until an x-ray is obtained may cause rapid and massive hemorrhage into the pelvic cavity, but an obvious amputation of the arm may have already stopped bleeding from the body's normal response of vasoconstriction.

Management

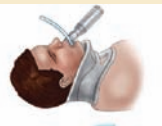

The goals of treatment are to determine the extent of injuries and to establish priorities of treatment. Any injury interfering with a vital physiologic function (eg, airway, breathing, circulation) is an immediate threat to life and has the highest priority for immediate treatment. Essential life-saving procedures are performed simultaneously by the emergency team. As soon as the patient is resuscitated, clothes are removed or cut off and a rapid physical assessment is performed. Transfer from field management to the ED must be orderly and controlled, with attention given to the verbal report from emergency medical services. Treatment in a trauma center is appropriate for patients experiencing major trauma. Treatment priorities are presented in Chart 71-6.

Intra-Abdominal Injuries

Intra-abdominal injuries are categorized as penetrating or blunt trauma. *Penetrating* abdominal injuries (ie, gunshot wounds, stab wounds) are serious and usually require surgery. Penetrating abdominal trauma results in a high incidence of injury to hollow organs, particularly the small bowel. The liver is the most frequently injured solid organ. In gunshot wounds, the most important prognostic factor is the velocity at which the missile enters the body. High-velocity missiles (bullets) produce extensive tissue damage. All abdominal gunshot wounds that cross the peritoneum or are associated with peritoneal signs require surgical exploration. On the other hand, some stab wounds may be managed nonoperatively due to low velocity and less penetration of the implement (ie, weapon).

Blunt trauma to the abdomen may result from motor vehicle crashes, falls, blows, or explosions. Blunt trauma is commonly associated with extra-abdominal injuries to the chest, head, or extremities. Patients with blunt trauma are a

Chart 71-6 • Priority Management in Patients with Multiple Injuries

1. Establish airway and ventilation.	
2. Control hemorrhage.	
3. Prevent and treat hypovolemic shock	
4. Assess for head and neck injuries.	
5. Evaluate for other injuries - reassess head and neck, chest, assess abdomen, back and extremities.	
6. Splint fractures.	
7. Perform a more thorough and ongoing examination and assessment.	

challenge because injuries may be difficult to detect. The incidence of delayed and trauma-related complications is greater than for penetrating injuries. This is especially true of blunt injuries involving the liver, kidneys, spleen, or blood vessels, which can lead to massive blood loss into the peritoneal cavity.

Assessment and Diagnostic Findings

As the history of the traumatic event is obtained, the abdomen is inspected as a part of the secondary survey for obvious signs of injury, including penetrating injuries, bruises, and abrasions. Abdominal assessment continues with auscultation of bowel sounds to provide baseline data from which changes can be noted. Absence of bowel sounds may be an early sign of intraperitoneal involvement, although stress can also decrease or halt peristalsis and bowel sounds. Further abdominal assessment may reveal progressive abdominal distention, involuntary guarding, tenderness, pain, muscular rigidity, or rebound tenderness along with changes in bowel sounds, all of which are signs of peritoneal irritation. Hypotension and signs and symptoms of shock may also be noted. Additionally, the chest and other body systems are assessed for injuries that frequently accompany intra-abdominal injuries.

Laboratory studies that aid in assessment include the following:

- Urinalysis to detect hematuria (indicative of a urinary tract injury)
- Serial hemoglobin and hematocrit levels to evaluate trends reflecting the presence or absence of bleeding
- White blood cell (WBC) count to detect elevation (generally associated with trauma)
- Serum amylase analysis to detect increasing levels, which suggest pancreatic injury or perforation of the gastrointestinal tract

Internal Bleeding

Hemorrhage frequently accompanies abdominal injury, especially if the liver or spleen has been traumatized. Therefore, the patient is assessed continuously for signs and symptoms of external and internal bleeding. The front of the body, flanks, and back are inspected for bluish discoloration, asymmetry, abrasion, and contusion. Abdominal computed tomography (CT) scans permit detailed evaluation of abdominal contents and retroperitoneal examination. Abdominal ultrasounds can rapidly assess hemodynamically unstable patients to detect intraperitoneal bleeding. This is referred to as the focused assessment sonography for trauma (FAST) examination (Kirkpatrick, Sirois, Laupland, et al., 2005). Pain in the left shoulder is common in a patient with bleeding from a ruptured spleen, whereas pain in the right shoulder can result from laceration of the liver. During the resuscitation period, pain is managed using administration of small dosages of opioids (ACS, 2008).

Intraperitoneal Injury

The abdomen is assessed for tenderness, rebound tenderness, guarding, rigidity, spasm, increasing distention, and pain. Referred pain is a significant finding because it suggests intraperitoneal injury. To determine if there is intraperitoneal injury and bleeding, the patient is usually prepared for diagnostic procedures, such as peritoneal lavage, abdominal ultrasonography, or abdominal CT scanning. **Diagnostic peritoneal lavage** (DPL), although no longer the standard diagnostic study used to evaluate a traumatized abdomen, remains a backup procedure that is easily performed and is very useful during mass casualty situations when CT scanners may not be readily available. DPL involves the instillation of 1 L of warmed lactated Ringer's or normal saline solution into the abdominal cavity. After a minimum of 400 mL has been returned, a fluid specimen is sent to the laboratory for analysis. Positive laboratory findings include a red blood cell count greater than 100,000/mm³; a WBC count greater than 500/mm³; or the presence of bile, feces, or food.

In patients with stab wounds, sinography may be performed to detect peritoneal penetration; a purse-string suture is placed around the wound and a small catheter is introduced through the wound. A contrast agent is then introduced through the catheter, and x-rays are taken to identify any peritoneal penetration.

Genitourinary Injury

A focused genitourinary examination, which typically includes a rectal and/or vaginal examination, is performed to determine any injury to the pelvis, bladder, urethra, or intestinal

wall. To decompress the bladder and monitor urine output, an indwelling catheter is inserted after a rectal examination has been completed (not before). In the male patient, a high-riding prostate gland (abnormal position) discovered during a rectal examination indicates a potential urethral injury.

NURSING ALERT

Urethral catheter insertion with a possible urethral injury is contraindicated; a urology consultation and further evaluation of the urethra are required.

Management

As indicated by the patient's condition, resuscitation procedures (restoration of airway, breathing, and circulation) are initiated as previously described.

With blunt trauma, the patient is kept on a stretcher to immobilize the spine. A backboard may be used for transporting the patient to the x-ray department, to the operating room, or to the intensive care unit. Cervical spine immobilization is maintained until cervical x-rays have been obtained and cervical spine injury has been ruled out. Likewise, once the patient has arrived at the definitive destination, the backboard is removed, and logrolling can be used to protect the spine until x-rays are obtained and confirm there is no evidence of injuries.

Knowing the mechanism of injury (eg, penetrating force from a gunshot or knife, blunt force from a blow) is essential to determining the type of management needed. All wounds are located, counted, and documented. If abdominal viscera protrude, the area is covered with sterile, moist saline dressings to keep the viscera from drying.

Typically, oral fluids are withheld in anticipation of surgery, and the stomach contents are aspirated with a nasogastric tube to reduce the risk of aspiration and to decompress the stomach in preparation for diagnostic procedures.

Trauma predisposes the patient to infection by disruption of mechanical barriers, exposure to exogenous bacteria from the environment at the time of injury, aspiration of vomitus, and diagnostic and therapeutic procedures (hospital-acquired infection). Tetanus prophylaxis and broad-spectrum antibiotics are administered as prescribed.

Throughout the stay in the ED, the patient's condition is continuously monitored for changes. If there is continuing evidence of shock, blood loss, free air under the diaphragm, evisceration, hematuria, severe head injury, or suspected or known abdominal injury, the patient is rapidly transported to surgery. In most cases, blunt liver and spleen injuries are managed nonsurgically.

Crush Injuries

Crush injuries occur when a person is caught between opposing forces (eg, run over by a moving vehicle, crushed between two cars, crushed under a collapsed building).

Assessment and Diagnostic Findings

The patient is observed for the following:

- Hypovolemic shock resulting from extravasation of blood and plasma into injured tissues after compression has been released

- Paralysis of a body part
- Erythema and blistering of skin
- Damaged body part (usually an extremity) appearing swollen, tense, and hard
- Renal dysfunction (prolonged hypotension causes kidney damage and acute renal insufficiency; myoglobinuria secondary to muscle damage can cause acute tubular necrosis and acute renal failure)

Management

In conjunction with maintaining the airway, breathing, and circulation, the patient is observed for acute renal insufficiency. Injury to the back can cause kidney damage. Severe muscular damage may cause rhabdomyolysis, which signifies a release of myoglobin from ischemic skeletal muscle, resulting in acute tubular necrosis. In addition, major soft tissue injuries are splinted promptly to control bleeding and pain. The serum lactic acid level is monitored; a decrease to less than 2.5 mmol/L is an indication of successful resuscitation (Blow, Magliore, Claridge, et al., 1999).

If an extremity is injured, it is elevated to relieve swelling and pressure. If compartment syndrome develops, the physician may perform a **fasciotomy** (ie, surgical incision to the level of the fascia) to restore neurovascular function (see Chapter 69). Medications for pain and anxiety are then administered as prescribed, and the patient is quickly transported to the operating suite for wound débridement and fracture repair. A hyperbaric oxygen chamber (if available) may be used to hyperoxygenate crushed tissue, if indicated.

Fractures

Immediate appropriate management of a fracture may determine the patient's eventual outcome and may mean the difference between recovery and disability. When the patient is being examined for fracture, the body part is handled gently and as little as possible. Clothing is cut off to visualize the affected body part. Assessment is conducted for pain over or near a bone, swelling (from blood, lymph, and exudate infiltrating the tissue), and circulatory disturbance. The patient is assessed for ecchymosis, tenderness, and crepitation (see Chapter 69). The nurse must remember that the patient may have multiple fractures accompanied by head, chest, spine, or abdominal injuries.

Management

Immediate attention is given to the patient's general condition. Assessment of airway, breathing, and circulation (which includes pulses in the extremities) is conducted. The patient is also evaluated for neurologic or abdominal injuries before the extremity is treated, unless a pulseless extremity is detected.

If a pulseless extremity is identified, repositioning of the extremity to proper alignment is required. If the pulseless extremity involves a fractured hip or femur, **Hare traction** (a portable in-line traction device) may be applied to assist with alignment. If repositioning is ineffective in restoring the pulse, a rapid total-body assessment must be completed, followed by transfer of the patient to the operating room for arteriography and possible arterial repair.

After the initial evaluation has been completed, all injuries identified are evaluated and treated. The fractured body part is inspected. Using a systematic head-to-toe approach, the nurse inspects the entire body, observing for lacerations, swelling, and deformities, including angulation (bending), shortening, rotation, and asymmetry. All peripheral pulses, especially those distal to the fractured extremity, are palpated. The extremity is also assessed for coolness, blanching, and decreased sensation and motor function, which are indicative of injury to the extremity's neurovascular supply.

A splint is applied before the patient is moved. Splinting immobilizes the joint at a site distal and proximal to the fracture, relieves pain, restores or improves circulation, prevents further tissue injury, and prevents a closed fracture from becoming an open one. To splint an extremity, one hand is placed distal to the fracture and some traction is applied while the other hand is placed beneath the fracture for support. The splints should extend beyond the joints adjacent to the fracture. Upper extremities must be splinted in a functional position. If the fracture is open, a moist, sterile dressing is applied.

After splinting, the vascular status of the extremity is checked by assessing color, temperature, pulse, and blanching of the nail bed. In addition, the patient is assessed for neurovascular compromise if pain or pressure is reported. (See Chapter 69 for a complete description of fracture management.)

ENVIRONMENTAL EMERGENCIES

Heat Stroke

Heat stroke is an acute medical emergency caused by failure of the heat-regulating mechanisms of the body. The most common cause of heat stroke is prolonged exposure to an environmental temperature of greater than 39.2°C (102.5°F). It usually occurs during extended heat waves, especially when they are accompanied by high humidity.

People at risk for heat stroke are those not acclimatized to heat, those who are elderly or very young, those unable to care for themselves, those with chronic and debilitating diseases, and those taking certain medications (eg, major tranquilizers, anticholinergics, diuretics, beta-blockers). Exertional heat stroke occurs in healthy individuals during sports or work activities (eg, exercising in extreme heat and humidity). Hyperthermia results because of inadequate heat loss. This type of heat stroke can also cause death. Strategies used to prevent heat stroke are reviewed in Chart 71-7.

Another form of heat stroke is heat exhaustion in which the patient's temperature may be normal to 40°C (104°F). The patient demonstrates weakness, hypotension, increased heart rate, and increased thirst.

Gerontologic Considerations

Most heat-related deaths occur in the elderly because their circulatory systems are unable to compensate for stress imposed by heat. Elderly people have a decreased ability to perspire as well as a decreased ability to vasodilate and vasoconstrict. They have less subcutaneous tissue, a decreased thirst mechanism, and a diminished ability to concentrate

CHART 71-7 HEALTH PROMOTION Preventing Heat Stroke

- Advise the patient treated for heat stroke to avoid immediate reexposure to high temperatures; hypersensitivity to high temperatures may remain for a considerable time.
- Emphasize the importance of maintaining adequate fluid intake, wearing loose clothing, and reducing activity in hot weather.
- Advise athletes to monitor fluid losses and weight loss during workout activities or exercise and to replace fluids and electrolytes.
- Advise the patient to use a gradual approach to physical conditioning, allowing sufficient time for return to baseline temperature.
- Direct frail elderly patients living in urban settings with high environmental temperatures to places where air conditioning is available (eg, shopping mall, library, church).
- Advise patients to plan outdoor activities to avoid the hottest part of the day (between 10 A.M. and 2 P.M.).

urine to compensate for heat. Many elderly people do not drink adequate amounts of fluid, partly because of fear of incontinence, and thus have a greater risk of heat stroke. In addition, many elderly people fear being victims of crime, so they tend to keep windows closed, even when the temperature and humidity levels are high.

Assessment and Diagnostic Findings

Heat stroke causes thermal injury at the cellular level, resulting in coagulopathies and widespread damage to the heart, liver, and kidneys. Recent patient history reveals exposure to elevated ambient temperature or excessive exercise during extreme heat. When assessing the patient, the nurse notes the following symptoms: profound central nervous system (CNS) dysfunction (manifested by confusion, delirium, bizarre behavior, coma); elevated body temperature (40.6°C [105°F] or higher); hot, dry skin; and usually anhidrosis (absence of sweating), tachypnea, hypotension, and tachycardia.

Management

The primary goal is to reduce the high body temperature as quickly as possible, because mortality is directly related to the duration of hyperthermia. Simultaneous treatment focuses on stabilizing oxygenation using the ABCs (airway, breathing, and circulation) of basic life support. This includes establishing IV access for fluid administration.

After the patient's clothing is removed, the core (internal) temperature is reduced to 39°C (102°F) as rapidly as possible, preferably within 1 hour (Hoyt & Selfridge-Thomas, 2007). One or more of the following methods may be used as prescribed:

- Cool sheets and towels or continuous sponging with cool water
- Ice applied to the neck, groin, chest, and axillae while spraying with tepid water
- Cooling blankets
- Immersion of the patient in a cold water bath (if possible) (Auerbach, 2007)

During cooling procedures, an electric fan is positioned so that it blows on the patient to augment heat dissipation by convection and evaporation. The patient's temperature is constantly monitored with a thermistor placed in the rectum, bladder, or esophagus to evaluate core temperature. Caution is used to avoid hypothermia and to prevent hyperthermia, which may recur spontaneously within 3 to 4 hours. The cooling process should stop at 38.8°C (102°F) in order to avoid iatrogenic hypothermia (Hoyt & Selfridge-Thomas, 2007).

Throughout treatment, the patient's status is monitored carefully, including vital signs, ECG findings (for possible myocardial ischemia, myocardial infarction, and dysrhythmias), central venous pressure (CVP), and level of responsiveness, all of which may change with rapid alterations in body temperature. A seizure may be followed by recurrence of hyperthermia. To meet tissue needs exaggerated by the hypermetabolic condition, 100% oxygen is administered. Endotracheal intubation and mechanical ventilation to support failing cardiopulmonary systems may be required.

IV infusion therapy of normal saline or lactated Ringer's solution is initiated as directed to replace fluid losses and maintain adequate circulation. Fluids are administered carefully because of the dangers of myocardial injury from high body temperature and poor renal function. Cooling redistributes fluid volume from the periphery to the core.

Urine output is also measured frequently, because acute tubular necrosis may occur as a complication of heat stroke from rhabdomyolysis (myoglobin in the urine). Blood specimens are obtained for serial testing to detect bleeding disorders, such as disseminated intravascular coagulation (DIC), and for serial enzyme studies to estimate thermal hypoxic injury to the liver, heart, and muscle tissue. Permanent liver, cardiac, and CNS damage may occur.

Additional supportive care may include dialysis for renal failure, antiseizure medications to control seizures, potassium for hypokalemia, and sodium bicarbonate to correct metabolic acidosis. Benzodiazepines (eg, diazepam [Valium]) or chlorpromazine (Thorazine) may be prescribed to suppress seizure activity. Patient education regarding the prevention of heat stroke (see Chart 71-7) is also important to prevent a recurrence.

Frostbite

Frostbite is trauma from exposure to freezing temperatures and freezing of the intracellular fluid and fluids in the intercellular spaces. It results in cellular and vascular damage. Frostbite can result in venous stasis and thrombosis. Body parts most frequently affected by frostbite include the feet, hands, nose, and ears. Frostbite ranges from first degree (redness and erythema) to fourth degree (full-depth tissue destruction).

Assessment and Diagnostic Findings

A frozen extremity may be hard, cold, and insensitive to touch and may appear white or mottled blue-white. The extent of injury from exposure to cold is not always initially known. The patient history should include environmental

temperature, duration of exposure, humidity, and the presence of wet conditions.

Management

The goal of management is to restore normal body temperature. Constrictive clothing and jewelry that could impair circulation are removed. Wet clothing is removed as rapidly as possible. If the lower extremities are involved, the patient should not be allowed to ambulate.

Controlled yet rapid rewarming is instituted. Frozen extremities are usually placed in a 37°C to 40°C (98.6°F to 104°F) circulating bath for 30- to 40-minute spans. This treatment is repeated until circulation is effectively restored. Early rewarming appears to decrease the amount of ultimate tissue loss. During rewarming, an analgesic for pain is administered as prescribed, because the rewarming process may be very painful. To avoid further mechanical injury, the body part is not handled. Massage is contraindicated.

Once rewarmed, the part is protected from further injury and is elevated to help control swelling. Sterile gauze or cotton is placed between affected fingers or toes to prevent maceration, and a bulky dressing is placed on the extremity. A foot cradle may be used to prevent contact with bedclothes if the feet are involved. Hemorrhagic blebs, which may develop 1 hour to a few days after rewarming, are left intact and not ruptured. Nonhemorrhagic blisters are debrided to decrease the inflammatory mediators found in the blister fluid.

A physical assessment is conducted with rewarming to observe for concomitant injury, such as soft tissue injury, dehydration, alcohol coma, or fat embolism. Problems such as hyperkalemia (eg, from release of potassium in the damaged cells) and hypovolemia, which occur frequently in people with frostbite, are corrected. Risk of infection is also great; therefore, strict aseptic technique is used during dressing changes, and tetanus prophylaxis is administered as indicated. Nonsteroidal anti-inflammatory medication is prescribed for its anti-inflammatory effects and to control pain.

Additional measures that may be carried out when appropriate include the following:

- Whirlpool bath for the affected body parts to aid circulation and debridement of necrotic tissue to help prevent infection
- Escharotomy (incision through the eschar) to prevent further tissue damage, to allow for normal circulation, and to permit joint motion
- Fasciotomy to treat compartment syndrome

After rewarming, hourly active motion of any affected digits is encouraged to promote maximal restoration of function and to prevent contractures. Discharge instructions also include encouraging the patient to avoid tobacco, alcohol, and caffeine because of their vasoconstrictive effects, which further reduce the already deficient blood supply to injured tissues.

Hypothermia

Hypothermia is a condition in which the core (internal) temperature is 35°C (95°F) or less as a result of exposure to cold or an inability to maintain body temperature in the

absence of low ambient temperatures. Urban hypothermia (extreme exposure to cold in an urban setting) is associated with a high mortality rate; elderly people, infants, people with concurrent illnesses, and the homeless are particularly susceptible. Alcohol ingestion increases susceptibility because it causes systemic vasodilation. Some medications (eg, phenothiazines) or medical conditions (eg, hypothyroidism, spinal cord injury) decrease the ability to shiver, hampering the body's innate ability to generate body heat. Trauma victims are also at risk for hypothermia resulting from treatment with cold fluids, unwarmed oxygen, and exposure during examination. The patient may also have frostbite, but hypothermia takes precedence in treatment.

Assessment and Diagnostic Findings

Hypothermia leads to physiologic changes in all organ systems. There is progressive deterioration, with apathy, poor judgment, ataxia, dysarthria, drowsiness, pulmonary edema, acid-base abnormalities, coagulopathy, and eventual coma. Shivering may be suppressed at a temperature of less than 32.2°C (90°F), because the body's self-warming mechanisms become ineffective. The heartbeat and blood pressure may be so weak that peripheral pulses become undetectable. Cardiac dysrhythmias may also occur. Other physiologic abnormalities include hypoxemia and acidosis.

Management

Management consists of removal of wet clothing, continuous monitoring, rewarming, and supportive care.

Monitoring

The ABCs of basic life support are a priority. The patient's vital signs, CVP, urine output, arterial blood gas levels, blood chemistry determinations (blood urea nitrogen, creatinine, glucose, electrolytes), and chest x-rays are evaluated frequently. Body temperature is monitored with an esophageal, bladder, or rectal thermistor. Continuous ECG monitoring is performed, because cold-induced myocardial irritability leads to conduction disturbances, especially ventricular fibrillation. An arterial line is inserted and maintained to record blood pressure and to facilitate blood sampling.

Rewarming

Rewarming methods include active internal (core) rewarming and passive or active external (spontaneous) rewarming.

Active internal (core) rewarming methods are used for moderate to severe hypothermia (less than 28°C to 32.2°C [82.5°F to 90°F]) and include cardiopulmonary bypass, warm fluid administration, warm humidified oxygen by ventilator, and warmed peritoneal lavage. Monitoring for ventricular fibrillation as the patient's temperature increases from 31°C to 32°C (88°F to 90°F) is essential.

Passive or active external rewarming is used for mild hypothermia (32.2°C to 35°C [90°F to 95°F]). Passive active rewarming uses over-the-bed heaters to the extremities and increases blood flow to the acidotic, anaerobic extremities. The cold blood from peripheral tissues has high lactic acid levels. As this blood returns to the core, it causes a significant drop in the core temperature (ie, core temperature

afterdrop) and can potentially cause cardiac dysrhythmias and electrolyte disturbances. Active external rewarming uses forced air warm blankets. Care must be taken to prevent extremity burn from these devices, because the patient may not have effective sensation to feel the burn.

Supportive Care

Supportive care during rewarming includes the following as directed:

- External cardiac compression (typically performed only as directed in patients with temperatures higher than 31°C [88°F]).
- Defibrillation of ventricular fibrillation. A patient whose temperature is less than 32°C [90°F] experiences spontaneous ventricular fibrillation if moved or touched. Defibrillation is ineffective in patients with temperatures lower than 31°C (88°F); therefore, the patient must be rewarmed first.
- Mechanical ventilation with positive end-expiratory pressure (PEEP) and heated humidified oxygen to maintain tissue oxygenation.
- Administration of warmed IV fluids to correct hypotension and to maintain urine output and core rewarming, as described previously.
- Administration of sodium bicarbonate to correct metabolic acidosis if necessary.
- Administration of antiarrhythmic medications.
- Insertion of an indwelling urinary catheter to monitor urinary output and renal function.

Near Drowning

Near drowning is defined as survival for at least 24 hours after submersion that caused a respiratory arrest. The most common consequence is hypoxemia. Drowning is the second most common cause of unintentional death in children younger than 14 years. An estimated 8000 drownings and 90,000 near drownings occur yearly in the United States (Hoyt & Selfridge-Thomas, 2007).

Factors associated with drowning and near drowning include alcohol ingestion, inability to swim, diving injuries, hypothermia, and exhaustion. The majority of drowning events occur in pools, lakes, and bathtubs. Suicide by drowning rarely occurs in pools and rarely involves alcohol (Auerbach, 2007).

Efforts to save the patient should not be abandoned prematurely. Successful resuscitation with full neurologic recovery has occurred in near-drowning patients after prolonged submersion in cold water. This is possible because of a decrease in metabolic demands and/or the diving reflex. The near-drowning process involves the onset of hypoxia, hypercapnia, bradycardia, and dysrhythmias. If there is a violent struggle associated with the near-drowning episode, exercise-induced acidosis and tachypnea can result in aspiration. Hypoxia and acidosis cause eventual apnea and loss of consciousness. When the victim loses consciousness and makes a final effort to breathe, the terminal gasp occurs. Water then moves passively into the airways prior to death.

After resuscitation, hypoxia and acidosis are the primary complications experienced by a person who has nearly

drowned; immediate intervention in the ED is essential. Resultant pathophysiologic changes and pulmonary injury depend on the type of fluid (fresh or salt water) and the volume aspirated. Fresh water aspiration results in a loss of surfactant and, therefore, an inability to expand the lungs. Salt water aspiration leads to pulmonary edema from the osmotic effects of the salt within the lungs. If a person survives submersion, acute respiratory distress syndrome (ARDS), resulting in hypoxia, hypercarbia, and respiratory or metabolic acidosis, can occur.

Management

Therapeutic goals include maintaining cerebral perfusion and adequate oxygenation to prevent further damage to vital organs. Immediate cardiopulmonary resuscitation is the factor with the greatest influence on survival. The most important priority in resuscitation is to manage the hypoxia, acidosis, and hypothermia. Prevention and management of hypoxia are accomplished by ensuring an adequate airway and respiration, thus improving ventilation (which helps correct respiratory acidosis) and oxygenation. Arterial blood gases are monitored to evaluate oxygen, carbon dioxide, bicarbonate levels, and pH. These parameters determine the type of ventilatory support needed. Use of endotracheal intubation with PEEP improves oxygenation, prevents aspiration, and corrects intrapulmonary shunting and ventilation–perfusion abnormalities (caused by aspiration of water). If the patient is breathing spontaneously, supplemental oxygen may be administered by mask. However, an endotracheal tube is necessary if the patient does not breathe spontaneously.

Because of submersion, the patient is usually hypothermic. A rectal probe is used to determine the degree of hypothermia. Prescribed rewarming procedures (eg, extracorporeal warming, warmed peritoneal dialysis, inhalation of warm aerosolized oxygen, torso warming) are started during resuscitation. The choice of warming method is determined by the severity and duration of hypothermia and available resources. Intravascular volume expansion and inotropic agents are used to treat hypotension and impaired tissue perfusion. ECG monitoring is initiated, because dysrhythmias frequently occur. An indwelling urinary catheter is inserted to measure urine output. Hypothermia and accompanying metabolic acidosis may compromise renal function. Nasogastric intubation is used to decompress the stomach and to prevent the patient from aspirating gastric contents.

Even if the patient appears healthy, close monitoring continues with serial vital signs, serial arterial blood gas values, ECG monitoring, intracranial pressure assessments, serum electrolyte levels, intake and output, and serial chest x-rays. After a near-drowning, the patient is at risk for complications such as hypoxic or ischemic cerebral injury, ARDS, pulmonary damage secondary to aspiration, and life-threatening cardiac arrest.

Decompression Sickness

Decompression sickness, also called “the bends,” occurs in patients who have engaged in diving (lake, as well as ocean, diving), high-altitude flying, or flying in commercial aircraft

within 24 hours after diving. It occurs relatively infrequently in the United States, but its effects can be hazardous. Being aware of decompression sickness and assessing the patient properly ensures proper management and results in the least morbidity possible.

Decompression sickness results from formation of nitrogen bubbles that occur with rapid changes in atmospheric pressure. They may occur in joint or muscle spaces, resulting in musculoskeletal pain, numbness, or hypesthesia. More significantly, nitrogen bubbles can become air emboli in the bloodstream and thereby produce stroke, paralysis, or death. Taking a rapid history about the events preceding the symptoms is essential. Recompression is necessary as soon as possible and may necessitate a low-altitude flight to the nearest hyperbaric chamber.

Assessment and Diagnostic Findings

To identify decompression sickness, a detailed history is obtained from the patient or diving partner. Evidence of rapid ascent, loss of air in the tank, buddy breathing, recent alcohol intake or lack of sleep, or a flight within 24 hours after diving suggests possible decompression sickness. Some patients describe a perfect dive yet still have the signs and symptoms of decompression sickness, and they must receive treatment for the condition.

Signs and symptoms include joint or extremity pain, numbness, hypesthesia, and loss of range of motion. Neurologic symptoms mimicking those of a stroke or spinal cord injury can indicate an air embolus. Cardiopulmonary arrest can also occur in severe cases and is usually fatal. Any neurologic symptoms should be rapidly assessed. All patients with decompression sickness need rapid transfer to a hyperbaric chamber.

Management

A patent airway and adequate ventilation are established, as described previously, and 100% oxygen is administered throughout treatment and transport. A chest x-ray is obtained to identify aspiration, and at least one IV line is started with lactated Ringer’s or normal saline solution.

The cardiopulmonary and neurologic systems are supported as needed. If an air embolus is suspected, the head of the bed should be lowered. The patient’s wet clothing is removed, and the patient is kept warm. Transfer to the closest hyperbaric chamber for treatment is initiated. If air transport is necessary, low-altitude flight (below 1000 feet) is required. However, the patient who is awake and alert without central neurologic deficits may be able to travel by ground ambulance or by automobile, depending on the severity of symptoms. Throughout treatment, the patient is continually assessed, and changes are documented. If aspiration is suspected, antibiotics and other treatment may be prescribed.

Anaphylactic Reaction

An anaphylactic reaction is an acute systemic hypersensitivity reaction that occurs within seconds or minutes after exposure to certain foreign substances, such as medications (eg, penicillin, iodinated contrast material), and other agents, such as latex, insect stings (eg, bee, wasp, yellow jacket, hornet), or foods (eg, eggs, peanuts). Repeated administration

Chart 71-8 • Nursing Interventions for Preventing Anaphylactic Reactions

- Be aware of the danger of anaphylactic reactions and the early signs of anaphylaxis.
- Ask the patient about previous allergies to medications, foods, stings, latex, pollen, peanuts, nuts from trees, eggs, and so on.
- Before giving a foreign serum or other type of antigenic agent, ask the patient or caregiver whether the agent was received at some earlier time.
- Avoid giving medications to patients with hay fever, asthma, or other allergic disorders unless necessary.
- Avoid giving parenteral medications unless absolutely necessary, because anaphylactic reactions are more likely to occur when the agent is given parenterally.
- Perform a skin test before administration of certain materials known to produce anaphylactic reactions (eg, horse serum). Remember that negative skin test results do not always indicate safety and that skin testing can precipitate anaphylaxis in highly sensitive patients. Have epinephrine, intravenous infusions, and intubation and tracheostomy equipment available as precautionary measures.
- If the patient is an outpatient, keep him or her in the office, hospital, or clinic for at least 30 minutes after injection of any agent. Caution the patient to return if symptoms develop.
- Caution patients who are highly sensitive (eg, to insect bites and stings) to carry kits equipped to treat insect stings (epinephrine). Instruct the patient, family, and significant others in the use of the emergency supplies.
- Encourage patients with allergies to wear medical identification tags or bracelets.

of parenteral or oral therapeutic agents (eg, repeated exposures to penicillin) may also precipitate an anaphylactic reaction when initially only a mild allergic response occurred. Anaphylaxis prevention strategies are given in Chart 71-8.

An anaphylactic reaction is the result of an antigen-antibody interaction in a sensitized person who, as a consequence of previous exposure, has developed a special type of antibody (immunoglobulin) that is specific for that particular allergen. Immunoglobulin E (IgE) is responsible for most of the immediate types of human allergic responses. A second exposure to the same antigen results in a more severe and more rapid response (see Chapter 53).

An anaphylactic reaction produces a wide range of clinical manifestations, especially respiratory symptoms (difficulty breathing and stridor secondary to laryngeal edema), fainting, itching, swelling of mucous membranes, and a sudden decrease in blood pressure secondary to massive vasodilation that may progress to shock (Chart 71-9). (See Chapters 15 and 53 for additional discussion and management of anaphylactic reactions.)

Insect Stings

A person may have an extreme sensitivity to the venoms of insects in the order Hymenoptera (bees, hornets, yellow jackets, fire ants, and wasps). Venom allergy is thought to be

CHART 71-9

Assessing for Anaphylaxis

Be alert for the following signs and symptoms:

Respiratory Signs

- Nasal congestion
- Itching
- Sneezing and coughing
- Possible respiratory distress that progresses rapidly (caused by bronchospasm or edema of the larynx)
- Chest tightness
- Other respiratory difficulties, such as wheezing, dyspnea, and cyanosis

Skin Manifestations

- Flushing with a sense of warmth and diffuse erythema
- Generalized itching over the entire body (indicates developing general systemic reaction)
- Urticaria (hives)
- Massive facial angioedema possible with accompanying upper respiratory edema

Cardiovascular Manifestations

- Tachycardia or bradycardia
- Peripheral vascular collapse as indicated by
 - Pallor
 - Imperceptible pulse
 - Decreasing blood pressure
 - Circulatory failure, leading to coma and death

Gastrointestinal Problems

- Nausea
- Vomiting
- Colicky abdominal pains
- Diarrhea

an IgE-mediated reaction, and it constitutes an acute emergency. Although stings in any area of the body can trigger anaphylaxis, stings of the head and neck or multiple stings are especially serious.

Clinical manifestations range from generalized urticaria, itching, malaise, and anxiety due to laryngeal edema to severe bronchospasm, shock, and death. Generally, the shorter the time between the sting and the onset of severe symptoms, the worse the prognosis.

Management includes stinger removal if the sting is from a bee because the venom is associated with sacs around the barb of the stinger itself. The stinger is removed with one quick scrape of a fingernail over the site. Wound care with soap and water is sufficient for stings. Scratching is avoided because it results in a histamine response. Ice application reduces swelling and also decreases venom absorption. An oral antihistamine and analgesic will decrease the itching and pain.

In the case of an anaphylactic or severe allergic response, the patient is treated as discussed previously in Chapter 53. Desensitization therapy should be given to people who have had systemic or significant local reactions. Patient and family education is an important measure in preventing exposure to stinging insects (Chart 71-10).

CHART
71-10

PATIENT EDUCATION

Limiting Exposure to Stinging Insects

To Minimize Your Chances of Being Stung:

- Avoid places where stinging insects congregate, such as camp and picnic sites, and insect feeding areas, such as flower beds, ripe fruit orchards, garbage, and fields of clover.
- Wear covering on the feet, and avoid going barefoot outdoors, because yellow jackets nest and pollinate on the ground.
- Avoid perfumes, scented soaps, and bright colors, which attract bees.
- Keep car windows closed.
- Spray garbage cans with quick-acting insecticide.
- Secure a professional exterminator to dispose of wasp and hornet nests or beehives in the home area.

- Remain motionless if an insect is buzzing around. Motion, especially running, increases the likelihood of being stung.
- If allergic, carry a self-treatment kit containing injectable (Epi-Pen) and inhalant forms of epinephrine, an oral antihistamine, and written instructions. Carry it with you at all times.

If You are Stung, Do the Following:

1. Inject self immediately with epinephrine if allergy is known or allergic response occurs.
2. Remove the stinger with one quick scrape of the fingernail. *Do not* squeeze the venom sac because this may cause injection of additional venom.
3. Clean the area with soapy water, and apply ice.
4. Report to the nearest health care facility for further examination if allergic response or allergy is suspected.

Animal and Human Bites

Bites are a common reason for visits to the ED. Dog bites constitute 90% of these bites and are responsible for the majority of deaths from bites by a nonvenomous animal. Cat bites have a high risk of infection because of the presence of *Pasteurella* in their saliva. All animal bites must be reported to public health authorities, which must provide follow-up screening of the offending animal for rabies. If the animal cannot be located and rabies vaccination verified, rabies prophylaxis for the person who has been bitten must be instituted.

Human bites are frequently associated with rapes, sexual assaults, or other forms of battery. The human mouth contains more bacteria than that of most other animals, so a high risk of bite-related infection exists. Depending on the circumstances surrounding the event, the victim may delay seeking treatment. The ED nurse should inspect any bitten tissue for pus, erythema, or necrosis. A health care provider should take photographs, which can be used as evidence in criminal and legal proceedings. Cleansing with soap and water is then necessary, followed by the administration of antibiotics and tetanus toxoid as prescribed.

Snake Bites

Venomous (poisonous) snakes cause 7000 to 8000 bites in the United States each year and result in 10 to 15 deaths (Hoyt & Selfridge-Thomas, 2007). Children between 1 and 9 years of age are the most likely victims. The greatest number of bites occurs during the daylight hours and early evening of the summer months. The most frequent poisonous snake bite occurs from pit vipers (Crotalidae). The most common site is the upper extremity. Of these bites, only 20% to 25% result in **envenomation** (injection of a poisonous material by sting, spine, bite, or other means). Venomous snake bites are medical emergencies (Daley & Barbee, 2008).

Nineteen different species of venomous snakes are found in various regions within the United States. Nurses should be familiar with the types of snakes common to the geographic region in which they practice.

Clinical Manifestations

Snake venom consists primarily of proteins and has a broad range of physiologic effects. It may affect multiple organ systems, especially the neurologic, cardiovascular, and respiratory systems.

Classic clinical signs of envenomation are edema, ecchymosis, and hemorrhagic bullae, leading to necrosis at the site of envenomation. Symptoms include lymph node tenderness, nausea, vomiting, numbness, and a metallic taste in the mouth. Without decisive treatment, these clinical manifestations may progress to include fasciculations, hypotension, paresthesias, seizures, and coma (Daley & Barbee, 2008).

Management

Initial first aid at the site of the snake bite includes having the person lie down, removing constrictive items such as rings, providing warmth, cleansing the wound, covering the wound with a light sterile dressing, and immobilizing the injured body part below the level of the heart. Airway, breathing, and circulation are the priorities of care. Ice or a tourniquet is *not* applied. Initial evaluation in the ED is performed quickly and includes information about the following:

- Whether the snake was venomous or nonvenomous; if the snake is dead, it should be transported to the ED with the patient for identification. However, caution should be taken when handling the transported snake. Frequently, the patient and family transport the snake in a stunned, not dead, state.
- Where and when the bite occurred and the circumstances of the bite
- Sequence of events, signs and symptoms (fang punctures, pain, edema, and erythema of the bite and nearby tissues)
- Severity of poisonous effects
- Vital signs
- Circumference of the bitten extremity or area at several points; the circumference of the extremity that was bitten is compared with the circumference of the opposite extremity

- Laboratory data (complete blood count, urinalysis, and coagulation studies)

The course and prognosis of snake bite injuries depend on the kind and amount of venom injected, where on the body the bite occurred, and the general health, age, and size of the patient. There is no one specific protocol for treatment of snake bites. Generally, ice, tourniquets, heparin, and corticosteroids are not used during the acute stage. Corticosteroids are contraindicated in the first 6 to 8 hours after the bite because they may depress antibody production and hinder the action of **antivenin** (antitoxin manufactured from the snake venom and used to treat snake bites).

Parenteral fluids may be used to treat hypotension. If vasopressors are used to treat hypotension, their use should be short term. Surgical exploration of the bite is rarely indicated. Typically, the patient is observed closely for at least 6 hours. The patient is *never* left unattended.

Administration of Antivenin (Antitoxin)

Although envenomation is rare, it can occur with snake bites. An assessment of progressive signs and symptoms is essential before considering administration of antivenin, which is most effective if administered within 4 hours and no greater than 12 hours after the snake bite. Two antivenins are available: Antivenin Polyvalent (ACP) and Crotalidae Polyvalent Immune Fab Antivenin (FabAV) (Auerbach, 2007). The dose depends on the type of snake and the estimated severity of the bite. Indications for antivenin depend on the progression of symptoms, including coagulopathy and systemic reaction. Children may require more antivenin than adults because their smaller bodies are more susceptible to the toxic effects of venom.

A skin or eye test should be performed before the initial dose to detect allergy to the antivenin, because as many as 33% of patients who are given ACP (horse serum–derived antivenin) develop hypersensitivity reactions to it. Because even the skin test can cause an anaphylactic reaction, patients should not be tested unless antivenin will be given. If the dose exceeds 10 vials, serum sickness will most likely occur. Serum sickness is a type of hypersensitivity response that results in fever, arthralgias, pruritus, lymphadenopathy, and proteinuria and can progress to neuropathies.

FabAV is more potent than ACP, with less associated hypersensitivity and serum sickness (Auerbach, 2007). However, FabAV must be administered cautiously to patients receiving anticoagulation therapy. Administration of FabAV may result in a recurring coagulopathy. The dosage and administration of FabAV are different from ACP and should be reviewed carefully before the medication is given.

Before administering antivenin and every 15 minutes thereafter, the circumference of the affected part is measured. Premedication with diphenhydramine (Benadryl) or cimetidine (Tagamet) is indicated because these antihistamines may decrease the allergic response to antivenin. Antivenin is administered as an IV infusion whenever possible, although IM administration can be used.

Depending on the severity of the snake bite, the antivenin is diluted in 500 to 1000 mL of normal saline solution. The infusion is started slowly, and the rate is increased after 10 minutes if there is no reaction. The total dose should be infused during the first 4 to 6 hours after the bite.

The initial dose is repeated until symptoms decrease. After symptoms decrease, the circumference of the affected part should be measured every 30 to 60 minutes for the next 48 hours to detect symptoms of compartment syndrome (swelling, loss of pulse, increased pain, and paresthesias).

The most common cause of allergic reaction to the antivenin is too-rapid infusion, although about 3% of patients with negative skin test results develop reactions unrelated to infusion rate. Reactions may consist of a feeling of fullness in the face, urticaria, pruritus, malaise, and apprehension. These symptoms may be followed by tachycardia, shortness of breath, hypotension, and shock. In this situation, the infusion should be stopped immediately and IV diphenhydramine administered. Vasopressors are used for patients in shock, and resuscitation equipment must be on standby while antivenin is infusing.

Spider Bites

There are two venomous spiders found in the United States that typically interact with humans: the brown recluse and the black widow. Both are usually found in dark places such as closets, woodpiles, and attics, as well as in shoes.

Brown recluse spider bites are painless. Systemic effects such as fever and chills, nausea and vomiting, malaise, and joint pain develop within 24 to 72 hours. The site of the bite may appear reddish to purple in color within 2 to 8 hours after the bite. Necrosis occurs in the next 2 to 4 days in approximately 10% of cases. The center of the bite may become necrotic, and surgical débridement may be necessary. Wound care consists of cleansing with soap and water, and hyperbaric oxygen treatments may be helpful. Most wounds heal within 2 to 3 months.

Black widow spider bites feel like pinpricks. Systemic effects usually occur within 30 minutes—much more rapidly than with brown recluse spider bites. Signs and symptoms include abdominal rigidity, nausea and vomiting, hypertension, tachycardia, and paresthesias. Severe pain also develops within 60 minutes and increases over 1 to 2 days. Treatment involves application of ice to the site to decrease systemic toxin delivery. Cardiopulmonary monitoring is essential. Antivenin is effective for black widow spider bites. This antivenin is horse serum–based; therefore, testing for sensitivity must be performed prior to administration (Auerbach, 2007).

Tick Bites

Tick bites are common in many areas of the United States, and they usually occur in grassy or wooded areas. It is important to learn the place where the bite occurred as well as the location of the bite on the body. The patient may demonstrate weakness; joint pain; skin rash, especially on the palms and soles of feet; headache; and fever. Ticks can carry diseases such as Rocky Mountain spotted fever, tularemia, and Lyme disease. The tick bite itself is not usually the problem; rather, it is the pathogen transmitted by the tick that can cause serious disease. The tick should be removed, and the patient should be informed of the signs and

symptoms of diseases carried by ticks, especially if the patient lives in an area endemic for tick-related diseases (eg, Lyme disease).

Lyme disease has three stages. Stage I presents with a “bull’s eye” rash (ie, erythema migrans) that typically can be found in the axilla, groin, or thigh area and that appears within 4 weeks after the tick bite, with a peak manifestation time of 7 days after the bite. Classically, this rash is at least 5 cm in diameter with bright red borders. It is accompanied by flulike signs and symptoms that may include chills, fever, myalgia, fatigue, and headache. Without treatment, the rash subsides within 3 to 4 weeks. However, the rash and flulike manifestations can be significantly reduced within days if prompt treatment with antibiotics is initiated. If antibiotics are not administered, stage II Lyme disease may present within 4 to 10 weeks following the tick bite and may manifest with joint pain, memory loss, poor motor coordination, and meningitis. Stage III can begin anywhere from weeks to more than a year after the bite and has serious long-term chronic sequelae, including arthritis, neuropathy, myalgia, and myocarditis.

POISONING

A poison is any substance that, when ingested, inhaled, absorbed, applied to the skin, or produced within the body in relatively small amounts, injures the body by its chemical action. Poisoning from inhalation and ingestion of toxic materials, both intentional and unintentional, constitutes a major health hazard and an emergency situation. Emergency treatment is initiated with the following goals:

- To remove or inactivate the poison before it is absorbed
- To provide supportive care in maintaining vital organ function
- To administer a specific antidote to neutralize a specific poison
- To implement treatment that hastens the elimination of the absorbed poison

Ingested (Swallowed) Poisons

Swallowed poisons may be corrosive. **Corrosive poisons** include alkaline and acid agents that can cause tissue destruction after coming in contact with mucous membranes. Alkaline products include lye, drain cleaners, toilet bowl cleaners, bleach, nonphosphate detergents, oven cleaners, and button batteries (batteries used to power watches, calculators, or cameras). Acid products include toilet bowl cleaners, pool cleaners, metal cleaners, rust removers, and battery acid.

Control of the airway, ventilation, and oxygenation are essential. In the absence of cerebral or renal damage, the patient’s prognosis depends largely on successful management of respiration and circulation. Measures are instituted to stabilize cardiovascular and other body functions. ECG, vital signs, and neurologic status are monitored closely for changes. Shock may result from the cardiodepressant action of the substance ingested, from venous pooling in the lower

extremities, or from reduced circulating blood volume resulting from increased capillary permeability. An indwelling urinary catheter is inserted to monitor renal function. Blood specimens are obtained to determine the concentration of drug or poison.

Efforts are made to determine what substance was ingested; the amount; the time since ingestion; signs and symptoms, such as pain or burning sensations, any evidence of redness or burn in the mouth or throat, pain on swallowing or an inability to swallow, vomiting, or drooling; age and weight of the patient; and pertinent health history.

NURSING ALERT

The local poison control center should be called if an unknown toxic agent has been taken or if it is necessary to identify an antidote for a known toxic agent.

Measures are instituted to remove the toxin or decrease its absorption. The patient who has ingested a corrosive poison, which can be a strong acid or alkaline substance, is given water or milk to drink for dilution. However, dilution is not attempted if the patient has acute airway edema or obstruction or if there is clinical evidence of esophageal, gastric, or intestinal burn or perforation. The following gastric emptying procedures may be used as prescribed:

- Syrup of ipecac to induce vomiting in the alert patient (*never* use with corrosive poisons)
- Gastric lavage for the obtunded patient (Chart 71-11); gastric aspirate is saved and sent to the laboratory for testing (toxicology screens)
- Activated charcoal administration if the poison is one that is absorbed by charcoal
- Cathartic, when appropriate

NURSING ALERT

Vomiting is never induced after ingestion of caustic substances (acid or alkaline) or petroleum distillates.

If there is a specific chemical or physiologic antagonist (antidote), it is administered as early as possible to reverse or diminish the effects of the toxin. If this measure is ineffective, procedures may be initiated to remove the ingested substance. These procedures include administration of multiple doses of charcoal, diuresis (for substances excreted by the kidneys), dialysis, or hemoperfusion. Hemoperfusion involves detoxification of the blood by processing it through an extracorporeal circuit and an adsorbent cartridge containing charcoal or resin, after which the cleansed blood is returned to the patient.

Throughout detoxification, the patient’s vital signs, CVP, and fluid and electrolyte balance are monitored closely. Hypotension and cardiac dysrhythmias are possible. Seizures are also possible because of CNS stimulation from the poison or from oxygen deprivation. If the patient complains of pain, analgesics are administered cautiously. Severe pain causes vasomotor collapse and reflex inhibition of normal physiologic functions.

After the patient’s condition has stabilized and discharge is imminent, written material should be given to the patient

CHART
71-11

Guidelines for Assisting With Gastric Lavage

Gastric lavage is the aspiration of stomach contents and washing out of the stomach by means of a large-bore gastric tube. Gastric lavage is contraindicated after acid or alkali ingestion, in the presence of seizures, or after ingestion of hydrocarbons or petroleum distillates. It is particularly dangerous after ingestion of strong corrosive agents.

Purposes:

- For urgent removal of ingested substance to decrease systemic absorption
- To empty the stomach before endoscopic procedures
- To diagnose gastric hemorrhage and to arrest hemorrhage

Equipment:

Large-bore Levin tubes or large-bore Ewald tube
 Large irrigating syringe with adapter
 Large plastic funnel with adapter to fit tube
 Water-soluble lubricant
 Tap water or appropriate antidote (milk, saline solution, sodium bicarbonate solution, fruit juice, activated charcoal)
 Container for aspirate; suction apparatus
 Nasotracheal or endotracheal tubes with inflatable cuffs
 Containers for specimens

During gastric lavage, the patient is positioned on the left side, which allows the gastric contents to pool and decreases the passage of fluid into the duodenum.

Action

1. Remove dentures and inspect the oral cavity for loose teeth.
2. Measure the distance between the bridge of the nose and the xiphoid process. Mark the tube with indelible pencil or tape.
3. Lubricate the tube with water-soluble lubricant.
4. If comatose, the patient is intubated with a cuffed nasotracheal or endotracheal tube before placement of the nasogastric tube.
5. Place the patient in a left lateral position with the head lowered about 15 degrees.
6. Pass the tube orally while keeping the patient's head in a neutral position. Pass the tube to the adhesive marking or about 50 cm (20 in). Encourage patient to swallow to assist with passage of the tube. Then lower the head of the stretcher or bed. Have standby suction available.
7. Aspirate the stomach contents with the syringe attached to the tube before instilling water or an antidote. Save the specimen for analysis. Ensure correct placement before installation.
8. Remove the syringe. Attach the funnel to the end of the tube, or use a 50-mL syringe to instill solution in the gastric tube. The volume of fluid placed in the stomach should be small.
9. Elevate the funnel above the patient's head and pour 150 to 200 mL of solution into the funnel.
10. Lower the funnel and siphon the gastric contents into the container or connect to suction.
11. Save samples of the first two washings.
12. Repeat the lavage procedure until the returns are relatively clear and no particulate matter is seen.

Rationale

1. This will prevent aspiration of teeth.
2. This distance is a rule-of-thumb measurement of the distance the tube must be passed to reach the stomach. This avoids curling and kinking of excess tubing in the stomach.
3. Lubrication eases insertion of the tube.
4. A cuffed nasotracheal or endotracheal tube decreases the risk of aspiration of gastric contents.
5. This position decreases passage of gastric contents into the duodenum during lavage.
6. The depth of insertion of the tube varies according to the size of the patient. If the tube enters the trachea instead of the esophagus, the patient will experience coughing, dyspnea, stridor, and cyanosis. Positive confirmation of tube placement is accomplished by x-ray.
7. Aspiration is carried out to determine that the tube is in the stomach and to remove the stomach contents. Positive confirmation of tube placement is accomplished by x-ray.
8. Overfilling of the stomach may cause regurgitation and aspiration or force the stomach contents through the pylorus.
9. Gravity allows the solution to flow into the tube.
10. The fluid should flow in freely and drain by gravity.
11. Keep the first washing sample isolated from other washings for toxicologic analysis.
12. This usually requires a total volume of at least 2 L; some clinicians advocate the use of 5 to 20 L.

Continued

CHART
71-11

Guidelines for Assisting With Gastric Lavage (Continued)

Action

13. At the completion of lavage:
 - a. The stomach may be left empty.
 - b. An adsorbent (powder form of activated charcoal mixed with water to form a liquid the consistency of thick soup) may be instilled in the tube and allowed to remain in the stomach.
 - c. A saline cathartic may be instilled in the tube.
14. Pinch off the tube during removal or maintain suction while the tube is being withdrawn. Keep the patient's head lower than the body.
15. Warn the patient that his stools will turn black from the charcoal.

Rationale

13.
 - a. The stomach is kept empty if no further medications are required.
 - b. Activated charcoal reduces absorption by adsorbing (attaching to its surface) a wide range of substances; it renders the poison inaccessible to the circulation, thereby reducing its toxicity.
 - c. A cathartic may be given to hasten the elimination of remaining ingested material.
14. Pinching off the tube prevents aspiration and the initiation of the gag reflex. Keeping the patient's head lower than the body also helps to prevent initiation of the gag reflex.
15. Patient teaching is important to reduce anxiety.

indicating the signs and symptoms of potential problems related to the poison ingested and signs or symptoms requiring evaluation by a physician. If poisoning was determined to be a suicide or self-harm attempt, a psychiatric consultation should be requested before the patient is discharged. In cases of inadvertent poison ingestion, poison prevention and home poison-proofing instructions should be provided to the patient and family.

Carbon Monoxide Poisoning

Carbon monoxide poisoning may occur as a result of industrial or household incidents or attempted suicide. It is implicated in more deaths than any other toxin except alcohol. Carbon monoxide exerts its toxic effect by binding to circulating hemoglobin and thereby reducing the oxygen-carrying capacity of the blood. Hemoglobin absorbs carbon monoxide 200 times more readily than it absorbs oxygen. Carbon monoxide-bound hemoglobin, called **carboxyhemoglobin**, does not transport oxygen.

Clinical Manifestations

Because the CNS has a critical need for oxygen, CNS symptoms predominate with carbon monoxide toxicity. A person with carbon monoxide poisoning may appear intoxicated (from cerebral hypoxia). Other signs and symptoms include headache, muscular weakness, palpitation, dizziness, and confusion, which can progress rapidly to coma. Skin color, which can range from pink or cherry-red to cyanotic and pale, is not a reliable sign. Pulse oximetry is also not valid, because the hemoglobin is well saturated. It is not saturated with oxygen, but the pulse oximeter indicates only if the hemoglobin is saturated; in this case, it is saturated with carbon monoxide rather than with oxygen.

Management

Exposure to carbon monoxide requires immediate treatment. Goals of management are to reverse cerebral and myocardial hypoxia and to hasten elimination of carbon

monoxide. Whenever a patient inhales a poison, the following general measures apply:

- Carry the patient to fresh air immediately; open all doors and windows.
- Loosen all tight clothing.
- Initiate cardiopulmonary resuscitation if required; administer 100% oxygen.
- Prevent chilling; wrap the patient in blankets.
- Keep the patient as quiet as possible.
- Do not give alcohol in any form or permit the patient to smoke.

In addition, for the patient with carbon monoxide poisoning, carboxyhemoglobin levels are analyzed on arrival at the ED and before treatment with oxygen if possible. One hundred percent oxygen is administered at atmospheric or preferably hyperbaric pressures to reverse hypoxia and accelerate the elimination of carbon monoxide. Oxygen is administered until the carboxyhemoglobin level is less than 5%. The patient is monitored continuously. Psychoses, spastic paralysis, ataxia, visual disturbances, and deterioration of mental status and behavior may persist after resuscitation and may be symptoms of permanent brain damage.

When unintentional carbon monoxide poisoning occurs, the health department should be contacted so that the dwelling or building in question can be inspected. A psychiatric consultation is warranted if poisoning was determined to be a suicide attempt.

Skin Contamination Poisoning (Chemical Burns)

Skin contamination injuries from exposure to chemicals are challenging because of the large number of possible offending agents with diverse actions and metabolic effects. The severity of a chemical burn is determined by the mechanism of action, the penetrating strength and concentration, and the amount and duration of exposure of the skin to the chemical.

The skin should be drenched immediately with running water from a shower, hose, or faucet, except in the case of lye and white phosphorus, which should be brushed off the skin, dry.

NURSING ALERT

Water should not be applied to burns from lye or white phosphorus because of the potential for an explosion or for deepening of the burn. All evidence of these chemicals should be brushed off the patient before any flushing occurs.

The skin should be flushed with a constant stream of water as the patient's clothing is removed. The skin of health care personnel assisting the patient should be appropriately protected if the burn is extensive or if the agent is significantly toxic or is still present. Prolonged lavage with generous amounts of tepid water is important.

Attempts to determine the identity and characteristics of the chemical agent are necessary in order to specify future treatment. The standard burn treatment appropriate for the size and location of the wound (antimicrobial treatment, débridement, tetanus prophylaxis, antidote administration as prescribed) is instituted. (see Chapter 57) The patient may require plastic surgery for further wound management. The patient is instructed to have the affected area reexamined at 24 and 72 hours and in 7 days because of the risk of underestimating the extent and depth of these types of injuries.

Food Poisoning

Food poisoning is a sudden illness that occurs after ingestion of contaminated food or drink. Botulism is a serious form of food poisoning that requires continual surveillance (see Chapter 72). Assessment questions for patients with food poisoning are discussed in Chart 71-12.

CHART
71-12

Assessment for Food Poisoning

Use the following questions to elicit information about the circumstances surrounding the possibility of food poisoning:

- How soon after eating did the symptoms occur? (Immediate onset suggests chemical, plant, or animal poisoning.)
- What was eaten in the previous meal? Did the food have an unusual odor or taste? (Most foods causing bacterial poisoning *do not* have unusual odor or taste.)
- Did anyone else become ill from eating the same food?
- Did vomiting occur? What was the appearance of the vomitus?
- Did diarrhea occur? (Diarrhea is usually absent with botulism and with shellfish or other fish poisoning.)
- Are any neurologic symptoms present? (These occur in botulism and in chemical, plant, and animal poisoning.)
- Does the patient have a fever? (Fever is characteristic in salmonella, ingestion of fava beans, and some fish poisoning.)

The key to treatment is determining the source and type of food poisoning. If possible, the suspected food should be brought to the medical facility and a history obtained from the patient or family.

Food, gastric contents, vomitus, serum, and feces are collected for examination. The patient's respirations, blood pressure, level of consciousness, central venous pressure (CVP) (if indicated), and muscular activity are monitored closely. Measures are instituted to support the respiratory system. Death from respiratory paralysis can occur with botulism, fish poisoning, and some other food poisonings.

Because large volumes of electrolytes and water are lost by vomiting and diarrhea, fluid and electrolyte status should be assessed. Severe vomiting produces alkalosis, and severe diarrhea produces acidosis. Hypovolemic shock may also occur from severe fluid and electrolyte losses. The patient is assessed for signs and symptoms of fluid and electrolyte imbalances, including lethargy, rapid pulse rate, fever, oliguria, anuria, hypotension, and delirium. Weight and serum electrolyte levels are obtained for future comparisons.

Measures to control nausea are also important to prevent vomiting, which could exacerbate fluid and electrolyte imbalances. An antiemetic medication is administered parenterally as prescribed if the patient cannot tolerate fluids or medications by mouth. For mild nausea, the patient is encouraged to take sips of weak tea, carbonated drinks, or tap water. After nausea and vomiting subside, clear liquids are usually prescribed for 12 to 24 hours, and the diet is gradually progressed to a low-residue, bland diet.

SUBSTANCE ABUSE

Substance abuse is the misuse of specific substances, such as drugs or alcohol, to alter mood or behavior. Drug abuse is the use of drugs for other than legitimate medical purposes. People who abuse drugs often take a variety of drugs simultaneously (such as alcohol, barbiturates, opioids, and tranquilizers), and the combination may have additive and addictive effects. "Rave" parties are large-scale parties attended by hundreds of teenagers involved in drug use. At these events, one of the most commonly used drugs is 3,4-methylenedioxymethamphetamine (MDMA), or Ecstasy, a methamphetamine-based drug that users believe produces a "harmless high." ED nurses should be aware of "rave" parties in their geographic area so they can prepare for a potential influx of patients who abuse this drug. Others may combine Ecstasy with sildenafil (Viagra); this drug combination is nicknamed "sextasy." People who abuse IV/injection drugs are at increased risk for HIV infection, acquired immunodeficiency syndrome (AIDS), hepatitis B and C, and tetanus.

Clinical manifestations vary with the substance used, but the underlying principles of management are essentially the same. Table 71-1 identifies commonly abused drugs, listing their clinical manifestations and therapeutic management. Treatment goals for a patient with a drug overdose are to support the respiratory and cardiovascular functions, to enhance clearance of the agent, and to provide for safety of the patient and staff.

Table 71-1 EMERGENCY MANAGEMENT OF PATIENTS WITH DRUG OVERDOSE

Drug	Clinical Manifestations	Therapeutic Management
Stimulants		
Cocaine	Cocaine is a central nervous system (CNS) stimulant that can increase heart rate and blood pressure and cause hyperpyrexia, seizures, increased energy, agitation, aggression, and ventricular dysrhythmias. It produces intense euphoria, then anxiety, sadness, insomnia, and sexual indifference; cocaine hallucinations with delusions; psychosis with extreme paranoia and ideas of persecution; and hypervigilance. Chronic psychotic symptoms may persist.	<ol style="list-style-type: none"> 1. Maintain airway and provide respiratory support 2. Control seizures. 3. Monitor cardiovascular effects; have lidocaine and defibrillator available. 4. Treat for hyperthermia. 5. If cocaine was ingested, evacuate stomach contents and use activated charcoal to treat. Whole bowel irrigation may be necessary to treat body packers ("mules"). 6. Refer for psychiatric evaluation and treatment in an inpatient unit that eliminates access to the drug. Include drug rehabilitation counseling.
Intranasally ("snorting"): inhaled into nostrils through straws		
By smoking ("freebasing"): cocaine hydrochloride dissolved in ether to yield a pure cocaine alkaloid base (called "crack," "rocks"); smoking in a small pipe delivers large quantities of cocaine to lungs		
Intravenously	Overall psychotic symptoms are short-lived compared to methamphetamines	
Polysubstance (cocaine and heroin)		
Opioids		
Heroin	Acute intoxication (overdose)	<ol style="list-style-type: none"> 1. Support respiratory and cardiovascular functions. 2. Establish an intravenous (IV) line; obtain blood for chemical and toxicologic analysis. Patient may be given bolus of glucose to eliminate possibility of hypoglycemia. 3. Give narcotic antagonist (naloxone hydrochloride IV, IM [Narcan]) as prescribed to reverse severe respiratory depression and coma. 4. Continue to monitor level of responsiveness and respirations, pulse, and blood pressure. Duration of action of naloxone hydrochloride is shorter than that of heroin; repeated dosages may be necessary. 5. Send urine for analysis; opioids can be detected in urine. 6. Obtain an electrocardiogram. 7. Do not leave patient unattended; he or she may lapse back into coma rapidly. Clinical status may change from minute to minute. Hemodialysis may be indicated for severe drug intoxication. Activated charcoal may be considered if opioids were taken orally and if the patient is alert. 8. Monitor for pulmonary edema, which is frequently seen in patients who abuse/overdose on narcotics. 9. Refer patient for psychiatric and drug rehabilitation evaluation before discharge.
Opium or paregoric	Pinpoint pupils (may be dilated with severe hypoxia); decreased blood pressure	
Morphine, codeine, semisynthetic derivatives: oxycodone (OxyContin), methadone, meperidine (Demerol), propoxyphene (Darvon), tramadol (Ultram), fentanyl (Sublimaze)	Marked respiratory depression/arrest Pulmonary edema Stupor → coma Seizures Fresh needle marks along course of any superficial vein; skin abscesses	
Barbiturates		
Pentobarbital (Nembutal), secobarbital (Seconal), amobarbital (Amytal), gamma-hydroxybutyrate (GHB, "liquid Ecstasy")	Acute intoxication (may mimic alcohol intoxication): <ul style="list-style-type: none"> • Respiratory depression • Flushed face • Decreased pulse rate; decreased blood pressure • Increasing nystagmus • Depressed deep tendon reflexes • Decreasing mental alertness • Difficulty in speaking • Poor motor coordination • Coma, death GHB: <ul style="list-style-type: none"> • Sexual disinhibition • Amnesia, myoclonus, agitation • Overdoses when mixed with alcohol 	<ol style="list-style-type: none"> 1. Maintain airway and provide respiratory support. 2. Endotracheal intubation or tracheostomy is considered if there is any doubt about the adequacy of airway exchange. <ol style="list-style-type: none"> a. Check airway frequently. b. Perform suctioning as necessary. 3. Support cardiovascular and respiratory functions; most deaths result from respiratory depression or shock. 4. Start infusion through large-gauge needle or IV catheter to support blood pressure; coma and dehydration result in hypotension and respond to infusion of intravenous fluids with elevation of blood pressure. Sodium bicarbonate may be prescribed to alkalinize urine; it promotes excretion of barbiturates. 5. Evacuate stomach contents or lavage as soon as possible to prevent absorption; repeated doses of activated charcoal may be administered.

Continued on following page

Table 71-1 EMERGENCY MANAGEMENT OF PATIENTS WITH DRUG OVERDOSE (Continued)

Drug	Clinical Manifestations	Therapeutic Management
		<ol style="list-style-type: none"> 6. Assist with hemodialysis for severely overdosed patient. 7. Maintain neurologic and vital sign flow sheet. 8. Patient awakening from overdose may demonstrate combative behavior. 9. Refer for psychiatric and drug rehabilitation consultation to evaluate suicide potential and drug abuse.
Inhalants		
Amyl nitrate	Effects mimic those of alcohol, with dizziness and imbalance	1. Provide airway support, ventilation, and oxygen.
Freon		2. Treat cardiac dysrhythmias and hypotension.
Propane	Euphoria, headache, altered level of consciousness to coma	3. Provide advanced cardiac life support (ACLS) as needed.
Trichloroethylene		4. Monitor for profound hypotension when amyl nitrate is combined with MDMA and sildenafil.
Gasoline	Renal, hepatic, and cardiac toxicity	
Perchloroethylene	Aplastic anemia	
Toluene (metallic paint spray)	Fetal growth retardation Respiratory depression Vasodilation Nosebleeding Circumoral red spots	
Amphetamine-Type Drugs (pep pills, “uppers,” “speed,” “crystal meth”)		
Amphetamine (Benzedrine)	Nausea, vomiting, anorexia, palpitations, tachycardia, increased blood pressure, tachypnea, anxiety, nervousness, diaphoresis, mydriasis	1. Provide airway support, ventilation, cardiac monitoring; insert IV line.
Dextroamphetamine (Dexedrine)		2. Use gastrointestinal (GI) evacuation in cases of oral overdose; activated charcoal, gastric lavage.
Methamphetamine (Desoxyn, “speed”)		3. Keep in calm, cool, quiet environment; elevated temperature potentiates amphetamine toxicity. Maintain normothermia cooling the patient as necessary.
3,4-Methylenedioxymethamphetamine (MDMA) (“Ecstasy,” “Adam”)*	Repetitive or stereotyped behavior	4. Use small doses of diazepam (Valium) (IV) or haloperidol (Haldol) as prescribed for CNS and muscular hyperactivity.
3,4-Methylenedioxymethamphetamine (MDEA) (“Eve”)	Irritability, insomnia, agitation Visual misperceptions, auditory hallucinations	5. Administer appropriate pharmacologic therapy as prescribed for severe hypertension and ventricular dysrhythmias.
3,4-Methylenedioxyamphetamine (MDA) methylphenidate (Ritalin)	Fearfulness, anxiety, depression, hostility, paranoia	6. Treat seizures with benzodiazepines (eg, diazepam) as prescribed.
“ice,” “rocks,” “crystal meth”	Hyperactivity, rapid speech, euphoria, hyper-alertness Decreased inhibition Seizures, coma, hyperthermia, cardiovascular collapse, rhabdomyolysis MDMA is both a hallucinogenic and stimulant	7. Treat sympathetic stimulation with beta-blocker agents as prescribed.
		8. Try to communicate with patient if delusions or hallucinations are present.
		9. Place in a protective environment (preferably psychiatric security room with video monitoring) to observe for suicide attempt.
		10. Refer for psychiatric and drug rehabilitation evaluation.
Hallucinogens or Psychedelic-Type Drugs		
Lysergic acid diethylamide (LSD)	Nystagmus	1. Evaluate and maintain patient’s airway, breathing, and circulation.
Phencyclidine HCl (PCP, “angel dust”)	Mild hypertension	2. Determine by urine or serum drug screen whether the patient has ingested hallucinogenic drug or has a toxic psychosis.
Mescaline, psilocybin	Marked confusion bordering on panic	3. Try to communicate with and reassure the patient.
Cannabinoids (marijuana)	Incoherence, hyperactivity	a. “Talking down” involves understanding the process through which the patient is proceeding and helping him overcome his fears while establishing contact with reality.
Ketamine (“special K”)	Withdrawn Combative behavior; delirium, mania, self-injury (lasts 6 to 12 hours) Hallucinations, body image distortion Hypertension, hyperthermia, renal failure Flashback: recurrence of LSD-like state without having taken the drug; may occur weeks or months after drug was taken Ketamine: “out-of-body” experience; increased aggressiveness	b. Remind the patient that fear is common with this problem.

Continued

Table 71-1 EMERGENCY MANAGEMENT OF PATIENTS WITH DRUG OVERDOSE (Continued)

Drug	Clinical Manifestations	Therapeutic Management
		<ul style="list-style-type: none"> c. Reassure the patient that he is not losing his mind but is experiencing the effect of drugs and that this will wear off. d. Instruct the patient to keep the eyes open; this reduces the intensity of reaction. e. Reduce sensory stimuli: minimize noise, lights, movement, tactile stimulation. <ol style="list-style-type: none"> 4. Sedate the patient as prescribed if hyperactivity cannot be controlled; diazepam (Valium) or a barbiturate may be prescribed. 5. Search for evidence of trauma; hallucinogen users have a tendency to “act out” their hallucinations. 6. Manage seizures with benzodiazepines (eg, diazepam) as necessary. 7. Observe patient closely; patient’s behavior may become hazardous. Have safety officers stationed near the patient’s room. 8. Monitor for hypertensive crisis if patient has prolonged psychosis due to drug ingestion. 9. Place patient in a protected environment under proper medical supervision to prevent self-inflicted bodily harm. <p>Management for Phencyclidine Abusers</p> <ol style="list-style-type: none"> 1. Place patient in a calm, supportive environment to minimize stimuli; protect from self-injury. 2. Avoid talking down. 3. Do not leave patient unobserved. Treat symptoms as they occur. <ul style="list-style-type: none"> a. Drug effects are unpredictable and prolonged. b. Symptoms are likely to exacerbate; patient becomes out of control. 4. Refer all patients in this category for psychiatric and drug evaluation/rehabilitation.
<p>Drugs Producing Sedation, Intoxication, or Psychological and Physical Dependence (nonbarbiturate sedatives)</p> <p>Diazepam (Valium) Chlordiazepoxide (Librium) Oxazepam (Serax) Lorazepam (Ativan) Midazolam (Versed) Flunitrazepam (Rohypnol, “roofies,” “date rape drug”)*</p>	<p>Seizures, coma, circulatory collapse, death</p> <p>Acute intoxication:</p> <ul style="list-style-type: none"> • Respiratory depression • Decreasing mental alertness • Confusion • Slurred speech, decreased blood pressure • Ataxia • Pulmonary edema • Coma, death <p>Flunitrazepam:</p> <ul style="list-style-type: none"> • Disinhibition with antegrade amnesia • Weakness and unsteadiness with impaired judgment • Powerlessness 	<ol style="list-style-type: none"> 1. Endotracheal tube is inserted as a precaution; use assisted ventilation to stabilize and correct respiratory depression. Observe for sudden apnea and laryngeal spasm. 2. Assess for hypotension <ul style="list-style-type: none"> a. Insert indwelling urinary catheter for comatose patient; decreased urinary volume is an index of reduced renal flow associated with reduced intravascular volume or vascular collapse. b. Start volume expansion with saline or dextrose as prescribed. 3. Evacuate stomach contents; emesis; lavage; activated charcoal; cathartic. 4. Start ECG monitoring. Observe for dysrhythmias. 5. Administer flumazenil (Romazicon), a benzodiazepine antagonist (reversal agent). 6. Refer patient for psychiatric evaluation (potential suicide intent).

Continued on following page

Table 71-1 EMERGENCY MANAGEMENT OF PATIENTS WITH DRUG OVERDOSE (Continued)

Drug	Clinical Manifestations	Therapeutic Management
Salicylate Poisoning Aspirin (present in compound analgesic tablets) Toxic levels (150–200 mg/kg body weight) Chronic toxicity (occurs in elderly due to decreased renal function) Long-term intoxication (>100 mg/kg/day for more than 2 days)	Restlessness, tinnitus, deafness, blurring of vision Hyperpnea, hyperpyrexia, sweating Epigastric pain, vomiting, dehydration Respiratory alkalosis and metabolic acidosis Disorientation, coma, cardiovascular collapse Coagulopathy	<ol style="list-style-type: none"> 1. Treat respiratory depression. 2. Induce gastric emptying by lavage. 3. Give activated charcoal to adsorb aspirin; a cathartic may be administered with charcoal to help ensure intestinal cleansing. 4. Support patient with IV infusions as prescribed to establish hydration and correct electrolyte imbalances, including administration of sodium bicarbonate. 5. Enhance elimination of salicylates as directed by forced diuresis, alkalinization of urine, peritoneal dialysis, or hemodialysis, according to severity of intoxication. 6. Monitor serum salicylate level for efficacy of treatment. 7. Administer specific prescribed pharmacologic agent for bleeding and other problems. 8. Concretions formed in the gut may result in prolonged exposure as they are digested. 9. Refer patient for psychiatric evaluation (potential suicide intent).
Acetaminophen (present in prescription and nonprescription analgesics, antipyretics, and cold remedies)	Lethargy to encephalopathy and death GI upset, diaphoresis Right upper quadrant pain Abnormal liver function tests, prolonged prothrombin time, increased bilirubin, disseminated intravascular coagulation Hepatomegaly leading to liver failure Metabolic acidosis Hypoglycemia	<ol style="list-style-type: none"> 1. Maintain airway. 2. Obtain acetaminophen level. Levels ≥ 140 mg/kg are toxic. 3. Laboratory studies—liver function tests, prothrombin time/partial thromboplastin time, complete blood count, blood urea nitrogen, creatinine. 4. Administer syrup of ipecac and follow emesis with activated charcoal. 5. Prepare for possible hemodialysis, which clears acetaminophen but does not halt liver damage. 6. Administer <i>N</i>-acetylcysteine (NAC, Mucomyst) as soon as possible. NAC replenishes essential liver enzymes and requires a total of 18 doses every 4 hours. Charcoal absorbs NAC; do not administer together. Repeat NAC dose if patient vomits. 7. Refer patient for psychiatric evaluation (potential suicide intent).
Tricyclic Antidepressants (TCAs) Amitriptyline (Elavil) Doxepin (Sinequan) Nortriptyline (Aventyl) Imipramine (Tofranil)	Dysrhythmia: ventricular fibrillation/tachycardia, tachycardia Hypotension Pulmonary edema, hypoxemia, acidosis Confusion, agitation, coma Visual hallucinations Clonus, tremors, hyperactive reflexes, nystagmus, myoclonic jerking Seizures Blurred vision, flushing, hyperthermia	<ol style="list-style-type: none"> 1. Provide airway support, ventilation, cardiac monitoring; insert IV line with normal saline solution. 2. If within 1–2 hours after overdose, insert a nasogastric tube and instill activated charcoal with sorbitol every 4 hours $\times 3$. 3. Administer a sodium bicarbonate drip to decrease dysrhythmias; the alkaline environment increases the protein binding of the metabolite. 4. Administer vasopressors. 5. Use only Class IB antiarrhythmics (eg, lidocaine), as some other types of antiarrhythmics have the same effect as TCA. 6. Manage seizure activity with benzodiazepines (eg, diazepam) as necessary. 7. Refer patient for psychiatric evaluation for potential suicide intent and evaluation of medication regimen for effectiveness.

Continued

Table 71-1 EMERGENCY MANAGEMENT OF PATIENTS WITH DRUG OVERDOSE (Continued)

Drug	Clinical Manifestations	Therapeutic Management
Selective Serotonin Reuptake Inhibitors (SSRIs) and Other Antidepressants		
Trazodone (Desyrel)	Decreased level of consciousness, confusion	<ol style="list-style-type: none"> Administer activated charcoal with possibly whole-bowel irrigation if a sustained-release medication was taken. Use seizure precautions and administer benzodiazepines (eg, diazepam) as ordered. Serotonin syndrome may occur if the SSRI was taken in conjunction with dextromethorphan or meperidine.
Fluoxetine (Prozac)	Respiratory depression	
Paroxetine (Paxil)	Increased heart rate	
Sertraline (Zoloft)	Serotonin syndrome:	
Venlafaxine (Effexor)	Agitation, seizures	
Escitalopram (Lexapro)	Hyperthermia, diaphoresis	
Bupropion (Wellbutrin)	Hypertension	

*Polydrug use at “rave clubs” frequently involves MDMA, alcohol, amphetamines, LSD, and sometimes dextromethorphan. Terms such as “Ecstasy” may refer to flunitrazepam (Rohypnol), GHB, ephedrine, and/or caffeine, in addition to MDMA. The Web site www.clubdrugs.gov provides more information about possible drug abuse and how it may relate to emergency nursing care.

Acute Alcohol Intoxication

Alcohol is a psychotropic drug that affects mood, judgment, behavior, concentration, and consciousness. Many heavy drinkers are young adults or people older than 60 years of age. There is a high prevalence of alcoholism among ED patients. Because patients who abuse alcohol return frequently to the ED, they often frustrate and tax the patience of the health care professionals who care for them. Their management requires patience and thoughtful, accurate, long-term treatment (Thompson, Lande & Kalapatapu, 2008).

Alcohol, or ethanol, is a multisystem toxin and CNS depressant that causes drowsiness, impaired coordination, slurring of speech, sudden mood changes, aggression, belligerence, grandiosity, and uninhibited behavior. In excess, it can also cause stupor, coma, and death. Increasingly, underage minors and college students arrive at the ED with alcohol poisoning from binge drinking. All too frequently, the result is death.

In the ED, the patient is assessed for head injury, hypoglycemia (which mimics intoxication), and other health problems. Possible nursing diagnoses include ineffective breathing pattern related to CNS depression and risk for violence (self-directed or other-directed) related to severe intoxication from alcohol.

Treatment involves detoxification of the acute poisoning, recovery, and rehabilitation. Commonly, the patient uses mechanisms of denial and defensiveness. The nurse should approach the patient in a nonjudgmental manner, using a firm, consistent, accepting, and reasonable attitude. Speaking in a calm and slow manner is helpful because alcohol interferes with thought processes. If the patient appears intoxicated, hypoxia, hypovolemia, and neurologic impairment must be ruled out before it is assumed that the patient is intoxicated. Typically, a blood specimen is obtained for analysis of the blood alcohol level.

If drowsy, the patient should be allowed to sleep off the state of alcoholic intoxication. During this time, maintenance of a patent airway and observation for symptoms of CNS depression are essential. The patient should be undressed and kept warm with blankets. On the other hand, if the patient is noisy or belligerent, sedation may be necessary. If sedation is used, the patient should be monitored

carefully for hypotension and decreased level of consciousness.

In addition, the patient is examined for alcohol withdrawal delirium and also for injuries and organic disease (such as head injury, seizures, pulmonary infections, hypoglycemia, and nutritional deficiencies) that may be masked by alcoholic intoxication. People with alcoholism suffer more injuries than the general population. Also, acute alcohol intoxication is the cause of trauma for many nonalcoholic patients. Pulmonary infections are also more common in patients with alcoholism, resulting from respiratory depression, an impaired defense system, and a tendency toward aspiration of gastric contents. The patient may show little increase in temperature or WBC count. The patient may be hospitalized or admitted to a detoxification center in an effort to examine problems underlying the substance abuse.

Alcohol Withdrawal Syndrome/Delirium Tremens

Alcohol withdrawal syndrome is an acute toxic state that occurs as a result of sudden cessation of alcohol intake after a bout of heavy drinking or, more typically, after prolonged intake of alcohol. Severity of symptoms depends on how much alcohol was ingested and for how long. Delirium tremens may be precipitated by acute injury or infection (pneumonia, pancreatitis, hepatitis) and is the most severe form of alcohol withdrawal syndrome (Larson, 2008).

Patients with alcohol withdrawal syndrome show signs of anxiety, uncontrollable fear, tremor, irritability, agitation, insomnia, and incontinence. They are talkative and preoccupied and experience visual, tactile, olfactory, and auditory hallucinations that often are terrifying. Autonomic overactivity occurs and is evidenced by tachycardia, dilated pupils, and profuse perspiration. Usually, all vital signs are elevated in the alcoholic toxic state. Delirium tremens is a life-threatening condition and carries a high mortality rate.

The goals of management are to give adequate sedation and support to allow the patient to rest and recover without danger of injury or peripheral vascular collapse. A physical examination is performed to identify preexisting or contributing illnesses or injuries (eg, head injury, pneumonia).

A drug history is obtained to elicit information that may facilitate adjustment of any sedative requirements. Baseline blood pressure is determined, because the patient's subsequent treatment may depend on blood pressure changes.

Usually, the patient is sedated as directed with a sufficient dosage of benzodiazepines to establish and maintain sedation, which reduces agitation, prevents exhaustion, prevents seizures, and promotes sleep. The patient should be calm, able to respond, and able to maintain an airway safely on his or her own. A variety of medications and combinations of medications are used (eg, chlordiazepoxide [Librium], lorazepam [Ativan], and clonidine [Catapres]). Haloperidol (Haldol) or droperidol (Inapsine) may be administered for severe acute alcohol withdrawal syndrome. Dosages are adjusted according to the patient's symptoms (agitation, anxiety) and blood pressure response.

The patient is placed in a calm, nonstressful environment (usually a private room) and observed closely. The room remains lighted to minimize the potential for illusions (visual misrepresentations) and hallucinations. Homicidal or suicidal responses may result from hallucinations. Closet and bathroom doors are closed to eliminate shadows. Someone is designated to stay with the patient as much as possible. The presence of another person has a reassuring and calming effect, which helps the patient maintain contact with reality. To orient the patient to reality, any illusions are explained.

NURSING ALERT

Restraints are used as prescribed, if necessary, if the client is aggressive or violent, but only when other alternatives have been unsuccessful. The least restrictive device that will prevent the patient from injuring self or others is used. Caution is taken to ensure that restraints are applied properly and that they are not impairing circulation to any part of the body or interfering with respirations. Restraints should be used in tandem with verbal intervention to calm the patient and promote compliance. Restraints must be released according to protocol. Physical observation (eg, skin integrity, circulatory status, respiratory status) is ongoing, and the patient's response is documented.

Fluid losses may result from gastrointestinal losses (vomiting), profuse perspiration, and hyperventilation. In addition, the patient may be dehydrated as a result of alcohol's effect of decreasing antidiuretic hormone. The oral or IV route is used to restore fluid and electrolyte balance.

Temperature, pulse, respiration, and blood pressure are recorded frequently (every 30 minutes in severe forms of delirium) to monitor for peripheral circulatory collapse or hyperthermia (the two most serious complications). Phenytoin (Dilantin) or other antiseizure medications may be prescribed to prevent repeated withdrawal seizures.

Frequently seen complications include infections (eg, pneumonia), trauma, hepatic failure, hypoglycemia, and cardiovascular problems. Hypoglycemia may accompany alcohol withdrawal, because alcohol depletes liver glycogen stores and impairs gluconeogenesis; many patients with

alcoholism also are malnourished. Parenteral dextrose may be prescribed if the liver glycogen level is depleted. Orange juice, Gatorade, or other sources of carbohydrates are given to stabilize the blood glucose level and counteract tremulousness. Supplemental vitamin therapy and a high-protein diet are provided as prescribed to counteract nutritional deficits. The patient should be referred to an alcoholic treatment center for follow-up care and rehabilitation.

VIOLENCE, ABUSE, AND NEGLECT

Family Violence, Abuse, and Neglect

EDs are often the first place where victims of family violence, abuse, or neglect go to seek help. Each year in the United States, there are 4.8 million women and 2.9 million men who experience physical assaults involving their intimate partners. Intimate partner violence (IPV) caused 1544 deaths in 2004; of these victims, 75% were females and 25% were male. Costs related to IPV are estimated to exceed \$8.3 billion annually (Centers for Disease Control and Prevention [CDC], 2006a).

It is estimated that up to one third of all patients in the ED have experienced IPV at some point in their lives. Research studies suggest that as many as 44% of all women murdered by a partner had visited an ED within the 2 years prior to death. Researchers believe that most persons who have experienced IPV are willing to disclose their causes of injury, but as few as 4% to 10% of cases are accurately identified in EDs (Daugherty & Houry, 2008). ED nurses must be vigilant in their assessments of both women and men who present with injuries that may be consistent with IPV. In addition, ED nurses must be aware that men and women with disabilities are at higher risk of domestic violence and abuse than nondisabled people and should include questions to that effect in their evaluations.

It is estimated that between 700,000 and 1.2 million elders are abused or neglected annually (American Geriatrics Society, 2005). Elder abuse takes many forms, including physical, emotional, and verbal abuse; neglect; violation of personal rights; and financial abuse (see Chapters 5 and 46).

Clinical Manifestations

When people who have been abused seek treatment, they may present with physical injuries or with health problems such as anxiety, insomnia, or gastrointestinal symptoms that are related to stress. The possibility of abuse should be investigated whenever a person presents with multiple injuries that are in various stages of healing, when injuries are unexplained, and when the explanation does not fit the physical picture (Chart 71-13). The possibility of neglect should be investigated whenever a dependent person shows evidence of inattention to hygiene, to nutrition, or to known medical needs (eg, unfilled medication prescriptions, missed appointments with health care providers). In the ED, the most common physical injuries seen are unexplained bruises, lacerations, abrasions, head injuries, or fractures. The most common clinical manifestations of neglect are malnutrition and dehydration.

CHART
71-13

Assessing for Abuse, Maltreatment, and Neglect

The following questions may be helpful when assessing a patient for abuse, maltreatment, and neglect:

- I noticed that you have a number of bruises. Can you tell me how they happened? Has anyone hurt you?
- You seem frightened. Has anyone ever hurt you?
- Sometimes patients tell me that they have been hurt by someone at home or at work. Could this be happening to you?
- Are you afraid of anyone at home or work, or of anyone with whom you come in contact?
- Has anyone failed to help you to take care of yourself when you needed help?
- Has anyone prevented you from seeing friends or other people whom you wish to see?
- Have you signed any papers that you did not understand or did not wish to sign?
- Has anyone forced you to sign papers against your will?
- Has anyone forced you to engage in sexual activities within the past year?
- Has anyone prevented you from using an assistive device (eg, wheelchair, walker) within the past year?
- Has anyone you depend on refused to help you take your medicine, bathe, groom, or eat within the past year?

Assessment and Diagnostic Findings

Nurses in EDs are in an ideal position to provide early detection and interventions for victims of IPV. This requires an acute awareness of the signs of possible abuse, maltreatment, and neglect. Nurses must be skilled in interviewing techniques that are likely to elicit accurate information. A careful history is crucial in the screening process. Asking questions in private—away from others—may be helpful in eliciting information about abuse, maltreatment, and neglect.

Whenever evidence leads one to suspect abuse or neglect, an evaluation with careful documentation of descriptions of events and drawings or photographs of injuries is important, because the medical record may be used as part of a legal proceeding. Assessment of the patient's general appearance and interactions with significant others, an examination of the entire surface area of the body, and a mental status examination are crucial.

Management

Whenever abuse, maltreatment, or neglect is suspected, the health care provider's primary concern should be the safety and welfare of the patient. Treatment focuses on the consequences of the abuse, violence, or neglect and on prevention of further injury. Protocols of most EDs require that a multidisciplinary approach be used. Nurses, physicians, social workers, and community agencies work collaboratively to develop and implement a plan for meeting the patient's needs.

If the patient is in immediate danger, he or she should be separated from the abusing or neglecting person whenever possible. Referral to a shelter may be the most appropriate action, but many shelters are inaccessible to people with mobility limitations.

When abuse or neglect is the result of stress experienced by a caregiver who is no longer able to cope with the burden of caring for an elderly person or a person with chronic disease or a disability, respite services may be necessary. Support groups may be helpful to these caregivers. When mental illness of the abuser or neglecter is responsible for the situation, alternative living arrangements may be required.

Nurses must be mindful that competent adults are free to accept or refuse the help that is offered to them. Some patients insist on remaining in the home environment where the abuse or neglect is occurring. The wishes of patients who are competent and not cognitively impaired should be respected. However, all possible alternatives, available resources, and safety plans should be explored with the patient.

Mandatory reporting laws in most states require health care workers to report *suspected* child or elder abuse to an official agency, usually Adult (or Child) Protective Services. All that is required for reporting is the suspicion of abuse; the health care worker is not required to prove abuse or neglect. Likewise, health care workers who report suspected abuse are immune from civil or criminal liability if the report is made in good faith. Subsequent home visits resulting from the report of suspected abuse are a part of gathering information about the patient in the home environment. In addition, many states have resource hotlines for use by health care workers and by patients who seek answers to questions about abuse and neglect.

Sexual Assault

The definition of *rape* is forced sexual acts, especially if these acts involve vaginal or anal penetration. Perpetrators and victims may be either male or female. Society is focused on the rights and care of people who have been sexually assaulted, and law enforcement agencies are increasingly sensitive and aggressive in managing these crimes. Rape crisis centers offer support and education and help people who have been sexually assaulted through the subsequent police investigation and courtroom experience.

The manner in which the patient is received and treated in the ED is important to his or her future psychological well-being. Crisis intervention should begin when the patient enters the health care facility. The patient should be seen immediately. Most hospitals have a written protocol that addresses the patient's physical and emotional needs as well as collection of forensic evidence.

In many states, the emergency nurse has the opportunity to become trained as a sexual assault nurse examiner (SANE). Preparing for this role requires specific training in forensic evidence collection, history taking, documentation, and ways to approach the patient and family. Specialized training also includes learning proper photographic methods and the use of colposcopy. Colposcopy facilitates assessment by magnifying tissues and looking for evidence of microtrauma. Evidence is collected through photography, videography, and analysis of specimens. Another tool useful to the SANE is the light-staining microscope, which enables the examiner to identify motile and nonmotile sperm

and infectious organisms. This tool saves time and also enhances assessment. The SANE complements the ED staff and they can spend more time with both the patient and police officers investigating the incident (Lynch, 2006).

Assessment and Diagnostic Findings

The patient's reaction to rape has been termed *rape trauma syndrome* and is seen as an acute stress reaction to a life-threatening situation. The nurse performing the assessment is aware that the patient may go through several phases of psychological reactions (Lynch, 2006), which have been described as follows:

- An acute disorganization phase, which may manifest as an expressed state in which shock, disbelief, fear, guilt, humiliation, anger, and other such emotions are encountered or as a controlled state in which feelings are masked or hidden and the victim appears composed
- A phase of denial and unwillingness to talk about the incident, followed by a phase of heightened anxiety, fear, flashbacks, sleep disturbances, hyperalertness, and psychosomatic reactions that is consistent with posttraumatic stress disorder (PTSD) (see Chapter 7 for further discussion of PTSD)
- A phase of reorganization, in which the incident is put into perspective; some victims never fully recover and go on to develop chronic stress disorders and phobias

Management

The goals of management are to provide support, to reduce the patient's emotional trauma, and to gather available evidence for possible legal proceedings. All of the interventions are aimed at encouraging the patient to gain a sense of control over his or her life.

Throughout the patient's stay in the ED, the patient's privacy and sensitivity must be respected. The patient may exhibit a wide range of emotional reactions, such as hysteria, stoicism, or feelings of being overwhelmed. Support and caring are crucial. The patient should be reassured that anxiety is natural and asked whether a support person may be called. Appropriate support is available from professional and community resources. The Rape Victim Companion Program, if available in the community, can be contacted, and the services of a volunteer can be requested. The patient should never be left alone.

Physical Examination

A written, witnessed informed consent must be obtained from the patient (or parent or guardian if the patient is a minor) for examination, for taking of photographs, and for release of findings to police. A history is obtained only if the patient has not already talked to a police officer, social worker, or crisis intervention worker. The patient should not be asked to repeat the history. Any history of the event that is obtained should be recorded in the patient's own words. The patient is asked whether he or she has bathed, doused, brushed his or her teeth, changed clothes, urinated, or defecated since the attack, because these actions may alter interpretation of subsequent findings. The time of admission, time of examination, date and time of the

alleged rape, and the patient's emotional state and general appearance (including any evidence of trauma, such as discoloration, bruises, lacerations, secretions, or torn and bloody clothing) are documented.

For the physical examination, the patient is helped to undress and is draped properly. Each item of clothing is placed in a separate paper bag. Plastic bags are not used because they retain moisture; moisture may promote mold and mildew formation, which can destroy evidence. The bags are labeled and given to appropriate law enforcement authorities.

The patient is examined (from head to toe) for injuries, especially injuries to the head, neck, breasts, thighs, back, and buttocks. Body diagrams and photographs aid in documenting the evidence of trauma. The physical examination focuses on the following:

- External evidence of trauma (bruises, contusions, lacerations, stab wounds)
- Dried semen stains (appearing as crusted, flaking areas) on the patient's body or clothes
- Broken fingernails and body tissue and foreign materials under nails (if found, samples are taken)
- Oral examination, including a specimen of saliva and cultures of gum and tooth areas

Pelvic and rectal examinations are also performed. The perineum and other areas are examined with a Wood lamp or other filtered ultraviolet light. Areas that appear fluorescent may indicate semen stains. The color and consistency of any discharge present is noted. A water-moistened rather than a lubricated vaginal speculum is used for the examination. Lubricant contains chemicals that may interfere with later forensic testing of specimens and acid phosphatase determinations. The rectum is examined for signs of trauma, blood, and semen. During the examination, the patient should be advised of the nature and necessity of each procedure and given the rationale for each question asked.

Specimen Collection

During the physical examination, numerous laboratory specimens may be collected, including the following:

- Vaginal aspirate, examined for presence or absence of motile and nonmotile sperm
- Secretions (obtained with a sterile swab) from the vaginal pool for acid phosphatase, blood group antigen of semen, and precipitin test against human sperm and blood
- Separate smears from the oral, vaginal, and anal areas
- Culture of body orifices for gonorrhea
- Blood serum for syphilis and HIV testing and DNA analysis; a sample of serum for syphilis may be frozen and saved for future testing
- Pregnancy test if there is a possibility that the patient may be pregnant
- Any foreign material (leaves, grass, dirt), which is placed in a clean envelope
- Pubic hair samples obtained by combing or trimming. Several pubic hairs with follicles are placed in separate containers and identified as the patient's hair

To preserve the chain of evidence, each specimen is labeled with the name of the patient, the date and time of collection, the body area from which the specimen was

obtained, and the names of personnel collecting specimens. Then the specimens are given to a designated person (eg, crime laboratory technician), and an itemized receipt is obtained.

Treating Potential Consequences of Rape

After the initial physical examination is completed and specimens have been obtained, any associated injuries are treated as indicated. The patient is given the option of prophylaxis against sexually transmitted disease (STD) (also referred to as sexually transmitted infection [STI]). Ceftriaxone (Rocephin), administered intramuscularly with 1% lidocaine (Xylocaine), may be prescribed as prophylaxis for gonorrhea. In addition, a single oral dose of metronidazole (Flagyl) and either a single oral dose of azithromycin (Zithromax) or a 7-day oral regimen of doxycycline (Vibramycin) may be prescribed as prophylaxis for syphilis and chlamydia (CDC, 2006b).

Antipregnancy measures may be considered if the patient is of childbearing age (CDC, 2006b). A postcoital contraceptive medication, such as an oral contraceptive medication that contains levonorgestrel and ethinyl estradiol (Alesse, Seasonique), may be prescribed after a pregnancy test. To promote effectiveness, the contraceptive medication should be administered within 12 to 24 hours and no later than 72 hours after intercourse. The 21-day package rather than the 28-day package is prescribed so that the patient does not take the inert tablets by mistake. An antiemetic may be administered as prescribed to decrease discomfort from side effects. A cleansing douche, mouthwash, and fresh clothing are usually offered (Lynch, 2006).

Follow-Up Care

The patient is informed of counseling services to prevent long-term psychological effects. Counseling services should be made available to both the patient and the family. A referral is made to the Rape Victim Companion Program, if available. Appointments for follow-up surveillance for pregnancy and for STD and HIV testing also are made (CDC, 2006b).

The patient is encouraged to return to his or her previous level of functioning as soon as possible. When leaving the health care facility, the patient should be accompanied by a family member or friend.

PSYCHIATRIC EMERGENCIES

A psychiatric emergency is an urgent, serious disturbance of behavior, affect, or thought that makes the patient unable to cope with life situations and interpersonal relationships. A patient presenting with a psychiatric emergency may display overactive or violent, underactive or depressed, or suicidal behaviors.

The most important concern of the ED personnel is determining whether the patient is at risk for injuring self or others. The aim is to try to maintain the patient's self-esteem (and life, if necessary) while providing care. Determining whether the patient is currently under psychiatric care is important so that contact can be made with the therapist or physician who works with the patient.

Overactive Patients

Patients who display disturbed, uncooperative, and paranoid behavior and those who feel anxious and panicky may be prone to assaultive and destructive impulses and abnormal social behavior. Intense nervousness, depression, and crying are evident in some patients. Disturbed and noisy behavior may be exacerbated or compounded by alcohol or drug intoxication.

A reliable source for obtaining an accurate history is needed to identify events leading to the crisis. Past mental illness, hospitalizations, injuries, serious illnesses, use of alcohol or drugs, crises in interpersonal relationships, or intrapsychic conflicts are explored. Because abnormal thoughts and behavior may be manifestations of an underlying physical disorder, such as hypoglycemia, drug or alcohol toxicity, a stroke, a seizure disorder, or head injury, a physical assessment is also performed.

The immediate goal is to gain control of the situation. If the patient is potentially violent, security or local police should be nearby. Restraints are used as a *last* resort and only as prescribed. Approaching the patient with a calm, confident, and firm manner is therapeutic and has a calming effect. Helpful interventions include the following:

- Introduce yourself by name.
- Tell the patient, "I am here to help you."
- Repeat the patient's name from time to time.
- Speak in one-thought sentences and be consistent.
- Give the patient space and time to slow down.
- Show interest in, listen to, and encourage the patient to talk about personal thoughts and feelings.
- Offer appropriate and honest explanations.

A psychotropic agent (eg, one that exerts an effect on the mind) may be prescribed for emergency management of functional psychosis. However, a patient with a personality disorder should not be treated with psychotropic medications, and psychotropic medications should not be used if the patient's behavior results from the use of hallucinogens (eg, lysergic acid diethylamide [LSD]).

Agents such as chlorpromazine and haloperidol act specifically against psychotic symptoms of thought fragmentation and perceptual and behavioral aberrations. The initial dose depends on the patient's body weight and the severity of the symptoms. After administration of the initial dose, the patient is observed closely to determine the degree of change in psychotic behavior. Subsequent doses depend on the patient's response. Typically, after stabilization, the patient is transferred to an inpatient psychiatric unit or psychiatric outpatient treatment is arranged.

Violent Behavior

Violent and aggressive behavior, usually episodic, is a means of expressing feelings of anger, fear, or hopelessness about a situation. Usually, the patient has a history of outbursts of rage, temper tantrums, or impulsive behavior. People with a tendency for violence frequently lose control when intoxicated with alcohol or drugs. Family members are the most

frequent victims of their aggression. Patients with a propensity for violence include those intoxicated by drugs or alcohol; those going through drug or alcohol withdrawal; and those diagnosed with acute paranoid schizophrenic state, acute organic brain syndrome, acute psychosis, paranoid character, borderline personality, or antisocial personality disorders.

The goal of treatment is to bring the violence under control. A specially designated room with at least two exits should be used for the interview. The door of the room should be kept open, and the nurse should remain in clear view of the staff, *staying between the patient and the door*. However, the patient's exit to the door must not be blocked, because the patient may feel trapped and threatened. No objects that could be used as weapons should be in sight, in the room, or carried in with health care personnel. If the interviewer feels anxious or uneasy about the patient's response, security staff, a family member, or another health care worker should be asked to remain in the hall nearby in the event that additional help is needed. The patient should never be left alone, because this may be interpreted as rejection or provide an opportunity for self-harm.

To bring the violence under control, it is crucial to use a calm, noncritical approach while remaining in control of the situation. Sudden movements are avoided. If the patient is carrying a weapon, the emergency health care provider should ask that it be surrendered. If the patient is unwilling to surrender the weapon, the security staff is called. If necessary, the security staff may seek further assistance from the local police department.

The patient's violent behavior is a crisis situation for the patient and the ED. Crisis intervention, achieved by talking and listening to the patient, is best accomplished by expressing an interest in the patient's well-being while attempting to tune in to the patient and remain firm. The patient's agitated state is acknowledged by statements such as, "I want to work with you to relieve your distress."

The patient is allowed the opportunity to express anger verbally. If the patient is delusional, challenging the patient is avoided. Trying to hear what the patient is saying, conveying an expectation of appropriate behavior, and making the patient aware that help is available are key. The patient should be informed that violent behavior may be frightening to others and that violence is not acceptable. Help that is available in crisis situations (from a clinic or mental health facility) should be described and offered. Often, the offer of protection by hospitalization is welcomed by the patient, who fears losing control or harming self or others. If the patient does not calm down, security personnel or police intervention may be necessary.

If these measures fail to alleviate the patient's tension, medication may be prescribed (rapid sedation with haloperidol, diazepam, or chlorpromazine) to reduce tension, anxiety, and hyperactivity. Soft restraints must be prescribed by a physician only if other measures to calm the patient have failed (Hoyt & Selfridge-Thomas, 2007). After combativeness, agitation, and fear have decreased, the patient is referred for further mental health treatment.

Posttraumatic Stress Disorder

PTSD is the development of characteristic symptoms after a psychologically stressful event that is considered outside the range of normal human experience (eg, rape, combat, motor vehicle crash, natural catastrophe, terrorist attack). Symptoms of this disorder include intrusive thoughts and dreams, phobic avoidance reaction (avoidance of activities that arouse recollection of the traumatic event), heightened vigilance, exaggerated startle reaction, generalized anxiety, and societal withdrawal. PTSD may be acute, chronic, or delayed. PTSD often presents as multiple readmissions to the ED for minor or recurring complaints without evidence of injury. Refer to Chapter 7 for further discussion of assessment, diagnostic findings, and management of patients with PTSD.

Underactive or Depressed Patients

In the ED, depression may be seen as the primary condition bringing the patient to the health care facility or it may be masked by anxiety and somatic complaints. The depressed person has a mood disturbance.

Any patient who is depressed may be at risk of suicide. Attempts are made to find out whether the patient has thought about or attempted suicide. Questions such as, "Have you ever thought about taking your own life?" may be helpful. Generally, the patient is relieved to have an opportunity to discuss personal feelings. If the patient is seriously depressed, relatives should be notified. The patient should never be left alone, because suicide is usually committed in solitude. See Chapter 7 for further discussion of assessment, diagnostic findings, and management of patients with depression.

Suicidal Patients

Attempted suicide is an act that stems from depression (eg, loss of a loved one, loss of body integrity or status, poor self-image) and can be viewed as a cry for help and intervention. Males are at greater risk than females. Others at risk are elderly people; young adults; people who are enduring unusual loss or stress; those who are unemployed, divorced, widowed, or living alone; those showing signs of significant depression (eg, weight loss, sleep disturbances, somatic complaints, suicidal preoccupation); and those with a history of a previous suicide attempt, suicide in the family, or psychiatric illness.

Being aware of people at risk and assessing for specific factors that predispose a person to suicide are key management strategies. Specific signs and symptoms of potential suicide include the following:

- Communication of *suicidal intent*, such as preoccupation with death or talking of someone else's suicide (eg, "I'm tired of living. I've put my affairs in order. I'm better off dead. I'm a burden to my family.")
- History of a previous suicide attempt (the risk is much greater in these cases)

- Family history of suicide
- Loss of a parent at an early age
- Specific plan for suicide
- A means to carry out the plan

Emergency management focuses on treating the consequences of the suicide attempt (eg, gunshot wound, drug overdose) and preventing further self-injury. A patient who has made a suicidal attempt may do so again. Crisis intervention is used to determine suicidal potential, to discover areas of depression and conflict, to find out about the patient's support system, and to determine whether hospitalization or psychiatric referral is necessary. Depending on the patient's potential for suicide, the patient may be admitted to the intensive care unit, referred for follow-up care, or admitted to the psychiatric unit.

CRITICAL THINKING EXERCISES

1 An elderly man arrives at the ED by ambulance after a car crash. He is immobilized on a backboard with a cervical collar and an oxygen mask is in place. There is a bruise across his abdomen where the seat belt was applied. He is groaning loudly and seems confused; he cannot tell you what has happened, where he is at present, nor what day of the week it is, although he can tell you his full name. You note a shallow, rapid breathing pattern of 26 breaths per minute. How would you prioritize the patient's needs? Develop an assessment strategy, identify diagnostic studies that will benefit the patient, and describe the patient's priority treatment needs.

EBP 2 Two men choose to go ice fishing for the first time of the season. They chose to wear light clothing, expecting the cabin to be warm, but neglected to take into account the 4 inches of snow on the ground and the high humidity. They spent the day fishing on the ice without moving much. One man now presents to the ED for treatment of frostbite of his feet. His friend has been massaging them en route to the ED, and the patient insists that this makes his feet feel better. You tell them to cease massage. Describe the explanation you would give to this patient and the evidence base that guides your response. Tell how you would proceed with managing this patient's care. Describe the treatment dilemmas for this type of injury.

3 The following four patients present to the triage desk of the ED within minutes of each other. How would you prioritize and categorize each of these patients? Which ones need immediate attention? What initial care would you provide at triage? Which patient could wait or be sent to the clinic for management?

- A college student with a history of exercise-induced asthma and known noncompliance to prescribed medications presents with rapid, shallow respirations and wheezing after jogging 5 miles. His girlfriend is very anxious. He has been this way for about 15 minutes.
- An attorney who has had a cold for 3 days says she has no primary care physician and must be seen right now because she cannot breathe. Her respirations are

- normal, pulse oxygenation saturations are 100%, and she has complaints of sinus drainage and a headache.
- A middle-age woman experienced sudden dyspnea and chest tightness while making dinner. Instead of calling 911, her husband drove her to the ED. She is complaining of left scapular pain and tingling in her left arm, her skin appears ashen, and she is diaphoretic.
- An elderly woman with a known history of diabetes presents with complaints of 24 hours of vomiting. Her vital signs are normal, but she is diaphoretic and appears weak.

4 A patient arrives to the triage area of the ED complaining of flulike symptoms. He has developed a rash that seems to be primarily located on the soles of his feet and palms of his hands. He cannot remember touching anything that he knows he is allergic to, and he has not been walking barefoot. He does like to hunt, and only a week ago was in his deer stand for most of the weekend. What potential disease symptoms are being exhibited by this patient? What other questions would you ask? What will you focus on when you examine his skin?

chapter 72

Terrorism, Mass Casualty, and Disaster Nursing

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify the necessary components of an emergency operations plan.
- 2 Discuss how triage in a disaster differs from triage in an emergency.
- 3 Develop a plan of care for a patient experiencing short-term or long-term psychological effects after a disaster.
- 4 Evaluate the different levels of personal protection and decontamination procedures that may be necessary during an event involving mass casualties or weapons of mass destruction (WMD).
- 5 Identify physical injuries that may occur after blast events.
- 6 Describe isolation precautions necessary for bioterrorism agents.
- 7 Identify the differences among the various chemical agents used in terrorist events, their effects, and the decontamination and treatment procedures that are necessary.
- 8 Determine the injuries associated with varying levels of radiation or chemical exposure and the associated decontamination processes.

GLOSSARY

biological warfare: use of a biological agent, such as anthrax, as a WMD

chemical warfare: use of a chemical agent, such as chlorine, as a WMD

decontamination: process of removing, or rendering harmless, contaminants that have accumulated on personnel, patients, and equipment

mass casualty incident (MCI): situation in which the number of casualties exceeds the number of resources

material safety data sheet (MSDS): provides information to employees and health care providers regarding specific chemical agents; includes chemical name, physical data, chemical ingredients, fire and explosive hazard data, health and reactive data, spill or leak procedures, special protection information, and special precautions; also known as the Worker's Right to Know

nuclear warfare: use of nuclear contamination as a WMD

personal protective equipment (PPE): equipment beyond standard precautions; may include level A, B, C, and D equipment

terrorism: unlawful use of violence or threats of violence against people in order to coerce or intimidate

weapons of mass destruction (WMD): weapons used to cause widespread death and destruction

The possibility and reality of mass casualties associated with disasters, terrorism, and biologic warfare are not new to human history; nor is the concept of using **weapons of mass destruction (WMD)**. In fact, the use of WMD dates as far back as the 6th century BCE for biological weapons and the year 436 BCE for chemical weapons (U.S. Army Medical Research Institute of Chemical Defense, 1999). However, geopolitical forces and interests and the availability of destructive technology have brought the possibility of more terrorist events to our doorstep. **Terrorism** systematically involves using violence to create feelings of fear. Examples include the 1993 bombing of the World Trade Center in New York City; the 1995 Oklahoma City bombing of the Murrah Federal Building; the total destruction of the World Trade Center towers and the damage to the Pentagon on September 11, 2001; and the London subway bombing of 2005. Terrorists have become increasingly sophisticated, organized, and therefore effective. It is no longer a question of *whether* a terrorist event will again lead to mass casualties, but *when* such an event will occur.

In 1999, the National Domestic Preparedness Organization, a federal agency, was developed to coordinate preparedness in the event of a terrorist attack. The Department of Homeland Security was created after the attacks of September 11, 2001, to coordinate federal and state efforts to combat terrorist activity. Every facility receiving preparedness funds must have a plan that adheres to guidelines devised by the National Incident Management System (NIMS), directed by the Federal Emergency Management Agency (FEMA).

Warfare and terrorism are just two of the reasons that health care providers need to plan for mass casualties. Airplane crashes, train crashes, toxic substance spills, and infectious disease outbreaks are other disasters that can result in casualties and tax the resources of health care facilities and their communities. In addition, natural phenomena such as floods, tornadoes, hurricanes (eg, Hurricane Katrina, the category 5 storm that struck New Orleans, Louisiana, and Biloxi, Mississippi, in 2006), fires, and earthquakes, kill and injure hundreds of thousands of people worldwide each year. Acute care facilities must be prepared for any and all of these disasters. This chapter focuses on disaster preparedness, especially providing information about possible terrorist-related injuries and illnesses that can occur after biologic, chemical, and nuclear or radiation attacks. Information about the process of responding to these emergencies is applicable to other types of mass disasters as well.

Federal, State, and Local Responses to Emergencies

Many resources are available at the federal, state, and local levels to assist in the management of **mass casualty incidents (MCIs)**, disasters, and emergencies. An MCI is defined as any incident that results in more patients than daily resources can handle (Emergency Nurses Association, 2007). Local communities must be prepared to act in isolation and provide competent care for up to 5 days before federal or other state resources become available (Hoyt &

Chart 72-1 • Disaster Levels

Disasters are often classified by the resultant anticipated necessary response:

Level I: Local emergency response personnel and organizations can contain and effectively manage the disaster and its aftermath.

Level II: Regional efforts and aid from surrounding communities are sufficient to manage the effects of the disaster.

Level III: Local and regional assets are overwhelmed; statewide or federal assistance is required.

Selfridge-Thomas, 2007). Initiating the request for federal assistance should not be delayed, however, so that resources do not become exhausted.

Disasters are often categorized by level to indicate the anticipated level of response (Chart 72-1). A list of local resources with specific instructions about how and when to contact these agencies or organizations should be readily available to local disaster planning committees and frequently reviewed by those committees for needed updates.

A disaster response strategy cannot succeed without appropriate physical assets and a staff trained and prepared to carry out the plan. Assets such as increased security; stockpiles of equipment and medications; and planning, drills, and training are essential (Lusby, 2006). Hazard vulnerability assessments should be performed to identify potential and actual threats that involve a particular facility and community. Mutual aid agreements among various communities must take these vulnerabilities into account. Successful execution of a response plan is based on knowledge, confidence, and readiness.

Federal Agencies

State authorities must request federal assistance with resources through appropriate government channels. A request for federal resources generally is made when local resources have become or are expected to become depleted.

Federal agencies that may provide resources in response to an MCI or a disaster include the Department of Health and Human Services (DHHS), the Department of Justice, Department of Defense, and the Department of Homeland Security. Each of these federal departments oversees hundreds of agencies that may respond to MCIs. For example, personnel from the Federal Bureau of Investigation (FBI) (structured under the Department of Justice) may be used for scene control and collection of forensic evidence. FEMA, which is overseen by the Department of Homeland Security, can activate teams such as the Urban Search and Rescue Teams (USRTs). The DHHS administers the Centers for Disease Control and Prevention (CDC) and the National Disaster Medical System. The National Disaster Medical System has many medical support teams, such as Disaster Medical Assistance Teams (DMATs), Disaster Mortuary Response Teams (DMORTs), Veterinary Medical Assistance Teams (VMATs), and National Medical Response Teams for Weapons of Mass Destruction (NMRTs).

The DMAT organizes voluntary medical personnel who can set up and staff a field hospital; DMATs are located across the country. There are four NMRTs: the

Table 72-1 DEPARTMENT OF HOMELAND SECURITY THREAT LEVELS

Level of Security Threat	Actions
Red: severe, usually site is specified	Lockdown for security Prevention of parking close to the site Activation of the Emergency Operation Plan and Incident Command System
Orange: high, risk of attack but a specific site may not yet be identified	Increased security and screenings Activation of the Incident Command System
Yellow: elevated, possible risk but no defined site	Increased awareness and monitoring of activities Continued training for the Emergency Operations Plan
Blue: guarded, general risk but no specific risks identified	Ensure readiness with drill practice
Green: low, little or no risk perceived or known	Continued preparedness with drill practice

U.S. Department of Homeland Security, 2003.

mobile California, North Carolina, and Colorado teams and the Washington, D.C., team, which is stationary. These specialty teams were developed to respond to situations involving WMD. They consist of specially trained medical and technical personnel. The National Guard Civil Strike Teams are specially trained units that may respond to MCIs or disasters. In addition, the Department of Homeland Security designates a level of security threat that is intended to alert the country to credible threats (Table 72-1).

Additional federal resources that may be activated include the teams from the CDC. This is the main federal agency for disease prevention, and it controls activities and provides backup support to state and local health departments. Additional support is available from the American Red Cross, which provides many support systems and shelter as needed.

State and Local Agencies

Some state and local agencies may be branches of the same agencies already listed (eg, local CDC and FBI). Other state and local resources may include the American Red Cross, poison control centers, and other local volunteer organizations. The Metro Medical Response Teams Systems are local teams of health care providers that are located in cities considered possible terrorist targets and are funded for specialty response to WMD. Many state and federal task forces have been developed to assist in the development and improvement of civilian medical response to chemical and biologic terrorism.

Most cities and all states have an Office of Emergency Management (OEM) or Office of Emergency Services (OES). The OEM/OES coordinates the disaster relief efforts at the state and local levels. The OEM/OES is responsible for providing interagency coordination during an emergency. It maintains a corps of emergency management personnel, including a leader, responders, planners, and administrative and support staff.

The Incident Command System

The Incident Command System (ICS) is a federally mandated command structure that coordinates personnel, facilities, equipment, and communication in any emergency situation. The ICS is the center of operations for organization, planning, and transport of patients in the event of a specific local MCI. Successful incident management requires equip-

ment compatibility, effective communication, adequate distribution of resources, and clear differentiation of members' roles. The ICS ensures that any hazardous substances used during an MCI are identified promptly and that appropriate personal protection equipment is distributed. In addition to all of these responsibilities, the ICS is also responsible for determining when an MCI has ended.

The hospital incident command system (HICS) is a modification of the ICS that is used by both hospitals and law enforcement agencies. The HICS incident commander is the hospital emergency preparedness coordinator who oversees and coordinates all efforts surrounding the event. The HICS team includes a safety officer, public information officer, liaison officer, operations chief, logistics chief, planning chief, and finance chief. Each team member has a specific responsibility and communicates directly back to the incident commander (Dara, Ashton, Farmer, et al., 2005).

Hospital Emergency Preparedness Plans

Health care facilities are required by the Joint Commission to create a plan for emergency preparedness and to practice this plan at least twice a year (Joint Commission, 2006). Generally, these plans are developed by the facility's safety committee and are overseen by an administrative liaison.

Before the basic emergency operations plan (EOP) can be developed, the planning committee of the health care facility first evaluates characteristics of the community to identify the likely types of natural and man-made disasters that might occur. This hazard vulnerability analysis process is the responsibility of the local health care facility and its safety committee, safety officer, or emergency department (ED) manager. This information can be gathered by questioning local law enforcement, fire departments, and emergency medical systems and assessing the patterns of local train traffic, automobile traffic, and flood, earthquake, tornado, or hurricane activity. Consideration is also given to possible mass casualties that could arise because of the community's proximity to chemical plants, nuclear facilities, or military bases. Federal, judicial, or financial buildings, schools, and any places where large groups of people gather can be considered high-risk areas.

The emergency preparedness planning committee must have a realistic understanding of its resources. It must determine, for example, whether the facility has or needs a pharmaceutical stockpile available to treat specific chemical or biological agents (Hoyt & Selfridge-Thomas, 2007). Another scenario that might be anticipated may include the dispersal of a pulmonary intoxicant or choking agent, which would require that emergency operations planners determine how many ventilators are available within the facility and throughout the greater community. The committee might also outline how staff would triage and assign priority to patients when the number of ventilators is limited. Multiple factors influence a facility's ability to respond effectively to a sudden influx of injured patients, and the committee must anticipate various scenarios to improve its preparedness.

Components of the Emergency Operations Plan

The principles of emergency management must be a part of the EOP design and include a comprehensive plan for tackling all potential and actual hazards. The primary goal is protection of the community. The EOP should be integrated with local, state, and federal government plans and coordinated with the private sector and volunteers. It must be coordinated in advance to achieve a single common purpose, yet the plan must be flexible enough to adapt to any likely situation at hand. Predetermined organization is essential to minimize confusion, ensure that all key operations are directed, and promote a well-coordinated response. Essential components of the EOP include the following:

- *An activation response:* The EOP activation response of a health care facility defines where, how, and when the response is initiated.
- *An internal/external communication plan:* Communication is critical for all parties involved, including communication to and from the prehospital arena (Dara, et al., 2005).
- *A plan for coordinated patient care:* A response is planned for coordinated patient care into and out of the facility, including transfers to other facilities. The site of the disaster can determine where the greater number of patients may self-refer.
- *Security plans:* A coordinated security plan involving facility and community agencies is key to the control of an otherwise chaotic situation.
- *Identification of external resources:* External resources are identified, including local, state, and federal resources and information about how to activate these resources.
- *A plan for people management and traffic flow:* "People management" includes strategies to manage the patients, the public, the media, and personnel. Specific areas are assigned, and a designated person is delegated to manage each of these groups (Dara, et al., 2005).
- *A data management strategy:* A data management plan for every aspect of the disaster will save time at every step. A backup system for charting, tracking, and staffing is developed if the facility has a computer system.

- *Demobilization response:* Deactivation of the response is as important as activation; resources should not be unnecessarily exhausted. The person who decides when the facility resumes daily activities is clearly identified. Any possible residual effects of a disaster must be considered before this decision is made.
- *An after-action report or corrective plan:* Facilities often see increased volumes of patients 3 months or more after an incident. Postincident response must include a critique and a debriefing for all parties involved, immediately and again at a later date.
- *A plan for practice drills:* Practice drills that include community participation allow for troubleshooting any issues before a real-life incident occurs.
- *Anticipated resources:* Food and water must be available for staff, families, and others who may be at the facility for an extended period.
- *MCI planning:* MCI planning includes such issues as planning for mass fatalities and morgue readiness.
- *An education plan for all of the above:* A strong education plan for all personnel regarding each step of the plan allows for improved readiness and additional input for fine-tuning of the EOP (Dara, et al., 2005).

Initiating the Emergency Operations Plan

Notification of a disaster situation to a health care facility varies with each situation. Generally, the notification to the facility comes from outside sources unless the initial incident occurred at the facility. The disaster activation plan should clearly state how the EOP is to be initiated. If communication is functioning, field incident command will give notice of the approximate number of arriving patients, although the number of self-referring patients will not be known.

Identifying Patients and Documenting Patient Information

Patient tracking is a critical component of casualty management. Disaster tags, which are numbered and include triage priority, name, address, age, location and description of injuries, and treatments or medications given, are used to communicate patient information. The tag should be securely placed on the patient and remain with the patient at all times. The tag number and the patient's name, if known, are recorded in a disaster log. The log is used by the command center to track patients, assign beds, and provide families with information.

Triage

Triage is the sorting of patients to determine the priority of their health care needs and the proper site for treatment. In nondisaster situations, health care workers assign a high priority and allocate the most resources to those who are the most critically ill. For example, a young adult who has a chest injury and is in full cardiac arrest would receive advanced cardiopulmonary resuscitation, including medications, chest tubes, intravenous (IV) fluids, blood, and possibly emergency surgery in an effort to restore life. However, in a disaster, when health care providers are faced with a large number of casualties, the fundamental principle

Table 72-2 TRIAGE CATEGORIES DURING A MASS CASUALTY INCIDENT (MCI)

Triage Category	Priority	Color	Typical Conditions
Immediate: Injuries are life-threatening but survivable with minimal intervention. Individuals in this group can progress rapidly to expectant if treatment is delayed.	1	Red	Sucking chest wound, airway obstruction secondary to mechanical cause, shock, hemothorax, tension pneumothorax, asphyxia, unstable chest and abdominal wounds, incomplete amputations, open fractures of long bones, and 2nd/3rd degree burns of 15%–40% total body surface area.
Delayed: Injuries are significant and require medical care, but can wait hours without threat to life or limb. Individuals in this group receive treatment only after immediate casualties are treated.	2	Yellow	Stable abdominal wounds without evidence of significant hemorrhage; soft tissue injuries; maxillofacial wounds without airway compromise; vascular injuries with adequate collateral circulation; genitourinary tract disruption; fractures requiring open reduction, débridement, and external fixation; most eye and CNS injuries.
Minimal: Injuries are minor and treatment can be delayed hours to days. Individuals in this group should be moved away from the main triage area.	3	Green	Upper extremity fractures, minor burns, sprains, small lacerations without significant bleeding, behavioral disorders or psychological disturbances.
Expectant: Injuries are extensive and chances of survival are unlikely even with definitive care. Persons in this group should be separated from other casualties, but not abandoned. Comfort measures should be provided when possible.	4	Black	Unresponsive patients with penetrating head wounds, high spinal cord injuries, wounds involving multiple anatomical sites and organs, 2nd/3rd degree burns in excess of 60% of body surface area, seizures or vomiting within 24 hours after radiation exposure, profound shock with multiple injuries, agonal respirations; no pulse, no blood pressure, pupils fixed and dilated.

guiding resource allocation is to do the greatest good for the greatest number of people. Decisions are based on the likelihood of survival and consumption of available resources. Therefore, this same patient, and others with conditions associated with a high mortality rate, would be assigned a low triage priority in a disaster situation, even if the person is conscious. Although this may sound uncaring, from an ethical standpoint the expenditure of limited resources on people with a low chance of survival, and denial of those resources to others with serious but treatable conditions, cannot be justified.

The triage officer rapidly assesses those injured at the disaster scene. Patients are immediately tagged and transported or given life-saving interventions. One person performs the initial triage while other emergency medical services (EMS) personnel perform life-saving measures (eg, intubation) and transport patients. Although EMS personnel carry out initial field triage, secondary and continuous triage at all subsequent levels of care is essential.

Staff should control all entrances to the acute care facility so that incoming patients are directed to the triage area first. The triage area may be outside the entry or just at the door of the ED. This facilitates the triage of all patients, including those arriving by medical transport and those who walk into the ED. Some patients who have already been seen in the field may be reclassified in the triage area, based on their current presentation.

Triage categories separate patients according to severity of injury. A special color-coded tagging system is used during an MCI so that the triage category is immediately obvious. There are several triage systems in use across the country, and every nurse should be aware of the system used by his or her facility and community. The North Atlantic Treaty Organization (NATO) triage system is one that is widely used. It consists of four colors—red, yellow,

green, and black. Each color signifies a different level of priority. Table 72-2 describes each category and gives examples of how different injuries would be classified. (See Chapter 71 for discussion of triage in non-MCI situations.)

Managing Internal Problems

Each facility must determine its supply lists based on its own needs assessment. The Red Cross has developed a basic survival/shelter resource kit. The EOP committee should determine the top 10 critical medications used during normal day-to-day operations and then anticipate which other medications may be required in a disaster or an MCI. For example, the health care facility might plan to have available a stockpile of antidotes (eg, cyanide kits) or antibiotics used in treating biologic agents. Information should be available about stocking or restocking any of the basic and special supplies, how those supplies are requested, and the time required to receive those supplies.

Communicating With the Media and Family

Communication is a key component of disaster management. Communication within the vast team of disaster responders is paramount; however, effective, informative communication with the media and worried family members is also crucial.

Managing Media Requests for Information

Although the media have an obligation to report the news and can play a significant positive role in communication, the number of reporters and newscasters and their support teams can be overwhelming, possibly compromising operations and patient confidentiality. A clearly defined process for managing media requests that includes a designated spokesperson, the public information officer, a site for the

Chart 72-2 • Cultural Considerations

Any disaster or mass casualty incident can be expected to involve members of diverse religious, ethnic, and cultural groups or may be targeted at and predominately affect a specific religious or ethnic group. Health care providers likewise include members of all religious, ethnic, and cultural backgrounds and should bear in mind that victims may have:

- Language difficulties that increase fears and frustrations
- Specific religious practices related to medical treatment, hygiene, or diet
- Specific places/times for prayer
- Rituals about handling the dead
- Timing of funeral services

Some religious communities have plans for emergencies and disasters, and local hospitals should integrate these plans to the extent possible into their emergency operations plans.

dissemination of information (away from patient care areas), and a regular schedule for providing updates should be part of the disaster plan.

The EOP helps prevent the release of contradictory or inaccurate information. Initial statements should focus on current efforts and what is being done to better understand the scope and impact of the situation. Information about casualties should not be released. Security staff should not allow media personnel access to patient care areas.

Caring for Families

Friends and family members converging on the scene must be cared for by the facility. The public information officer's role is to provide direction for the families and provide them with information as it becomes available. They may be feeling intense anxiety, shock, or grief and should be provided with information and updates about their loved ones as soon as possible and regularly thereafter. They should not be in the triage or treatment areas but in a designated area staffed by available social workers, counselors, therapists, or clergy. Access to this area should be controlled to prevent families from being disturbed. Chart 72-2 discusses cultural variables to consider when coping with disaster-related injuries and death.

The Nurse's Role in Disaster Response Plans

The role of the nurse during a disaster varies. Nurses may be asked to perform duties outside their areas of expertise and may take on responsibilities normally held by physicians or advanced practice nurses. For example, a critical care nurse may intubate a patient or even insert a chest tube. A nurse may perform wound débridement or suturing. A nurse may serve as the triage officer.

Although the exact role of a nurse in disaster management depends on the specific needs of the facility at the time, it should be clear which nurse or physician is in charge of a given patient care area and which procedures each individual nurse may or may not perform. Assistance can be obtained through the HICS, and nonmedical personnel can provide services where possible. For example, family members can provide nonskilled interventions for

their loved ones. Nurses should remember that nursing care in a disaster focuses on essential care from a perspective of what is best for all patients.

New settings and atypical roles for nurses arise during a disaster; for example, the nurse may provide shelter care in a temporary housing area or bereavement support and assistance with identification of deceased loved ones. People may require crisis intervention, or the nurse may participate in counseling other staff members and in Critical Incident Stress Management. Special care may be warranted for at-risk populations during a disaster (Chart 72-3).

Considering Ethical Conflicts

Disasters can present a disparity between the resources of the health care agency and the needs of the victims. This generates ethical dilemmas for nurses and other health care providers. Issues include conflicts related to the following:

- Rationing care
- Futile therapy
- Consent
- Duty
- Confidentiality
- Resuscitation
- Assisted suicide

Nurses may find it difficult to not provide care to the dying or to withhold information to avoid spreading fear and panic. Clinical scenarios that are unimaginable in normal circumstances confront the nurse in extreme instances. Other ethical dilemmas may arise out of health care providers' instincts for self-protection and protection of their families. For example, what should a pregnant nurse do when incoming disaster victims have been exposed to radiation yet too few nurses are available?

Nurses can plan for the ethical dilemmas they will face during disasters by establishing a framework for evaluating

Chart 72-3 • Caring for People With Disabilities During a Disaster

When a disaster occurs, the multiple agencies involved attempt to provide food, water, and shelter to all those affected. People with disabilities have specific needs that require attention. It is recommended that people with disabilities have a personal support network to check on them after a disaster and to provide needed assistance. They should also have a back-up system and an evacuation plan. Agencies need to be aware that service animals are also affected during a disaster and may be brought to shelters with their companions.

Evacuation assistance is imperative for people with disabilities. Directions to personal equipment (eg, communication aids, medications, oxygen) should be available to rescue personnel. In a rapid evacuation, mobility devices, oxygen, suction, and medications will be needed at the shelters. Special efforts to keep those with vision or hearing impairment informed should be implemented. People skilled in sign language are also valuable resources during a disaster. On its Web site, the American Red Cross provides a handbook for disaster preparedness for people with disabilities: www.redcross.org/services/disaster/beprepared/disability/html

ethical questions before they arise and by identifying and exploring possible responses to difficult clinical situations. They can consider how the fundamental ethical principles of utilitarianism, beneficence, and justice will influence their decisions and care in disaster response (see Chapter 3).

Managing Behavioral Issues

Although most people pull together and function well during a disaster, both people and communities suffer immediate and sometimes long-term psychological trauma. Common responses to disaster include the following:

- Depression
- Anxiety
- Somatization (fatigue, general malaise, headaches, gastrointestinal disturbances, skin rashes)
- Posttraumatic stress disorder (PTSD)
- Substance abuse
- Interpersonal conflicts
- Impaired performance

Factors that influence a person's response to disaster include the degree and nature of the exposure to the disaster, loss of friends and loved ones, existing coping strategies, available resources and support, and the personal meaning attached to the event. Other factors, such as loss of home and valued possessions, extended exposure to danger, and exposure to toxic contamination, also influence response and increase the risk of adjustment problems. Those exposed to the dead and injured, those endangered by the event, the elderly, children, emergency first responders, and health care personnel caring for victims are considered to be at higher risk for emotional sequelae.

Nurses can assist disaster victims through active listening and providing emotional support, giving information, and referring patients to therapists or social workers. Health care workers must refer people to mental health care services because experience has shown that few disaster victims seek these services, and early intervention minimizes psychological consequences. Nurses can also discourage victims from subjecting themselves to repeated exposure to the event through media replays and news articles, and encourage them to return to normal activities and social roles when appropriate.

Critical Incident Stress Management

Critical Incident Stress Management (CISM) is an approach to preventing and treating the emotional trauma that can affect emergency responders as a consequence of their jobs and that can also occur to anyone involved in a disaster or MCI. CISM is handled by its own teams, which are available to the OEM. There are 350 such teams in the United States. All branches of emergency services have CISM teams, as do the military and many industries (eg, airline industry).

Components of a management plan include education before an incident occurs about critical incident stress and coping strategies; field support (ensuring that staff get adequate rest, food, and fluids, and rotating work loads) during an incident; and defusing, debriefings, demobilization, and follow-up care after the incident.

Defusing is a process by which the person receives education about recognition of stress reactions and man-

agement strategies for handling stress. Debriefing is a more complicated intervention; it involves a 2- to 3-hour process during which participants are asked about their emotional reactions to the incident, what symptoms they may be experiencing (eg, flashbacks, difficulty sleeping, intrusive thoughts), and other psychological ramifications. In follow-up, members of the CISM team contact the participants of a debriefing and schedule a follow-up meeting if necessary. People with ongoing stress reactions are referred to mental health specialists.

Preparedness and Response

Recognition and Awareness

Preparedness for terrorism and other disasters includes awareness of the potential for covert use of WMD, self-protection, and early detection, containment, or decontamination of substances and agents that may affect others by secondary exposure. The strength of many toxins, mobility of many members of society, and long incubation periods for some organisms and diseases can result in an epidemic that can quickly and silently spread across the entire country. For example, a formerly healthy person with a rapid onset of flulike symptoms can have an ominous illness, such as anthrax or severe acute respiratory syndrome (SARS), both of which are discussed in more detail later in the chapter.

Nurses should have a heightened awareness of trends that may suggest deliberate dispersal of toxic or infectious agents, including the following:

- An unusual increase in the number of people seeking care for fever, respiratory, or gastrointestinal symptoms
- Clusters of patients who present with the same unusual illness from a single location. For example, clusters can be from a specific geographic location, such as a city, or from a single sporting or entertainment event.
- A large number of rapidly fatal cases, especially when death occurs within 72 hours after hospital admission.
- Any increase in disease incidence in a normally healthy population. These cases should be reported to the state health department and to the CDC.

If any of these trends are noted, an extensive patient history is taken in an attempt to identify the possible agent involved. This history includes an occupational, work, and environmental assessment, in addition to the regular admission history. An exposure history contains, at a minimum, information about current and past exposures to possible hazards and an assessment of the patient's typical day and any deviations in routines. The work history includes, at a minimum, a description of all previous jobs, including short-term, seasonal, and part-time employment and any military service. The environmental history includes assessment of present and previous home locations, water supply, and any hobbies, to name a few factors. The admission history should include such information as recent travel and contact with others who have been ill or have recently died of a fatal illness. This is just a brief review of the extensive history that may need to be obtained to identify an

exposure agent (Agency for Toxic Substances and Disease Registry, 2009).

Suspicious or findings are reported to the appropriate resources in the facility and to proper authorities in the community. Resources can include the infection control department, **material safety data sheets (MSDS)** or the Chemtrac database, the state health department, the CDC, the local poison control center, and many Internet sites (Dara, et al., 2005). Reporting furnishes data elements to those agencies responsible for epidemiology and response. Reporting also allows for sharing of information among facilities and jurisdictions and can help determine the source of infections or exposure and prevent further exposures and even deaths.

Personal Protective Equipment

Another component of preparedness and response involves the protection of the health care provider by additional **personal protective equipment (PPE)**. Chemical or biologic agents and radiation are silent killers and are generally colorless and odorless. The purpose of PPE is to shield health care workers from the chemical, physical, biologic, and radiologic hazards that may exist when caring for contaminated patients. The U.S. Environmental Protection Agency (EPA) has divided protective clothing and respiratory protection into the following four categories, levels A through D:

- Level A protection is worn when the highest level of respiratory, skin, eye, and mucous membrane protection is required. This includes a self-contained breathing apparatus (SCBA) and a fully encapsulating, vapor-tight, chemical-resistant suit with chemical-resistant gloves and boots.
- Level B protection requires the highest level of respiratory protection but a lesser level of skin and eye protection than with level A situations. This level of protection includes the SCBA and a chemical-resistant suit, but the suit is not vapor tight (Hoyt & Selfridge-Thomas, 2007).
- Level C protection requires the air-purified respirator, which uses filters or sorbent materials to remove harmful substances from the air. A chemical-resistant coverall with splash hood, chemical-resistant gloves, and boots are included in level C protection.
- Level D protection is the typical work uniform.

Levels C and D PPE are the levels most often used in hospital facilities (Hoyt & Selfridge-Thomas, 2007).

Protective equipment must be donned before contact with a contaminated patient. The acute care facility's standard precaution PPE (level D) generally is not adequate for protection from a chemically, biologically, or radiologically contaminated patient. Level C PPE is adequate for the average patient exposure. The health care provider must use equipment that is capable of providing protection against the agent involved. This may mean using a splash suit along with a full-face positive-pressure or negative-pressure respirator (a filter-type gas mask) or even an SCBA for medical personnel in the field.

No single PPE is capable of protecting against all hazards. Under no circumstances should responders wear any PPE without proper training, practice, and fit testing of respirator masks as necessary.

Decontamination

Decontamination, the process of removing accumulated contaminants, is critical to the health and safety of health care providers by preventing secondary contamination. The decontamination plan should establish procedures and educate employees about decontamination procedures, identify the equipment needed and methods to be used, and establish methods for disposal of contaminated materials (Dara, et al., 2005).

Although many principles and theories surround decontamination of a patient, authorities agree that, to be effective, decontamination must include a minimum of two steps. The first step is removal of the patient's clothing and jewelry and then rinsing the patient with water. Depending on the type of exposure, this step alone can remove a large amount of the contamination and decrease secondary contamination. The second step consists of a thorough soap-and-water wash and rinse. When patients arrive at the facility after being assessed and treated by a prehospital provider, it should not be assumed that they have been thoroughly decontaminated. The hospital must be prepared to perform additional decontamination prior to entry into the facility. The hospital personnel may also treat "walking wounded" who did not receive any decontamination at the scene.

Natural Disasters

Natural disasters may result in mass casualties. Natural disasters can occur anywhere at any time and include events such as tornadoes, hurricanes, floods, avalanches, tidal waves (eg, tsunamis), earthquakes, and volcanic eruptions. In the event of a natural disaster, loss of communications, potable water, and electricity is usually the greatest obstacle to a well-coordinated emergency response, and preparatory planning is essential. Even wireless technology (eg, cellular phones, computers, other communication devices) may not be functional.

The majority of the immediate casualties are trauma related. These mass casualties tax the trauma system to its limits to provide triage, transport of patients (in poor weather and road conditions), and management within the trauma centers. The majority of patients usually begin arriving within an hour of the event. However, the "walking wounded" may not seek care for 5 days to 2 weeks after the event or may seek care for injuries received during clean-up activities. Casualties arrive at hospitals in three waves. The first wave consists of minimally (generally) injured people who arrive of their own accord. The second wave consists of severely injured patients. The third wave consists of injured patients who arrive after they are discovered by rescuers. For example, in the event of earthquakes, buildings collapse and cause the majority of fatalities from injuries that primarily involve the head and chest (Kano, 2005). The majority of the patients usually begin arriving within an hour of the event; the "walking wounded" may not seek care for 5 days to 2 weeks after the event or may seek care for injuries inflicted during the clean-up activities.

Excessive exposure to the natural elements and the need for food and water (by both patients and emergency responders) are critical issues. Without cover (eg, buildings may be unsafe or destroyed) or potable water (eg, water may

be either contaminated or unavailable), injuries from exposure to heat, cold, or contaminated food or water can occur. Safety equipment that protects rescue workers from injury, exposure, and potentially dangerous animals (eg, snakes, alligators, spiders) must be readily available. Rescue workers may also injure themselves in the process of extrication or clean-up (eg, chain saws, building collapse). Hypothermia can occur rapidly in workers who are exposed to water at temperatures of 23.9°C (75°F) or less. As is true during all disasters, mental health workers and shelters are needed throughout the community. Veterinary assistance is also essential because pets are frequently abandoned and injured. In addition, emergency response workers must be prepared to treat the most common ailments experienced after exposure to a specific natural disaster. For instance, pulmonary problems peak with earthquakes and volcanic eruptions because of the increased particulate matter in the air. Most volcano-related deaths are from suffocation. After floods or water disasters, waterborne transmission of agents such as *Escherichia coli*, salmonella, shigella, typhoid, leptospirosis, malaria, and tularemia are common and cause widespread disease. In addition, other waterborne hazards can include human exposure to poisonous snakes and alligators in the flood waters.

In some instances, early warning systems have assisted in decreasing the number of deaths from tornadoes and hurricanes. However, even with the advent of early warning systems, some people are unable or unwilling to leave prior to the occurrence of the natural disaster. When buildings collapse, rapid response to identify and remove trapped victims is the only means of improving survivability. There is a direct relationship between time trapped and survival; fewer than 50 percent of people survive if they are trapped more than 2 to 6 hours. Water-damaged buildings are not safe and require extensive examination before experts can ensure safe occupancy. Larger-scale issues that can cause significant later morbidity and mortality include the absence of water purification, waste removal, removal of human and animal remains, and vector control. Removal or disposal of biologic, chemical, and nuclear agents must also be considered.

Weapons of Terror

Although biologic, chemical, and radiologic events are not everyday events, they can occur at any facility, and every nurse needs to know the basics of caring for affected patients. An explosion may spread the dangerous material. Therefore, treatment of blast injuries must be anticipated and planned.

Blast Injury

Examples of recent highly publicized bombings that have caused significant injuries or loss of lives include those in a disco in Tel Aviv in 2001, in the London subway system in 2005, and on the Mumbai (India) commuter trains in 2006. Terrorist bombings occur frequently throughout the Middle East today, particularly in Iraq and Afghanistan. Several types of bombs are typically used, resulting in various injuries.

Types of Explosive Devices

Commonly used bombs include pipe bombs, Molotov cocktails, fertilizer bombs, and “dirty” bombs (so-called because

they spread radiation). The most commonly utilized bomb is the pipe bomb, which consists of relatively low-velocity explosives and may also contain nails or other implements that cause more damage when the explosive ignites. Another type of commonly used explosive device is the Molotov cocktail, which uses a common flammable liquid such as gasoline in a glass bottle and a source of ignition, such as a rag. This forms a simple yet effective incendiary device. Other common explosive devices include fertilizer bombs, which were used in the Oklahoma City bombing in 1995, and dirty bombs, which include a radioactive source that spreads radiation after the initial blast. Common hazards following a bombing include secondary devices (set to explode at a predetermined time, typically after the arrival of rescue personnel), building collapse, contamination from biological, chemical, or radiological weapons, and the presence of terrorists among the patients and bystanders. The entire scene of the bombing is a crime scene and is treated as such. Triage of patients involved in a bombing is the same as for all disasters, with a heightened awareness that serious internal injuries from the blast wave may not be evident.

Physical Injuries

The actual blast that occurs during the initial seconds of the bombing causes a pressure wave or primary blast wave. Injuries can result from the impact of the explosion, the primary blast wave, or shrapnel within the bomb. The majority of injuries are caused by the primary blast wave (CDC, 2006). A blast wave has four effects. These include spalling, which refers to the pressure wave; implosion, which refers to rupture of organs from entrapped gases; shearing, which refers to the blast response of different body tissues dependent on their density; and irreversible work, which refers to the presence of forces that exceed the tensile strength of an organ or tissue.

Different phases of the blast may result in common injuries that include blast lung, tympanic membrane rupture, and head and abdominal injuries (Table 72-3). Although approximately 50% to 70% of deaths result from head injuries, the majority of head injuries are not life-threatening (CDC, 2006). Bombings that occur in enclosed spaces amplify the blast wave, resulting in more pressure wave injuries. Distance from the blast, whether the blast space was enclosed, composition of the explosive, whether a building collapsed, and the efficiency of medical resources available after the blast all affect patient outcomes after a blast injury.

Blast Lung

Blast lung results from the blast wave as it passes through air-filled lungs. The result is hemorrhage and tearing of the lung, ventilation-perfusion mismatch, and possible air emboli. Typical signs and symptoms include dyspnea, hypoxia, tachypnea or apnea (depending on severity), cough, chest pain, and hemodynamic instability. Management involves providing respiratory support that includes administration of supplemental oxygen, but may also require intubation and mechanical ventilation. If a hemothorax or pneumothorax is present, a chest tube must be inserted to re-expand the lung. In the event of an air embolus, the patient should be immediately placed in the prone left lateral position to

Table 72-3 PHASES OF BLASTS AND ASSOCIATED COMMON INJURIES

Phase of Blast Injury	Common Injuries
Primary: results from pressure wave	Pulmonary barotraumas, including pulmonary contusions Head injuries, including concussion, other severe brain injuries Tympanic membrane rupture, middle ear injury Abdominal hollow organ perforation, hemorrhage
Secondary: results from debris or shrapnel within the bomb or from the scene	Penetrating trunk, skin, and soft tissue injuries Fractures, traumatic amputations
Tertiary: results from pressure wave that causes the victim to be thrown, resulting in traumatic injury	Head injuries Fractures, including skull
Quaternary: results from preexisting conditions exacerbated by the force of the blast or by postblast injury complications	Severe injuries with complex injury patterns: burns, crush injuries, head injuries Common preexisting conditions that become exacerbated: COPD, asthma, cardiac conditions, diabetes, and hypertension
Quinary: thought to result from a hyperinflammatory state commonly seen in bystanders near to the blast and due to toxic substances or uncommon explosives	Hyperpyrexia Diaphoresis

COPD, chronic obstructive pulmonary disease

Kluger, Y., Nimrod, A., Biderman, P., et al. (2006). The quinary pattern of blast injury. *Journal of Emergency Management*, 4(1), 51–55.

prevent migration of the embolus and will require emergent treatment in a hyperbaric chamber. Complications following blast lung can include respiratory failure as well as acute respiratory distress syndrome (ARDS) (see Chapter 23 for further discussion).

Tympanic Membrane Rupture

The tympanic membrane (TM) is the most frequent injury after subjection to a pressure wave because it is the body's most sensitive organ to pressure. There is an increased incidence of TM rupture when a blast occurs in close proximity to the patient and when it occurs in an enclosed space. Signs and symptoms include hearing loss, tinnitus, pain, dizziness, and otorrhea. The majority of TM ruptures heal spontaneously. Approximately 5% of patients with TM rupture from a blast will require hearing aids, whereas the majority will suffer only mild high-frequency hearing loss (Ritenour, Wickley, Ritenour, et al., 2008). Other ear injuries may include ossicular disruption and impaction of foreign bodies.

Abdominal and Head Injuries

Blast abdomen may be evidenced by abdominal hemorrhage and internal organ injury. The typical signs and symptoms of internal abdominal injury can include pain, guarding, rebound tenderness, rectal bleeding, nausea, and vomiting (see Chapter 71 for further discussion of abdominal trauma) (CDC, 2006).

Head injuries are typically minor but those that are severe result in the majority of postblast deaths. These injuries can occur without a direct blow to the head and may result from the blast itself, building collapse, or flying debris. Concussions commonly occur postblast and the usual follow-up evaluation and treatment for postconcussive syndrome is indicated (see Chapter 62 for further discussion of head injuries) (CDC, 2006).

Special Populations

Special populations may have different blast-associated risks. For instance, the elderly are particularly susceptible

to bone fractures because they tend to have decreased bone density. They also tend to have more preexisting morbid conditions that may be exacerbated by the explosion. Pregnant patients' abdomens are particularly susceptible to placental shear forces that may result in abruptio placentae. People with mobility disabilities may have difficulty extricating themselves from the site of the blast (CDC, 2006).

Biologic Weapons

Biologic weapons are weapons that spread disease among the general population or the military.

Effects of Biologic Weapons

Biologic warfare is a covert method of effecting terrorist objectives. Biologic weapons are easily obtained and easily disseminated and can result in significant mortality and morbidity. The potential use of biologic agents calls for continuous increased surveillance by health departments and an increased index of suspicion by clinicians. Many biologic weapons result in signs and symptoms similar to those of common disease processes. Appropriate management of a biologic threat includes rapid recognition of the potential agent; use of proper PPE; decontamination, isolation or quarantine of infected patients when appropriate; and the administration of appropriate vaccinations, antidotes, or medications to people at risk.

Biologic agents are delivered in either a liquid or dry state, applied to foods or water, or vaporized for inhalation or direct contact. Vaporization may be accomplished through spray or explosives loaded with the agent. Because of increases in business and pleasure travel by people in industrialized nations, an agent could be released in one city and affect people in other cities thousands of miles away. The vector can be an insect, animal, or person, or there may be direct contact with the agent itself.

The following is a discussion of two of the agents most likely to be used or weaponized. Table 72-4 describes other easily weaponized biologic agents.

Table 72-4 EXAMPLES OF BIOLOGIC AGENTS THAT CAN BE USED AS WEAPONS

Agent/Organism	Contagion	Decontamination and Protective Equipment	Signs and Symptoms	Treatment (Mortality Rate)
Tularemia— <i>Francisella tularensis</i> : gram-negative coccobacillus, one of the most infectious bacteria known	Direct contact with infected animals or aerosolized as a bioterror weapon; bites Not contagious through human-to-human contact	Standard barrier precautions Clothing and linens should be laundered under the usual hospital protocol	<i>Initial</i> : Abrupt onset of fever, fatigue, chills, headache, lower backache, malaise, rigor, coryza, dry cough, and sore throat without adenopathy. Nausea and vomiting or diarrhea possible. <i>As disease progresses</i> : Sweating, fever, progressive weakness, anorexia, and weight loss demonstrate continued illness. <i>Mortality secondary to</i> : pneumonitis (if inhalation is the source) with copious watery or purulent sputum, hemoptysis, respiratory insufficiency, sepsis, and shock.	Streptomycin or gentamicin/aminoglycoside for 10–14 days. Inhalation tularemia must be treated within 48 hours of onset. In mass casualty situations, doxycycline or ciprofloxacin is recommended. For persons exposed to tularemia, tetracycline or doxycycline is recommended for 14 days. (Mortality rate = 2%)
<i>Botulism</i> — <i>Clostridium botulinum</i> : Botulinum blocks acetylcholine-containing vesicles from fusing with the terminal membranes of the motor-neuron end-plate, resulting in a flaccid paralysis.	Direct contact Not contagious through human-to-human contact	Any skin exposure to the botulism toxin can be treated with soap and water or a 0.1% hypochlorite solution Standard precautions are used when treating patients with botulism	<i>Gastrointestinal botulism</i> : abdominal cramps, nausea, vomiting, and diarrhea. <i>Inhalation botulism</i> : fever; symmetric descending flaccid paralysis with multiple cranial nerve palsies. Classic signs and symptoms include diplopia, dysphagia, dry mouth, lack of fever, and alert mental status. Other possible symptoms include ptosis of the eyelids, blurred vision, enlarged sluggish pupils, dysarthria, and dysphonia. <i>Mortality secondary to</i> : airway obstruction and inadequate tidal volume.	Supportive ventilatory therapy is necessary if respiratory infection occurs. Aminoglycosides and clindamycin are contraindicated because they exacerbate neuromuscular blockage. Equine antitoxin is used to minimize subsequent nerve damage. There is a 2% rate of anaphylaxis to the antitoxin; therefore, diphenhydramine (Benadryl) and epinephrine must be immediately available for use. Supportive care—mechanical ventilation, nutrition, fluids, prevention of complications (Mortality rate = 5%)
Plague— <i>Yersinia pestis</i> : non-sporulating gram-negative coccobacillus. The bacterium causes destruction and necrosis of the lymph nodes.	Contagious <i>Bubonic plague</i> : transmitted through flea bites with no person-to-person transmission <i>Pneumonic plague</i> : transmitted through respiratory droplet contact	Isolation barrier precautions with full face respirators; the patient should wear a mask Rooms should receive a terminal cleaning Clothing and linens with body fluids on them should be cleaned with the usual disinfectant Routine precautions should be used in the case of death	<i>Bubonic plague</i> : Sudden fever and chills, weakness, a swollen and tender lymph node (bubo) in the groin, axilla, or cervical area. The resultant bacteremia progresses to septicemia from the endotoxin and, finally, shock and death. <i>Primary septicemic plague</i> : Disseminated intravascular coagulation (DIC), necrosis of small vessels, purpura, and gangrene of the digits and nose (black death). <i>Pneumonic plague</i> : Severe bronchospasm, chest pain, dyspnea, cough, and hemoptysis. There is a 100% mortality associated with pneumonic plague if not treated within the first 24 hours.	Streptomycin or gentamicin for 10–14 days. Tetracycline or doxycycline is an acceptable alternative if an aminoglycoside cannot be given. People with close contact exposure (<2 m) require prophylaxis with doxycycline for 7 days. (Mortality rate = 50%)

Types of Biologic Agents

Anthrax

Anthrax is recognized as the most likely weaponized biologic agent available and has been recognized as a highly debilitating agent for centuries. *Bacillus anthracis* is a naturally occurring gram-positive, encapsulated rod that lives in the soil in the spore state throughout the world. The bacterium sporulates (ie, is liberated) when exposed to air and

is infective only in the spore form. Contact with infected animal products (raw meat) or inhalation of the spores results in infection. Cattle and other herbivores are vaccinated against anthrax to prevent transmission through contaminated meat.

It is believed that approximately 8000 to 50,000 spores must be inhaled to put a person at risk (Tasota, Henker & Hoffman, 2002). As an aerosol, anthrax is odorless and invisible and can travel a great distance before disseminating;

hence, the site of release and the site of infection can be miles apart.

Clinical Manifestations. Anthrax is caused by replicating bacteria that release toxin, resulting in hemorrhage, edema, and necrosis. The incubation period is 1 to 6 days. There are three primary methods of infection: skin contact, inhalation, and gastrointestinal ingestion. Skin lesions (the most common infection) cause edema with pruritus and macule or papule formation, resulting in ulceration with 1- to 3-mm vesicles. A painless eschar develops, which falls off in 1 to 2 weeks.

Ingestion of anthrax results in fever, nausea and vomiting, abdominal pain, bloody diarrhea, and occasionally ascites. If severe diarrhea develops, decreased intravascular volume becomes the primary treatment concern. The bacterium targets the terminal ileum and cecum. Sepsis can occur.

Inhaling anthrax results in the most severe clinical manifestations. Its symptoms mimic those of the flu, and usually treatment is sought only when the second stage of severe respiratory distress occurs. Current antibiotic therapy does not halt the progress of the disease. Inhaled anthrax can incubate for up to 60 days, making it difficult to identify its source. Initial signs and symptoms include cough, headache, fever, vomiting, chills, weakness, mild chest discomfort, dyspnea, and syncope, without rhinorrhea or nasal congestion. Most patients have a brief recovery period followed by the second stage within 1 to 3 days, characterized by fever, severe respiratory distress, stridor, hypoxia, cyanosis, diaphoresis, hypotension, and shock. These patients require optimization of oxygenation, correction of electrolyte imbalances, and ventilatory and hemodynamic support. More than 50% of these patients have hemorrhagic mediastinitis on a chest x-ray (a hallmark sign) (Auerbach, 2007). The disease can also progress to include meningitis with subarachnoid hemorrhage. Death results approximately 24 to 36 hours after the onset of severe respiratory distress. The mortality rate approaches 100%.

Treatment. At present, anthrax is penicillin sensitive; however, strains of penicillin-resistant anthrax are thought to exist. Recommended treatment includes penicillin (Penicillin V), erythromycin (E-mycin, Erythrocin), gentamicin (Garamycin), or doxycycline (Vibramycin). If antibiotic treatment begins within 24 hours after exposure, death can be prevented. In a mass casualty situation, treatment with ciprofloxacin (Cipro) or doxycycline is recommended. Treatment is continued for 60 days. For patients who have been directly exposed to anthrax but have no signs and symptoms of disease, ciprofloxacin or doxycycline is used for prophylaxis for 60 days.

Standard precautions are the only ones indicated to protect the caregiver exposed to a patient infected with anthrax. The patient is not contagious, and the disease cannot spread from person to person. Equipment should be cleaned using standard hospital disinfectant. After death, cremation is recommended because the spores can survive for decades and represent a threat to morticians and forensic medicine personnel.

There is a vaccine for anthrax that has been used in the military; however, it is not yet widely used because it requires multiple time-interval-sensitive boosters and has up to a 48% systemic reaction rate. The federal government is

investigating the potential for development of a community-wide vaccine that has fewer side effects and that requires fewer boosters.

Smallpox

Smallpox (variola) is classified as a DNA virus. It has an incubation period of approximately 12 days. It is extremely contagious and is spread by direct contact, by contact with clothing or linens, or by droplets from person to person only after the fever has decreased and the rash phase has begun (Karwa, Currie & Kvetan, 2005). There is an associated 30% case-fatality rate (ie, the likelihood of fatality per case diagnosed). Aerosolization of the virus would result in widespread dissemination.

The World Health Organization declared smallpox eradicated in 1977 and stopped worldwide vaccination in 1980. In the United States, the last child was vaccinated in 1972. Therefore, a large portion of the current population has no immunity to the virus. A smallpox vaccination plan introduced in 2003 proposed that a designated number of ED staff receive the first vaccinations to ensure that ED staff would be immunized in the event of a smallpox outbreak. The government estimated that 0.1% of those people receiving the vaccine would have serious side effects. Of these, approximately 4% would have life-threatening complications, and 0.1% would die. Plans for any type of select or mass vaccinations for smallpox are not under current consideration, given the risks associated with vaccination.

Clinical Manifestations. Signs and symptoms of smallpox infection include high fever, malaise, headache, backache, and prostration. After 1 to 2 days, a maculopapular rash appears, evolving at the same rate, beginning on the face, mouth, pharynx, and forearms (Fig. 72-1). Only then does the rash progress to the trunk and also become vesicular to pustular (Hoyt & Selfridge-Thomas, 2007). There is a large amount of the virus in the saliva and pustules. Smallpox is contagious only after the appearance of the rash. There are two forms of smallpox, variola major and variola minor. Variola major is more common, results in a higher fever and more extensive rash, and has a 30% case-fatality rate. Hemorrhagic smallpox, a subtype of variola major, includes all of the above signs and symptoms plus a dusky erythema and petechiae leading to frank hemorrhage of the skin and mucous membranes, and it results in death by day 5 or 6.

Treatment. Treatment includes supportive care with antibiotics for any additional infection. The patient must be isolated with the use of transmission precautions. Laundry and biologic wastes should be autoclaved before being washed with hot water and bleach. Standard decontamination of the room is effective. All people who have household or face-to-face contact with the patient after the fever begins should be vaccinated within 4 days to prevent infection and death. A patient with a temperature of 38°C (101°F) or higher within 17 days after exposure must be placed in isolation. Cremation is preferred for all deaths because the virus can survive in scabs for up to 13 years.

Severe Acute Respiratory Syndrome

Not all mass casualty biologic events are terrorist based. The SARS outbreak in 2003 is a prime example of a

Figure 72-1 Comparison of progression of smallpox rash and chicken pox rash. From World Health Organization. (2001). WHO slide set on the diagnosis of smallpox. Reproduced by permission of the World Health Organization. Available at: www.who.int/emc/diseases/smallpox/slideset/index.htm

non-terrorist-based mass casualty biologic event. The disease started as “atypical” pneumonia in China in February and spread to 29 countries throughout the world by July. Air travel and worldwide trade have increased the possibility that any contagious disease may spread rapidly.

SARS is caused by a virus, officially named SARS-CoV. Its incubation period is 2 to 10 days. People at risk include health care workers who have had unprotected exposure to SARS-CoV. See Chapter 23 for further discussion of SARS.

Chemical Weapons

Agents that may be used in **chemical warfare** or for terrorist purposes are overt agents in that the effects are more apparent and occur more quickly than those caused by biologic weapons. Refer to Table 72-5 for an overview of common chemical agents.

Characteristics of Chemicals

Volatility

Volatility is the tendency for a chemical to become a vapor. The most common volatile agents are phosgene and cyanide. Most chemicals are heavier than air, except for

hydrogen cyanide. Therefore, in the presence of most chemicals, people should stand up to avoid heavy exposure (because the chemical will sink toward the floor or ground).

Persistence

Persistence means that the chemical is less likely to vaporize and disperse. More volatile chemicals do not evaporate very quickly. Most industrial chemicals (eg, cyanide) are not very persistent. Weaponized agents (chemicals developed as weapons by the military or terrorists [eg, mustard gas]) are more likely than industrial chemicals to penetrate skin and mucous membranes and also cause secondary exposure.

Toxicity

Toxicity is the potential of an agent to cause injury to the body. The median lethal dose (LD_{50}) is the amount of the chemical that will cause death in 50% of those who are exposed. The median effective dose (ED_{50}) is the amount of the chemical that will cause signs and symptoms in 50% of those who are exposed. The concentration time (CT) is the concentration released multiplied by the time exposed (mg/min). For example, if 1000 mg of a chemical is released

TABLE 72-5 COMMON CHEMICAL AGENTS

Agent	Action	Signs and Symptoms	Decontamination and Treatment
Nerve Agents Sarin Soman organophosphates	Inhibition of cholinesterase	Increased secretions, gastrointestinal motility, diarrhea, bronchospasm.	Soap and water Supportive care Benzodiazepine Pralidoxime Atropine
Blood Agent Cyanide	Inhibition of aerobic metabolism	Inhalation—tachypnea, tachycardia, coma, seizures. Can progress to respiratory arrest, respiratory failure, cardiac arrest, death.	Sodium nitrite Sodium thiocyanate Amyl nitrate Hydroxocobalamin
Vesicant Agents Lewisite Sulfur mustard Nitrogen mustard Phosgene	Blistering agents	Superficial to partial-thickness burn with vesicles that coalesce.	Soap and water Blot; do not rub dry
Pulmonary Agents Phosgene Chlorine	Separation of alveoli from capillary bed	Pulmonary edema, bronchospasm.	Airway management Ventilatory support Bronchoscopy

and the time a person is exposed to this amount of chemical is 10 minutes, then the concentration time would be 10,000 mg/min.

Latency

Latency is the time from absorption to the appearance of signs and symptoms. Sulfur mustards and pulmonary agents have the longest latency, whereas other vesicants, nerve agents, and cyanide produce signs and symptoms within seconds.

Limiting Exposure

Evacuation is essential, as is removal of the person's clothing and decontamination as close to the scene as possible and before transport of the exposed person. Soap and water are effective means of decontamination in most cases. Staff involved in decontamination efforts must wear PPE and contain and dispose of the runoff after decontamination procedures.

Types of Chemicals

Vesicants

Vesicants are chemicals that cause blistering and result in burning, conjunctivitis, bronchitis, pneumonia, hematopoietic suppression, and death. Examples of vesicants include lewisite, phosgene, nitrogen mustard, and sulfur mustard. In World War I and in the Iran–Iraq conflict of 1980 to 1988, vesicants were used to disable opponents. Vesicants were the primary incapacitating agents, resulting in minimal (less than 5%) death but large numbers of injuries (Dara, et al., 2005). Liquid sulfur mustard was the most frequently used vesicant in these conflicts.

Clinical Manifestations. The initial presentation after exposure to a vesicant is similar to that of a large superficial to partial-thickness burn in the warm and moist areas of the body (ie, perineum, axillae, antecubital spaces). There is stinging and erythema for approximately 24 hours, followed by pruritus, painful burning, and small vesicle formation after 2 to 18 hours. These vesicles can coalesce into large, fluid-filled bullae. Lewisite and phosgene result in immediate pain after exposure. Tissue damage occurs within minutes.

If the eye is exposed, there is pain, photophobia, lacrimation, and decreased vision. This progresses to conjunctivitis, blepharospasm, corneal ulcer, and corneal edema.

Respiratory effects are more serious and often are the cause of mortality with vesicant exposure. Purulent fibrinous pseudomembrane discharge may cause obstruction of the airways. Gastrointestinal exposure may cause nausea and vomiting, leukopenia, and upper gastrointestinal bleeding.

Treatment. Appropriate decontamination includes soap and water. Scrubbing and the use of hypochlorite solutions should be avoided because they increase penetration. Once the substance has penetrated, it cannot be removed. Eye exposure requires copious irrigation. For respiratory exposure, intubation and bronchoscopy to remove necrotic tissue are essential. With lewisite exposure, dimercaprol (BAL in oil) is administered intravenously for systemic toxicity and topically for skin lesions. All persons with sulfur mustard expo-

sure should be monitored for 24 hours for delayed (latent) effects.

Nerve Agents

The most toxic agents in existence are the nerve agents such as sarin, soman, tabun, VX, and organophosphates (pesticides). They are inexpensive, effective in small quantities, and easily dispersed. In the liquid form, nerve agents evaporate into a colorless, odorless vapor. Organophosphates are similar in nature to the nerve agents used in warfare and are readily available. Nerve agents can be inhaled or absorbed percutaneously or subcutaneously. These agents bond with acetylcholinesterase, so that acetylcholine is not inactivated; the adverse result is continuous stimulation (hyperstimulation) of the nerve endings. Carbamates, which are insecticides originally extracted from the Calabar bean, are derivatives of carbamic acid; they are nerve agents that specifically inhibit acetylcholinesterase for several hours and then spontaneously become unbound from the acetylcholinesterase. However, organophosphates require the formation of new enzyme (acetylcholinesterase) before nervous system function can be restored.

A very small drop of a nerve agent is enough to result in sweating and twitching at the site of exposure. A larger amount results in more systemic symptoms. Effects can begin anywhere from 30 minutes up to 18 hours after exposure. The more common organophosphates and carbamates (eg, sevin and malathion) that are used in agriculture result in less severe symptoms than do those used in warfare or in terrorist attacks. In an ordinary situation (eg, nonwarfare, nonterrorist attack situation), a patient could arrive at the ED having been unintentionally or intentionally exposed to organophosphates in a suicidal attempt.

Clinical Manifestations. Signs and symptoms of nerve gas exposure are those of cholinergic crisis and include bilateral miosis, visual disturbances, increased gastrointestinal motility, nausea and vomiting, diarrhea, substernal spasm, indigestion, bradycardia and atrioventricular block, bronchoconstriction, laryngeal spasm, weakness, fasciculations, and incontinence. The patient must be examined in a dark area to truly identify miosis. Neurologic responses include insomnia, forgetfulness, impaired judgment, depression, and irritability. A lethal dose results in loss of consciousness, seizures, copious secretions, fasciculations, flaccid muscles, and apnea.

Treatment. Decontamination with copious amounts of soap and water or saline solution for 8 to 20 minutes is essential. The water is blotted off, not wiped off, the skin. Fresh 0.5% hypochlorite solution (bleach) can also be used. The airway is maintained, and suctioning is frequently required. Plastic airway equipment should not be used because plastic will absorb sarin gas and may result in continued exposure to the agent.

Atropine 2 to 4 mg is administered by IV, followed by 2 mg every 3 to 8 minutes for up to 24 hours of treatment. Alternatively, IV atropine 1 to 2 mg/h may be administered until clear signs of anticholinergic activity have returned (decreased secretions, tachycardia, and decreased gastrointestinal motility). Another medication that may serve as an antidote is pralidoxime (Protopam), which allows cholinesterase

to become active against acetylcholine. Pralidoxime 1 to 2 g in 100 to 150 mL of normal saline solution is administered over 15 to 30 minutes. Pralidoxime has no effect on secretions and may have any of the following side effects: hypertension, tachycardia, weakness, dizziness, blurred vision, and diplopia. Diazepam (Valium) or other benzodiazepines are used to control seizures, to decrease fasciculations, and to alleviate apprehension and agitation.

Military personnel believed to be at risk for chemical attack are provided with Mark I automatic injectors, which contain 2 mg atropine and 600 mg pralidoxime chloride. Diazepam may be administered by a partner.

Blood Agents

Blood agents such as hydrogen cyanide and cyanogen chloride have a direct effect on cellular metabolism, resulting in asphyxiation through alterations in hemoglobin. Cyanide is an agent that has profound systemic effects. It is commonly used in the mining of gold and silver and in the plastics and dye industries. In 1984, the Union Carbide pesticide plant in Bhopal, India, inadvertently released large amounts of cyanide in an industrial disaster and hundreds of deaths occurred.

A cyanide release is often associated with the odor of bitter almonds. In house fires, cyanide is released during the combustion of plastics, rugs, silk, furniture, and other construction materials. There is a significant correlation between blood cyanide and carbon monoxide levels in patients who survive fires, and in many cases, the cause of death is cyanide poisoning.

Clinical Manifestations. Cyanide can be ingested, inhaled, or absorbed through the skin and mucous membranes. Cyanide is protein bound and inhibits aerobic metabolism, leading to respiratory muscle failure, respiratory arrest, cardiac arrest, and death. Its inhalation results in flushing, tachypnea, tachycardia, nonspecific neurologic symptoms, stupor, coma, and seizure preceding respiratory arrest.

Treatment. Rapid administration of amyl nitrate, sodium nitrite, and sodium thiosulfate is essential to the successful management of cyanide exposure. First, the patient is intubated and placed on a ventilator. Next, amyl nitrate pearls are crushed and placed in the ventilator reservoir to induce methemoglobinemia. Cyanide has a 20% to 25% higher affinity for methemoglobin than it does for hemoglobin; it binds methemoglobin to form either cyanomethemoglobin or sulfmethemoglobin. The cyanomethemoglobin is then detoxified in the liver by the enzyme rhodanese. Next, IV sodium nitrite is administered to induce the rapid formation of methemoglobin. IV sodium thiosulfate is then administered; it has a higher affinity for cyanide than methemoglobin does and stimulates the conversion of cyanide to sodium thiocyanate, which can be excreted by the kidneys. Although they may be life-saving, these emergency medications do have side effects: sodium nitrite can result in severe hypotension, and thiocyanate can cause vomiting, psychosis, arthralgia, and myalgia.

The production of methemoglobin is contraindicated in patients with smoke inhalation, because they already have decreased oxygen-carrying capacity secondary to the

carboxyhemoglobin produced by smoke inhalation. In facilities where a hyperbaric chamber is available, it may be used to provide oxygenation while the previously discussed therapies are initiated. An alternative suggested treatment for cyanide poisoning is hydroxocobalamin (vitamin B_{12a}). Hydroxocobalamin binds cyanide to form cyanocobalamin (vitamin B₁₂). It must be administered by IV in large doses. Administration of vitamin B_{12a} can result in a transient pink discoloration of mucous membranes, skin, and urine. In high doses, tachycardia and hypertension can occur, but they usually resolve within 48 hours.

Pulmonary Agents

Pulmonary agents such as phosgene and chlorine destroy the pulmonary membrane that separates the alveolus from the capillary bed, disrupting alveolar–capillary oxygen transport mechanisms. Capillary leakage results in fluid-filled alveoli. Phosgene and chlorine both vaporize, rapidly causing this pulmonary injury. Phosgene has the odor of fresh-mown hay.

Signs and symptoms include pulmonary edema with shortness of breath, especially during exertion. An initial hacking cough is followed by frothy sputum production. A particulate air-filter mask is the only protection required to protect health care personnel. Phosgene does not injure the eyes.

Nuclear Radiation Exposure

The threat of **nuclear warfare** or radiation exposure is very real with the availability of nuclear material and easily concealed simple devices, such as the so-called dirty bomb, for dispersal. A dirty bomb is a conventional explosive (eg, dynamite) that is packaged with radioactive material that scatters when the bomb is detonated. It disperses radioactive material and may be called a radiologic weapon, but is not a nuclear weapon, which uses a complex nuclear fission reaction that is thousands of times more devastating than the dirty bomb.

Sources of radioactive material include not only nuclear weapons but also reactors and simple radioactive samples, such as weapons-grade plutonium or uranium, freshly spent nuclear fuel, or medical supplies (eg, radium, certain cesium isotopes) used in cancer treatments and radiology. Exposure of a large number of people can be accomplished by placing a radioactive sample in a public place. Thousands may be exposed this way; some may be immediately affected, and others may require health monitoring for many years to assess long-term effects. The effectiveness of these weapons was demonstrated in the devastating results of the bombings of Hiroshima and Nagasaki in World War II.

Nuclear reactor incidents have occurred in the Chernobyl (1986) and Three Mile Island (1979) nuclear facilities. There were 31 official deaths on the day of the Chernobyl incident, which involved a core meltdown and explosion, releasing radiation throughout the community. The long-term effects of this incident, including increased incidence of thyroid cancers and leukemia, continue to be evaluated.

Any terrorist-sponsored or unintentional radiation release can be sizable and may require the entire hospital and prehospital staff to be prepared, recognize signs and symptoms of exposure, and rapidly treat victims without contamination of personnel, visitors, patients, or the facility itself.

Types of Radiation

Atoms consist of protons, neutrons, and electrons. The protons and neutrons are in balance in the nucleus. The protons repel each other because they are all positively charged. The number of protons is specific for each element in the periodic table. There is a specific ratio of protons and neutrons for each different atom, and the result is element stability. When an element is radioactive, there is an imbalance in the nucleus, resulting from an excess of neutrons.

To achieve stability, a radioactive nuclide can eject particles until the most stable number (an even number) of protons and neutrons exists. A proton can become a neutron by ejecting a positron; conversely, a neutron can become a proton by ejecting a negative electron. An alpha particle is released when two protons and two electrons are ejected.

Alpha particles cannot penetrate the skin. A thin layer of paper or clothing is all that is necessary to protect the skin from alpha radiation. However, this low-level radiation can enter the body through inhalation, ingestion, or injection (open wound). Only localized damage occurs.

Beta particles have the ability to moderately penetrate the skin to the layer in which skin cells are being produced. This high-energy radiation can cause skin damage if the skin is exposed for a prolonged period and can cause injury if beta particles penetrate the skin.

Gamma radiation is a short-wavelength electromagnetic energy that is emitted when there is excess core nucleus energy. Gamma particles are penetrating. Therefore, it is difficult to shield against gamma radiation. X-rays are an example of gamma radiation. Gamma radiation often accompanies both alpha particle and beta particle emission.

Measurement and Detection

Radiation is measured in several different units. The *rad* is the basic unit of measurement. A rad is equivalent to 0.01 J of energy per kilogram of tissue. To determine the damaging effect of the rad, a conversion to the *rem* (roentgen equivalents human) is necessary. The rem reflects the type of radiation absorbed and the potential for damage. For example, 200,000 mrem results in mild radiation sickness (1 rem = 1000 mrem) (Dara, et al., 2005). Typical natural yearly exposure for a person is 360 mrem. Another important concept is *half-life*. The half-life of a radioactive product is the time it takes to lose half of its radioactivity.

The only way to detect radiation is through a device that determines the exposure per minute. There are various devices for this purpose. The Geiger counter (or Geiger-Mueller survey meter) can measure background radiation quickly through detection of gamma radiation and some beta radiation. With high-level radiation, the Geiger counter may underestimate exposure. Other devices include the ionization chamber survey meter, alpha monitors, and dose-rate meters. Personal dosimeters are simple tools that identify radiation exposure and are worn by radiology personnel.

Exposure

Exposure is affected by time, distance, and shielding. The longer a person is within the radiation area, the higher the exposure. Also, the larger the amount of radioactive material in the area, the greater the exposure. The farther away

the person is from the radiation source, the lower the exposure. Shielding from the radiation source also decreases exposure.

Three types of radiation-induced injury can occur: external irradiation, contamination with radioactive materials, and incorporation of radioactive material into body cells, tissues, or organs:

- *External irradiation* exposure occurs when all or part of the body is exposed to radiation that penetrates or passes completely through the body. In this type of exposure, the person is not radioactive and does not require special isolation or decontamination measures. Irradiation does not necessarily constitute a medical emergency.
- *Contamination* occurs when the body is exposed to radioactive gases, liquids, or solids either externally or internally. If internal, the contaminant can be deposited within the body. Contamination requires immediate medical management to prevent incorporation.
- *Incorporation* is the actual uptake of radioactive material into the cells, tissues, and susceptible organs. The organs involved are usually the kidneys, bones, liver, and thyroid.

Sequelae of contamination and incorporation can occur days to years later. The thyroid gland can be largely protected from radiation exposure by administration of stable iodine (potassium iodide, or KI) before or promptly after the intake of radioactive iodine (Dara, et al., 2005).

Priorities in the treatment of any type of radiation exposure are always treatment of life-threatening injuries and illnesses first, followed by measures to limit exposure, contamination control, and finally decontamination.

Decontamination

Hospital and community disaster plans should be in effect when managing a radiation disaster. Access restriction is essential to prevent contamination of other areas of the hospital. Triage outside the hospital is the most effective means of preventing contamination of the facility itself. Floors are covered to prevent tracking of contaminants throughout the treatment areas. Strict isolation precautions should be in effect. All air ducts and vents must be sealed to prevent spread. Waste is controlled through double-bagging and the use of plastic-lined containers outside of the facility. All radiation-contaminated waste must be disposed in appropriate color-coded yellow and magenta canisters.

Staff are required to wear protective clothing, such as water-resistant gowns, two pairs of gloves, masks, caps, goggles, and booties. Dosimetry devices should be worn by all staff members participating in patient care. The radiation safety officer in the hospital should be notified immediately to assist with surveys (using a radiation survey meter) of the incoming patients and to provide dosimeters to all staff personnel involved in direct care of exposed patients. There is minimal risk to staff if the patients are properly surveyed and decontaminated. The majority of patients can be safely decontaminated with soap and water.

Each patient arriving at the hospital should first be surveyed with the radiation survey meter for external contamination and then directed toward the decontamination area as needed. Decontamination occurs outside of the ED with

a shower, collection pool, tarp, and collection containers for patient belongings, as well as soap, towels, and disposable paper gowns for patients. Water runoff needs to be contained. Patients who are uninjured can perform self-decontamination with handheld showers. After the patient has showered, a resurvey is conducted to determine whether the radioactive contaminants have been removed. Additional washings should occur until the patient is free of contamination. It is important to ensure that during showers previously clean areas are not contaminated with runoff from the washed contaminated areas (eg, hair should be washed in a position that protects the body from contamination). Wounds are irrigated and then covered with a water-resistant dressing prior to total body decontamination.

Internal contamination or incorporation requires decontamination through catharsis, gastric lavage with chelating agents (agents that bind with radioactive substances and are then excreted), or both. Samples of urine, feces, and vomitus are surveyed to determine internal contamination levels. Biologic samples are taken through nasal and throat swabs, and a complete blood count with differential is obtained.

Acute Radiation Syndrome

Acute radiation syndrome (ARS) can occur after exposure to radiation. It is the dose, rather than the source, that determines whether ARS develops. Factors that determine whether the patient's response to exposure will result in ARS include a high dose (minimum 100 rad) and rate of radiation with total body exposure and penetrating-type radiation. Age, medical history, and genetics also affect the outcome after exposure. The course is predictable. Table 72-6 identifies the phases of ARS.

Each body system is affected differently in ARS. Systems with cells that rapidly reproduce are most commonly affected. The effects on the hematopoietic system include decreased numbers of lymphocytes, granulocytes, thrombocytes, and reticulocytes. It is the first system affected and serves as an indicator of the severity of radiation exposure (Dara, et al., 2005). A predictor of outcome is the absolute lymphocyte count at 48 hours after exposure. A significant exposure would be indicated by blood lymphocyte counts of 300 to 1200/mm³. Barrier precautions should be implemented to protect the patient from infection. Neutrophils decrease within 1 week, platelets decrease within 2 weeks, and red blood cells decrease within 3 weeks. Hemorrhagic complications, fever, and sepsis are common.

The gastrointestinal system, with its rapidly reproducing cells, is also readily affected by radiation. Doses of radiation required to produce symptoms are approximately 600 rad or higher. The gastrointestinal symptoms usually occur at the same time as the changes in the hematopoietic system. Nausea and vomiting occur within 2 hours after exposure. Sepsis, fluid and electrolyte imbalance, and opportunistic infections can occur as complications. An ominous sign is the presence of high fever and bloody diarrhea; these typically appear on day 10 after exposure.

The central nervous system is affected when the dose exceeds 1000 rad (Dara, et al., 2005). The symptoms occur when damage to the blood vessels of the brain results in fluid leakage. Signs and symptoms include cerebral edema, nausea, vomiting, headache, and increased intracranial pressure (ICP). Increased ICP heralds a poor outcome and imminent death. Central nervous system injury with this amount of exposure is irreversible and occurs before hematopoietic or gastrointestinal system symptoms appear. Cardiovascular collapse is usually seen in conjunction with these injuries.

Skin effects can also indicate the dose of radiation exposure. With exposure of 600 to 1000 rad, erythema occurs; it can disappear within hours, and then reappear. The exposed patient must be evaluated hourly for the presence of erythema. With exposures greater than 1000 rad, desquamation (radiation dermatitis) of the skin occurs. Necrosis becomes evident within a few days to months at doses greater than 5000 rad.

Secondary injury can occur when the radiation exposure occurs during a traumatic event such as a blast or burn. Trauma in addition to radiation exposure increases patient mortality. Attention must first be directed toward the primary assessment for trauma. Airway, breathing, circulation, and fracture reduction require immediate attention. All definitive treatments must occur within the first 48 hours. Thereafter, all surgical procedures should be delayed for 2 to 3 months because of the potential for delayed wound healing and the possible development of opportunistic infections several weeks after exposure.

Survival

There are three categories of predicted survival after radiation exposure: probable, possible, and improbable. Triage of victims at the scene, after decontamination, is conducted using the routine system for disaster triage. Presenting signs

TABLE 72-6 PHASES OF EFFECTS OF RADIATION EXPOSURE

Phase	Time of Occurrence	Signs and Symptoms
Prodromal phase (presenting symptoms)	48–72 h after exposure	Nausea, vomiting, loss of appetite, diarrhea, fatigue High-dose radiation: fever, respiratory distress, and increased excitability
Latent phase (a symptom-free period)	After resolution of prodromal phase; can last up to 3 wk With high-dose radiation, latent period is shorter	Decreasing lymphocytes, leukocytes, thrombocytes, red blood cells
Illness phase	After latent period phase	Infection, fluid and electrolyte imbalance, bleeding, diarrhea, shock, and altered level of consciousness
Recovery phase OR	After illness phase	Can take weeks to months for full recovery
Death	After illness phase	Increased intracranial pressure is a sign of impending death

and symptoms determine the potential for survival and therefore the category of predicted survival during triage.

Probable survivors have either no initial symptoms or only minimal symptoms (eg, nausea and vomiting), or these symptoms resolve within a few hours. These patients should have a complete blood count drawn and may be discharged with instructions to return if any symptoms recur.

Possible survivors present with nausea and vomiting that persist for 24 to 48 hours. They experience a latent period, during which leukopenia, thrombocytopenia, and lymphocytopenia occur. Barrier precautions and protective isolation are implemented if the patient's lymphocyte count is less than $1200/\text{mm}^3$. Supportive treatment includes administration of blood products, prevention of infection, and provision of enhanced nutrition.

Improbable survivors have received more than 800 rad of total body penetrating irradiation. People in this group demonstrate an acute onset of vomiting, bloody diarrhea, and shock. Any neurologic symptoms suggest a lethal dose of radiation (CDC, 2005). These patients still require decontamination to prevent further contamination of the area and of others. Personal protection is essential, because it is virtually impossible to fully decontaminate these patients; all of their internal organs have been irradiated. The survival time is variable; however, death usually occurs swiftly due to shock. If there are no neurologic symptoms, patients may be alert and oriented, similar to a patient with extensive burns. In a mass casualty situation, these patients would be triaged into the black category, where they will receive comfort measures and emotional support. If it is not a mass casualty situation, aggressive fluid and electrolyte therapies are essential.

CRITICAL THINKING EXERCISES

1 You are the triage nurse at the receiving facility for casualties after a tornado. As you prepare to set up a triage station, "walking wounded" begin to arrive on their own. Among them is a hysterical adult woman with a facial abrasion who is otherwise apparently unharmed, carrying a 7-year-old child who has a Glasgow Coma Scale (GCS) score of 6 and is apneic. A 20-year-old man believes he has broken his arm; if fractured, it appears to be a closed fracture and the arm is warm with good pulses. As you quickly assess these patients, an ambulance arrives with an 80-year-old man with a sucking chest wound who is apneic and with a pulse barely palpable only at the carotids. The emergency medical services (EMS) personnel were unable to intubate him. In addition, a 15-year-old girl arrives with a cold pulseless foot from an obvious ankle fracture dislocation. How would you initially tag and triage these patients to provide optimal use of resources, remembering that this is only the first wave of injuries from multiple building collapses? Family members, members of the press, and city officials also begin arriving at the hospital in large numbers. How should the family members be managed? How should the other people be managed?

2 A patient arrives at the triage desk of the emergency department complaining of a sudden onset of a high fever

and respiratory flulike symptoms. He has recently returned from a trip to Asia. At this point, there are no skin signs that suggest disease. What signs and symptoms should you identify if you suspect a biologic warfare agent or contagious process? Which agents cause pneumonia-like signs and symptoms? What precautions should be taken to protect staff and patients? What type of isolation would be typical if you suspected a contagion that is transmitted by the respiratory tract? Would you consider the patient's recent travel to Asia an important piece of information?

3 You are a member of the safety committee at your hospital. The committee is charged with updating the hospital's emergency operations plan (EOP). What types of disasters may occur in and around your facility? How do you determine the hazards and vulnerability of your facility? How does your facility plan comply with the National Incident Management System requirements? What plan for triage will be included in the EOP? What types of personal protective equipment (PPE) will you recommend?

4 Your facility is closest to a bombing event on the mass transit system. You initiate the hospital emergency plan. What special considerations should you address, including possible use of chemical and biological weapons? What types of blast injuries do you expect? How many phases of injury are involved with a blast effect?

- mIU = milliInternational Unit

SI Units

- g = gram
- L = liter
- d = day
- h = hour
- mol = mole
- mmol = millimole
- µmol = micromole
- nmol = nanomole
- pmol = picomole

Table A-1 REFERENCE RANGES—HEMATOLOGY*

Determination	Reference Range		Clinical Significance
	Conventional Units	SI Units	
A ₂ hemoglobin	2.0%–3.2% of total hemoglobin	Mass fraction: 0.015–0.035 of total hemoglobin	Increased in certain types of thalassemia
Bleeding time	1.5–9.5 min	1.5–9.5 min	Prolonged in thrombocytopenia, defective platelet function, and aspirin therapy
Factor V assay (pro-acclerlin factor)	60%–140%		
Factor VIII assay (antihemophilic factor)	60%–140%		Deficient in classical hemophilia
Factor IX assay (plasma thromboplastin component)	60%–140%		Deficient in Christmas disease (pseudohemophilia)
Factor X (Stuart factor)	60%–140%		Deficient in Stuart clotting defect
Fibrinogen	200–400 mg/dL	2–4 g/dL	Increased in pregnancy, infections accompanied by leukocytosis, nephrosis Decreased in severe liver disease, abruptio placentae
Fibrin split (degradation) products	<5 µg/mL	<5 µg/mL	Increased in disseminated intravascular coagulation
Fibrinolysins (whole blood clot lysis time)	No lysis in 24 h		Increased activity associated with massive hemorrhage, extensive surgery, transfusion reactions

Continued on following page

Table A-1 REFERENCE RANGES—HEMATOLOGY* (Continued)			
Determination	Reference Range		Clinical Significance
	Conventional Units	SI Units	
Partial thrombo-plastin time (activated)	Lower limit of normal: 20–25 sec; Upper limit of normal: 32–39 sec		Prolonged in deficiency of fibrinogen, factors II, V, VIII, IX, X, XI, and XII, and in heparin therapy
Prothrombin consumption	Lower limit of normal: 10 sec Lower limit of normal: 14 sec		Impaired in deficiency of factors VIII, IX, and X
Prothrombin time INR	9.5–12 sec 1.0		Prolonged by deficiency of factors I, II, V, VII, and X, fat malabsorption, severe liver disease, coumarin anticoagulant therapy INR used to standardize the prothrombin time and anticoagulation therapy
Erythrocyte count	2–3 for therapy in atrial fibrillation, deep vein thrombosis, and pulmonary embolism 2.5–3.5 for therapy in prosthetic heart valves Males: 4,600,000–6,200,000/cu mm Females: 4,200,000–5,400,000/cu mm	4.6–6.2 × 10 ¹² /L 4.2–5.4 × 10 ¹² /L	Increased in severe diarrhea and dehydration, polycythemia, acute poisoning, pulmonary fibrosis Decreased in all anemias, in leukemia, and after hemorrhage when blood volume has been restored
Erythrocyte indices			
Mean corpuscular volume (MCV)	84–96 cu μm	84–96 fL	Increased in macrocytic anemias; decreased in microcytic anemia
Mean corpuscular hemoglobin (MCH)	28–33 μg/cell	28–33 pg	Increased in macrocytic anemias; decreased in microcytic anemia
Mean corpuscular hemoglobin concentration (MCHC)	33%–35%	Concentration fraction: 0.33–0.35	Decreased in severe hypochromic anemia
Reticulocytes	0.5%–1.5% of red cells	Number fraction: 0.005–0.015	Increased with any condition stimulating increase in bone marrow activity (ie, infection, blood loss [acute and chronically following iron therapy in iron deficiency anemia], polycythemia rubra vera) Decreased with any condition depressing bone marrow activity, acute leukemia, late stage of severe anemias
Erythrocyte sedimentation rate (ESR)—Westergren method	Males under 50 yr: <15 mm/h Males over 50 yr: <20 mm/h Females under 50 yr: <25 mm/h Females over 50 yr: <30 mm/h	<15 mm/h <20 mm/h <25 mm/h <30 mm/h	Increased in tissue destruction, whether inflammatory or degenerative; during menstruation and pregnancy; and in acute febrile diseases
Erythrocyte sedimentation ratio—Zeta centrifuge	<50 yr: <55% 50–80 yr: 40%–60%	Volume fraction: <0.55 0.40–0.60	Significance similar to ESR
Hematocrit	Males: 42%–52% Females: 35%–47%	Volume fraction: 0.42–0.52 Volume fraction: 0.35–0.47	Decreased in severe anemias, anemia of pregnancy, acute massive blood loss Increased in erythrocytosis of any cause, and in dehydration or hemoconcentration associated with shock
Hemoglobin	Males: 13–18 gm/dL Females: 12–16 gm/dL	2.02–2.79 mmol/L 1.86–2.48 mmol/L	Decreased in various anemias, pregnancy, severe or prolonged hemorrhage, and with excessive fluid intake Increased in polycythemia, chronic obstructive pulmonary disease, failure of oxygenation because of congestive heart failure, and normally in people living at high altitudes
Hemoglobin F	Less than 2% of total hemoglobin	Mass fraction: <0.02	Increased in infants and children, and in thalassemia and many anemias

Continued

Table A-1 REFERENCE RANGES—HEMATOLOGY* (Continued)

Determination	Reference Range		Clinical Significance
	Conventional Units	SI Units	
Leukocyte alkaline phosphatase	Score of 15–130 (varies among labs)		Increased in polycythemia vera, myelofibrosis, and infections Decreased in chronic granulocytic leukemia, paroxysmal nocturnal hemoglobinuria, hypoplastic marrow, and viral infections, particularly infectious mononucleosis
Leukocyte count	Total: 4,500–11,000/cu mm	4.5–11 × 10 ⁹ /L	Neutrophils increased with acute infections, trauma or surgery, leukemia, malignant disease, necrosis; decreased with viral infections, bone marrow suppression, primary bone marrow disease
Neutrophils	45%–73%	Number fraction: 0.45–0.73	
Eosinophils	0%–4%	Number fraction: 0.00–0.04	Eosinophils increased in allergy, parasitic disease, collagen disease, subacute infections; decreased with stress, use of some medications (ACTH, epinephrine, thyroxine)
Basophils	0%–1%	Number fraction: 0.00–0.01	Basophils increased with acute leukemia and following surgery or trauma; decreased with allergic reactions, stress, allergy, parasitic disease, use of corticosteroids
Lymphocytes	20%–40%	Number fraction: 0.2–0.4	Lymphocytes increased with infectious mononucleosis, viral and some bacterial infections, hepatitis; decreased with aplastic anemia, SLE, immunodeficiency including AIDS
Monocytes	2%–8%	Number fraction: 0.02–0.08	Monocytes increased with viral infections, parasitic disease, collagen and hemolytic disorders; decreased with use of corticosteroids, RA, HIV infection
Platelet count	150,000–450,000/cu mm	0.15–0.45 × 10 ¹² /L	Increased in malignancy, myeloproliferative disease, rheumatoid arthritis, and postoperatively; about 50% of patients with unexpected increase of platelet count will be found to have a malignancy Decreased in thrombocytopenic purpura, acute leukemia, aplastic anemia, and during cancer chemotherapy

*Laboratory values may vary according to the techniques used in different laboratories.

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Acetoacetate	0.2–1.0 mg/dL	19.6–98 μmol/L	Diabetic ketoacidosis	
Acetone	0.3–2.0 mg/dL	51.6–344.0/μmol/L	Fasting Diabetic ketoacidosis Toxemia of pregnancy Carbohydrate-free diet High-fat diet	
Acid, total phosphatase	Males: 2–12 UL Females: 0.3–9.2 UL	Males: 2–12 UL Females: 0.3–9.2 UL	Carcinoma of prostate Advanced Paget's disease Hyperparathyroidism Gaucher's disease	
Acid, phosphatase, prostatic—RIA	2.5–3.37 ng/mL	2.5–3.37 μg/L	Carcinoma of prostate	
Alkaline phosphatase	Adults: 50–120 UL	50–120 UL	Conditions reflecting increased osteoblastic activity of bone Rickets Hyperparathyroidism Hepatic disease Bone disease	

Continued on following page

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)				
Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Alkaline phosphatase, thermostable fraction	Hepatic: >25% Combined: 10%–25% Skeletal: <10%			
Adrenocorticotrophic hormone (ACTH) (plasma)—RIA*	<50 pg/mL	<50 ng/L	Pituitary-dependent Cushing's syndrome Ectopic ACTH syndrome Primary adrenal atrophy	Adrenocortical tumor Adrenal insufficiency secondary to hypopituitarism
Aldolase	3–8 Sibley-Lehninger U/dL at 37°C	22–59 mU/L at 37°C	Hepatic necrosis Granulocytic leukemia Myocardial infarction Skeletal muscle disease	
Aldosterone (plasma)—RIA	Supine: 3–10 ng/dL Upright: 5–30 ng/dL Adrenal vein: 200–800 ng/dL	0.08–0.30 nmol/L 0.14–0.90 nmol/L 5.54–22.16 nmol/L	Primary aldosteronism Secondary aldosteronism	Addison's disease
Alpha-1-antitrypsin	110–140 mg/dL	1.1–1.4 g/L		Certain forms of chronic lung and liver disease in young adults
Alpha-1-fetoprotein	<15 ng/mL	<15 µg/L	Hepatocarcinoma Metastatic carcinoma of liver Germinal cell carcinoma of the testicle or ovary Fetal neural tube defects—elevation in maternal serum	
Alpha-hydroxybutyric dehydrogenase	<140 U/L	<140 U/L	Myocardial infarction Granulocytic leukemia Hemolytic anemias Muscular dystrophy	
Ammonia (plasma)	15–45 µg/dL (varies with method)	11–32/µmol/L	Severe liver disease Hepatic decompensation	
Amylase	60–160 Somogyi U/dL	111–296 U/L	Acute pancreatitis Mumps Duodenal ulcer Carcinoma of head of pancreas Prolonged elevation with pseudocyst of pancreas Increased by medications that constrict pancreatic duct sphincters: morphine, codeine, cholinergics	Chronic pancreatitis Pancreatic fibrosis and atrophy Cirrhosis of liver Pregnancy (2nd and 3rd trimesters)
Arsenic	<70 µg/dL; poisoning: 100–150 µg/dL	<0.93–2.6 µmol/L; poisoning: 133–6.65 µmol/L	Intentional or unintentional poisoning Excessive occupational exposure	
Ascorbic acid (vitamin C)	0.4–1.5 mg/dL	23–85 µmol/L	Large doses of ascorbic acid as a prophylactic against the common cold	
ALT (alanine aminotransferase), formerly SGPT	Males: 10–40 U/mL Females: 8–35 U/mL	Males: 0.17–0.68 µkat/L Females: 0.14–0.60 µkat/L	Same conditions as AST (SGOT), but increase is more marked in liver disease than AST (SGOT)	
AST (aspartate aminotransferase), formerly SGOT	Males: 10–40 U/L Females: 15–30 U/L	Males: 0.34–0.68 µkat/L Females: 0.25–0.51 µkat/L	Myocardial infarction Skeletal muscle disease Liver disease	
Bilirubin	Total: 0.3–1.0 mg/dL Direct: 0.1–0.4 mg/dL Indirect: 0.1–0.4 mg/dL	5–17 µmol/L 1.7–3.7 µmol/L 3.4–11.2 µmol/L	Hemolytic anemia (indirect) Biliary obstruction and disease Hepatocellular damage (hepatitis) Pernicious anemia Hemolytic disease of newborn	
Blood gases				
Oxygen, arterial (whole blood): Partial pressure (PaO ₂)	85–95 mm Hg	10.64–12.64 kPa	Polycythemia	Anemia Cardiac or pulmonary disease

Continued

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Saturation (SaO ₂)	95%–99%	Volume fraction: 0.95–0.99		Cardiac decompensation Chronic obstructive lung disease
Carbon dioxide, arterial (whole blood) partial pressure (PaCO ₂)	35–45 mm Hg	4.66–5.99 kPa	Respiratory acidosis Metabolic alkalosis	Respiratory alkalosis Metabolic acidosis
pH (whole blood, arterial)	7.35–7.45	7.35–7.45	Vomiting Hyperventilation Fever Intestinal obstruction	Uremia Diabetic ketoacidosis Hemorrhage Nephritis
Brain (B-type) natriuretic peptide (BNP)	<100 pg/mL	100 ng/L	Heart failure Cardiac volume overload	
Calcitonin	Basal: <19 pg/mL Stimulation test Males: <350 pg/mL Females: <100 pg/mL	19 ng/L <350 ng/L <100 ng/L	Medullary carcinoma of the thyroid Some nonthyroid tumors Zollinger-Ellison syndrome	
Calcium	8.6–10.2 mg/dL	2.15–2.55 mmol/L	Tumor or hyperplasia of parathyroid Hypervitaminosis D Multiple myeloma Nephritis with uremia Malignant tumors Sarcoidosis Hypoparathyroidism Skeletal immobilization Excess calcium intake: milk alkali syndrome	Hyperthyroidism Diarrhea Celiac disease Vitamin D deficiency Acute pancreatitis Nephrosis After parathyroidectomy
CO ₂ , venous	Adults: 24–32 mEq/L Infants: 18–24 mEq/L	24–32 mmol/L 18–24 mmol/L	Tetany Respiratory disease Intestinal obstruction Vomiting	Acidosis Nephritis Eclampsia Diarrhea Anesthesia
Catecholamines (plasma)—RIA	Epinephrine: <100 pg/mL Norepinephrine: <400 pg/mL Dopamine: <143 pg/mL	<540 pmol/L <2360 pmol/L <935 pmol/L	Pheochromocytoma	
Ceruloplasmin	20–40 mg/dL	1.26–2.52 μmol/L		Wilson's disease (hepatolenticular degeneration)
Chloride	97–107 mEq/L	97–107 mmol/L	Nephrosis Nephritis Urinary obstruction Cardiac decompensation Anemia	Diabetes mellitus Diarrhea Vomiting Pneumonia Heavy metal poisoning Cushing's syndrome Intestinal obstruction Febrile conditions
Cholesterol	150–200 mg/dL	3.9–5.2 mmol/L	Lipemia Obstructive jaundice Diabetes Hyperthyroidism	Pernicious anemia Hemolytic anemia Hypothyroidism Severe infection Terminal states of debilitating disease
Cholesterol esters	60%–70% of total	Fraction of total cholesterol: 0.6–0.7		The esterified fraction decreases in liver diseases
Cholinesterase	Serum: 0.6–1.6 delta pH Red cells: 0.6–1 delta pH	0.6–1.6 U 0.6–1 U	Nephrosis Exercise	Nerve gas exposure (greater effect on red cell activity) Insecticide poisoning
Chorionic gonadotropin, beta subunit	0–5 IU/L	0–5 IU/L	Pregnancy Hydatidiform mole Choriocarcinoma	Threatened abortion Ectopic pregnancy

Continued on following page

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)				
Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Complement, C ₃	80–170 mg/dL	0.8–1.7 g/L	Some inflammatory diseases, acute myocardial infarction, cancer	Acute glomerulonephritis Disseminated lupus erythematosus with renal involvement
Complement, C ₄	18–51 mg/dL	180–510 mg/L	Some inflammatory diseases, acute myocardial infarction, cancer	Often decreased in immunologic disease, especially with active systemic lupus erythematosus Hereditary angioneurotic edema
Complement, total (hemolytic)	90%–94% complement	25–70 U/mL	Some inflammatory diseases	Acute glomerulonephritis Epidemic meningitis Subacute bacterial endocarditis
Copper	70–150 µg/dL	11–24 µmol/L	Cirrhosis of liver Pregnancy	Wilson's disease
Cortisol-RIA	8 AM: 5–25 µg/dL 4 PM: 3–16 µg/dL	138–690 nmol/L 83–442 nmol/L	Stress: infectious disease, surgery, burns, etc. Pregnancy Cushing's syndrome Pancreatitis Eclampsia	Addison's disease Anterior pituitary hypofunction
C-peptide reactivity	0.9–4.0 ng/mL	0.9–4.0 µg/L	Insulinoma	Diabetes mellitus
Creatine	0.2–0.8 mg/mL	15.3–61 µmol/L	Pregnancy Skeletal muscle necrosis or atrophy Starvation	
Creatine phosphokinase (CPK)	Males: 50–325 mU/mL Females: 50–250 mU/mL	50–325 U/L 50–250 U/L	Hyperthyroidism Myocardial infarction Skeletal muscle diseases Intramuscular injections Crush syndrome Hypothyroidism Alcohol withdrawal delirium Alcoholic myopathy Cerebrovascular disease	
Creatine kinase (CK) isoenzymes	MM band present (skeletal muscle)- MB band absent (heart muscle)		MB band increased in myocardial infarction, ischemia	
Creatinine	0.7–1.4 mg/dL	62–124 µmol/L	Nephritis Chronic renal disease	
Creatinine clearance	Males: 85–125 mL/min Females: 75–115 mL/min	1.42–2.08 mL/s 1.25–1.92 mL/s		Kidney diseases Kidney diseases
Cryoglobulins, qualitative	Negative		Multiple myeloma Chronic lymphocytic leukemia Lymphosarcoma Systemic lupus erythematosus Rheumatoid arthritis Infective subacute endocarditis Some malignancies Scleroderma	
11-Deoxycortisol	1 µg/dL	<0.029 µmol/L	Hypertensive form of virilizing adrenal hyperplasia due to an 11-β-hydroxylase defect	
Dibucaine number	Normal: 70%–85% inhibition Heterozygote: 50%–65% inhibition Homozygote: 16%–25% inhibition			Important in detecting carriers of abnormal cholinesterase activity who are susceptible to succinylcholine anesthetic shock

Continued

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Dihydrotestosterone	Males: 50–210 ng/dL Females: none detectable	1.72–7.22 nmol/L		Testicular feminization syndrome
Estradiol—RIA	Females: Follicular: 10–90 pg/mL Midcycle: 100–500 pg/mL Luteal: 50–240 pg/mL Follicular phase: 2–20 ng/dL Midcycle: 12–40 ng/dL Luteal phase: 10–30 ng/dL Postmenopausal: 1–5 ng/dL	37–370 pmol/L 367–1835 pmol/L 184–881 pmol/L	Pregnancy, ovarian tumor	Ovarian failure
Estriol—RIA	Males: 0.5–5 ng/dL Nonpregnant females: <0.5 ng/mL Pregnant females: 1st trimester: up to 1 ng/mL 2nd trimester: 0.8–7 ng/mL 3rd trimester: 5–25 ng/mL	<1.75 nmol/L Up to 3.5 nmol/L 2.8–24.3 nmol/L 17.4–86.8 nmol/L	Pregnancy	Ovarian failure
Estrogens, total—RIA	Females: cycle days: Day 1–10: 61–394 pg/mL Day 11–20: 122–437 pg/mL Day 21–30: 156–350 pg/mL Males: 40–115 pg/mL	61–394 ng/L 122–437 ng/L 156–350 ng/L 40–115 ng/L	Pregnancy Measured on a daily basis, can be used to evaluate response of hypogonadotropic, hypoestrogenic women to human menopausal or pituitary gonadotropin	Fetal distress Ovarian failure
Estrone—RIA	Females: Day 1–10: 4.3–18 ng/dL Day 11–20: 7.5–19.6 ng/dL Day 21–30: 13–20 ng/dL Males: 2.5–7.5 ng/dL	15.9–66.6 pmol/L 27.8–72.5 pmol/L 48.1–74 pmol/L 9.3–27.8 pmol/L	Pregnancy	Ovarian failure
Ferritin—RIA	Males: 20–250 ng/mL Females: 12–250 ng/mL	20–250 µg/L 12–250 µg/L	Nephritis Hemochromatosis Certain neoplastic diseases Acute myelogenous leukemia Multiple myeloma	Iron deficiency
Folic acid—RIA	2.5–20 ng/mL	6–46 nmol/L		Megaloblastic anemias of infancy and pregnancy Inadequate diet Liver disease Malabsorption syndrome Severe hemolytic anemia Pituitary failure
Follicle stimulating hormone (FSH)—RIA	Males: 2–10 mIU/mL Females: Follicular phase: 5–20 mIU/mL Peak of middle cycle: 12–30 mIU/mL Luteinic phase: 5–15 mIU/mL Menopausal females: 40–200 mIU/mL	5–20 IU/L 12–30 IU/L 5–15 IU/L 40–200 IU/L	Menopause and primary ovarian failure	
Galactose	<5 mg/dL	<0.28 mmol/L		Galactosemia
Gamma glutamyl transpeptidase	Males: 20–30 U/L Females: 1–24 U/L	0.03–0.5 µkat/L 0.02–0.4 µkat/L	Hepatobiliary disease Drug toxicity Myocardial infarction Renal infarction Zollinger-Ellison syndrome	
Gastrin—RIA	Fasting: 50–155 pg/mL Postprandial: 80–170 pg/mL	50–155 ng/L 80–170 ng/L	Peptic ulceration of the duodenum Pernicious anemia	

Continued on following page

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)				
Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Glucose	Fasting: 60–110 mg/dL Postprandial (2 h): 65–140 mg/dL	3.3–6.05 mmol/L 3.58–7.7 mmol/L	Diabetes mellitus Nephritis Hypothyroidism Early hyperpituitarism Cerebral lesions Infections Pregnancy Uremia	Hyperinsulinism Hyperthyroidism Late hyperpituitarism Pernicious vomiting Addison's disease Extensive hepatic damage
Glucose tolerance (oral)	Features of a normal response: 1. Normal fasting between 60–110 mg/dL 2. No sugar in urine 3. Upper limits of normal: Fasting = 125 1 hour = 190 2 hours = 140 3 hours = 125	3.3–6.05 mmol/L 6.88 mmol/L 10.45 mmol/L 7.70 mmol/L 6.88 mmol/L	Two-hour value >200 mg/dL (11.1 mmol/L) is diagnostic for diabetes mellitus	Decreased 2- and 3-hour values may occur with hypoglycemia in diabetes mellitus
Glucose-6-phosphate dehydrogenase (red cells)	Screening: Decolorization in 20–100 min Quantitative: 1.86–2.5 IU/mL RBC	1860–2500 U/L		Drug-induced hemolytic anemia Hemolytic disease of newborn
Glycoprotein (alpha-1-acid)	50–120 mg/dL	0.5–1.2 g/L	Neoplasm Tuberculosis Diabetes mellitus complicated by degenerative vascular disease Pregnancy Rheumatoid arthritis Rheumatic fever Infectious liver disease Lupus erythematosus Acromegaly	
Growth hormone—RIA	Males: 0–4 ng/mL Females: 0–18 ng/mL	0.4 µg/L 0–18 µg/L		Hypopituitarism
Haptoglobin	30–200 mg/dL	0.3–2.0 g/L	Pregnancy Estrogen therapy Chronic infections Various inflammatory conditions	Hemolytic anemia Hemolytic blood transfusion reaction
Hemoglobin (plasma)	0.5–5 mg/dL	5–50 mg/L	Transfusion reactions Paroxysmal nocturnal hemoglobinuria Intravascular hemolysis Suboptimal glucose control	Anemia, pregnancy, chronic renal failure
Glycohemoglobin (GHB, hemoglobin A _{1c} , hemoglobin A1)	Nondiabetics and diabetics with good control: 4.4%–6.4%			
Hexosaminidase, total	Controls: 333–375 nM/mL/h	333–375 µmol/L/h	Sandhoff's disease	Tay-Sachs disease and heterozygotes
Hexosaminidase A	Controls: 49%–68% of total Heterozygotes: 26%–45% of total Tay-Sachs disease: 0%–4% of total Diabetics: 39%–59% of total	Fraction of total: 0.49–0.68 0.26–0.45		
High-density lipoprotein cholesterol (HDL cholesterol)	Males: 35–70 mg/dL Females: 35–85 mg/dL	0.91–1.81 mmol/L 0.91–2.20 mmol/L		HDL cholesterol is lower in patients with increased risk for coronary heart disease
17 Hydroxyprogesterone—RIA	Males: 0.5–2.0 ng/mL Females: 0.2–3.0 ng/mL Children: <1.0 ng/mL	1.5–6.0 nmol/L 0.6–9.0 nmol/L <3.0 nmol/L	Congenital adrenal hyperplasia Pregnancy Some cases of adrenal or ovarian adenomas	

Continued

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Immunoglobulin A	Adults: 80–400 mg/dL	0.8–4.0 g/L	Gamma A myeloma Wiskott-Aldrich syndrome Autoimmune disease Hepatic cirrhosis	Ataxia telangiectasis Agammaglobulinemia Hypogamma-globulinemia, transient Dysgammaglobulinemia Protein-losing enteropathies
Immunoglobulin D	0.5–12.0 mg/dL	5–120 mg/L	IgD multiple myeloma Some patients with chronic infectious diseases	
Immunoglobulin E	<1.0 mg/mL	<10 mg/L	Allergic patients and those with parasitic infections	
Immunoglobulin G	Adults: 600–1800 mg/dL	6.0–18.0 g/L	IgG myeloma Following hyperimmunization Autoimmune disease states Chronic infections	Congenital and acquired hypogammaglobulinemia IgA myelomas, Waldenström's (IgM) macroglobulinemia Some malabsorption syndromes
Immunoglobulin M	Adults: 55–250 mg/dL	0.55–2.5 g/L	Waldenström's macroglobulinemia Parasitic infections Hepatitis	Extensive protein loss Agammaglobulinemias Some IgG and IgA myelomas Chronic lymphatic leukemia
Insulin—RIA	5–25 μ U/mL	0.2–1 μ g/L	Insulinoma Acromegaly	Diabetes mellitus
Iron	50–160/ μ g/dL	9–29 μ mol/L	Pernicious anemia Aplastic anemia Hemolytic anemia Hepatitis Hemochromatosis	Iron deficiency anemia
Iron-binding capacity	IBC: 250–350 μ g/dL TIBC: 250–475 μ g/dL % Saturation: 20–50	45–63 μ mol/L 45–85 μ mol/L Fraction of total iron-binding capacity: 0.2–0.5	Iron deficiency anemia Acute and chronic blood loss Hepatitis	Chronic infectious diseases Cirrhosis
Isocitric dehydrogenase	50–180 U	0.83–3 UI/L	Hepatitis, cirrhosis Obstructive jaundice Metastatic carcinoma of the liver Megaloblastic anemia	
Lactic acid (whole blood)	Venous: 5–15 mg/dL Arterial: 3–11 mg/dL	0.5–1.7 mmol/L 0.36–1.25 mmol/L	Increased muscular activity Congestive heart failure Hemorrhage Shock Lactic acidosis Some febrile infections May be increased in severe liver disease	
Lactic dehydrogenase (LDH)	90–176 mU/mL	90–176 U/L	Untreated pernicious anemia Myocardial infarction Pulmonary infarction Liver disease	
*Lactic dehydrogenase isoenzymes	90–176 mU/mL	90–176 U/L	LDH-1 and LDH-2 are increased in myocardial infarction, megaloblastic anemia, and hemolytic anemia	
Total lactic dehydrogenase		Fraction of total LDH:	LDH-4 and LDH-5 are increased in pulmonary infarction, congestive heart failure, and liver disease	
LDH-1	22%–36%	0.2–0.36		
LDH-2	35%–46%	0.35–0.46		
LDH-3	13%–26%	0.13–0.26		
LDH-4	3%–10%	0.03–0.10		
LDH-5	2%–12%	0.02–0.12		
Lead (whole blood)	Up to 40 μ g/dL	Up to 2 μ mol/L	Lead poisoning	
Leucine aminopeptidase	80–200 U/mL	19.2–48 U/L	Liver or biliary tract diseases Pancreatic disease Metastatic carcinoma of liver and pancreas Biliary obstruction	

Continued on following page

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)				
Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
†Lipase	<200 U/mL	<200 U/L	Acute and chronic pancreatitis Biliary obstruction Cirrhosis Hepatitis Peptic ulcer	
Lipids, total	400–800 mg/dL	4–8 g/L	Hypothyroidism Diabetes mellitus Nephrosis Glomerulonephritis Hyperlipoproteinemias LDL cholesterol is higher in patients with increased risk for coronary heart disease	Hyperthyroidism
Low-density lipoprotein cholesterol (LDL cholesterol)	mg/dL desirable levels: <160 if no coronary artery disease (CAD) and <2 risk factors <130 if no CAD and 2 or more risk factors <100 if CAD present			
Luteinizing hormone—RIA	Males: 1.5–9.3 mU/mL Females: Follicular phase: 1.9–12.5 mU/mL Midcycle: 8.7–76.3 mU/mL	1.5–9.3 U/L 1.9–12.5 U/L 8.7–76.3 U/L	Pituitary tumor Ovarian failure	Pituitary failure
Lysozyme (muramidase)	4.0–15.6 µg/mL	0.28–1.10 µmol/L	Certain types of leukemia (acute monocytic leukemia) Inflammatory states and infections	Acute lymphocytic leukemia
Magnesium	1.3–2.3 mg/dL	0.62–0.95 mmol/L	Excess ingestion of magnesium-containing antacids	Chronic alcoholism Severe renal disease Diarrhea Defective growth
Mercury	<10 µg/L	<50 µmol/L	Mercury poisoning	
Myoglobin	5–70 ng/mL	5–70 µg/mL	Myocardial infarction Myocardial ischemia Rhabdomyolysis Malignant hyperthermia	Rheumatoid arthritis Myasthenia gravis
5' Nucleotidase	3.2–11.6 IU/L	3.2–11.6 U/L	Hepatobiliary disease	
Osmolality	275–300 mOsm/kg	275–300 mmol/L	Diabetes insipidus, osmotic diuresis	Inappropriate secretion of ADH Addison's disease Hypoparathyroidism
Parathyroid hormone	10–65 pg/mL	10–65 ng/L	Hyperparathyroidism, chronic renal failure Phenylketonuria	
Phenylalanine	1.2–3.5 mg/dL 1st week 0.7–3.5 mg/dL thereafter	0.07–0.21 mmol/L 0.04–0.21 mmol/L		
Phosphohexose isomerase	20–90 IU/L	20–90 U/L	Malignancy Disease of heart, liver, and skeletal muscles	
Phospholipids	125–300 mg/dL	1.25–3 g/L	Diabetes mellitus Nephritis	
Phosphorus, inorganic	2.5–4.5 mg/dL	0.8–1.45 mmol/L	Chronic nephritis Hypoparathyroidism	
Potassium	3.5–5 mEq/L	3.5–5 mmol/L	Renal Failure Acidosis Cell lysis Tissue breakdown or hemolysis	Hyperparathyroidism Vitamin D deficiency GI losses Diuretic administration
Prealbumin	16.0–35.0 mg/dL	160–350 mg/L	Malnutrition Severe or chronic illness Liver disease	

Continued

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Progesterone—RIA	Follicular phase: up to 0.8 ng/mL Luteal phase: 10–20 ng/mL End of cycle: <1 ng/mL Pregnant: up to 50 ng/mL in 20th week	2.5 nmol/L 31.8–63.6 nmol/L <3 nmol/L Up to 160 nmol/L	Useful in evaluation of menstrual disorders and infertility and in the evaluation of placental function during pregnancies complicated by toxemia, diabetes mellitus, or threatened miscarriage	
Prolactin—RIA	4–30 ng/mL	4–30 µg/L	Pregnancy Functional or structural disorders of the hypothalamus Pituitary stalk section Pituitary tumors Prostatic cancer, benign prostatic hyperplasia, prostatitis	
Prostate-specific antigen	<4 ng/mL		Hemoconcentration Shock Globulin fraction increased in multiple myeloma, chronic infection, liver disease	
Protein, total	6–8 gm/dL	60–80 g/L		Malnutrition
Albumin	3.5–5.5 g/dL	40–55 g/L		Hemorrhage
Globulin	1.7–3.3 g/dL	17–33 g/L		Loss of plasma from burns Proteinuria
Protein		35–50 g/L		
Electrophoresis				
Albumin	3.5–5.5 g/dL	40–55 g/L		
Alpha-1 globulin	0.15–0.25 g/dL	1.5–2.5 g/L		
Alpha-2 globulin	0.43–0.75 g/dL	4.3–7.5 g/L		
Beta globulin	0.5–1.0 g/dL	5–10 g/L		
Gamma globulin	0.6–1.3 g/dL	6–13 g/L		
Protoporphyrin erythrocyte (whole blood)	Males: 11–45 µg/dL Females: 19–52 µg/dL	0.20–0.80 µmol/L 0.34–0.92 µmol/L	Lead toxicity Erythropoietic porphyria	
Pyridoxine	5–30 ng/mL	20–1.21 nmol/L		A wide spectrum of clinical conditions, such as mental depression, peripheral neuropathy, anemia, neonatal seizures, and reactions to certain drug therapies
Pyruvic acid (whole blood)	0.3–0.9 mg/dL	34–102 µmol/L	Diabetes mellitus Severe thiamine deficiency Acute phase of some infections, possibly secondary to increased glycogenolysis and glycolysis	
Renin (plasma)—RLA	Normal diet: Supine: 0.3–1.9 ng/mL/h Upright: 0.6–3.6 ng/mL/h Low salt diet: Supine: 0.9–4.5 ng/mL/h Upright: 4.1–9.1 ng/mL/h	0.08–0.52 ng/L/S 0.16–1.00 µg/L/S 0.25–1.25 µg/L/S 1.13–2.53 µg/L/S	Renovascular hypertension Malignant hypertension Untreated Addison's disease Primary salt-losing nephropathy Low-salt diet Diuretic therapy Hemorrhage Hemoconcentration Nephritis Pyloric obstruction	
Sodium	135–145 mEq/L	135–145 mmol/L	Frank primary aldosteronism Increased salt intake Salt-retaining steroid therapy Antidiuretic hormone therapy Blood transfusion	
Sulfate (inorganic)	0.5–1.5 mg/dL	0.05–0.15 mmol/L	Alkali deficit Addison's disease Myxedema	
			Nephritis Nitrogen retention	

Continued on following page

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)				
Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Testosterone—RIA	Females: 20–80 ng/dL Males: 240–1200 ng/dL	0.7–2.8 nmol/L 18.3–41.8 nmol/L	Females: Polycystic ovary Virilizing tumors	Males: Orchidectomy for neoplastic disease of the prostate or breast Estrogen therapy Klinefelter’s syndrome Hypopituitarism Hypogonadism Hepatic cirrhosis Hypothyroidism
T ₃ (triiodothyronine) uptake	24%–34%	Relative uptake fraction: 0.24–0.34	Hyperthyroidism Thyroxine-binding globulin (TBG) deficiency Androgens and anabolic steroids Pregnancy	Pregnancy TBG excess Estrogens and antiovarulatory drugs Hypothyroidism
T ₃ total circulating—RIA	70–204 ng/dL	1.08–3.14 nmol/L	Hyperthyroidism Thyroiditis	Primary and pituitary hypothyroidism
T ₄ (thyroxine)—RIA	5–11 µg/dL	65–138 nmol/L	Elevated thyroxine-binding proteins caused by oral contraceptives Pregnancy	Idiopathic involvement Cases of diminished thyroxine-binding proteins caused by androgenic and anabolic steroids Hypoproteinemia Nephrotic syndrome
T ₄ , free	0.8–2.7 ng/dL	10.3–35 pmol/L	Euthyroid patients with normal free thyroxine levels may have abnormal T ₃ and T ₄ levels caused by drug preparations	
Thyroid-stimulating hormone (TSH)—RIA		0.4–4.2 mIU/L	Hypothyroidism	Hyperthyroidism
Thyroid-binding globulin	10–26 µg/dL	100–260/µg/L	Hypothyroidism Pregnancy Estrogen therapy Oral contraceptive use Genetic and idiopathic liver disease	Use of androgens and anabolic steroids Nephrotic syndrome Marked hypoproteinemia
Transferrin	200–380 mg/dL	2.3–3.2 g/L	Pregnancy Iron deficiency anemia due to hemorrhaging Acute hepatitis Polycythemia Oral contraceptive use	Pernicious anemia in relapse Thalassemic and sickle cell anemia Chromatosis Neoplastic and hepatic diseases Malnutrition
Triglycerides	100–200 mg/dL	1.13–3.8 mmol/L	Increased risk for atherosclerosis	
Troponin Troponin I Troponin T	<0.35 ng/mL <0.2 ng/mL	<0.35 µg/L <0.2 µg/L	Myocardial infarction Rhabdomyolysis Severe crushing injuries	
Tryptophan	1.4–3 mg/dL	68.6–147 nmol/L	Tyrosinosis	Tryptophan-specific malabsorption syndrome
Tyrosine	0.5–4 mg/dL	27.6–220.8 mmol/L	Acute glomerulonephritis Obstructive uropathy Mercury poisoning Nephrotic syndrome	Severe hepatic failure Pregnancy
Urea nitrogen (BUN)	10–20 mg/dL	3.6–7.2 mmol/L		
Uric acid	2.5–8 mg/dL	0.15–0.5 mmol/L	Gouty arthritis Acute leukemia Lymphomas treated by chemotherapy Toxemia of pregnancy Patients with marked increases of the gamma globulins Hypervitaminosis A	Defective tubular reabsorption
Viscosity	1.4–1.8 relative to water at 37°C (98.6°F)			

Continued

Table A-2 REFERENCE RANGES—SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES (Continued)

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Vitamin A	30–120 µg/dL	1.05–4.20 µmol/L		Vitamin A deficiency Celiac disease Sprue Obstructive jaundice Giardiasis Parenchymal hepatic disease
Vitamin B ₁ (thiamine)	1.6–4 µg/dL	47.4–135.7 nmol/L		Anorexia Beriberi Polyneuropathy Cardiomyopathies Chronic alcoholism Malnutrition Uremia Neonatal seizures Malabsorption, such as celiac syndrome
Vitamin B ₆ (pyridoxal phosphate)	5–30 ng/mL	20–121 nmol/L		Strict vegetarianism Alcoholism Pernicious anemia Total or partial gastrectomy Ileal resection Sprue and celiac disease Fish tapeworm infestation Vitamin E deficiency Malabsorption syndrome
Vitamin B ₁₂ —RIA	200–900 pg/mL	148–666 pmol/L	Hepatic cell damage and in association with the myeloproliferative disorders (the highest levels are encountered in myeloid leukemia)	Metastatic liver disease Tuberculosis Sprue
Vitamin E	0.5–1.8 mg/dL	12–42 µmol/L		
Xylose absorption test	2 hr, 30–50 mg/dL	2–3.35 mmol/L		
Zinc	55–150 µg/dL	7.65–22.95 µmol/L	Coronary artery disease Arteriosclerosis Industrial exposure	

*By radioimmunoassay.

†Varies among methods.

Table A-3 REFERENCE RANGES—IMMUNODIAGNOSTIC TEST

Determination	Normal Value	Clinical Significance
Acetylcholine receptor binding antibody	Negative or <0.03 nmol/L	Considered to be diagnostic for myasthenia gravis in patients with symptoms.
Anti-ds-DNA antibody	<70 U by enzyme-linked immunosorbent assay (ELISA) <1:20 by indirect fluorescence	Valuable in supporting diagnosis or monitoring disease activity and prognosis of systemic lupus erythematosus (SLE).
Antiglomerular basement membrane antibody	Negative or less than 5εUL	Primarily used in the differential diagnosis of glomerular nephritis induced by antiglomerular basement membrane antibodies from other types of glomerular nephritis.
Anti-insulin antibody	<3% binding of labeled beef and pork insulin by patient's serum; or <9 mIU/L	Helpful in determining the best therapeutic agent in diabetics and the cause of allergic manifestations. Also used to identify insulin resistance.
Antinuclear antibody	Negative, <1:40	Increased in SLE, chronic hepatitis, scleroderma, leukemia, and mononucleosis.
Anti-parietal cell antibody	Negative	Helpful in diagnosing chronic gastric disease and differentiating autoimmune pernicious anemia from other megaloblastic anemias.
Antiribonucleoprotein antibody	Negative	Helpful in differential diagnosis of systemic rheumatic disease.
Antiscleroderma antibody	Negative	Highly diagnostic for scleroderma.
Anti-Smith antibody	Negative	Highly diagnostic of SLE.
Anti-SS-A/anti-SS-B antibody	Negative	SS-A antibodies are found in Sjögren's syndrome alone or associated with lupus. SS-B antibodies are associated with primary Sjögren's syndrome.
Antithyroglobulin and antimicrosomal antibodies	<1:100 titer by gelatin or hemagglutination	Presence and concentration is important in evaluation and treatment of various thyroid disorders, such as Hashimoto's thyroiditis and Graves' disease. May indicate previous autoimmune disorders.
CA 15-3 tumor marker	<30 IU/mL	Increased in metastatic breast cancer.
CA 19-9 tumor marker	<37 IU/mL	Increased in pancreatic, hepatobiliary, gastric, and colorectal cancer, gallstones.

Continued on following page

Table A-3 REFERENCE RANGES—IMMUNODIAGNOSTIC TEST (Continued)

Determination	Normal Value	Clinical Significance
CA 125	0–35 IU/mL	Increased in colon, upper gastrointestinal (GI), ovarian, and other gynecologic cancers; pregnancy, peritonitis.
Carcinoembryonic antigen (CEA)—RLK	0–2.5 µg/L (nonsmoker) 0–5/µg/L (smoker)	The repeatedly high incidence of this antigen in cancers of the colon, rectum, pancreas, and stomach suggests that CEA levels may be useful in the therapeutic monitoring of these conditions, but it is not a screening test.
Cold agglutinins	Negative or <1:32	Increased in mycoplasma pneumonia, viral illness, mononucleosis, multiple myeloma, scleroderma.
C-reactive protein	<1mg/dL (<10 mg/L)	Increase indicates active inflammation.
High sensitivity assay for C-reactive protein (hs-CRP)	0.2–8.0 mg/L	Cardiovascular disease risk.
Cytomegalovirus antibodies (CMV IgG)	Negative: <0.9 units/mL	Positive >1:0 unit/mL if exposed to CMV at any time. Acute and convalescent specimens can help identify acute infection.
Cytomegalovirus antibodies (CMV IgM)	Negative: <0:79 Equivocal: 0:80–1:20	Positive >1:20 usually indicates acute infection. Repeat specimen in 1–2 weeks for equivocal result.
Epstein-Barr virus serology (viral capsid antigen IgG and IgM, early antigen IgG, and nuclear antigen IgG)	Negative: <1:20 or <1:20 for each individual test	Differentiation of acute from chronic or old infection by interpretation of table below.

EBV Interpretation

	VCA-IgG	VCA-IgM	EA-IgG	EBV-NA
Susceptible	–	–	–	–
Acute infection	+	+	±	–
Convalescent phase	+	±	±	+
Chronic or reactivated	+	–	+	±
Old infection	±	–	–	+

Antibody present: +

Antibody absent: –

VCA, viral capsid antigen; EA, early antigen; EBV-NA, Epstein Barr virus-nuclear antigen

Hepatitis A virus antibodies, IgM (HAV-Ab/IgM)	Negative	Positive in acute-stage hepatitis A; develops early in disease.
Hepatitis A virus antibodies, IgG (HAV-Ab/IgG)	Negative	Positive if previous exposure and immunity to hepatitis A.
Hepatitis B surface antigen (HBsAg)	Negative	Positive in acute-stage hepatitis B.
Hepatitis B surface antibody (HBsAb)	Negative	Positive if previous exposure and immunity to hepatitis B.
Hepatitis C virus antibodies	Negative	Positive in exposure to hepatitis C virus; may indicate acute, chronic, or cleared infection.
Hepatitis C virus RNA	Negative	Positive in hepatitis C infection, can be quantitative
Homocysteine	0.54–2.30 mg/L (4–17 µmol/L)	Cardiovascular disease risk Folic acid deficiency Vitamin B ₁₂ deficiency
Infectious mononucleosis tests (monospot, monotest, heterophile antigen test, Epstein-Barr virus [EBV], antiviral capsid antigen IgM and IgG)	Negative	Positive monospot and monotest are presumptive, positive EBV IgM and IgG indicate acute and recent or past infection, respectively.
Lyme disease titer	Negative, <1:256 by indirect fluorescent antibody method; nonreactive by ELISA	Positive results help diagnose Lyme disease. False positive may occur with high rheumatoid factor titers or syphilis.
Pyroglobulin test	Negative	Positive ELISA confirmed by Western blot test. These abnormal proteins may be associated with myeloma, lymphoma, polycythemia vera, and SLE.
Rheumatoid factor	Negative or less than 40 IU/mL	Elevated in rheumatoid arthritis, lupus endocarditis, tuberculosis, syphilis, sarcoidosis, cancer.
T and B cell lymphocyte surface markers	T and B cell lymphocyte surface markers: Percent T cells (CD2) 60–88% Percent helper cells (CD4) 34–67% Percent suppressor cells (CD8) 10–42% Percent B cells (CD19) 3–21%	Used to evaluate immune system by identifying the specific cells involved in the immune response. Valuable in diagnosis of lymphocytic leukemia, lymphoma, and immunodeficiency diseases including acquired immunodeficiency syndrome, and in the assessment of patient response to chemotherapy and radiation.
T-helper/T-suppressor ratio	Absolute counts: Lymphocytes 0.66–4.60 thou/mL T cells 644–2201 cells/mL Helper cells 493–1191 cells/mL Suppressor T cells 182–785 cells/mL B cells 92–392 cells/mL Lymphocyte ratio: T _H /T _S ratio >1	

Table A-4 REFERENCE RANGES—URINE CHEMISTRY

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Acetone and acetoacetate	Zero		Diabetic ketoacidosis Starvation	
Aldosterone	With normal salt diet: Normal: 4–20 µg/24 h Renovascular: 10–40 µg/24 h Tumor: 20–100 µg/24 h	11.1–55.5 nmol/24h 27.7–111 nmol/24 h 55.4–277 nmol/24 h	Primary aldosteronism (adrenocortical tumor) Secondary aldosteronism Salt depletion Potassium loading ACTH in large doses Cardiac failure Cirrhosis with ascites formation Nephrosis Pregnancy Leukemia	
Alpha amino nitrogen	50–200 mg/24 h	3.6–14.3 nmol/24 h	Phenylketonuria Other metabolic diseases Acute pancreatitis	
Amylase	35–260 units excreted per h	6.5–48.1 U/h		
Arylsulfatase A	>2.4 U/mL			
Bence-Jones protein	None detected		Myeloma	Metachromatic leukodystrophy
Calcium	100–250 mg/24 h	2.5–6.2 mmol/24 h	Hyperparathyroidism Vitamin D intoxication Fanconi's syndrome Pheochromocytoma Neuroblastoma	Hypoparathyroidism Vitamin D deficiency
Catecholamines	Total: 0–275 µg/24 h Epinephrine: 10%–40% Norepinephrine: 60%–90%	0–275 µg/24 h Fraction total: 0.10–8.4 Fraction total: 0.60–0.90		
Chorionic gonadotrophin, qualitative (pregnancy test)	Negative		Pregnancy Chorionepithelioma Hydatidiform mole	
Copper	15–60 µg/24 h	0.22–0.9 µmol/24 h	Wilson's diseases Cirrhosis Nephrosis	
Coproporphyrin	50–300 µg/24 h	0.075–0.45 µmol/24 h	Poliomyelitis Lead poisoning Porphyria	
Cortisol, free	20–90 µg/24 h	55.2–248.4 nmol/d	Cushing's syndrome	
Creatinine	Males: 1–2 g/24 h Females: 0.8–1.8 g/24 h	8.8–17.7 mmol/24 h 7.1–15.9 mmol/24 h	Muscular dystrophy Fever Carcinoma of liver Pregnancy Hyperthyroidism Myositis	
Creatine	0–270 mg/24 h	0–2.05 mmol/24 h	Typhoid fever Salmonella infections Tetanus	Muscular atrophy Anemia Advanced degeneration of kidneys Leukemia Renal diseases
Creatinine clearance	Males: 85–125 mL/min Females: 75–115 mL/min	1.42–2.08 mL/s 1.25–1.92 mL/s		
Cystine and cysteine	10–100 mg/24 h	0.08–0.83 mmol/24 h	Cystinuria	
Delta aminolevulinic acid	0–0.54 mg/dL	0–40/µmol/L	Lead poisoning Porphyria hepatica Hepatitis Hepatic carcinoma	
11-Desoxycortisol	20–100 µg/24 h	0.6–2.9/µmol/d	Hypertensive form of virilizing adrenal hyperplasia due to an 11-beta hydroxylase defect	
Estriol (placental)	Weeks of pregnancy 12 16 20 24 28 32 36 40	µm/24 h <1 2–7 4–9 6–13 8–22 12–43 14–45 19–46	mmol/24 h <3.5 7–24.5 14–32 21–45.5 28–77 42–150 49–158 66.5–160	Decreased values occur with fetal distress of many conditions, including preeclampsia, placental insufficiency, and poorly controlled diabetes mellitus

Continued on following page

Table A-4 REFERENCE RANGES—URINE CHEMISTRY (Continued)				
Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Estrogens, total (fluorometric)	Females: Onset of menstruation: 4–25 µg/24 h Ovulation peak: 28–100 µg/24 h Luteal peak: 22–105 µg/24 h Menopausal: 1.4–19.6 µg/24 h	4–25 µg/24 h 28–100 µg/24 h 22–105 µg/24 h 1.4–19.6 µg/24 h	Hyperestrogenism due to gonadal or adrenal neoplasm	Primary or secondary amenorrhea
Etiocolanalone	Males: 5–18 µg/24 h Males: 1.9–6 mg/24 h Females: 0.5–4 mg/24 h	5–18 µg/24 h 6.5–20.6 µmol/24 h 1.7–13.8 µmol/24 h	Adrenogenital syndrome Idiopathic hirsutism	
Follicle-stimulating hormone—RIA	Females: Follicular: 5–20 IU/24 h Luteal: 5–15 IU/24 h Midcycle: 15–60 IU/24 h Menopausal: 50–100 IU/24 h	5–20 IU/d 5–15 IU/d 15–60 IU/d 50–100 IU/d	Menopause and primary ovarian failure	Pituitary failure
Glucose	Negative		Diabetes mellitus Pituitary disorders Increased ICP Lesion in floor of 4th ventricle	
Hemoglobin and myoglobin	Negative		Extensive burns Transfusion of incompatible blood Myoglobin increased in severe crushing injuries to muscles	
Homovanillic acid		5.5–27.5 µmol/d	Neuroblastoma	Addison's disease
17-hydroxycorticosteroids	8 mg/24 h 2–10 mg/24 h	5.5–27.5 µmol/d	Cushing's disease	Anterior pituitary hypofunction
5-Hydroxyindoleacetic acid, qualitative	Negative		Malignant carcinoid tumors	
17-ketosteroids, total	Males: 10–22 mg/24 h Females: 6–16 mg/24 h	35–76 µmol/24h 21–55 µmol/24h	Interstitial cell tumor of testes Simple hirsutism, occasionally Adrenal hyperplasia Cushing's syndrome Adrenal cancer, virilism Adrenoblastoma	Thyrotoxicosis Female hypogonadism Diabetes mellitus Hypertension Debilitating disease of mild to moderate severity Eunuchoidism Addison's disease Panhypopituitarism Myxedema Nephrosis
Lead	<125 µg/24 h	<60 µmol/24 h	Lead poisoning	
Luteinizing hormone	Males: 5–18 IU/24 h Females: Follicular phase: 2–25 IU/24 h Ovulatory peak: 30–95 IU/24 h Luteal phase: 2–20 IU/24 h Postmenopausal: 40–110 IU/24 h	2–25 IU/d 30–95 IU/d 2–20 IU/d 40–110 IU/d	Pituitary tumor Ovarian failure	Failure of pituitary or hypothalamus Anorexia nervosa
Metanephrines, total	<1.4 mg/24 h	<7 µmol/24h	Pheochromocytoma; a few patients with pheochromocytoma may have elevated urinary metanephrines but normal catecholamines and vanillylmandelic acid (VMA)	
Osmolality	250–900 mOsm/kg	250–900 mmol/kg	Useful in the study of electrolyte and water balance	

Continued

Table A-4 REFERENCE RANGES—URINE CHEMISTRY (Continued)

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Oxalate	Up to 45 mg/24 h	Up to 500/μmol/24 h	Primary hyperoxaluria	
Phenylpyruvic acid qualitative	Negative		Phenylketonuria	
Phosphorus, inorganic	0.9–1.3 g/24 h	29–42 mmol/24 h	Hypoparathyroidism Vitamin D intoxication Paget's disease Metastatic neoplasm to bone	Hypoparathyroidism Vitamin D deficiency
Porphobilinogen, qualitative	Negative		Chronic lead poisoning Acute porphyria Liver disease	
Porphobilinogen quantitative	0–1 mg/24 h	0–4.4 μmol/24 h	Acute porphyria Liver disease	
Porphyryns, qualitative	Negative		See porphyryns, quantitative	
Porphyryns, quantitative (coproporphyrin and uroporphyrin)	Coproporphyrin: 50–160 μg/24 h Uroporphyrin: up to 50 μg/24 h	0.075–0.24 μmol/24h Up to 0.06 μmol/24 h	Porphyria Lead poisoning (only coproporphyrin increased)	
Potassium	26–123 mEq/24 h	26–123 mmol/24 h	Hemolysis Chronic renal failure Acidosis Cushing's disease Corpus luteum cysts	Diarrhea Adrenocortical insufficiency
Pregnanediol	Females: Proliferative phase: 0.5–1.5 mg/24 h Luteal phase: 2–7 mg/24 h Menopause: 0.2–1 mg/24 h	1.6–4.8 μmol/24 h 6–22 μmol/24 h 0.6–3.1 μmol/24 h	When placental tissue remains in the uterus following parturition Some cases of adrenocortical tumors	Placental dysfunction Threatened abortion Intrauterine death
Pregnancy: Weeks of gestation	mg/24 h	μmol/24 h		
10–12	5–15	15.6–47		
12–18	5–25	15.6–78.0		
18–24	15–33	47.0–103.0		
24–28	20–42	62.4–131.0		
28–32	27–47	84.2–146.6		
Pregnanetriol	Females: 0.1–2.2 mg/24 h Males: 0.4–2.5 mg/24 h	0.3–6.5 μmol/24 h 1.2–7.5 μmol/24 h	Congenital adrenal androgenic hyperplasia	
Protein	<150 mg/24 h	<150 mg/24 h	Nephritis Cardiac failure Mercury poisoning Bence-Jones protein in multiple myeloma Febrile states Hematuria	
Sodium	75–200 mEq/24 h	75–200 mmol/24 h	Useful in detecting gross changes in water and salt balance	
Titrateable acidity	20–40 mEq/24 h	20–40 mmol/24 h	Metabolic acidosis	Metabolic alkalosis
Urea nitrogen	9–16 gm/24 h	0.32–0.57 mol/L	Excessive protein catabolism	Impaired kidney function
Uric acid	250–750 mg/24 h	1.48–4.43 mmol/24 h	Gout	Nephritis
Urobilinogen	Random urine: <0.25 mg/dL 24-hour urine: up to 4 mg/24 h	<0.42 mol/24 h Up to 6.76 μmol/24 h	Liver and biliary tract disease Hemolytic anemias	Complete or nearly complete biliary obstruction Diarrhea
Vanillylmandelic acid (VMA)	0.7–6.8 mg/24 h	3.5–34.3 μmol/24 h	Pheochromocytoma Neuroblastoma Ingestion of coffee, tea, aspirin, bananas, and several different drugs	Renal insufficiency
Xylose absorption test (5-hour)	16%–33% of ingested xylose	Fraction absorbed: 0.16–0.33		
Zinc	0.15–1.2 mg/24 h	2.3–18.4 μmol/24h		Malabsorption syndromes

Determination	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Albumin	15–30 mg/dL	150–300 mg/L	Certain neurologic disorders Lesion in the choroid plexus or blockage of the flow of CSF Damage to the blood–brain barrier	
Cell count (white blood cells)	0–5 cells per cu mm	0–5 × 10 ⁶ /L	Bacterial meningitis Neurosyphilis Anterior poliomyelitis Encephalitis lethargica	
Chloride	120–130 mEq/L	120–130 mmol/L	Uremia	Acute generalized meningitis Tuberculous meningitis
Glucose	40–80 mg/dL; 50%–80% of blood glucose value	2.75–4.13 mmol/L	Diabetes mellitus Diabetic coma Epidemic encephalitis Uremia	Acute meningitis Tuberculous meningitis Insulin shock Subarachnoid hemorrhage
Glutamine	6–15 mg/dL	0.41–1 mmol/L	Hepatic encephalopathies, including Reye's syndrome Hepatic coma Cirrhosis	
IgG	<5 mg/dL	<50 mg/L	Damage to the blood– brain barrier Multiple sclerosis Neurosyphilis Subacute sclerosing panencephalitis Chronic phases of CNS infections	
Lactic acid	4.5–28.8 mg/dL	0.5–3.2 mmol/L	Bacterial meningitis Hypocapnia Hydrocephalus Brain abscesses Cerebral ischemia Fungal meningitis

TABLE A-6 MISCELLANEOUS VALUES

Determination	Normal Values	Clinical Significance	
		Conventional Units	SI Units
Acetaminophen	Zero	Therapeutic level = 10–30 µg/mL	10–30 mg/L
Aminophylline (theophylline)	Zero	Therapeutic level = 10–20 µg/mL	10–20 mg/L
Bromide	Zero	Therapeutic level = 5–50 mg/dL	50–500 mg/L
Carbamazepine	Zero	Therapeutic level = 4–12 µg/mL	34–51 µmol/L
Carbon monoxide	0%–2%	Symptoms with 10%–30% saturation	
Chlordiazepoxide	Zero	Therapeutic level = 0.7–1.0 µg/mL	0.7–1.0 mg/L
Diazepam	Zero	Therapeutic level = 0.2–1.0 µg/mL	0.2–1.0 mg/L
Digitoxin	Zero	Therapeutic level = 18–35 ng/mL	18–35 µg/L
Digoxin	Zero	Therapeutic level = 0.8–2 ng/mL	0.8–2 µg/L
Ethanol	0%–0.01%	Legal intoxication level = 0.1% or above 0.3%–0.4% = marked intoxication 0.4%–0.5% = alcoholic stupor	
Fosphenytoin	Zero	10–20 mg/L	
Gentamicin	Zero	Therapeutic level = 4–10 µg/mL	4–10 mg/L
Lithium	Zero	Therapeutic level = 0.6–1.2 mEq/L	0.6–1.2 mmol/L
Methanol	Zero	May be fatal in concentration as low as 10 mg/dL	100 mg/L
Phenobarbital	Zero	Therapeutic level = 15–40 µg/mL	15–40 mg/L
Phenytoin	Zero	Therapeutic level = 10–20 µg/mL	10–20 mg/L
Primidone	Zero	Therapeutic level = 5–12 µg/mL	5–12 mg/L
Quinidine	Zero	Therapeutic level = 0.2–0.5 mg/dL	2–5 mg/L
Salicylate	Zero	Therapeutic level = 2–25 mg/dL Toxic level = >30 mg/dL	20–250 mg/L 300 mg/L
Vancomycin	Zero	Therapeutic peak 20–40 µg/mL	
Amitriptyline	Zero	Therapeutic trough 5–10 µg/mL Therapeutic level 80–200 ng/mL	289–722 nmol/L
Doxepin	Zero	Therapeutic level 150–250 ng/mL (includes metabolites)	540–900 nmol/L
Imipramine	Zero	Therapeutic level 100–300 ng/mL (includes metabolites)	360–1070 nmol/L
Lidocaine	Zero	Therapeutic level 1.5–5 µg/mL	6.4–21.4 µmol/L
Methotrexate	Zero	Toxic (48 h after high dose) 454 mg/mL	1000 nmol/L
Propranolol	Zero	Therapeutic level 50–100 ng/mL	193–386 nmol/L
Valproic acid	Zero	Therapeutic level 50–100 ng/mL	347–693 µmol/L

Understanding Clinical Pathways

Clinical pathways (also called critical pathways) are care plans developed collaboratively by physicians, nurses, physical and occupational therapists, technicians, pharmacists, speech therapists, case managers, and other staff members involved in patient care. Nurses are instrumental in ensuring the successful use of clinical pathways and can best contribute by gaining a thorough understanding of why and how pathways are used.

Understanding and Using Clinical Pathways in Patient Care

Clinical pathways grew out of financial upheaval in the health care industry. They represent a significant change in how patient care is managed. In the past (and currently for many patients), each health care discipline developed its own plan of care and used the patient's medical record as the primary communication tool. Each care provider needed to read the notes of health care providers of other disciplines to get a complete picture of the plan of care and the patient's progress. Although there was probably general agreement about how patient progress would be facilitated and measured, individual steps in the processes of care and outcomes to be achieved were often not identified and communicated. The physician managed the case and most patients remained in the hospital until they required very little care or could be discharged home or transferred to a convalescent center. A hospital stay of 2 to 3 weeks in an acute care facility was not unusual.

Cost and Effects

Although this system worked for decades, it was expensive. The federal government and insurance companies balked at paying these costs when highly skilled care was no longer needed. As a result, the number of days of hospitalization that a patient with a specific diagnosis required was determined. Then insured parties were paid only for that number of days. Decreasing the length of stay was seen as one way to decrease costs and save money. Patients were discharged to home or rehabilitation centers much sooner than before. They were weaker, had relatively fresh incisions, or often could not independently perform even minimal self-care. As hospital stays became shorter, nurses, physicians, consumers, and regulatory agencies expressed concerns about the quality of care. These concerns compelled hospital administrators and clinicians to develop new ways to measure and manage costs, quality, and outcomes. Assessment of how patient care was provided exposed inefficiencies, in-

cluding lack of face-to-face communication among disciplines. Case management was developed and widely adopted to provide more cost-effective care while saving hundreds of thousands of dollars yearly.

Case Management

Using the case management model, care is planned collaboratively so that important events, such as initiation of physical therapy, home care consultation, or discontinuation of invasive treatments, occur on a schedule that clinicians, through research or experience, have identified as optimum for enhancing recovery. Care is mapped out by day or by other pivotal time intervals, and goals or desired outcomes are specified for each time frame. When the patient has met all the goals, he or she is ready for discharge to home or to the next level of care. Responsibility for monitoring the patient's progress and tracking variance or deviation from the pathway is given to the case manager, who usually (but not always) is a nurse. The tool on which all this information is contained is the clinical pathway. The purposes of a clinical pathway are to

- Promote quality care and improve clinical outcomes
- Standardize important aspects of care
- Reduce unnecessary delays in care
- Reduce costs

Elements of a Clinical Pathway

Clinical pathways are now used in a variety of settings and cover diverse diagnoses and conditions. They are often developed by individual organizations and, although the format varies from institution to institution, clinical pathways have major features in common.

Patient Population

The first important element of the clinical pathway is the patient population (Fig. B-1A). Each pathway clearly specifies those patients who are appropriate for inclusion on the pathway. Pathways tend to cover patient groups in which the treatment and recovery are relatively predictable. Diagnosis-related groups (DRGs) are usually used to identify patients for a specific pathway, but qualifiers may be added. For example, a pathway for community-acquired pneumonia may exclude patients with *Pneumocystis pneumonia* or underlying obstructive pulmonary disease because those patients require highly individualized treatment plans and may not respond as quickly to intervention as patients without these underlying disorders.

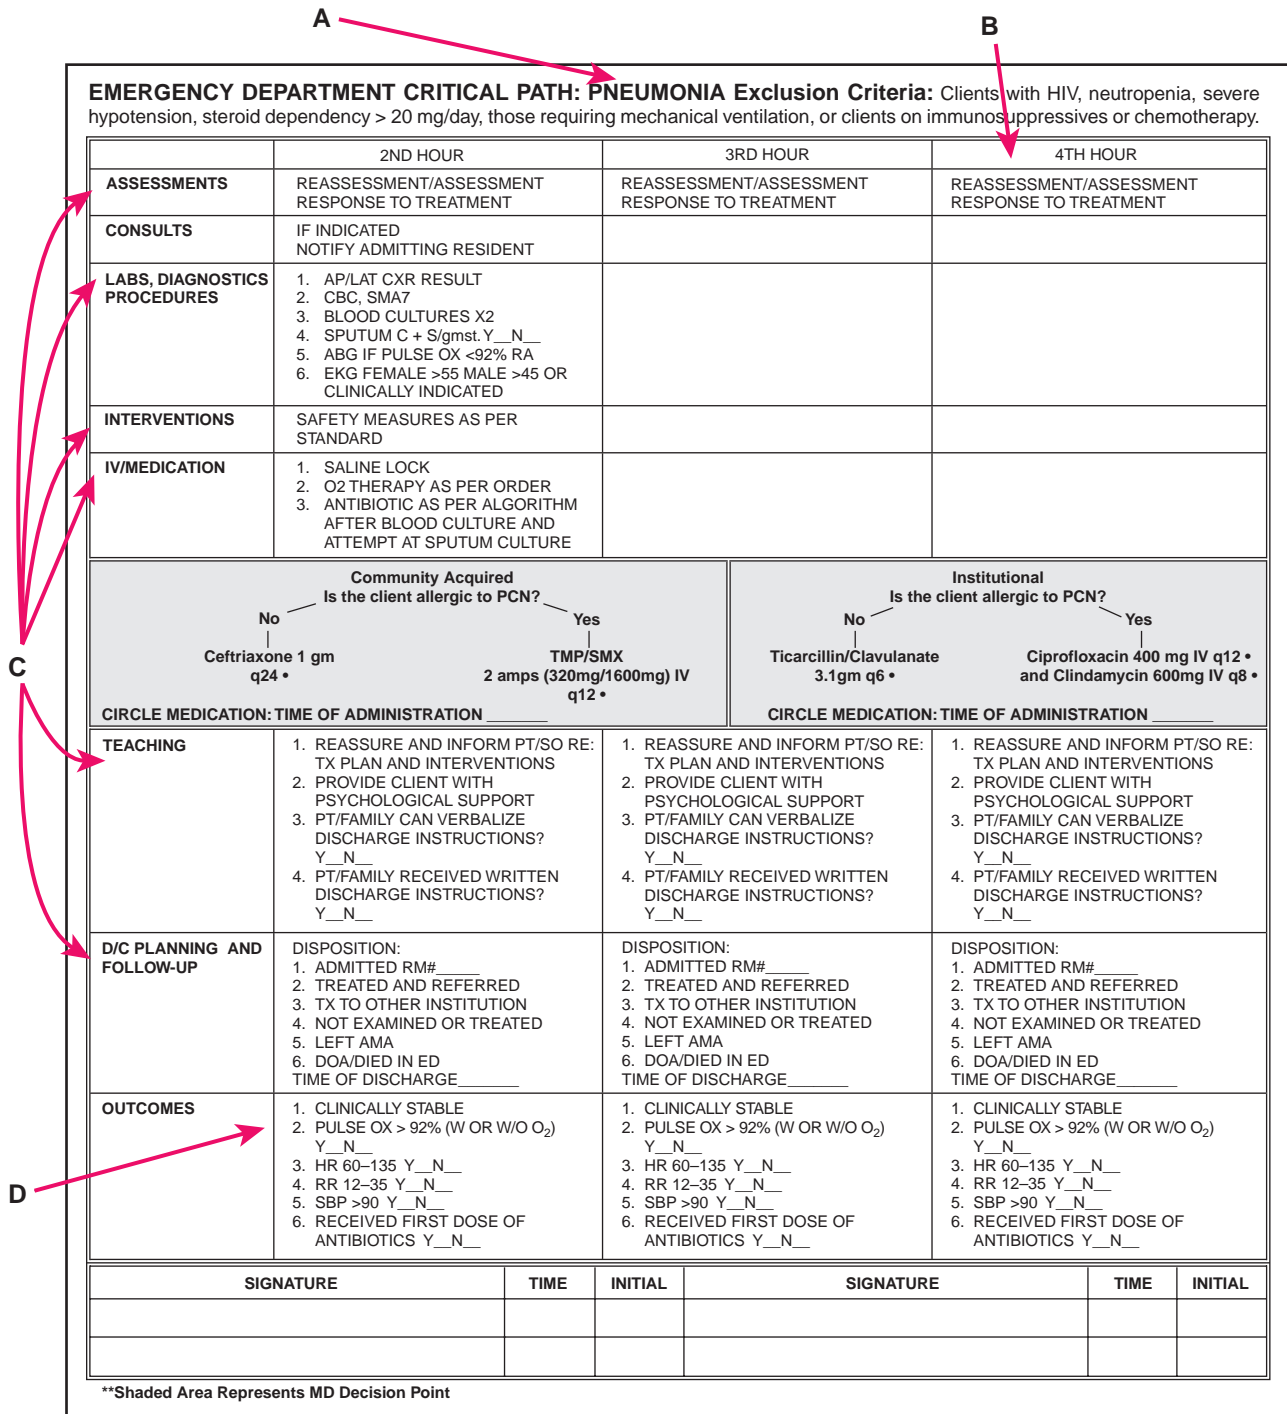

Figure B-1 Key elements of a clinical pathway. (A) Patient population clearly defined. (B) Clinically meaningful time frames. (C) Interventional categories. (D) Outcomes for each time frame should be specific and measurable. Reproduced with permission from Graduate Hospital, Philadelphia, Pennsylvania.

Time Frames

All pathways are divided into useful time frames, for example, minutes, hours, days, weeks, or phases (Fig. B-1B). Conditions requiring emergency treatment (eg, myocardial infarction, head injury, stroke) might be divided into

15-minute intervals, whereas conditions requiring chronic care (eg, chronic pain, spinal cord injury rehabilitation) may be divided into weekly or monthly intervals. An example of interventions by phases might be seen in postanes-thesia care pathways.

Figure B-4 (Continued).

Interventional Categories

Interventional categories consist of the groups of activities that make up a comprehensive treatment plan and are shown in the left-hand column of the pathway (Fig. B-1C). Although the order in which they are listed varies, these categories typically include

- Tests
- Treatments and nursing interventions
- Consultations
- Medications
- Diet
- Activity
- Patient and family education
- Discharge planning

Outcomes

Defined outcomes provide the focus for patient care activities for the various disciplines. Pathways include outcomes identified for each time interval (Fig. B-1D). They should be realistic, reflect incremental progress, and be achievable by 90% of the population. Pathway outcomes include physiologic, psychological, social, and educational outcomes.

Variance Record

The variance record (Fig. B-2) is an extremely important part of the pathway and represents the mechanism through which improvements in patient care can be accomplished. Variance is defined as any deviation from the pathway. Because all events on the pathway are critical to recovery, deviations can negatively affect outcomes. If the pathway calls for a specific test or treatment on day 2 and it is not carried out on day 2, a variance has occurred. If the patient is to ambulate 3 times a day and ambulates only once, a variance has occurred. The variance and the causes are recorded. Some variance records require a written note; others use code numbers or electronic systems to record variance (see Fig. B-2).

Case managers collect and analyze the variance data to identify trends in patient care and outcomes. For example, a pneumonia pathway may specify that the first dose of antibiotics be given within 3 hours of admission to the hospital (delays in administration of the first dose of an antibiotic are associated with increased morbidity and mortality). The case manager reviews the variance records and determines that only 40% of pneumonia patients are receiving the antibiotic in the specified time frame. Assessment of the issue reveals that delays are a result of the length of time it takes for the medication order to be taken off the chart and delivered to the pharmacy and the length of time it takes for the medication to be delivered. The pneumonia pathway team discusses this issue and determines that the first dose of medication should be given in the emergency department since the emergency department stocks these medications. The pathway is then revised to reflect this change in care. At the next review, the case manager reports that 92% of pneumonia patients on the clinical pathway received their antibiotics within 1 to 2 hours of admission. This ex-

ample illustrates how pathway use and variance data collection provide the forum for assessing an issue, determining a plan of action, implementing the plan, and evaluating the effectiveness of the plan.

The Nurse's Role

Nurses have a key role in all aspects of clinical pathway use. Participating in the development of the pathway is the first step. Because nurses begin and end the chain of staff involved in delivering care, they have a unique perspective in how health care systems work to enhance or impede the delivery of care. In the above example about antibiotic administration, staff nurses were able to identify the issue quickly and suggest solutions. Staff from other disciplines, being single links in the chain, cannot supply this global view of the problem.

Nurses are also responsible for initiating the pathway for appropriate patients and ensuring that the various events occur as planned. In some care settings or conditions, case managers who are advanced practice nurses closely follow pathway patients; in others, staff nurses or community-based nurses function as case managers. In any setting, enhancing and monitoring outcome achievement is a nursing activity. Patients may be given a printed copy of the patient pathway for reference. The pathway describes the care plan in simple language and pictures. The nurse discusses the pathway with the patient and focuses on achieving specific outcomes.

Nurses are also responsible for completing required documentation. Well-designed pathways strive for simplicity and should not duplicate documentation required elsewhere. For example, a separate nursing plan of care is not necessary when using a clinical pathway. The outcome section of the pathway usually requires documentation; other areas may need to be checked off or initialed so that other providers can readily see what has been accomplished. Documenting variance and initiating steps to address the variance are equally important, as is participating in redesigning care practices to promote the highest quality of cost-effective care.

Pathways in Practice

Several pathways are provided in the following pages to demonstrate the variety of formats the nurse may encounter. Figure B-3 is a pathway used at Thomas Jefferson University Hospital for patients with acute ischemic stroke. The pathway provides clear expected outcomes as well as a variety of checklists identifying all significant and sequential aspects of patient care. Figure B-4 is a pathway used at Yale New Haven Hospital for a patient with acute coronary syndrome with or without percutaneous coronary intervention.

Whatever format is used or condition treated, clinical pathways are documents in transition; they will change as research suggests better treatment strategies and as variance data are analyzed. Nurses' participation in these processes is essential for the successful implementation of clinical pathways and, ultimately, the opportunity to improve patient care.
