The combination of spleen cells and the cancer cells is referred to as a hybridoma. From hybridomas that continue to grow in the culture medium, the desired antibodies are harvested, purified, and prepared for diagnostic or therapeutic use (Fig. 16-5). Recent advances in genetic engineering have led to the production of MoAbs with combi-

nations of mouse and human components (*chimeric MoAbs*) or all-human components (*humanized MoAbs*). MoAbs made with human genes have greater immunologic properties and are less likely to cause allergic reactions (Yarbro, et al., 2005).

MoAbs are being used as aids in diagnostic evaluation of both primary and metastatic tumors through radiologic techniques. For example, MoAbs are used to assist in diagnosing ovarian and colorectal cancers. Their use in detecting breast, gastric, and prostate cancers and lymphoma is under investigation. MoAbs are also used in purging residual tumor cells from the bone marrow or peripheral blood of patients who are undergoing BMT or peripheral stem cell rescue after high-dose cytotoxic therapy.

Several MoAbs have been approved for treatment in cancer using a variety of extracellular (outside the cell membrane) and intracellular (inside the cell membrane) targets. Some of the MoAbs are used alone, whereas others are used in combination with agents that facilitate their antitumor actions. For example, gemtuzumab ozogamicin (Mylotarg) is used for the treatment of a specific type of acute myeloid leukemia (Wilkes & Barton-Burke, 2007);

Figure 16-5 Antibody-producing spleen cells are fused with cancer cells. This process produces cells called hybridomas. These cells, which can grow indefinitely in a culture medium, produce antibodies that are harvested, purified, and prepared for diagnostic or treatment purposes.

ibrutumomab-tiuxetan (Zevalin) and tositumomab (Bexxar) are used for the treatment of specific types of non-Hodgkin lymphoma. Some MoAbs target specific genetic mutations expressed by certain tumors, as in chronic myelogenous leukemia with the Philadelphia chromosome abnormality (Bcr-Abl). Imatinib mesylate (Gleevec) was developed to specifically bind with the Bcr-Abl abnormality, thus inhibiting cell proliferation.

Researchers continue to explore the development and use of MoAbs, either alone or in combination with other substances such as radioactive materials, chemotherapeutic agents, toxins, hormones, or other BRMs. Some specific targets for MoAbs under investigation include malignant cell growth factors, cell proteins, and substances that stimulate tumors to develop blood vessels (angiogenesis factors) (Kay, 2006; Wilkes & Barton-Burke, 2007).

Epidermal Growth Factor Receptors and Tyrosine Kinase Pathways. Normal cell growth is regulated by well-defined communication pathways between the environment surrounding the cell and the internal cell environment, the nucleus, and the intracellular cytoplasm. The cell membrane contains important protein receptors that respond to signals transmitted from the external environment and transmit that signal to the internal cell environment using enzymatic pathways called signal transduction pathways. Advances in understanding the genetic nature of cancers have resulted in these protein receptors and the cellular communication pathways to be used as targets for new cancer treatment agents. Much like a lock and key mechanism, new drugs are being developed that will target these specific receptors and pathways and prevent the continued growth of the cancer cells. The family of epidermal growth factor receptors (EGFR) have been proven to be a critical communication pathway. EGFRs are widely expressed by many normal cell types and in certain cancer tumors can be overexpressed or underexpressed (Franson & Lapka, 2005; Viele, 2005). The amount of EGFR that is expressed by a tumor can be measured by reliable laboratory testing. Overexpression of EGFR is associated with advanced tumor stage, more aggressive tumors, a predictor of resistance to standard chemotherapy, and a poor patient prognosis (Oishi, 2008). Recent scientific advances have enabled the development of numerous new targeted therapy drugs that bind to a specific protein receptor or block a specific signal transduction pathway expressed by a tumor but not by a normal cell, enabling a very targeted, specific cell kill. Monoclonal antibodies bind to the extracellular protein receptors and are larger molecules that are administered by IV. Tyrosine kinase inhibitors are smaller molecules that target the intracellular signaling pathways and are given orally. The efficacy of these new targeted agents depends on consistent and reliable delivery, and because they involve the patient's natural immune system they can precipitate very significant adverse events specific to each agent. It is important for nurses to be familiar with the administration issues related to patient education about self-administered oral agents and patient safety related to adverse events (Khoukaz, 2006).

Vascular Endothelial Growth Factors. Angiogenesis requires growth factors, cytokines, enzymes, and proteins, all

generated by the tumor to stimulate the formation of new capillaries to deliver oxygen and other nutrients to the hypoxic tumor. The major pathway for angiogenesis is activation of the VEGF family of proteins (Franson & Lapka, 2005; Viele, 2005). VEGF is essential for the growth and proliferation of malignant cells and when activated stimulates growth of new blood vessels. These new blood vessels differ greatly from normal vessels with less well-organized structure, increased permeability allowing migration of tumor cells, and increased interstitial pressure preventing chemotherapy from reaching the tumor. VEGF is overexpressed in many solid tumors and is associated with advanced tumor stage and poor prognosis (Viele, 2005). In colorectal cancer, increased VEGF expression has been correlated with increased vascularity, invasiveness, metastasis, and poor prognosis (Franson & Lapka, 2005).

Bevacizumab (Avastin) is a MoAb directed toward VEGF to prevent the activation of endothelial cells and inhibit growth of new blood vessels. It is currently the only U.S. Food and Drug Administration (FDA)-approved angiogenesis inhibitor and is used for the treatment of colorectal cancer. Research is ongoing to evaluate its effectiveness with other solid tumors. Side effects of bevacizumab include delays in wound healing, hemorrhage, hypertension, thromboembolism and proteinuria. Newer agents such as sorafenib (Nexavar) and sunitinib (Sutent) have shown multitargeted activity against VEGF cell receptors and tyrosine kinase pathways and have been approved for metastatic renal cell carcinoma.

Cytokines

Cytokines, substances produced by cells of the immune system to enhance the production and functioning of components of the immune system, are also the focus of cancer treatment research. Cytokines are grouped into families, such as interferons, interleukins, colony-stimulating factors, and tumor necrosis factors. Colony-stimulating factors have been described earlier in this chapter for their supportive role in myelosuppressive treatment modalities. Refer to Chapter 50 for more detailed discussion of the immune system.

Interferons. Interferons (IFNs) are cytokines with both antiviral and antitumor properties. Multiple antitumor effects of IFNs include antiangiogenesis, direct destruction of tumor cells, inhibition of growth factors, and disruption of the cell cycle. IFN- α is used in treatment of hairy-cell leukemia, Kaposi's sarcoma, chronic myelogenous leukemia, high-grade non-Hodgkin lymphoma, renal cell cancer, cutaneous T-cell lymphoma, and melanoma. IFN is administered by subcutaneous, intramuscular, intravenous, and intracavitary routes. Efforts are under way to establish the effectiveness of IFN in combination with other treatment regimens for treatment of various malignancies.

Interleukins. Interleukins (ILs) are a subgroup of cytokines known as lymphokines and monokines produced by lymphocytes and monocytes. About 25 different ILs have been identified (Yarbro, et al., 2005) that act by signaling and coordinating other cells of the immune system and thus require an intact immune system to achieve their therapeutic effects. IL-2 is an approved treatment option for renal cell

cancer and metastatic melanoma in adults. IL-2 stimulates the production and activation of several different types of lymphocytes, enhances the production of other types of cytokines, and affects both humoral and cell-mediated immunity. Side effects of ILs include flulike symptoms, fatigue, and anorexia as well as serious side effects (eg, profound diarrhea, pulmonary edema, hypotension, and oliguria). When combined with other cytokines, IL-2 can cause hypersensitivity reactions or cardiac dysrhythmias and hypotension (Tyre & Quan, 2007).

Clinical trials are being conducted on the role of ILs in treatment of other cancers. Some early stage clinical trials are assessing their effects when combined with chemotherapy and as growth factors for treatment of myelosuppression after the use of some forms of chemotherapy.

Retinoids

Retinoids are vitamin A derivatives (retinol, all-*trans*-retinoic acid [ATRA], and 13-*cis*-retinoic acid) that play a role in growth, reproduction, apoptosis, epithelial cell differentiation, and immune function. Retinoids are believed to have a role in cancer prevention as well as treatment. Specific receptors in the cell nucleus are retinoid-dependent, thus when retinoids bind with these receptors, cell differentiation and replication are affected.

ATRA (tretinoin [Renova, Retin-A]) is used in treating acute promyelocytic leukemia, a rare form of leukemia, and cutaneous T-cell lymphoma. Synthetic retinoid agents such as 4HRP (Fenretinide) have been shown to play a role in cellular apoptosis and are being evaluated for prevention of second breast cancers. Retinoids are being tested for treatment of various epithelial cancers, leukemias, melanoma, and neuroblastoma, and for prevention of breast, lung, prostate, and brain cancers (Wilkes & Barton-Burke, 2007; Yarbrow, et al., 2005).

Cancer Vaccines

Cancer vaccines are used to mobilize the body's immune response to recognize and attack cancer cells (Sinkovics & Horvath, 2006). Cancer vaccines contain either portions of cancer cells alone or portions of cells in combination with other substances (adjuvants) that can augment or boost immune responses. *Autologous* vaccines are made from the patient's own cancer cells, which are obtained during diagnostic biopsy or surgery. The cancer cells are killed and prepared for injection back into the patient. *Allogeneic* vaccines are made from cancer cells that are obtained from other people who have a specific type of cancer. These cancer cells are grown in a laboratory and eventually killed and prepared for injection.

Prophylactic vaccines are given to prevent disease. Quadrivalent human papillomavirus (HPV) recombinant vaccine (Gardasil) protects against HPV types 6, 11, 16, and 18 associated with common genital warts (type 6 and 11) and development of cervical cancer (type 16 and 18). It is administered over a series of three doses to females aged 9 to 26 (McLemore, 2006).

Therapeutic vaccines are given to kill existing cancer cells and to provide long-lasting immunity against further cancer development. Challenges to the therapeutic activity of cancer vaccines include the size of the tumor burden, the

mechanisms that allow tumor cells to avoid recognition as "nonself" by the immune system, and immune tolerance as the result of previous exposure to the tumor antigens. Multiple clinical trials are being conducted to develop therapeutic vaccines for cancers of the prostate, breast, kidney, and lung, as well as for melanoma, myeloma, and lymphoma (Schlom, Arlen & Gulley, 2007).

Nursing Management in Biologic Response Modifier Therapy

Patients receiving BRM therapy have many of the same needs as patients undergoing other cancer treatment. However, manipulation and stimulation of the immune system create unique challenges. Consequently, it is essential for the nurse to assess the need for education, support, and guidance for both the patient and the family and assist in planning and evaluating patient care.

Monitoring Therapeutic and Adverse Effects. The nurse must become familiar with each agent given and its potential effects. Adverse effects such as fever, myalgia, nausea, and vomiting, as seen with IFN therapy, may not be life-threatening. However, the nurse must be aware of the impact of these side effects on the patient's quality of life. Other life-threatening adverse effects (eg, capillary leak syndrome, pulmonary edema, hypotension) may occur with IL-2 therapy.

Promoting Home and Community-Based Care. The nurse teaches patients self-care and assists in providing for continuing care. Some BRMs, such as IFN, EPO, and G-CSF, can be administered by the patient or family members at home. As needed, the nurse teaches the patient and family how to administer these agents through subcutaneous injections. The nurse also provides instructions about side effects and helps the patient and family identify strategies to manage many of the common side effects of BRM therapy, such as fatigue, anorexia, and flulike symptoms.

Referral for home care is usually indicated to monitor the patient's responses to treatment and to continue and reinforce patient and family teaching. During home visits, the nurse assesses the patient's and family members' technique in administering medications. The nurse collaborates with physicians, third-party payors, and pharmaceutical companies to help the patient obtain reimbursement for home administration of BRM therapies. The nurse also reminds the patient about the importance of keeping follow-up appointments with the physician and assesses the patient's need for changes in care.

Gene Therapy

Gene therapy includes approaches that correct genetic defects or manipulate genes to induce tumor cell destruction in the hope of preventing or combating disease. One of the challenges confronting cancer gene therapy is the multiple somatic mutations involved in the development of a cancer, making it difficult to identify the most effective gene therapy approach.

Considerable advances have been made in the identification of effective tumor cell targets and evaluation of the most appropriate vectors. Vectors serve as a vehicle or carrier that transports a gene into the target cell via the cell

membrane. With the improved understanding of cell surface proteins and signaling pathways, many phase I and phase II studies are currently evaluating the use of target specific vectors to disrupt tumor proliferation. The National Institutes of Health Web site identifies over 300 ongoing gene therapy trials targeting a variety of tumors and tumor cell markers. Examples include CEA, HER2/neu, and herpes simplex vaccine (NIH, 2007).

Viruses have long been hypothesized as an ideal delivery system because of the ease with which they cross the cell membrane and enter the intracellular space; however, their drawback includes their short-lived effect due to the strong immune response. Viruses used as vectors include retroviruses, adenoviruses (common cold virus), vaccinia virus (smallpox vaccine), fowlpox (avian poxvirus), herpes simplex viruses, and Epstein-Barr viruses (Yang, Wang, Zhao, et al., 2007). Clinical research studies are evaluating gene therapy across all cancer sites, including melanoma, prostate cancer, breast cancer, pancreatic cancer, head and neck squamous cell cancer, and non-small cell lung cancer. There are currently no FDA-approved cancer gene therapies in the United States.

Three general approaches have been used in the development of gene therapies, with adenoviruses showing effective promise in each approach.

- *Tumor-directed therapy* is introduction of a therapeutic gene (suicide gene) into tumor cells in an attempt to destroy them. This approach is very challenging because it is difficult to identify which gene would be the most beneficial. In addition, patients with widespread disease would require multiple injections to treat every site of disease.
- *Active immunotherapy* is the administration of genes that will invoke the antitumor responses of the immune system (Liu, 2003).
- *Adoptive immunotherapy* is the administration of genetically altered lymphocytes that are programmed to cause tumor destruction (Yang, et al., 2007).

Complementary and Alternative Medicine (CAM)

For many patients and their clinicians, a challenge in managing their cancer treatments is in finding the balance between achieving a reasonable quality of life while undergoing potentially toxic and life-saving modalities. Many patients seek a more holistic or nontraditional approach, turning to complementary and alternative therapies while continuing to utilize conventional medicine (Mumber, 2006).

The National Center for Complementary and Alternative Medicine (NCCAM) at the National Institutes of Health defines CAM as diverse medical and health care systems, practices, and products that are not presently considered to be part of conventional medicine. Complementary medicine denotes therapies in conjunction with conventional medicine, whereas alternative medicine denotes therapies used instead of conventional medicine. More recently, the term Integrative Medicine has been used, which denotes a combination of conventional medicine and CAM that have a strong scientific base for use and safety (NCCAM, 2007).

CAM is used by 28% to 85% of patients with cancer (Chart 16-6). More importantly, patients are using CAM but not communicating this to their health care providers either because they were never asked about its use or be-

cause they withheld the information fearing that their physicians would not approve (Chong, 2006; Rojas-Cooley & Grant, 2006). Many of the CAM modalities can be a source of comfort and emotional support for the patient, but assessment of CAM use is important for patient safety.

Mind-body and biofield therapies have a holistic focus on channeling positive energy, promoting relaxation, and reducing stress and have been reported as being beneficial to patients as measured by wound healing and reduction in pain, edema, and anxiety (Hibdon, 2005). There is, however, risk associated with some of the CAM modalities. Because of the possibility of herb-vitamin-drug interactions, there is concern about the use of biologicals and dietary supplements, which are not regulated by the FDA nor subjected to rigorous scientific evaluation. Patients often perceive vitamins and dietary supplements as harmless, natural products that have no side effects or potential toxicities. One example of herbal-drug interaction is the effect of St. John's wort on the efficacy of irinotecan (Camptosar), cyclophosphamide, tamoxifen, cyclosporine, warfarin (Coumadin), and indinavir (Crixivan). Each nursing assessment should include an open discussion with patients about their use of CAM. This requires that nurses develop the appropriate familiarity and knowledge related to CAM in order to direct patients to safe, reliable, and credible sources for information.

Unproven and Unconventional Therapies

Despite increasing 5-year survival rates with the use of traditional methods of treatment, a significant number of patients use or seriously consider using some form of unconventional treatment. Hopelessness, desperation, unmet needs, lack of factual information, and family or social pressures are major factors that motivate patients to seek unconventional methods of treatment and allow them to fall prey to deceptive practices and quackery.

Unconventional treatments are those without scientific evidence of the ability to cure or control cancer. In addition to being ineffective, some unconventional treatments may also be harmful to the patient and may cost thousands of dollars.

In the age of the Internet, patients have unlimited access to frequently unreliable claims of "miracle cures" that range from plant remedies to metabolic therapy using special diets, supplements, or "detoxification" regimens involving unconventional enemas and colonic cleansing procedures. The ACS established a clearinghouse along with NCCAM to investigate and identify potentially dangerous and harmful unproven therapies. ACS maintains this listing on its Web site.

Nursing Management in Unconventional Therapies

The most effective way to protect patients and families from fraudulent therapies and questionable cancer cures is to establish a trusting relationship, provide supportive care, and promote hope. Truthful responses given in a nonjudgmental manner to questions and inquiries about unproven methods of cancer treatments may alleviate the fear and guilt on the part of the patient and family that they are not "doing everything we can" to obtain a cure. The nurse should inform the patient and family of the characteristics common to fraudulent therapies so that they will be informed and

Use of Acupressure to Reduce Chemotherapy-induced Nausea and Vomiting

Dribble, S. L., Luce, J., Cooper, B. A., et al. (2007). Acupressure for chemotherapy-induced nausea and vomiting: A randomized clinical trial. *Oncology Nursing Forum*, 34(4), 813–820.

Purpose

The purpose of this study was to compare the effectiveness of acupressure, placebo acupressure, and usual care in reducing chemotherapy-induced nausea and vomiting (CINV) in women with breast cancer. Although significant advances have been made in the medications available to treat CINV, delayed nausea and vomiting continue to be problematic for many patients. Acupressure is a traditional Chinese nonpharmacologic, noninvasive pressure applied by the thumbs, fingers, and hands on the surface of the skin at specific points. The belief is that symptoms such as nausea may be lessened through the use of acupressure.

Design

This was a multicenter, longitudinal randomized clinical trial conducted throughout one cycle of highly emetogenic chemotherapy. Ten community oncology programs associated with a major cancer center and nine independent sites located throughout the United States served as the study sites. To be eligible, the women had to be receiving the second or third cycle of chemotherapy classified as moderate to highly emetogenic. In addition, during the previous cycle of chemotherapy, the women had to have experienced at least moderate nausea as measured by the Morrow Assessment of Nausea and Emesis.

A total of 160 women were randomly assigned to one of three intervention groups: acupressure, placebo acupressure, and usual care. Each woman received a prescription for antiemetic therapy to use at home; thus, acupressure was studied in the context of usual clinical care for nausea. The patients in the acupressure groups were taught how to use the actual or placebo acupressure techniques immediately prior to receiving chemotherapy. The acupressure and placebo acupressure groups completed daily logs for 3 weeks and recorded acupressure use as well as medications and other methods used to control their nausea. The usual care group

also completed daily logs about efforts used to control nausea. On the eighth day of the chemotherapy cycle, women were reminded to complete the daily logs. Anxiety measures were obtained for all participants using the State-Trait Anxiety Inventory Scale at baseline and at the exit appointment at the time of the next chemotherapy cycle. Demographic data and diagnostic, cancer treatment, and treatment of nausea data were also collected. The occurrence of acute nausea and vomiting on the day of chemotherapy (study day 1) and its occurrence on the 2nd to 11th days after chemotherapy (delayed emesis) were analyzed.

Findings

The three groups were similar on demographic variables, disease, and treatment. There were no significant differences in episodes of acute CINV by treatment group. Although episodes of delayed CINV decreased for all three treatment groups over time, women in the acupressure group reported fewer episodes than both the placebo acupressure group and the usual care group. Many of the participants noted that acupressure was most effective when the nausea was mild, but that it was helpful in addition to pharmaceutical agents when the nausea was severe. The researchers also found that 30% of the participants experienced delayed nausea at 11 days after chemotherapy. They concluded that in future studies delayed nausea assessment should extend for at least 11 days versus the usual length of assessment of 5 days. The researchers reported differences in the incidence of CINV by age, with younger women reporting a greater intensity of nausea than older women.

Nursing Implications

The results of this study suggest that acupressure may be a valid addition to other interventions for the management of CINV, including CINV that occurred 2 to 11 days after chemotherapy treatment. Acupressure offers a nonpharmacologic, alternative approach to care of a significant problem for many patients. The technique is easily learned without significant expense or prolonged training. Future research might assess the role of acupressure in the treatment of CINV in both genders and for other types of cancer.

cautious when evaluating other forms of “therapy.” The nurse also should encourage patients who use unconventional therapies to inform their physicians about such use. This knowledge can help prevent interactions with medications and other therapies that may be prescribed and avoid attributing the side effects of unconventional therapies to prescribed medications.

Nursing Care of Patients With Cancer

The outlook for patients with cancer has greatly improved because of scientific and technologic advances. However, as a result of the underlying disease or various treatment modalities, patients with cancer may experience a variety of secondary problems such as infection, reduced WBC counts, bleeding, skin problems, nutritional problems, pain,

fatigue, and psychological stress. Chart 16-7 provides a nursing care plan for patients with cancer.

Maintaining Tissue Integrity

Some of the most frequently encountered disturbances of tissue integrity, in addition to stomatitis, include skin and tissue reactions to radiation therapy, alopecia, and metastatic skin lesions.

Stomatitis

Mucositis is a common side effect of radiation and some types of chemotherapy that may lead to inflammation and ulceration of any portion of the gastrointestinal tract from the oral cavity throughout the alimentary canal. One form of mucositis, stomatitis, is an inflammatory response of the oral tissues that is characterized by mild redness (erythema) and edema or, if severe, by painful ulcerations, bleeding, and secondary infection. Stomatitis commonly develops 5

 CHART
16-7

PLAN OF NURSING CARE
The Patient With Cancer

NURSING DIAGNOSIS: Risk for infection related to inadequate defenses related to myelosuppression secondary to radiation or antineoplastic agents

GOAL: Prevention of infection

Nursing Interventions

1. Assess patient for evidence of infection:
 - a. Check vital signs every 4 hours.
 - b. Monitor white blood cell (WBC) count and differential each day.
 - c. Inspect all sites that may serve as entry ports for pathogens (intravenous sites, wounds, skin folds, bony prominences, perineum, and oral cavity).
2. Report fever ($\geq 38.3^{\circ}\text{C}$ [101°F] or $\geq 38^{\circ}\text{C}$ [100.4°F] for longer than 1 hour), chills, diaphoresis, swelling, heat, pain, erythema, exudate on any body surfaces. Also report change in respiratory or mental status, urinary frequency or burning, malaise, myalgias, arthralgias, rash, or diarrhea.
3. Obtain cultures and sensitivities as indicated before initiation of antimicrobial treatment (wound exudate, sputum, urine, stool, blood).
4. Initiate measures to minimize infection.
 - a. Discuss with patient and family
 - (1) Placing patient in private room if absolute WBC count $< 1000/\text{mm}^3$.
 - (2) Importance of patient avoiding contact with people who have known or recent infection or recent vaccination.
 - b. Instruct all personnel in careful hand hygiene before and after entering room.
 - c. Avoid rectal or vaginal procedures (rectal temperatures, examinations, suppositories; vaginal tampons).
 - d. Use stool softeners to prevent constipation and straining.
 - e. Assist patient in practice of meticulous personal hygiene.
 - f. Instruct patient to use electric razor.
 - g. Encourage patient to ambulate in room unless contraindicated.
 - h. Avoid fresh fruits, raw meat, fish, and vegetables if absolute WBC count $< 1000/\text{mm}^3$; remove fresh flowers and potted plants.
 - i. Each day: change water pitcher, denture cleaning fluids, and respiratory equipment containing water.

Rationale

1. Signs and symptoms of infection may be diminished in the immunocompromised host. Prompt recognition of infection and subsequent initiation of therapy will reduce morbidity and mortality associated with infection.
2. Early detection of infection facilitates early intervention.
3. Tests identify the organism and indicate the most appropriate antimicrobial therapy. Use of inappropriate antibiotics enhances proliferation of additional flora and encourages growth of antibiotic-resistant organisms.
4. Exposure to infection is reduced.
 - a. Preventing contact with pathogens helps prevent infection.
 - b. Hands are significant source of contamination.
 - c. Incidence of rectal and perianal abscesses and subsequent systemic infection is high. Manipulation may cause disruption of membrane integrity and enhance progression of infection.
 - d. Minimizes trauma to tissues.
 - e. Prevents skin irritation.
 - f. Minimizes skin trauma.
 - g. Minimizes chance of skin breakdown and stasis of pulmonary secretions.
 - h. Fresh fruits and vegetables harbor bacteria not removed by ordinary washing. Flowers and potted plants are sources of organisms.
 - i. Stagnant water is a source of infection.

Expected Outcomes

- Demonstrates normal temperature and vital signs.
- Exhibits absence of signs of inflammation: local edema, erythema, pain, and warmth.
- Exhibits normal breath sounds on auscultation.
- Takes deep breaths and coughs every 2 hours to prevent respiratory dysfunction and infection.
- Exhibits absence of pathologic bacteria on cultures.
- Avoids contact with others with infections.
- Avoids crowds.
- All personnel carry out hand hygiene after each voiding and bowel movement.
- Excoriation and trauma of skin are avoided.
- Trauma to mucous membranes is avoided (avoidance of rectal thermometers, suppositories, vaginal tampons, perianal trauma).
- Uses recommended procedures and techniques if participating in management of invasive lines or catheters.
- Uses electric razor.
- Is free of skin breakdown and stasis of secretions.
- Adheres to dietary and environmental restrictions.
- Exhibits no signs of septicemia or septic shock.
- Exhibits normal vital signs, cardiac output, and arterial pressures when monitored.
- Demonstrates ability to administer colony-stimulating factor.

PLAN OF NURSING CARE
The Patient With Cancer (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 5. Assess intravenous sites every day for evidence of infection: <ol style="list-style-type: none"> a. Change peripheral short-term intravenous sites every other day. b. Cleanse skin with povidone-iodine before arterial puncture or venipuncture. c. Change central venous catheter dressings every 48 hours. d. Change all solutions and infusion sets every 72–96 hours. e. Follow Infusion Nursing Society guidelines for care of peripheral and central venous access devices. 6. Avoid intramuscular injections. 7. Avoid insertion of urinary catheters; if catheters are necessary, use strict aseptic technique. 8. Teach patient or family member to administer granulocyte (or granulocyte-macrophage) colony-stimulating factor when prescribed. 9. Advise patient to avoid exposure to animal excreta; discuss dental procedures with physician; avoid vaginal douche; and avoid vaginal or rectal manipulation during sexual contact during period of neutropenia (Marrs, 2006; Zitella, et al., 2006). 	<ol style="list-style-type: none"> 5. Nosocomial staphylococcal septicemia is closely associated with intravenous catheters. <ol style="list-style-type: none"> a. Incidence of infection is increased when catheter is in place >72 hours. b. Povidone-iodine is effective against many gram-positive and gram-negative pathogens. c. Allows observation of site and removes source of contamination. d. Once introduced into the system, microorganisms are capable of growing in infusion sets despite replacement of container and high flow rates. e. Infusion nursing society collaborates with other nursing subspecialties in determining guidelines for intravenous access care. 6. Reduces risk for skin abscesses. 7. Rates of infection greatly increase after urinary catheterization. 8. Granulocyte colony-stimulating factor decreases the duration of neutropenia and the potential for infection. 9. Minimizes exposure to potential sources of infection and disruption of skin integrity. 	

NURSING DIAGNOSIS: Impaired skin integrity: erythematous and wet desquamation reactions to radiation therapy

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. In erythematous areas: <ol style="list-style-type: none"> a. Avoid the use of soaps, cosmetics, perfumes, powders, lotions and ointments, deodorants. b. Use only lukewarm water to bathe the area. c. Avoid rubbing or scratching the area. d. Avoid shaving the area with a straight-edged razor. e. Avoid applying hot-water bottles, heating pads, ice, and adhesive tape to the area. f. Avoid exposing the area to sunlight or cold weather. g. Avoid tight clothing in the area. Use cotton clothing. h. Apply vitamin A and D ointment to the area. 	<ol style="list-style-type: none"> 1. Care to the affected areas must focus on preventing further skin irritation, drying, and damage. <ol style="list-style-type: none"> a. These substances may cause pain and additional skin irritation and damage. b. Avoiding water of extreme temperatures minimizes additional skin damage, irritation and pain. c. Rubbing and or scratching will lead to additional skin irritation, damage and increased risk of infection. d. Use of razors may lead to additional irritation and disruption of skin integrity and increased risk of infection. e. Avoiding extreme temperatures minimizes additional skin damage, irritation, burns and pain. f. Sun exposure or extreme cold weather may lead to additional skin damage and pain. g. Allows air circulation to affected area. h. Aids healing. 	<ul style="list-style-type: none"> • Avoids use of soaps, powders, and other cosmetics on site of radiation therapy. • States rationale for special care of skin. • Exhibits minimal change in skin. • Avoids trauma to affected skin region (avoids shaving, constricting and irritating clothing, extremes of temperature, and use of adhesive tape). • Reports change in skin promptly. • Demonstrates proper care of blistered or open areas. • Exhibits absence of infection of blistered and opened areas. • Wound is free from development of eschar.

Continued

 CHART
16-7

 PLAN OF NURSING CARE
 The Patient With Cancer (Continued)
Nursing Interventions

2. If wet desquamation occurs:
 - a. Do not disrupt any blisters that have formed.
 - b. Avoid frequent washing of the area.
 - c. Report any blistering.
 - d. Use *prescribed* creams or ointments.
 - e. If area weeps, apply a nonadhesive absorbent dressing.
 - f. If the area is without drainage, use moisture and vapor-permeable dressings such as hydrocolloids and hydrogels on noninfected areas (Swearingen, 2008).
 - g. Consult with enterostomal therapist (ET) and physician if eschar forms.

Rationale

2. Open weeping areas are susceptible to bacterial infection. Care must be taken to prevent introduction of pathogens.
 - a. Disruption of skin blisters disrupts skin integrity and may lead to increased risk of infection.
 - b. Frequent washing may lead to increased irritation and skin damage, with increased risk for infection.
 - c. Blistering of skin represents progression of skin damage.
 - d. Decreases irritation and inflammation of the area.
 - e. Enhances drying.
 - f. Promotes healing.
- g. Eschar must be removed to promote healing and prevent infection. ET nurses have expertise in the care of wounds.

Expected Outcomes**NURSING DIAGNOSIS:** Impaired oral mucous membrane: stomatitis**GOAL:** Maintenance of intact oral mucous membranes**Nursing Interventions**

1. Assess oral cavity daily.
2. Instruct patient to report oral burning, pain, areas of redness, open lesions on the lips, pain associated with swallowing, or decreased tolerance to temperature extremes of food.
3. Encourage and assist in oral hygiene.

Preventive

- a. Advise patient to avoid irritants such as commercial mouthwashes, alcoholic beverages, and tobacco.
- b. Brush with soft toothbrush; use nonabrasive toothpaste after meals and bedtime; floss every 24 hours unless painful or platelet count falls below 40,000 cu/mm.

Mild stomatitis (generalized erythema, limited ulcerations, small white patches: *Candida*)

- c. Use normal saline mouth rinses every 2 hours while awake; every 6 hours at night.
- d. Use soft toothbrush or toothette.
- e. Remove dentures except for meals; be certain dentures fit well.
- f. Apply water soluble lip lubricant.
- g. Avoid foods that are spicy or hard to chew and those with extremes of temperature.

Rationale

1. Provides baseline for later evaluation.
2. Identification of initial stages of stomatitis will facilitate prompt interventions, including modification of treatment as prescribed by physician.
3. Patients who are having discomfort or pain, or other symptoms related to the disease and treatment may require encouragement and assistance in performing oral hygiene.
 - a. Alcohol content of mouthwashes will dry oral tissues and potentiate breakdown.
 - b. Limits trauma and removes debris.
 - c. Assists in removing debris, thick secretions, and bacteria.
 - d. Minimizes trauma.
 - e. Minimizes friction and discomfort.
 - f. Promotes comfort.
 - g. Prevents local trauma.

Expected Outcomes

- States rationale for frequent oral assessment and hygiene.
- Identifies signs and symptoms of stomatitis to report to nurse or physician.
- Participates in recommended oral hygiene regimen.
- Avoids mouthwashes with alcohol.
- Brushes teeth and mouth with soft toothbrush.
- Uses lubricant to keep lips soft and nonirritated.
- Avoids hard-to-chew, spicy, and hot foods.
- Exhibits clean, intact oral mucosa.
- Exhibits no ulcerations or infections of oral cavity.
- Exhibits no evidence of bleeding.
- Reports absent or decreased oral pain.
- Reports no difficulty swallowing.
- Exhibits healing (reepithelialization) of oral mucosa within 5 to 7 days (mild stomatitis).
- Exhibits healing of oral tissues within 10 to 14 days (severe stomatitis).

Continued on following page

 CHART
16-7

PLAN OF NURSING CARE
The Patient With Cancer (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p>Severe stomatitis (confluent ulcerations with bleeding and white patches covering more than 25% of oral mucosa)</p> <p>h. Obtain tissue samples for culture and sensitivity tests of areas of infection.</p> <p>i. Assess ability to chew and swallow; assess gag reflex.</p> <p>j. Use oral rinses (may combine in solution saline, anti-<i>Candida</i> agent, such as Mycostatin, and topical anesthetic agent as described below) as prescribed or place patient on side and irrigate mouth; have suction available.</p> <p>k. Remove dentures.</p> <p>l. Use toothette or gauze soaked with solution for cleansing.</p> <p>m. Use water soluble lip lubricant.</p> <p>n. Provide liquid or pureed diet.</p> <p>o. Monitor for dehydration.</p> <p>4. Minimize discomfort.</p> <p>a. Consult physician for use of topical anesthetic, such as dyclonine and diphenhydramine, or viscous lidocaine.</p> <p>b. Administer systemic analgesics as prescribed.</p> <p>c. Perform mouth care as described.</p>	<p>h. Assists in identifying need for antimicrobial therapy.</p> <p>i. Patient may be in danger of aspiration.</p> <p>j. Facilitates cleansing, provides for safety and comfort.</p> <p>k. Prevents trauma from ill-fitting dentures.</p> <p>l. Limits trauma, promotes comfort.</p> <p>m. Promotes comfort.</p> <p>n. Ensures intake of easily digestible foods.</p> <p>o. Decreased oral intake and ulcerations potentiate fluid deficits.</p> <p>a. Alleviates pain and increases sense of well-being; promotes participation in oral hygiene and nutritional intake.</p> <p>b. Adequate management of pain related to severe stomatitis can facilitate improved quality of life, participation in other aspects of activities of daily living, oral intake and verbal communication.</p> <p>c. Promotes removal of debris, healing, and comfort.</p>	<ul style="list-style-type: none"> • Exhibits no bleeding or oral ulceration. • Consumes adequate fluid and food. • Exhibits absence of dehydration and weight loss.

NURSING DIAGNOSIS: Impaired tissue integrity: alopecia**GOAL:** Maintenance of tissue integrity; coping with hair loss

Nursing Interventions	Rationale	Expected Outcomes
<p>1. Discuss potential hair loss and regrowth with patient and family; advise that hair loss may occur on body parts other than the head.</p> <p>2. Explore potential impact of hair loss on self-image, interpersonal relationships, and sexuality.</p> <p>3. Prevent or minimize hair loss through the following:</p> <p>a. Use scalp hypothermia and scalp tourniquets, if appropriate.</p> <p>b. Cut long hair before treatment.</p> <p>c. Use mild shampoo and conditioner, gently pat dry, and avoid excessive shampooing.</p> <p>d. Avoid electric curlers, curling irons, dryers, clips, barrettes, hair sprays, hair dyes, and permanent waves.</p> <p>e. Avoid excessive combing or brushing; use wide-toothed comb.</p>	<p>1. Provides information so patient and family can begin to prepare cognitively and emotionally for loss.</p> <p>2. Facilitates coping.</p> <p>3. Retains hair as long as possible.</p> <p>a. Decreases hair follicle uptake of chemotherapy (not used for patients with leukemia or lymphoma because tumor cells may be present in blood vessels or scalp tissue).</p> <p>b–e. Minimizes hair loss due to the weight and manipulation of hair.</p>	<ul style="list-style-type: none"> • Identifies alopecia as potential side effect of treatment. • Identifies positive and negative feelings and threats to self-image. • Verbalizes meaning that hair and possible hair loss have for him or her. • States rationale for modifications in hair care and treatment. • Uses mild shampoo and conditioner and shampoos hair only when necessary. • Avoids hair dryer, curlers, sprays, and other stresses on hair and scalp. • Wears hat or scarf over hair when exposed to sun. • Takes steps to deal with possible hair loss before it occurs; purchases wig or hairpiece.

Continued

CHART
16-7
PLAN OF NURSING CARE
The Patient With Cancer (Continued)
Nursing Interventions

4. Prevent trauma to scalp.
 - a. Lubricate scalp with vitamin A and D ointment to decrease itching.
 - b. Have patient use sunscreen or wear hat when in the sun.
5. Suggest ways to assist in coping with hair loss:
 - a. Purchase wig or hairpiece before hair loss.
 - b. If hair loss has occurred, take photograph to wig shop to assist in selection.
 - c. Begin to wear wig before hair loss.
 - d. Contact the American Cancer Society for donated wigs, or a store that specializes in this product.
 - e. Wear hat, scarf, or turban.
6. Encourage patient to wear own clothes and retain social contacts.
7. Explain that hair growth usually begins again once therapy is completed.

Rationale

4. Preserves tissue integrity.
 - a. Assists in maintaining skin integrity.
 - b. Prevents ultraviolet light exposure.
5. Minimizes change in appearance.
 - a. Wig that closely resembles hair color and style is more easily selected if hair loss has not begun.
 - b. Facilitates adjustment.
 - c. Enables patient to be prepared for loss and facilitates adjustment.
 - d. Provides options to patient.
 - e. Conceals loss.
6. Assists in maintaining personal identity.
7. Reassures patient that hair loss is usually temporary.

Expected Outcomes

- Maintains hygiene and grooming.
- Interacts and socializes with others.
- States that hair loss and necessity of wig are temporary.

NURSING DIAGNOSIS: Imbalanced nutrition, less than body requirements, related to nausea and vomiting

GOAL: Patient experiences less nausea and vomiting associated with chemotherapy; weight loss is minimized

Nursing Interventions

1. Assess the patient's previous experiences and expectations of nausea and vomiting, including causes and interventions used.
2. Adjust diet before and after drug administration according to patient preference and tolerance.
3. Prevent unpleasant sights, odors, and sounds in the environment.
4. Use distraction, music therapy, biofeedback, self-hypnosis, relaxation techniques, and guided imagery before, during, and after chemotherapy.
5. Administer prescribed antiemetics, sedatives, and corticosteroids before chemotherapy and afterward as needed.
6. Ensure adequate fluid hydration before, during, and after drug administration; assess intake and output.
7. Encourage frequent oral hygiene.
8. Provide pain relief measures, if necessary.

Rationale

1. Identifies patient concerns, misinformation, potential strategies for intervention. Also gives patient sense of empowerment and control.
2. Each patient responds differently to food after chemotherapy. A diet containing foods that relieve the patient's nausea or vomiting is most helpful.
3. Unpleasant sensations can stimulate the nausea and vomiting center.
4. Decreases anxiety, which can contribute to nausea and vomiting. Psychological conditioning may also be decreased.
5. Administration of antiemetic regimen before onset of nausea and vomiting limits the adverse experience and facilitates control. Combination drug therapy reduces nausea and vomiting through various triggering mechanisms.
6. Adequate fluid volume dilutes drug levels, decreasing stimulation of vomiting receptors.
7. Reduces unpleasant taste sensations.
8. Increased comfort increases physical tolerance of symptoms.

Expected Outcomes

- Identifies previous triggers of nausea and vomiting.
- Exhibits decreased apprehension and anxiety.
- Identifies previously used successful interventions for nausea and vomiting.
- Reports decrease in nausea.
- Reports decrease in incidence of vomiting.
- Consumes adequate fluid and food when nausea subsides.
- Demonstrates use of distraction, relaxation, and imagery when indicated.
- Exhibits normal skin turgor and moist mucous membranes.
- Reports no additional weight loss.

Continued on following page

 CHART
16-7

PLAN OF NURSING CARE
The Patient With Cancer (Continued)

Nursing Interventions	Rationale	Expected Outcomes
9. Consult with dietician as needed. 10. Assess and address other contributing factors to nausea and vomiting, such as other symptoms, constipation, gastrointestinal irritation, electrolyte imbalance, radiation therapy, medications, and central nervous system metastasis.	9. Interdisciplinary collaboration essential in addressing complex patient needs. 10. Multiple factors may contribute nausea and vomiting.	
NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements, related to anorexia, cachexia, or malabsorption GOAL: Maintenance of nutritional status and of weight within 10% of pretreatment weight		
Nursing Interventions	Rationale	Expected Outcomes
1. Teach patient to avoid unpleasant sights, odors, sounds in the environment during mealtime. 2. Suggest foods that are preferred and well tolerated by the patient, preferably high-calorie and high-protein foods. Respect ethnic and cultural food preferences. 3. Encourage adequate fluid intake, but limit fluids at mealtime. 4. Suggest smaller, more frequent meals. 5. Promote relaxed, quiet environment during mealtime with increased social interaction as desired. 6. If patient desires, serve wine at mealtime with foods. 7. Consider cold foods, if desired. 8. Encourage nutritional supplements and high-protein foods between meals. 9. Encourage frequent oral hygiene. 10. Provide pain relief measures. 11. Provide control of nausea and vomiting. 12. Increase activity level as tolerated. 13. Decrease anxiety by encouraging verbalization of fears, concerns; use of relaxation techniques; imagery at mealtime. 14. Position patient properly at mealtime. 15. For collaborative management, provide enteral tube feedings of commercial liquid diets, elemental diets, or blenderized foods as prescribed. 16. Provide parenteral nutrition with lipid supplements as prescribed.	1. Anorexia can be stimulated or increased with noxious stimuli. 2. Foods preferred, well tolerated, and high in calories and protein maintain nutritional status during periods of increased metabolic demand. 3. Fluids are necessary to eliminate wastes and prevent dehydration. Increased fluids with meals can lead to early satiety. 4. Smaller, more frequent meals are better tolerated because early satiety does not occur. 5. A quiet environment promotes relaxation. Social interaction at mealtime increases appetite. 6. Wine often may stimulate appetite and add calories. 7. Cold, high-protein foods are often more tolerable and less odorous than hot foods. 8. Supplements and snacks add protein and calories to meet nutritional requirements. 9. Oral hygiene stimulates appetite and increases saliva production. 10. Pain impairs appetite. 11. Nausea and vomiting increase anorexia. 12. Increased activity promotes appetite. 13. Relief of anxiety may increase appetite. 14. Proper body position and alignment are necessary to aid chewing and swallowing. 15. Tube feedings may be necessary in the severely debilitated patient who has a functioning gastrointestinal system. 16. Parenteral nutrition with supplemental fats supplies needed calories and proteins to meet nutritional demands, especially in the nonfunctional gastrointestinal system.	<ul style="list-style-type: none"> • Patient and family identify minimal nutritional requirements. • Exhibits weight loss no greater than 10% of pretreatment weight. • Reports decreasing anorexia and increased interest in eating. • Demonstrates normal skin turgor. • Identifies rationale for dietary modifications. Patient and family verbalize strategies to address minimize nutritional deficits. • Participates in calorie counts and diet histories. • Uses appropriate relaxation and imagery before meals. • Exhibits laboratory and clinical findings indicative of adequate nutritional intake: normal serum protein and transferrin levels; normal serum iron levels; normal hemoglobin, hematocrit, and lymphocyte levels; normal urinary creatinine levels. • Consumes diet high in required nutrients. • Carries out oral hygiene before meals. • Reports that pain does not interfere with meals. • Reports decreasing episodes of nausea and vomiting. • Participates in increasing levels of activity. • States rationale for use of tube feedings or parenteral nutrition. • Participates in management of tube feedings or parenteral nutrition, if prescribed.

Continued

CHART
16-7
PLAN OF NURSING CARE
The Patient With Cancer (Continued)
Nursing Interventions

17. Administer appetite stimulants as prescribed by physician.
18. Encourage family and friends not to nag or cajole patient about eating.
19. Assess and address other contributing factors to nausea, vomiting, and anorexia such as other symptoms, constipation, GI irritation, electrolyte imbalance, radiation therapy, medications, and central nervous system metastasis.

Rationale

17. Although the mechanism is unclear, medications such as megestrol acetate (Megace) have been noted to improve appetite in patients with cancer and human immunodeficiency virus (HIV) infection.
18. Pressuring patient to eat may cause conflict and unnecessary stress.
19. Multiple factors contribute to anorexia and nausea.

Expected Outcomes**NURSING DIAGNOSIS:** Fatigue**GOAL:** Increased activity tolerance and decreased fatigue level**Nursing Interventions**

1. Encourage rest periods during the day, especially before and after physical exertion.
2. At minimum, promote patient's normal sleep habits.
3. Rearrange daily schedule and organize activities to conserve energy expenditure.
4. Encourage patient to ask for others' assistance with necessary chores, such as housework, child care, shopping, cooking.
5. Encourage reduced job workload, if necessary and possible, by reducing number of hours worked per week.
6. Encourage adequate protein and calorie intake.
7. Encourage use of relaxation techniques, mental imagery.
8. Encourage participation in planned exercise programs.
9. For collaborative management, administer blood products as prescribed.
10. Assess for fluid and electrolyte disturbances.
11. Assess for sources of discomfort.
12. Provide strategies to facilitate mobility.

Rationale

1. During rest, energy is conserved and levels are replenished. Several shorter rest periods may be more beneficial than one longer rest period.
2. Sleep helps to restore energy levels. Prolonged napping during day may interfere with sleep habits.
3. Reorganization of activities can reduce energy losses and stressors.
4. Conserves energy.
5. Reducing workload decreases physical and psychological stress and increases periods of rest and relaxation.
6. Protein and calorie depletion decreases activity tolerance.
7. Promotion of relaxation and psychological rest decreases physical fatigue.
8. Proper exercise programs increase endurance and stamina and lower fatigue.
9. Lowered hemoglobin and hematocrit predispose patient to fatigue due to decreased oxygen availability.
10. May contribute to altered nerve transmission and muscle function.
11. Coping with discomfort requires energy expenditure.
12. Impaired mobility requires increased energy expenditure.

Expected Outcomes

- Reports decreasing levels of fatigue.
- Increases participation in activities gradually.
- Rests when fatigued.
- Reports restful sleep.
- Requests assistance with activities appropriately.
- Reports adequate energy to participate in activities important to him or her (eg, visiting with family, hobbies).
- Consumes diet with recommended protein and caloric intake.
- Uses relaxation exercises and imagery to decrease anxiety and promote rest.
- Participates in planned exercise program gradually.
- Reports no breathlessness during activities.
- Exhibits acceptable hemoglobin and hematocrit levels.
- Exhibits normal fluid and electrolyte balance.
- Reports decreased discomfort.
- Exhibits improved mobility.

Continued on following page

 CHART
16-7

PLAN OF NURSING CARE
The Patient With Cancer (Continued)
NURSING DIAGNOSIS: Chronic pain**GOAL:** Relief of pain and discomfort**Nursing Interventions**

1. Use pain scale to assess pain and discomfort characteristics: location, quality, frequency, duration, etc.
2. Assure patient that you know that pain is real and will assist him or her in reducing it.
3. Assess other factors contributing to patient's pain: fear, fatigue, anger, etc.
4. Administer analgesics to promote optimum pain relief within limits of physician's prescription.
5. Assess patient's behavioral responses to pain and pain experience.
6. Collaborate with patient, physician, and other health care team members when changes in pain management are necessary.
7. Encourage strategies of pain relief that patient has used successfully in previous pain experience.
8. Teach patient new strategies to relieve pain and discomfort: distraction, imagery, relaxation, cutaneous stimulation, etc.

Rationale

1. Provides baseline for assessing changes in pain level and evaluation of interventions.
2. Fear that pain will not be considered real increases anxiety and reduces pain tolerance.
3. Provides data about factors that decrease patient's ability to tolerate pain and increase pain level.
4. Analgesics tend to be more effective when administered early in pain cycle.
5. Provides additional information about patient's pain.
6. New methods of administering analgesia must be acceptable to patient, physician, and health care team to be effective; patient's participation decreases the sense of powerlessness.
7. Encourages success of pain relief strategies accepted by patient and family.
8. Increases number of options and strategies available to patient.

Expected Outcomes

- Reports decreased level of pain and discomfort on pain scale.
- Reports less disruption from pain and discomfort.
- Explains how fatigue, fear, anger, etc., contribute to severity of pain and discomfort.
- Accepts analgesia as prescribed.
- Exhibits decreased physical and behavioral signs of pain and discomfort in acute pain (no grimacing, crying, moaning; displays interest in surroundings and activities around him).
- Takes an active role in administration of analgesia.
- Identifies additional effective pain relief strategies.
- Uses alternative pain relief strategies appropriately.
- Reports effective use of new pain relief strategies and decrease in pain intensity.
- Reports that decreased level of pain permits participation in other activities and events.

NURSING DIAGNOSIS: Anticipatory grieving related to loss; altered role functioning**GOAL:** Appropriate progression through grieving process**Nursing Interventions**

1. Encourage verbalization of fears, concerns, and questions regarding disease, treatment, and future implications.
2. Explore previous successful coping strategies.
3. Encourage active participation of patient or family in care and treatment decisions.
4. Visit family frequently to establish and maintain relationships and physical closeness.
5. Encourage ventilation of negative feelings, including projected anger and hostility, within acceptable limits.
6. Allow for periods of crying and expression of sadness.
7. Involve spiritual advisor as desired by the patient and family.
8. Advise professional counseling as indicated for patient or family to alleviate pathologic grieving.
9. Allow for progression through the grieving process at the individual pace of the patient and family.

Rationale

1. An increased and accurate knowledge base decreases anxiety and dispels misconceptions.
2. Provides frame of reference and examples of coping.
3. Active participation maintains patient independence and control.
4. Frequent contacts promote trust and security and reduce feelings of fear and isolation.
5. This allows for emotional expression without loss of self-esteem.
6. These feelings are necessary for separation and detachment to occur.
7. This facilitates the grief process and spiritual care.
8. This facilitates the grief process.
9. Grief work is variable. Not every person uses every phase of the grief process, and the time spent in dealing with each phase varies with every person. To complete grief work, this variability must be allowed.

Expected Outcomes

- The patient and family progress through the phases of grief as evidenced by increased verbalization and expression of grief.
- The patient and family identify resources available to aid coping strategies during grieving.
- The patient and family use resources and supports appropriately.
- The patient and family discuss the future openly with each other.
- The patient and family discuss concerns and feelings openly with each other.
- The patient and family use nonverbal expressions of concern for each other.

Continued

CHART
16-7
PLAN OF NURSING CARE
The Patient With Cancer (Continued)

NURSING DIAGNOSIS: Disturbed body image and situational low self-esteem related to changes in appearance, function, and roles
GOAL: Improved body image and self-esteem

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess patient's feelings about body image and level of self-esteem. 2. Identify potential threats to patient's self-esteem (eg, altered appearance, decreased sexual function, hair loss, decreased energy, role changes). Validate concerns with patient. 3. Encourage continued participation in activities and decision making. 4. Encourage patient to verbalize concerns. 5. Individualize care for the patient. 6. Assist patient in self-care when fatigue, lethargy, nausea, vomiting, and other symptoms prevent independence. 7. Assist patient in selecting and using cosmetics, scarves, hair pieces, and clothing that increase his or her sense of attractiveness. 8. Encourage patient and partner to share concerns about altered sexuality and sexual function and to explore alternatives to their usual sexual expression. 9. Refer to collaborating specialists as needed. 	<ol style="list-style-type: none"> 1. Provides baseline assessment for evaluating changes and assessing effectiveness of interventions. 2. Anticipates changes and permits patient to identify importance of these areas to him or her. 3. Encourages and permits continued control of events and self. 4. Identifying concerns is an important step in coping with them. 5. Prevents or reduces depersonalization and emphasizes patient's self-worth. 6. Physical well-being improves self-esteem. 7. Promotes positive body image. 8. Provides opportunity for expressing concern, affection, and acceptance. 9. Interdisciplinary collaboration essential in meeting patient needs. 	<ul style="list-style-type: none"> • Identifies concerns of importance. • Takes active role in activities. • Maintains previous role in decision making. • Verbalizes feelings and reactions to losses or threatened losses. • Participates in self-care activities. • Permits others to assist in care when he or she is unable to be independent. • Exhibits interest in appearance and uses aids (cosmetics, scarves, etc.) appropriately. • Participates with others in conversations and social events and activities. • Verbalizes concern about sexual partner and/or significant others. • Explores alternative ways of expressing concern and affection.

COLLABORATIVE PROBLEM: Potential complication: risk for bleeding problems
GOAL: Prevention of bleeding

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess for potential for bleeding: monitor platelet count. 2. Assess for bleeding: <ol style="list-style-type: none"> a. Petechiae or ecchymosis b. Decrease in hemoglobin or hematocrit c. Prolonged bleeding from invasive procedures, venipunctures, minor cuts or scratches d. Frank or occult blood in any body excretion, emesis, sputum e. Bleeding from any body orifice f. Altered mental status 	<ol style="list-style-type: none"> 1. Mild risk: 50,000–100,000/mm³ (0.05–0.1 × 10¹²/L) Moderate risk: 20,000–50,000/mm³ (0.02–0.05 × 10¹²/L) Severe risk: less than 20,000/mm³ (0.02 × 10¹²/L) 2. Early detection promotes early intervention. <ol style="list-style-type: none"> a. Indicates injury to microcirculation and larger vessels. b–e. Indicates blood loss. f. Indicates neurologic involvement. 	<ul style="list-style-type: none"> • Signs and symptoms of bleeding are identified. • Exhibits no blood in feces, urine, or emesis. • Exhibits no bleeding of gums or of injection or venipuncture sites. • Exhibits no ecchymosis (bruising). • Patient and family identify ways to prevent bleeding. • Uses recommended measures to reduce risk of bleeding (uses soft toothbrush, shaves with electric razor only). • Exhibits normal vital signs. • Reports that environmental hazards have been reduced or removed. • Consumes adequate fluid. • Reports absence of constipation. • Avoids substances interfering with clotting. • Absence of tissue destruction.

Continued on following page

 CHART
16-7

PLAN OF NURSING CARE
The Patient With Cancer (Continued)
Nursing Interventions

3. Instruct patient and family about ways to minimize bleeding:
 - a. Use soft toothbrush or toothette for mouth care.
 - b. Avoid commercial mouthwashes.
 - c. Use electric razor for shaving.
 - d. Use emery board for nail care.
 - e. Avoid foods that are difficult to chew.
4. Initiate measures to minimize bleeding.
 - a. Draw all blood for lab work with one daily venipuncture.
 - b. Avoid taking temperature rectally or administering suppositories and enemas.
 - c. Avoid intramuscular injections; use smallest needle possible.
 - d. Apply direct pressure to injection and venipuncture sites for at least 5 minutes.
 - e. Lubricate lips with petrolatum.
 - f. Avoid bladder catheterizations; use smallest catheter if catheterization is necessary.
 - g. Maintain fluid intake of at least 3 L per 24 hours unless contraindicated.
 - h. Use stool softeners or increase bulk in diet.
 - i. Avoid medications that will interfere with clotting (eg, aspirin).
 - j. Recommend use of water-based lubricant before sexual intercourse.
5. When platelet count is less than 20,000/mm³, institute the following:
 - a. Bed rest with padded side rails.
 - b. Avoidance of strenuous activity.
 - c. Platelet transfusions as prescribed; administer prescribed diphenhydramine hydrochloride (Benadryl) or hydrocortisone sodium succinate (Solu-Cortef) to prevent reaction to platelet transfusion.
 - d. Supervise activity when out of bed.
 - e. Caution against forceful nose blowing.

Rationale

3. Patient can participate in self-protection.
 - a. Prevents trauma to oral tissues.
 - b. Contain high alcohol content that will dry oral tissues.
 - c. Prevents trauma to skin.
 - d. Reduces risk of trauma to nailbeds.
 - e. Prevents oral tissue trauma.
4. Preserves circulating blood volume.
 - a. Minimizes trauma and blood loss.
 - b. Prevents trauma to rectal mucosa.
 - c. Prevents intramuscular bleeding.
 - d. Minimizes blood loss.
 - e. Prevents skin from drying.
 - f. Prevents trauma to urethra.
 - g. Hydration helps to prevent skin drying.
 - h. Prevents constipation and straining that may injure rectal tissue.
 - i. Minimizes risk of bleeding.
 - j. Prevents friction and tissue trauma.
5. Platelet count of less than 20,000/mm³ ($0.02 \times 10^{12}/L$) is associated with increased risk of spontaneous bleeding.
 - a. Reduces risk of injury.
 - b. Increases intracranial pressure and risk of cerebral hemorrhage.
 - c. Allergic reactions to blood products are associated with antigen-antibody reaction that causes platelet destruction.
 - d. Reduces risk of falls.
 - e. Prevents trauma to nasal mucosa and increased intracranial pressure.

Expected Outcomes

- Exhibits normal mental status and absence of signs of intracranial bleeding.
- Avoids medications that interfere with clotting (eg, aspirin).
- Absence of epistaxis and cerebral bleeding.

to 14 days after patients receive certain chemotherapeutic agents, such as doxorubicin and 5-fluorouracil, and BRMs, such as IL-2 and IFN. As many as 40% of patients receiving chemotherapy experience some degree of stomatitis during treatment. Patients receiving high-dose chemotherapy, such as those patients undergoing stem cell transplant, are at increased risk. Stomatitis may also occur after radiation treatments to the head and neck. Oropharyngeal mucositis may be worse in patients with head and neck cancers who receive combined modality therapy of both radiation and chemotherapy (Cady, 2007).

As a result of normal everyday wear and tear, the epithelial cells that line the oral cavity undergo rapid turnover and slough off routinely. Both chemotherapy and radiation lead to the destruction of cells in the oral cavity (Sonis, 2004). This initiates the inflammatory process, leading to further tissue damage and ulceration of oral tissues. Normal flora invade the ulcerations and cause additional damage. Poor oral hygiene, existing dental disease, use of other medications that dry mucous membranes, advanced age, smoking, previous cancer treatment, diminished renal function, and impaired nutritional status further contribute to the severity of stomatitis. Radiation-induced xerostomia (dry mouth) associated with decreased function of the salivary glands may contribute to stomatitis in patients who have received radiation to the head and neck.

Myelosuppression (bone marrow depression), resulting from underlying disease or its treatment, predisposes the patient to oral bleeding and infection. Severe oral pain can significantly affect swallowing, nutritional intake, speech, and a willingness to maintain oral hygiene. As a result of the ability to give higher doses of chemotherapy due to improvements in managing neutropenia with growth factors, stomatitis is a common reason for treatment delays and dose reductions (Cawley & Benson, 2005). Advanced stomatitis may cause or prolong hospitalizations, significantly reduce the patient's quality of life, and ultimately lead to poor patient outcomes (Eilers & Million, 2007).

There is no standard of practice for the assessment of stomatitis. It is important for nurses to assess the oropharyngeal cavity of patients prior to, throughout the course of, and after treatment. It is important that the same tool or method of assessment is used by all clinicians involved in the patient's care. Nursing assessment begins with understanding the patient's usual practices for oral hygiene and identification of individuals at risk for stomatitis. Assessment of the patient's subjective experience and an objective assessment of the oropharyngeal tissues and teeth are important. The patient is also assessed for dehydration, infection, pain, and nutritional impairment resulting from stomatitis.

Optimal, evidence-based prevention and treatment approaches have not yet been identified (Eilers & Million, 2007). Ongoing studies are addressing the inflammation and release of chemical substances that lead to stomatitis. At this time, most clinicians agree that good oral hygiene, including brushing, flossing, and rinsing, is necessary to minimize the risk of oral complications associated with cancer therapies.

Palifermin (Kepivance), a synthetic form of human keratinocyte growth factor, is an IV medication approved by

the FDA for treatment of oral mucositis in patients with hematologic cancer who are undergoing chemotherapy and radiation prior to hematopoietic stem cell support. Palifermin promotes epithelial cell repair and more rapid replacement of cells in the mouth and gastrointestinal tract (Oncology Nursing Society, 2006). It is not yet been approved for use in patients with other types of cancer. Careful timing of administration and monitoring are essential for maximum effectiveness and to detect adverse effects.

Radiation Associated Skin Impairment

Although advances in radiation therapy have resulted in decreased incidence and severity of skin impairments, patients may still develop skin reactions that lead to pain, irritation, pruritis, burning, and diminished quality of life. Nursing care for patients with skin reactions includes maintaining skin integrity, cleansing the skin, promoting comfort, reducing pain, preventing additional trauma, and preventing and managing infection (McQuestion, 2006). Although a variety of methods and products are used in clinical practice for patients with radiation-induced skin reactions, there is limited evidence to support their value. Patients with skin and tissue reactions to radiation therapy require careful skin care to prevent further skin irritation, drying, and damage, as discussed in the nursing care plan (see Chart 16-7), under Impaired skin integrity: erythematous and wet desquamation reactions to radiation therapy.

Alopecia

The temporary or permanent thinning or complete loss of hair is a potential adverse effect of radiation therapy to the brain and various chemotherapeutic agents. Alopecia usually begins 2 to 3 weeks after the initiation of treatment; regrowth usually begins within 8 weeks after the last treatment. Some patients who undergo radiation to the head may sustain permanent hair loss. Although health care providers may view hair loss as a minor issue, for many patients it is a major assault on body image, resulting in challenges to self-esteem, depression, anxiety, anger, rejection, and isolation. In some cases, patients may initially refuse treatment due to fears regarding hair loss (Nolte, Donnelly, Kelly, et al., 2006). To patients and families, hair loss can serve as a constant reminder of the challenges cancer places on their coping abilities, interpersonal relationships, and sexuality.

Although few studies have addressed methods to minimize the impact of alopecia, nurses provide information about hair loss and support the patient and family in coping with changes in body image, as discussed in the nursing care plan (see Chart 16-7) under Impaired tissue integrity: alopecia.

Malignant Skin Lesions

Skin lesions may occur with local extension or metastasis of the tumor into the epithelium and its surrounding lymph and blood vessels. Either locally invasive or metastatic cancer to the skin may result in redness (erythema), discolored nodules, or progression to wounds involving edema, exudates, and tissue necrosis. The most extensive lesions may ulcerate with an overgrowth of micro-organisms that result in a very distressing malodor. These lesions are a source of considerable pain, discomfort, and embarrassment.

Ulcerating skin lesions usually indicate widely disseminated disease that is unlikely to be eradicated. Managing these lesions becomes a nursing priority. Nurses carefully assess malignant skin lesions for the size, appearance, condition of the surrounding tissue, odor, bleeding, drainage, and associated pain or other symptoms including evidence of infection. The potential for serious complications such as hemorrhage, vessel compression/obstruction, or airway obstruction should be noted so that the caregiver can be instructed in palliative measures to maintain patient comfort (Seaman, 2006). Since this type of lesion is associated with advanced disease, the nurse assesses the wound for progression over time.

Nursing care also includes cleansing the skin, reducing superficial bacteria, controlling bleeding, reducing odor, protecting the skin from further trauma, and relieving pain. The patient and family require emotional support, assistance, and guidance to care for these skin lesions and to address comfort measures at home. Referral for home care is indicated.

Promoting Nutrition

Nutritional Problems

Most patients with cancer experience some weight loss during their illness. Anorexia, malabsorption, and cachexia are common examples of nutritional problems. Impaired nutritional status may contribute to both physical and psychosocial consequences (Chart 16-8). Nutritional concerns include decreased protein and caloric intake, metabolic or mechanical effects of the cancer, systemic disease, side effects of the treatment, or the patient's emotional status.

Anorexia

Among the many causes of anorexia in patients with cancer are alterations in taste, manifested by increased salty, sour, and metallic taste sensations, and altered responses to sweet and bitter flavors. Taste changes contribute to decreased appetite and nutritional intake and protein-calorie malnutrition. Taste alterations may result from mineral (eg, zinc) deficiencies, increases in circulating amino acids and cellular metabolites, or the administration of chemotherapeutic agents. Patients undergoing radiation therapy to the head and neck may experience "mouth blindness," which is a severe impairment of taste.

Anorexia may occur because people feel full after eating only a small amount of food. This sense of fullness occurs secondary to a decrease in digestive enzymes, abnormalities in the metabolism of glucose and triglycerides, and prolonged stimulation of gastric volume receptors, which convey the feeling of being full. Psychological distress (eg, fear, pain, depression, and isolation) throughout illness may also have a negative impact on appetite. Patients may develop an aversion to food because of nausea and vomiting associated with treatment.

Malabsorption

Many patients with cancer are unable to absorb nutrients from the gastrointestinal system as a result of tumor activity and cancer treatment. Tumors can affect the gastrointestinal activity in several ways. They may impair enzyme production or produce fistulas. Some tumors secrete hormones and enzymes, such as gastrin, that lead to increased gastrointestinal irritation, peptic ulcer disease, and decreased fat digestion. Tumors may interfere with protein digestion.

Chemotherapy and radiation may irritate and damage mucosal cells of the bowel, inhibiting absorption. Radiation therapy has been associated with sclerosis of the blood vessels in the bowel and fibrotic changes in the gastrointestinal tissue. Surgical intervention may change peristaltic patterns, alter gastrointestinal secretions, and reduce the absorptive surfaces of the gastrointestinal mucosa, all leading to malabsorption.

Cachexia

Cachexia is common in patients with cancer, especially in advanced disease. Cancer cachexia is related to inadequate nutritional intake, along with increasing metabolic demand, increased energy expenditure due to anaerobic metabolism of the tumor, impaired glucose metabolism, competition of the tumor cells for nutrients, altered lipid metabolism, and a suppressed appetite. In addition, current literature suggests that cachexia in cancer may be related to a cytokine-induced inflammatory response (Tchekmedyan, 2006). Cachexia is characterized by loss of body weight, adipose tissue, visceral protein, and skeletal muscle. Patients with cachexia complain of loss of appetite, early satiety, and fatigue. As a result of protein losses, patients develop anemia and peripheral edema.

Nurses assess patients who are at risk of altered nutritional intake so that appropriate measures may be instituted prior to nutritional decline (Cady, 2007).

General Nutritional Considerations

Assessment of the patient's nutritional status is conducted at diagnosis and throughout the course of treatment and the disease process. The patient's weight and caloric intake are monitored closely. Diet history, episodes of anorexia, changes in appetite, situations and foods that aggravate or relieve anorexia, and medication history are assessed. Difficulty in chewing or swallowing and the presence of nausea, vomiting, or diarrhea are noted.

Clinical and laboratory data useful in assessing nutritional status include anthropometric measurements (triceps skin fold and middle-upper arm circumference), serum protein levels (albumin and transferrin), serum electrolytes,

Chart 16-8 • Potential Consequences of Impaired Nutrition in Patients With Cancer

- Decreased survival
- Immune incompetence
- Anemia
- Increased incidence of infection
- Delayed tissue and wound healing
- Fatigue
- Diminished functional ability
- Decreased capacity to continue antineoplastic therapy
- Increased hospital admissions
- Increased length of hospital stay
- Impaired psychosocial functioning

lymphocyte count, skin response to intradermal injection of antigens, hemoglobin levels, hematocrit, urinary creatinine levels, and serum iron levels. Whenever possible, every effort is made to maintain adequate nutrition through the oral route. Prokinetic agents such as metoclopramide are used in some settings to increase gastric emptying in patients with early satiety and delayed gastric emptying.

If adequate nutrition cannot be maintained by oral intake, nutritional support via the enteral route may be necessary. Patients with head and neck cancers who receive radiation therapy or some combination of surgery, radiation, and chemotherapy are at particularly high risk for impaired oral intake and inadequate fluid and nutritional status. Increasingly, patients at risk for significantly impaired nutrition have prophylactic percutaneous endoscopic gastrostomy (PEG) tubes inserted prior to initiation of antineoplastic treatment and the onset of weight loss and other consequences of limited oral intake (Cady, 2007). When needed, the patient and family are taught to administer enteral nutrition in the home.

If malabsorption is a problem, enzyme and vitamin replacement may be instituted. Additional strategies include changing the feeding schedule, using simple diets, and relieving diarrhea. If malabsorption is severe, parenteral nutrition may be necessary. However, patients with advanced end-stage cancer, who have a life expectancy of less than 3 months, are usually not considered to be candidates for parenteral nutrition (Mirhosseini, Fainsinger & Baracos, 2005). Parenteral nutrition can be administered in several ways: by a long-term venous access device (eg, right atrial catheter), by an implanted venous port, or by a PICC (Fig. 16-6). The nurse teaches the patient and family to care for the venous access device and to administer parenteral nutrition. Home care nurses may assist with or supervise parenteral nutrition administration in the home.

Interventions to reduce cachexia usually do not prolong survival or improve nutritional status significantly. Before invasive nutritional strategies are instituted, the nurse should assess the patient carefully and discuss options with the patient and family. Creative dietary therapies, enteral (tube) feedings, or parenteral nutrition may be necessary to ensure adequate nutrition. Care is also directed toward preventing trauma, infection, and other complications that increase metabolic demands.

Relieving Pain

It is estimated that 90% to 95% of patients with progressive cancer experience pain (Stoneberg & von Gunten, 2006). Although the pain may be acute, it is more frequently char-

Figure 16-6 A peripherally inserted central catheter (PICC) is advanced through the cephalic or basilic vein to the axillary, subclavian, or brachiocephalic vein or the superior vena cava.

acterized as chronic. (For more information on cancer-related pain, see Chapter 13.) As in other situations involving pain, the experience of cancer pain is influenced by physical, psychosocial, cultural, and spiritual factors.

Cancer can cause pain in various ways (Table 16-7). Pain related to the underlying cancer process accounts for the pain experienced by 75% of all patients with cancer (Abrahm, 2005). Pain is also associated with various cancer treatments. Acute pain is linked with trauma from surgery. Occasionally, chronic pain syndromes, such as postsurgical neuropathies (pain related to nerve tissue injury), occur. Some chemotherapeutic agents cause tissue necrosis, peripheral neuropathies, and stomatitis—all potential sources of pain—whereas radiation therapy can cause pain secondary to skin or organ inflammation. Cancer patients may have other sources of pain, such as arthritis or migraine headaches, that are unrelated to the underlying cancer or its treatment.

The nurse assesses the patient for the source and site of pain as well as those factors that increase the patient's perception of pain, such as fear and apprehension, fatigue, anger, and social isolation. Pain assessment scales (see Chapter 13) are useful for assessing the patient's pain before pain-relieving interventions are instituted and for evaluating the effectiveness of these interventions. Other symptoms that contribute to the pain experience, such as nausea and fatigue, are assessed as well.

Table 16-7 EXAMPLES OF SOURCES OF CANCER PAIN

Source	Descriptions	Underlying Cancer
Bone metastasis	Throbbing, aching	Breast, prostate, myeloma
Nerve compression, infiltration	Burning, sharp, tingling	Breast, prostate, lymphoma
Lymphatic or venous obstruction	Dull, aching, tightness	Lymphoma, breast, Kaposi's sarcoma
Ischemia	Sharp, throbbing	Kaposi's sarcoma
Organ obstruction	Dull, crampy, gnawing	Colon, gastric
Organ infiltration	Distention, crampy	Liver, pancreatic
Skin inflammation, ulceration, infection, necrosis	Burning, sharp	Breast, head and neck, Kaposi's sarcoma

In today's society, most people expect pain to disappear or resolve quickly, and in fact it usually does. Although it is often controllable, advanced cancer pain is commonly irreversible and not quickly resolved. For many patients, pain is often seen as a signal that the tumor is growing and that death is approaching. As patients anticipate the pain and their anxiety increases, pain perception heightens, producing fear and further pain. Chronic cancer pain, then, can lead to a cycle progressing from pain to anxiety to fear and back to pain, especially when the pain is not adequately managed. Inadequate pain management is most often the result of misconceptions and insufficient knowledge about pain assessment and pharmacologic interventions on the part of patients, families, and health care providers (Xue, Schulman-Green, Czaplinski, et al., 2007). Chapter 13 provides information concerning factors contributing to the pain experience, pain perception, and tolerance as well as pharmacologic and nonpharmacologic nursing interventions addressing pain. The nursing care plan (see Chart 16-7) also provides strategies for nursing assessment and management.

Inadequate pain management is most often the result of misconceptions and insufficient knowledge about pain assessment and pharmacologic interventions on the part of patients, families, and health care providers (Xue, et al., 2007).

The World Health Organization advocates a three-step approach to treat cancer pain (Fig. 16-7). Analgesics are administered based on the patient's level of pain. A cancer pain algorithm, developed as a set of analgesic guiding principles, is given in Figure 16-8.

No reasonable pharmacologic and nonpharmacologic approaches, even those that may be invasive, should be overlooked because of a poor or terminal prognosis. The nurse helps the patient and family take an active role in managing pain. The nurse provides education and support to correct

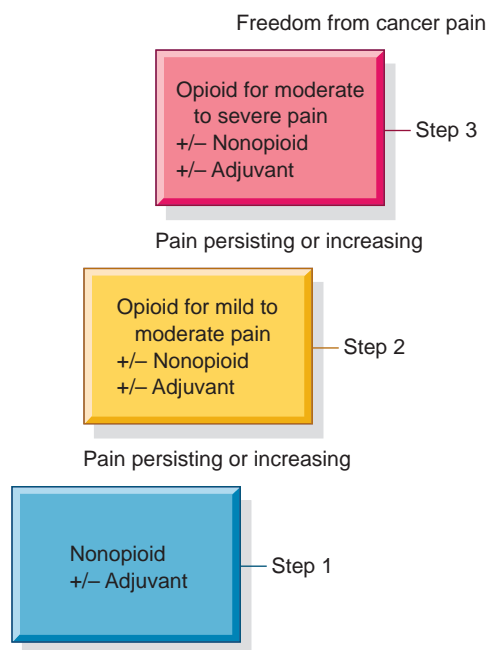

Figure 16-7 Adapted from the World Health Organization three-step ladder approach to relieving cancer pain. Various opioid (narcotic) and nonopioid medications may be combined with other medications to control pain.

fears and misconceptions about opioid use. Inadequate pain control leads to a diminished quality of life characterized by suffering, anxiety, fear, immobility, isolation, and depression. Improving the patient's quality of life through palliative care is as important as preventing a painful death.

Decreasing Fatigue

Fatigue is one of the most significant and frequent symptoms experienced by patients receiving cancer therapy. Fatigue also results from the stress of coping with cancer. It does not always signify that the cancer is advancing or that the treatment is failing. Potential factors contributing to the experience of fatigue are summarized in Chart 16-9.

In assessing fatigue the nurse distinguishes between acute fatigue, which occurs after an energy-demanding experience, and cancer-related fatigue, which is defined as "a distressing persistent, subjective sense of tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning" (National Comprehensive Cancer Network, 2006b). Acute fatigue serves a protective function, whereas cancer-related fatigue does not.

Fatigue is distressing for patients with cancer who are receiving treatment, for survivors, and for those in the late stages of disease (Mitchell, et al., 2007). Although patients may describe fatigue in a variety of ways, nurses assess for feelings of weariness, weakness, lack of energy, inability to carry out necessary and valued daily functions, lack of motivation, and inability to concentrate. Several assessment tools, such as a simple visual analogue scale, may be used to assess levels of fatigue (Madden & Newton, 2006). The nurse assesses physiologic and psychological stressors that can contribute to fatigue, including anemia, electrolyte imbalances, organ dysfunction, pain, nausea, dyspnea, constipation, fear, and anxiety.

The role of exercise as a helpful intervention has been supported by several controlled trials (Mitchell, et al., 2007; Young-McCaughan & Arzola, 2007). The nurse assists patients with additional nonpharmacologic strategies to minimize fatigue or help the patient cope with existing fatigue as described in the nursing care plan (see Chart 16-7) under Fatigue. Occasionally pharmacologic interventions are utilized, including antidepressants for patients with depression; anxiolytics for those with anxiety; hypnotics for patients with sleep disturbances; and psychostimulants for some patients with advanced cancer or fatigue that does not respond to other interventions (Abraham, 2005).

The nurse assists patients with nonpharmacologic strategies to minimize fatigue or help the patient cope with existing fatigue.

Improving Body Image and Self-Esteem

The nurse identifies potential threats to the patient's body image and assesses the patient's ability to cope with the many assaults to body image experienced throughout the course of disease and treatment. Entry into the health care system is often accompanied by depersonalization. Threats to self-concept occur as the patient faces the realization of illness, disfigurement, possible disability, and death. To accommodate treatments or because of the disease, many patients with cancer are forced to alter their lifestyles. Priorities and values change when body image is threatened.

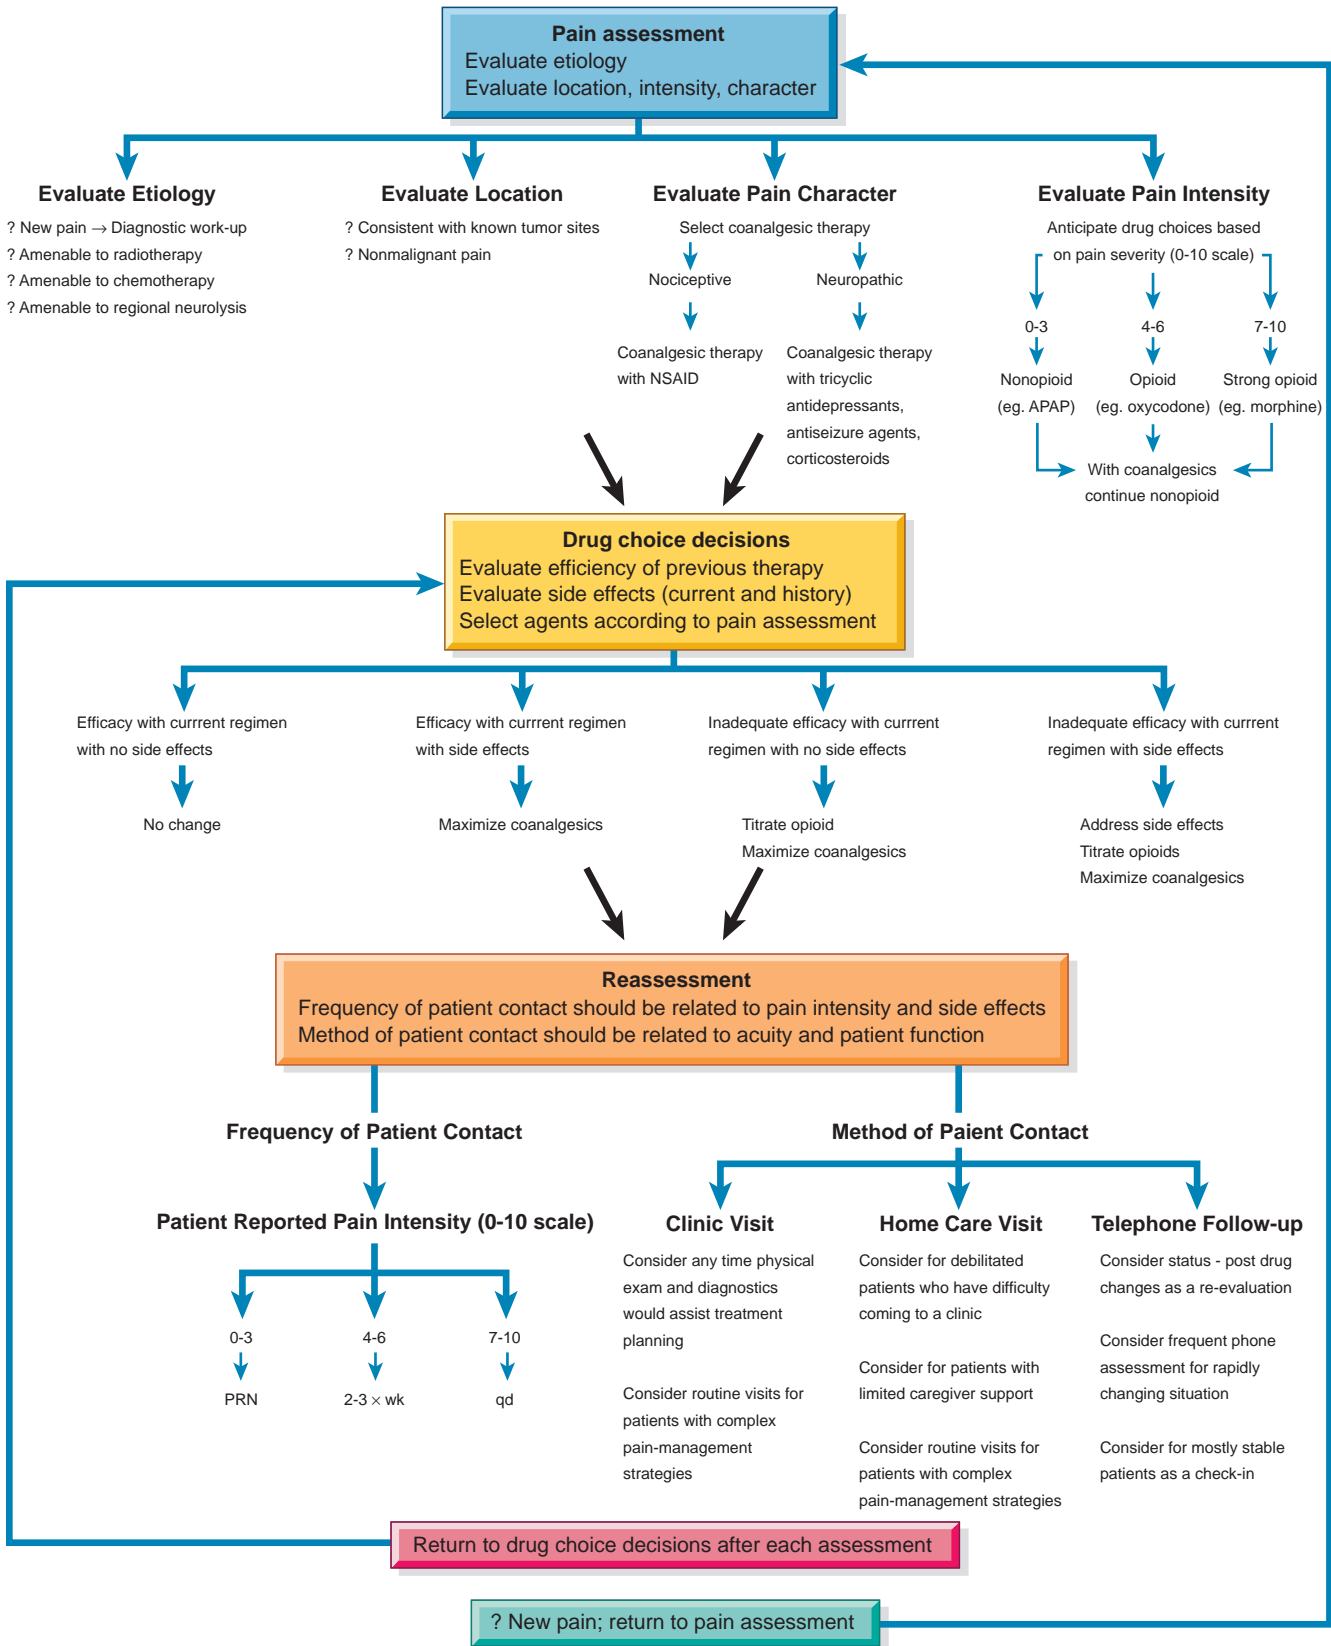

Figure 16-8 The cancer pain algorithm (highest-level view) is a decision-tree model for pain treatment that was developed as an interpretation of the AHCPR Guideline for Cancer Pain, 1994. Redrawn with permission from DuPen, A. R., DuPen, S., Hansberry, J., et al. (2000). An educational implementation of a cancer pain algorithm for ambulatory care. *Pain Management Nursing*, 1(4), 118.

Chart 16-9 • Sources of Fatigue in Cancer Patients

- Pain, pruritus
- Imbalanced nutrition related to anorexia, nausea, vomiting, cachexia
- Electrolyte imbalance related to vomiting, diarrhea
- Ineffective protection related to neutropenia, thrombocytopenia, anemia
- Impaired tissue integrity related to stomatitis, mucositis
- Impaired physical mobility related to neurologic impairments, surgery, bone metastasis, pain, and analgesic use
- Uncertainty and deficient knowledge related to disease process, treatment
- Anxiety related to fear, diagnosis, role changes, uncertainty of future
- Ineffective breathing patterns related to cough, shortness of breath, and dyspnea
- Disturbed sleep pattern related to cancer therapies, anxiety, and pain

Disfiguring surgery, hair loss, cachexia, skin changes, altered communication patterns, and sexual dysfunction treatment can threaten the patient's self-esteem and body image.

A creative and positive approach is essential when caring for patients with altered body image. Nursing approaches for addressing issues related to body image and self-esteem are and approaches for addressing issues related to body image and self-esteem are also included in the nursing care plan (see Chart 16-7). The nurse serves as a listener and counselor to both the patient and the family. Possible influences of the patient's culture and age are considered when discussing concerns and potential interventions (Romanek, McCaul & Sandgren, 2006).

As a result of the underlying cancer, treatments, and psychosocial responses to the experience, patients may experience a variety of sexuality-based issues. Patients who experience alterations in sexuality and sexual function are encouraged to discuss their concerns. Major barriers to addressing sexual dysfunction in patients with cancer include the lack of assessment tools and evidence-based interventions (Bakewell & Volker, 2005). In addition, nurses and other health care providers often fail to ask patients about sexual concerns, and patients may be hesitant to discuss them. However, standards of oncology nursing practice include the need for nurses to assess patients' sexuality and to help patients and their partners achieve the outcomes of importance to them (Wilmoth, 2006). Nurses who identify physiologic, psychological, or communication difficulties related to sexuality or sexual function are in a key position to help patients seek further specialized evaluation and intervention if necessary.

Assisting in the Grieving Process

Nurses assess the patient's psychological and mental status as the patient and family face this life-threatening experience, unpleasant diagnostic tests and treatment modalities, and progression of disease. The nurse assesses the patient's mood and emotional reaction to the results of diagnostic testing and prognosis and looks for evidence that the patient is progressing through the stages of grief and can talk about the diagnosis and prognosis with family members.

A cancer diagnosis need not indicate a fatal outcome. Many forms of cancer are curable, while others may be cured or controlled for long periods of time if treated early. Despite these facts, many patients and their families view cancer as a fatal disease that is inevitably accompanied by pain, suffering, debilitation, and emaciation. Grieving is a normal response to these fears and to actual or potential losses: loss of health, normal sensations, body image, social interaction, sexuality, and intimacy. Patients, families, and friends may grieve for the loss of quality time to spend with others, the loss of future and unfulfilled plans, and the loss of control over the patient's body and emotional reactions.

Patients and their families who have just been informed of a cancer diagnosis frequently respond with shock, numbness, and disbelief. It is often during this stage that the patient and family are called on to make important initial decisions about treatment. They require the support of physicians, nurses, and all members of the health care team to make these decisions. The nurse plays an important role in answering any questions the patient and family have and clarifying information provided by physicians. The plan of nursing care addresses anticipatory grieving and nursing strategies for promoting appropriate progression through the grieving process.

If the patient enters the terminal phase of disease, the nurse may realize that the patient and family members are at different stages of grief. In such cases, the nurse helps the patient and family to acknowledge and cope with their reactions and feelings. The nurse also helps the patient and family to explore preferences for issues related to end-of-life care, such as withdrawal of active disease treatment, desire for the use of life-support measures, and symptom management. Support, which can be as simple as holding a patient's hand or just being with a patient at home or at the bedside, often contributes to peace of mind. After the death of a patient with cancer, maintaining contact with surviving family members may help them work through their feelings of loss and grief. See Chapter 17 for further discussion of end-of-life issues.

Monitoring and Managing Potential Complications

Infection

For patients in all stages of cancer, the nurse assesses factors that can promote infection. Although the infection-associated mortality rate has decreased, infection remains a major cause of morbidity and mortality in patients with cancer (Zitella, Friese, Hauser, et al., 2006). Factors predisposing patients to infection are summarized in Table 16-8. Often, more than one predisposing factor is present in patients with cancer (Friese, 2007). The nurse monitors laboratory studies to detect early changes in WBC counts. Common sites of infection, such as the pharynx, skin, perianal area, urinary tract, and respiratory tract, are assessed on a regular basis. However, the typical signs of infection (swelling, redness, drainage, and pain) may not occur in immunosuppressed patients because of decreased circulating white blood cells (WBC) (the cause purulent drainage) and a diminished local inflammatory response. Fever may be the only sign of infection (Marrs, 2006). The nurse monitors the patient for sepsis, particularly if invasive catheters or infusion lines are in place.

Table 16-8 FACTORS PREDISPOSING CANCER PATIENTS TO INFECTION

Factors	Underlying Mechanisms
Impaired skin and mucous membrane integrity Chemotherapy	Loss of body's first line of defense against invading organisms. Chemotherapy agents that cause mucositis impair skin and mucous membrane integrity. Organ damage associated with certain agents may also predispose patients to infection. Organ damage such as pulmonary fibrosis or cardiomyopathy that is associated with certain agents may also predispose patients to infection.
Radiation therapy	Radiation involving sites of bone marrow production may result in bone marrow suppression. May also lead to impaired tissue integrity.
Biologic response modifiers Malignancy	Some biologic response modifiers may cause bone marrow suppression and organ dysfunction. Malignant cells may infiltrate the bone marrow and interfere with production of white blood cells and lymphocytes. Hematologic malignancies (leukemias and lymphomas) are associated with impaired function and production of blood cells.
Malnutrition	Malnutrition results in impaired production and function of cells of the immune response. It may contribute to impaired skin integrity.
Medications	Antibiotics disturb the balance of normal flora, allowing them to become pathogenic. This process occurs most commonly in the gastrointestinal tract. Corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs) mask inflammatory responses.
Urinary catheter Intravenous catheter Other invasive procedures (eg, surgery, paracentesis, thoracentesis, drainage tubes, endoscopy, mechanical ventilation)	The catheter creates a port and mechanism of entry for organisms. The catheter is a site of entry for organisms. These procedures create a port of entry and possible introduction of exogenous organisms into the system.
Contaminated equipment Age	Stagnant water in oxygen equipment is associated with growth of microorganisms. Increasing age is associated with declining organ function and decreased production and functioning of the cells of the immune system.
Chronic illness Prior infections	Chronic illness is associated with impaired organ function and altered immune responses. Recent infection may be associated with depleted immune responses and debilitation; prior infections may not have completely resolved; previous use of antibiotics may have altered normal flora allowing flora to become pathogenic.
Recent travel Pet excreta	Travel, especially to less developed areas, may have lead to exposure to microbial infection and disease. Exposure to pet excreta, especially in the immunocompromised patient, may be associated with infections such as <i>Toxoplasma gondii</i> (toxoplasmosis).
Prolonged hospitalization	Hospitalization allows increased exposure to nosocomial infection and colonization by new organisms.

WBC function is often impaired in patients with cancer. There are five types of WBCs: neutrophils (granulocytes), lymphocytes, monocytes, basophils, and eosinophils. Neutrophils, which comprise 60% to 70% of all the body's WBCs, serve as the body's primary defense against invading organisms by engulfing and destroying infective organisms through phagocytosis. Both the total WBC count and the concentration of neutrophils are important in determining the patient's ability to fight infection. A decrease in circulating WBCs is referred to as leukopenia. Granulocytopenia is a decrease in neutrophils.

A differential WBC count identifies the relative numbers of WBCs and permits tabulation of polymorphonuclear neutrophils or segmented neutrophils (mature neutrophils, reported as "polys," PMNs, or "segs") and immature forms of neutrophils (reported as bands, metamyelocytes, and "stabs"). The absolute neutrophil count (ANC) is calculated by the following formula:

$$\text{ANC} = \frac{(\text{Total WBC}) \times [\% \text{ segmented neutrophils} + \text{bands}]}{100}$$

For example, if the total WBC count is 6000 cells/mm³, with segmented neutrophils 25% and bands 25%, the ANC is 3000 cells/mm³.

Neutropenia, an abnormally low ANC, is associated with an increased risk for infection. The risk for infection

rises as the ANC decreases. As the ANC declines below 1500 cells/mm³, the risk for infection increases. An ANC less than 500 cells/mm³ reflects a severe risk of infection (Marrs, 2006). **Nadir** is the lowest ANC after myelosuppressive chemotherapy or radiation therapy that suppresses bone marrow function. Febrile patients who are neutropenic are assessed for factors that increase the risk for infection and for sources of infection through cultures of blood, sputum, urine, stool, IV or urinary catheters, and wounds, if appropriate. In addition, a chest x-ray is often obtained to assess for pulmonary infections.

Defense against infection is compromised in many different ways. The integrity of the skin and mucous membranes is challenged by multiple invasive diagnostic and therapeutic procedures, by adverse effects of radiation and chemotherapy, and by the detrimental effects of immobility.

Impaired nutrition as a result of anorexia, nausea, vomiting, diarrhea, and the underlying disease alters the body's ability to combat invading organisms. Medications such as antibiotics disturb the balance of normal flora, allowing the overgrowth of normal flora and pathogenic organisms. Other medications can also alter the immune response (see Chapter 50). Cancer itself may lead to defects in cellular and humoral immunity. Advanced cancer can cause obstruction of the hollow viscera (eg, intestines), blood vessels, and lymphatic vessels, creating a favorable environment for proliferation of pathogenic organisms. In some patients, tumor cells infiltrate bone marrow

and prevent normal production of WBCs. However, most often, a decrease in WBCs is a result of bone marrow suppression after chemotherapy or radiation therapy. Severe neutropenia may necessitate delays in administration of myelosuppressive therapies or treatment dose adjustments, although the use of the hematopoietic growth factors, also called colony-stimulating factors (see previous discussion), has reduced the severity and duration of neutropenia associated with myelosuppressive chemotherapy and radiation therapy. The administration of these factors assists in reducing the risk for infection and, possibly, in maintaining treatment schedules, drug dosages, treatment effectiveness, and quality of life.

Nurses are in a key position to assist in preventing and identifying symptoms of infection, as discussed in the nursing care plan (see Chart 16-7). Although multiple infection control practices are employed, there is a significant lack of evidence to support many of them (Zitella, et al., 2006). Clinical practice guidelines developed by the Oncology Nursing Society (ONS), the Infusion Nurses Society (INS), the National Comprehensive Cancer Network (NCCN), and the American Society of Clinical Oncology (ASCO) are used to guide interventions. Interventions to prevent infection and education formats to teach patients and families about infection are high research priorities.

Gram-positive bacteria (*Streptococcus*, enterococci, and *Staphylococcus* species) and gram-negative organisms (*Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*) are the most frequently isolated causes of infection. Fungal organisms, such as *Candida albicans*, also contribute to the incidence of serious infection. Viral infections in immunocompromised patients are caused most often by herpes viruses and respiratory viruses.

Fever is probably the most important sign of infection in immunocompromised patients. In neutropenic patients, any one-time temperature of 38.3°C (101°F) or higher or 38.0°C (100.4°F) or higher for 1 hour or more is reported and dealt with promptly (NCCN, 2008c). Antibiotics may be prescribed to treat infections after cultures of wound drainage, exudates, sputum, urine, stool, or blood are obtained. Careful consideration is given to the underlying malignancy, prior antineoplastic treatment, absolute neutrophil count, comorbidities, and other patient-related factors prior to the identification of the most appropriate initial antibiotic therapy. The NCCN provides guidelines for prevention and treatment of cancer-related infections (NCCN, 2008c). Patients with neutropenia are treated with broad-spectrum antibiotics before the infecting organism is identified because of the high incidence of mortality associated with untreated infection. Broad-spectrum antibiotic therapy targets the most likely major pathogenic organisms. It is important for the nurse to administer these medications promptly and as scheduled to achieve adequate blood levels of the medications. Once the offending organism is identified, more specific antimicrobial therapy is prescribed if appropriate.

Septic Shock

The nurse assesses the patient frequently for infection and inflammation throughout the course of the disease. Septicemia and septic shock are life-threatening complications that must be prevented or detected and treated promptly. Although all patients with cancer are at risk, patients who are neutropenic

or who have hematologic malignancies are at the greatest risk. Patients with signs and symptoms of impending sepsis and septic shock require immediate hospitalization and aggressive treatment in the intensive care setting.

Signs and symptoms of septic shock (see Chapter 15) include altered mental status, either subnormal or elevated temperature, cool and clammy skin, decreased urine output, hypotension, tachycardia, other dysrhythmias, electrolyte imbalances, tachypnea, and abnormal arterial blood gas values. Patients and family members are instructed about signs of septicemia, methods for preventing infection, and actions to take if signs and symptoms of infection or septicemia occur.

Although septic shock is most often associated with overwhelming gram-negative bacterial infections, there is an increasing incidence of gram-positive infections related to the use of long-term venous access devices. Patients with prolonged neutropenia or hematologic malignancies are also more susceptible to fungal and viral sources of sepsis as well. In a patient with impending shock, the nurse monitors temperature and hemodynamic and respiratory status on a frequent basis. Neurologic assessments are carried out to detect changes in orientation and responsiveness. Fluid and electrolyte status is monitored by measuring fluid intake and output and serum electrolytes. Arterial blood gas values and pulse oximetry are monitored to determine tissue oxygenation. Nurses administer IV fluids, blood products, vasopressor and inotropic agents as prescribed to maintain blood pressure and tissue perfusion, as well as broad-spectrum antibiotics, which may be prescribed initially to combat the underlying infection (see Chapter 15). Supplemental oxygen and mechanical ventilation are often necessary. Systemic steroids and drotrecogin alfa (Xigris; recombinant human activated protein C) have been used in some centers for patients who have severe and prolonged septic shock or those that at risk for development of clotting disturbances (Gobel & Peterson, 2006).

Bleeding and Hemorrhage

Platelets are essential for normal blood clotting and coagulation (hemostasis). Thrombocytopenia, a decrease in the circulating platelet count, is the most common cause of bleeding in patients with cancer and is usually defined as a platelet count of less than 100,000/mm³ (0.1 × 10¹²/L). When the platelet count decreases to between 20,000 and 50,000/mm³ (0.02 to 0.05 × 10¹²/L), the risk of bleeding increases. Platelet counts lower than 20,000/mm³ (0.02 × 10¹²/L) are associated with an increased risk for spontaneous bleeding, for which patients require a platelet transfusion.

Thrombocytopenia often results from bone marrow depression after certain types of chemotherapy and radiation therapy and with tumor infiltration of the bone marrow. In some cases, platelet destruction is associated with an enlarged spleen (hypersplenism) and abnormal antibody function, which occur with leukemia and lymphoma. The nursing care plan addresses nursing assessment parameters and interventions for patients at risk for bleeding (see Chart 16-7).

In limited circumstances, the nurse may administer IL-11, which has been approved by the FDA to prevent severe thrombocytopenia and to reduce the need for platelet transfusions after myelosuppressive chemotherapy in patients with nonmyeloid malignancies, as previously described. Additional

medications may be prescribed to address bleeding due to disorders of coagulation.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Increasingly, patients with cancer are diagnosed and treated in the outpatient setting with minimal or no period of hospitalization. Nurses in outpatient settings often have the responsibility for patient teaching and for coordinating care in the home. The shift of care from acute care to the home or outpatient setting places a great deal of the responsibility for care on the patient and family; this requires teaching that enables them to provide care. Teaching initially focuses on the most immediate care needs likely to be encountered at home.

Side effects of treatments and changes in the patient's status that should be reported are reviewed verbally and reinforced with written information. Strategies to deal with side effects of treatment are discussed with the patient and family. Other learning needs are based on the priorities conveyed by the patient and family as well as on the complexity of care required in the home.

Technologic advances allow home administration of chemotherapy, parenteral nutrition, blood products, parenteral antibiotics, and analgesics, as well as management of symptoms and care of vascular access devices. Although home care nurses provide care and support for patients receiving this type of care, patients and families need instruction and support to enable them to feel comfortable and proficient in managing these treatments at home. Follow-up visits and telephone calls from the nurse assist in identifying problems and are often reassuring, increasing the patient's and family's comfort in dealing with complex and new aspects of care. Continued contact facilitates evaluation of the patient's progress and assessment of the ongoing needs of the patient and family.

Continuing Care

Referral for home care is often indicated for patients with cancer. The responsibilities of the home care nurse include assessing the home environment, suggesting modifications in the home or in care to help the patient and family address the patient's physical needs, providing physical care, and assessing the psychological and emotional impact of the illness on the patient and family.

Assessing changes in the patient's physical status and reporting relevant changes to the physician help ensure that appropriate and timely modifications in therapy are made. The home care nurse also assesses the adequacy of pain management and the effectiveness of other strategies to prevent or manage the side effects of treatment modalities and disease progression.

It is necessary to assess the patient's and family's understanding of the treatment plan and management strategies and to reinforce previous teaching. The nurse facilitates coordination of patient care by maintaining close communication with all involved health care providers. The nurse may make referrals and coordinate available community resources (eg, local office of the American Cancer Society,

home aides, church groups, parish nurses, support groups) to assist patients and caregivers.

Gerontologic Considerations

More than 60% of all new cancers occur in people older than 65 years of age, and about 70% of all cancer deaths occur in people 65 years of age and older (Lynch, Marcone & Kagan, 2007). The rising numbers of individuals over age 65 with cancer has led to the emergence of geriatric oncology, a multidimensional and multidisciplinary approach to treating growing numbers of older adults with cancer (Lynch, et al., 2007).

Nurses working with the elderly population must understand the normal physiologic changes that occur with aging and the implications for the patient with cancer (Table 16-9). These changes that affect all body systems may ultimately influence elderly patients' responses to cancer treatment (Lichtman, 2006). In addition, many elderly patients have other chronic diseases requiring multiple medications. The existence of comorbidities and multiple medications may contribute to drug interactions and toxicities in elderly patients (Extermann & Hurria, 2007).

The understanding of the effects and tolerance of chemotherapy, biotherapy, and radiation in the elderly is limited because there have been few studies of the effects of cancer treatments in this population (Lichtman, 2006). In addition, the elderly have been underrepresented in oncology clinical trials (Lichtman, Wildiers, Chatelut, et al., 2007). Potential chemotherapy-related toxicities, such as renal impairment, myelosuppression, fatigue, and cardiomyopathy, may increase as a result of declining organ function and diminished physiologic reserves. The recovery of normal tissues after radiation therapy may be delayed, and older patients may experience more severe adverse effects, such as mucositis, nausea and vomiting, and myelosuppression. Because of impaired healing and declining pulmonary and cardiovascular functioning, older patients are slower to recover from surgery. Elderly patients are also at increased risk for complications such as atelectasis, pneumonia, and wound infections.

Several studies have shown that when compared to younger patients, some elderly patients with cancer have received substandard or suboptimal treatment (Bouchardy, Rapiti, Blagojevic, et al., 2007). Access to quality cancer care for elderly patients may be limited by discriminatory or fatalistic attitudes of health care providers, caregivers, and patients themselves. Issues such as the gradual loss of supportive resources, declining health or loss of a spouse, and unavailability of relatives or friends may result in limited access to care and unmet needs for assistance with activities of daily living. In addition, the economic impact of health care may be difficult for those living on fixed incomes.

It is not uncommon for elderly patients to delay reporting symptoms, attributing them to "old age." Many elderly people do not want to report illness for fear of losing their independence or financial security. Sensory losses (eg, hearing and visual losses) and memory deficits are considered when planning patient education, because they may affect the patient's ability to process and retain information. In such cases, the nurse acts as a patient advocate, encouraging independence and identifying resources for support when indicated. Nurses must be aware of the

Table 16-9 AGE-RELATED CHANGES AND THEIR EFFECTS ON PATIENTS WITH CANCER

Age-Related Changes	Implications
Impaired immune system	Use special precautions to avoid infection; monitor for atypical signs and symptoms of infection.
Altered drug absorption, distribution, metabolism, and elimination	Mandates careful calculation of chemotherapy and frequent assessment for drug response and side effects; dose adjustments may be necessary.
Increased prevalence of other chronic diseases	Monitor for effect of cancer or its treatment on patient's other chronic diseases; monitor patient's tolerance for cancer treatment; monitor for interactions with medications used to treat chronic diseases.
Diminished renal, respiratory, and cardiac reserve	Be proactive in prevention of decreased renal function, atelectasis, pneumonia, and cardiovascular compromise; monitor for side effects of cancer treatment.
Decreased skin and tissue integrity; reduction in body mass; delayed healing	Prevent pressure ulcers secondary to immobility; monitor skin and mucous membranes for changes related to radiation or chemotherapy; monitor nutritional status.
Decreased musculoskeletal strength	Prevent falls; assess support for performing activities of daily living in home setting; encourage safe use of assistive mobility devices.
Decreased neurosensory functioning: loss of vision, hearing, and distal extremity tactile senses	Provide teaching and instructions modified for patient's hearing and vision changes; provide instruction concerning safety and skin care for distal extremities; assess home for safety.
Altered social and economic resources	Assess for financial concerns, living conditions, and resources for support.
Potential changes in cognitive and emotional capacity	Provide teaching and support modified for patient's level of functioning and safety.

special needs of the aging population and work collaboratively with other disciplines to address identified needs.

Providing Care in Oncologic Emergencies

Table 16-10 discusses nursing and medical care of oncologic emergencies.

Providing Care of the Patient With Advanced Cancer

Patients with advanced cancer are likely to experience many of the problems previously described, but all to a greater degree. Symptoms of gastrointestinal disturbances, nutritional problems, weight loss, and cachexia make patients more susceptible to skin breakdown, fluid and electrolyte problems, and infection.

Although not all cancer patients experience pain, those who do commonly fear that it will not be adequately treated. Although treatment at this stage of illness is likely to be palliative rather than curative, prevention and appropriate management of problems can improve the patient's quality of life considerably. For example, use of analgesia at set intervals is recommended rather than on an "as needed" basis. Working with the patient and family as well as with other health care providers to manage pain frequently increases the patient's comfort and sense of control. Other medications (eg, sedatives, tranquilizers, muscle relaxants, antiemetics) are added to assist in promoting patient comfort.

If the patient is a candidate for radiation therapy or surgical intervention to relieve pain, the consequences of these procedures (eg, percutaneous nerve block, cordotomy) are explained to the patient and family. Measures are taken to prevent complications that result from altered sensation, immobility, and changes in bowel and bladder function.

With the appearance of each new symptom, patients may fear that the disease is progressing. However, one cannot assume that all symptoms are related to the cancer. The new symptoms are evaluated and treated aggressively if possible to increase the patient's comfort and improve quality of life.

Weakness, immobility, fatigue, and inactivity typically increase with advanced cancer as a result of the disease, treatment, inadequate nutritional intake, or dyspnea. The nurse works with the patient and family to set realistic goals and promote comfort. Measures include use of energy-conserving methods to accomplish tasks and activities that the patient values most.

Efforts are made to provide the patient with as much control and independence as desired but with assurance that support and assistance are available when needed. In addition, health care teams work with the patient and family to ascertain and comply with the patient's wishes about treatment methods and care as the terminal phase of illness and death approach.

Hospice

For many years, society was unable to cope appropriately with patients in the most advanced stages of cancer, and patients died in acute care settings rather than at home or in facilities designed to meet their needs. The needs of patients with terminal illnesses are best met by a comprehensive multidisciplinary specialty program that focuses on quality of life, palliation of symptoms, and provision of psychosocial and spiritual support for patients and families when cure and control of the disease are no longer possible. The concept of hospice best addresses these needs. Most important, the focus of care is on the family, as well as the patient. Hospice care can be provided in several settings: free-standing, hospital-based, and community or home-based settings.

Table 16-10 ONCOLOGIC EMERGENCIES: MANIFESTATIONS AND MANAGEMENT

Emergency	Clinical Manifestations and Diagnostic Findings	Management
<p>Superior Vena Cava Syndrome (SVCS) Compression or invasion of the superior vena cava by tumor, enlarged lymph nodes, intraluminal thrombus that obstructs venous circulation, or drainage of the head, neck, arms, and thorax. Typically associated with lung cancer, SVCS can also occur with breast cancer, Kaposi's sarcoma, thymoma, lymphoma, and mediastinal metastases (Kuzin, 2006). If untreated, SVCS may lead to cerebral anoxia (because not enough oxygen reaches the brain), laryngeal edema, bronchial obstruction, and death.</p>	<p>Clinical Gradually or suddenly impaired venous drainage giving rise to:</p> <ul style="list-style-type: none"> • Progressive shortness of breath (dyspnea), cough, hoarseness, chest pain, and facial swelling • Edema of the neck, arms, hands, and thorax and reported sensation of skin tightness and difficulty swallowing • Possibly engorged and distended jugular, temporal, and arm veins • Dilated thoracic vessels causing prominent venous patterns on the chest wall • Increased intracranial pressure, associated visual disturbances, headache, and altered mental status <p>Diagnostic Diagnosis is confirmed by:</p> <ul style="list-style-type: none"> • Clinical findings • Chest x-ray • Thoracic computed tomography (CT) scan • Thoracic magnetic resonance imaging (MRI) <p>Intraluminal thrombosis is identified by venogram.</p>	<p>Medical</p> <ul style="list-style-type: none"> • Radiation therapy to shrink tumor size and relieve symptoms • Chemotherapy for chemosensitive cancers (eg, lymphoma, small cell lung cancer) or when the mediastinum has been irradiated to maximum tolerance (Kuzin, 2006) • Anticoagulant or thrombolytic therapy for intraluminal thrombosis • Percutaneously placed intravascular stents are increasingly being used to reopen the occluded SVC (Kuzin, 2006) • Surgery (less common), such as vena cava bypass graft (synthetic or autologous), to redirect blood flow around the obstruction • Supportive measures such as oxygen therapy, corticosteroids, and diuretics <p>Nursing</p> <ul style="list-style-type: none"> • Identify patients at risk for SVCS • Monitor and report clinical manifestations of SVCS • Monitor cardiopulmonary and neurologic status • Avoid upper extremity venipuncture and blood pressure measurement • Facilitate breathing by positioning the patient properly; this helps to promote comfort and reduce anxiety produced by difficulty breathing resulting from progressive edema • Promote energy conservation to minimize shortness of breath • Monitor the patient's fluid volume status and administer fluids cautiously to minimize edema • Assess for thoracic radiation-related problems such as dysphagia (difficulty swallowing) and esophagitis • Monitor for chemotherapy-related problems, such as myelosuppression • Provide postoperative care as appropriate
<p>Spinal Cord Compression Potentially leading to permanent neurologic impairment and associated morbidity and mortality; compression of the cord and its nerve roots may result from tumor, lymphomas, intervertebral collapse, or interruption of blood supply to the nerve tissues (Kaplan, 2006b). The prognosis depends on the severity and rapidity of onset. About 70% of compressions occur at the thoracic level, 20% in the lumbosacral level, and 10% in the cervical region (Marrs, 2006). Metastasis from breast, lung, kidney, prostate cancers, myeloma, lymphoma to the bone or between the bone and the epidural space are associated with spinal cord compression (Kaplan, 2006b).</p>	<p>Clinical</p> <ul style="list-style-type: none"> • Local inflammation, edema, venous stasis, and impaired blood supply to nervous tissues • Local or radicular back or neck pain along the dermatomal areas innervated by the affected nerve root (Marrs, 2006) (eg, thoracic radicular pain extends in a band around the chest or abdomen) • Pain exacerbated by movement, supine recumbent position, coughing, sneezing, or the Valsalva maneuver • Neurologic dysfunction, and related motor and sensory deficits (numbness, tingling, feelings of coldness in the affected area, inability to detect vibration, loss of positional sense) • Motor loss ranging from subtle weakness to flaccid paralysis • Bladder and/or bowel dysfunction depending on level of compression (above S2, overflow incontinence; from S3 to S5, flaccid sphincter tone, and bowel incontinence) 	<p>Medical</p> <ul style="list-style-type: none"> • Radiation therapy to reduce tumor size to halt progression and corticosteroid therapy to decrease inflammation and swelling at the compression site • Surgery to debulk tumor and stabilize the spine if symptoms progress despite radiation therapy or if vertebral fracture or bone fragments lead to additional nerve damage; surgery is also an option when the tumor is not radiosensitive or is located in an area that was previously irradiated (Kaplan, 2006b) • Vertebroplasty is used to stabilize vertebrae when patients have pain without neurologic dysfunction; vertebroplasty involves percutaneous injection of polymethyl methacrylate (PMMA), a bone cement filler, into the vertebral body (Kaplan, 2006b) • Chemotherapy as adjuvant to radiation therapy for patients with lymphoma or small cell lung cancer • <i>Note:</i> Despite treatment, patients with poor neurologic function before treatment are less likely to regain complete motor and sensory function; patients who develop complete paralysis usually do not regain all neurologic function (Kaplan, 2006b)

Table 16-10 ONCOLOGIC EMERGENCIES: MANIFESTATIONS AND MANAGEMENT (Continued)		
Emergency	Clinical Manifestations and Diagnostic Findings	Management
	<p>Diagnostic</p> <ul style="list-style-type: none"> Percussion tenderness at the level of compression Abnormal reflexes Sensory and motor abnormalities MRI, spinal cord x-rays, bone scans, and CT scan. CT-guided myelogram is reserved for patients who are unable to undergo MRI (Kaplan, 2006b). 	<p>Nursing</p> <ul style="list-style-type: none"> Perform ongoing assessment of neurologic function to identify existing and progressing dysfunction Control pain with pharmacologic and nonpharmacologic measures Prevent complications of immobility resulting from pain and decreased function (eg, skin breakdown, urinary stasis, thrombophlebitis, decreased clearance of pulmonary secretions) Maintain muscle tone by assisting with range-of-motion exercises in collaboration with physical and occupational therapists Institute intermittent urinary catheterization and bowel training programs for patients with bladder or bowel dysfunction Provide encouragement and support to patient and family coping with pain and altered functioning, lifestyle, roles, and independence
<p>Hypercalcemia</p> <p>In patients with cancer, hypercalcemia is a potentially life-threatening metabolic abnormality resulting when the calcium released from the bones is more than the kidneys can excrete or the bones can reabsorb. It may result from:</p> <ul style="list-style-type: none"> Production of cytokines, hormonal substances and growth factors by cancer cells, or by the body in response to substances produced by cancer cells; which lead to bone breakdown and calcium release (Kaplan, 2006a). Excessive use of vitamins and minerals and conditions unrelated to cancer, such as dehydration, renal impairment, primary hyperparathyroidism, thyrotoxicosis, thiazide diuretics, and hormone therapy. 	<p>Clinical</p> <p>Fatigue, weakness, confusion, decreased level of responsiveness, hyporeflexia, nausea, vomiting, constipation, ileus, polyuria (excessive urination), polydipsia (excessive thirst), dehydration, and dysrhythmias</p> <p>Diagnostic</p> <p>Serum calcium level exceeding 11 mg/dL (2.74 mmol/L)</p>	<p>Medical</p> <p>See Chapter 14.</p> <p>Nursing</p> <ul style="list-style-type: none"> Identify patients at risk for hypercalcemia and assess for signs and symptoms of hypercalcemia Educate patient and family; prevention and early detection can prevent fatality Teach at-risk patients to recognize and report signs and symptoms of hypercalcemia Encourage patients to consume 2–4 L of fluid daily unless contraindicated by existing renal or cardiac disease Explain the use of dietary and pharmacologic interventions such as stool softeners and laxatives for constipation Advise patients to maintain nutritional intake without restricting normal calcium intake Discuss antiemetic therapy if nausea and vomiting occur Promote mobility by emphasizing its importance in preventing demineralization and breakdown of bones Institute safety precautions for patients with impaired mental and mobility status
<p>Pericardial Effusion and Cardiac Tamponade</p> <p>Pericardial effusion is an accumulation of fluid in the pericardial space. Cardiac tamponade occurs when the accumulation compresses the heart and thereby impedes expansion of the ventricles and cardiac filling during diastole. As ventricular volume and cardiac output fall, the heart pump fails, and circulatory collapse develops.</p> <p>With gradual onset, fluid accumulates gradually, and the outer layer of the pericardial space stretches to compensate for rising pressure. Large amounts of fluid accumulate before symptoms of heart failure occur. With rapid onset, pressures rise too quickly for the pericardial space to compensate.</p>	<p>Clinical</p> <ul style="list-style-type: none"> Neck vein distention during inspiration (Kussmaul's sign) Pulsus paradoxus (systolic blood pressure decrease exceeding 10 mm Hg during inspiration; pulse gets stronger on expiration) Distant heart sounds, rubs and gallops, cardiac dullness Compensatory tachycardia (heart beats faster to compensate for decreased cardiac output) Increased venous and vascular pressures <p>Diagnostic</p> <ul style="list-style-type: none"> Electrocardiography (ECG) helps diagnose pericardial effusion In small effusion, chest x-rays show small amounts of fluid in the pericardium; in large effusions, x-ray films disclose “water-bottle” heart (obliteration of vessel contour and cardiac chambers) CT scans help diagnose pleural effusions and evaluate effect of treatment Narrow pulse pressure Shortness of breath and tachypnea 	<p>Medical</p> <ul style="list-style-type: none"> Patients with small effusions who are not symptomatic do not require treatment. These patients are monitored for signs and symptoms of increasing fluid accumulation (Higdon & Higdon, 2006) Pericardiocentesis (the aspiration or withdrawal of pericardial fluid by a large-bore needle inserted into the pericardial space); in malignant effusions, pericardiocentesis provides only temporary relief; fluid may reaccumulate (Story, 2006); windows or openings in the pericardium can be created surgically as a palliative measure to drain fluid into the pleural space; catheters may also be placed in the pericardial space and sclerosing agents (such as bleomycin or thiotepa) injected to prevent fluid from reaccumulating (Story, 2006) Radiation therapy or antineoplastic agents, depending on how sensitive the primary tumor is to these treatments and the degree of symptoms that exist; in mild effusions, prednisone and diuretic medications may be prescribed and the patient's status carefully monitored

Continued

Table 16-10 ONCOLOGIC EMERGENCIES: MANIFESTATIONS AND MANAGEMENT (Continued)

Emergency	Clinical Manifestations and Diagnostic Findings	Management
<p>Cancerous tumors, particularly from adjacent thoracic tumors (lung, esophagus, breast cancers), and cancer treatment are the most common causes of cardiac tamponade. Radiation therapy of 4000 cGy or more to the mediastinal area has also been implicated in pericardial fibrosis, pericarditis, and resultant cardiac tamponade. Untreated pericardial effusion and cardiac tamponade lead to circulatory collapse and cardiac arrest (Story, 2006).</p>	<ul style="list-style-type: none"> Weakness, chest pain, orthopnea, anxiety, diaphoresis, lethargy, and altered consciousness from decreased cerebral perfusion 	<p>Nursing</p> <ul style="list-style-type: none"> Monitor vital signs and oxygen saturation frequently Assess for pulsus paradoxus Monitor ECG tracings Assess heart and lung sounds, neck vein filling, level of consciousness, respiratory status, and skin color and temperature Monitor and record intake and output Review laboratory findings (eg, arterial blood gas and electrolyte levels) Elevate the head of the patient's bed to ease breathing Minimize patient's physical activity to reduce oxygen requirements; administer supplemental oxygen as prescribed Provide frequent oral hygiene Reposition and encourage the patient to cough and take deep breaths every 2 hours As needed, maintain patent intravenous access, reorient the patient, and provide supportive measures and appropriate patient instruction
<p>Disseminated Intravascular Coagulation (DIC; also called consumption coagulopathy) Complex disorder of coagulation or fibrinolysis (destruction of clots), which results in thrombosis or bleeding. DIC is most commonly associated with hematologic cancers (leukemia and lymphoma); cancer of prostate, gastrointestinal (GI) tract, and lungs; chemotherapy (methotrexate, prednisone, L-asparaginase, vincristine, 5-fluorouracil, cyclophosphamide; targeted agents bevacizumab, thalidomide, interferon; hormonal agents (tamoxifen, Megace); and other processes such as trauma, sepsis, hepatic failure, and anaphylaxis (Enzone, 2006; Viable, 2005). Blood clots form when normal coagulation mechanisms are triggered. Once activated, the clotting cascade continues to consume clotting factors and platelets faster than the body can replace them. Clots are deposited in the microvasculature, placing the patient at great risk for impaired circulation, tissue hypoxia, and necrosis. In addition, fibrinolysis occurs, breaking down clots and increasing the circulating levels of anticoagulant substances, thereby placing the patient at risk for hemorrhage (Enzone, 2006).</p>	<p>Clinical <i>Chronic DIC:</i> Few or no observable symptoms or easy bruising, prolonged bleeding from venipuncture and injection sites, bleeding of the gums, and slow GI bleeding <i>Acute DIC:</i> Life-threatening hemorrhage and infarction; clinical symptoms of this syndrome are varied and depend on the organ system involved in thrombus and infarction or bleeding episodes</p> <p>Diagnostic</p> <ul style="list-style-type: none"> Prolonged prothrombin time (PT or protime) Prolonged partial thromboplastin time (PTT) Prolonged thrombin time (TT) Decreased fibrinogen level Decreased platelet level Decrease in clotting factors Decreased hemoglobin Decreased hematocrit Elevated fibrin split products Positive protamine sulfate precipitation test (thrombin activation test) Elevated D-dimer Prolonged international normalized ratio (INR) Decreased plasminogen levels 	<p>Medical</p> <ul style="list-style-type: none"> Chemotherapy, biologic response modifier therapy, radiation therapy, or surgery is used to treat the underlying cancer Antibiotic therapy is used for sepsis Anticoagulants, such as heparin or antithrombin III, decrease the stimulation of the coagulation pathways Drotrecogin alfa is used with caution in patients with DIC related to sepsis (Ezzone, 2006) Transfusion of fresh-frozen plasma or cryoprecipitates (which contain clotting factors and fibrinogen), packed red blood cells, and platelets may be used as replacement therapy to prevent or control bleeding Although controversial, antifibrinolytic agents such as aminocaproic acid (Amicar), which is associated with increased thrombus formation, may be used <p>Nursing</p> <ul style="list-style-type: none"> Monitor vital signs Measure and document intake and output Assess skin color and temperature; lung, heart, and bowel sounds; level of consciousness, headache, visual disturbances, chest pain, decreased urine output, and abdominal tenderness Inspect all body orifices, tube insertion sites, incisions, and bodily excretions for bleeding Review laboratory test results Minimize physical activity to decrease injury risks and oxygen requirements Prevent bleeding; apply pressure to all venipuncture sites, and avoid nonessential invasive procedures; provide electric rather than straight-edged razors; avoid tape on the skin and advise gentle but adequate oral hygiene Assist the patient to turn, cough, and take deep breaths on regular schedule Reorient the patient, if needed; maintain a safe environment; and provide appropriate patient education and supportive measures

Continued on following page

Table 16-10 ONCOLOGIC EMERGENCIES: MANIFESTATIONS AND MANAGEMENT (Continued)

Emergency	Clinical Manifestations and Diagnostic Findings	Management
<p>Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH)</p> <p>The continuous, uncontrolled release of antidiuretic hormone (ADH), produced by tumor cells or by the abnormal stimulation of the hypothalamic–pituitary network, leads to increased extracellular fluid volume, water intoxication, hyponatremia, and increased excretion of urinary sodium. As fluid volume increases, stretch receptors in the right atrium respond by releasing a second hormone, atrial natriuretic factor (ANF). The release of ANF causes increased renal excretion of sodium, which worsens hyponatremia.</p> <p>The most common cause of SIADH is cancer, especially small cell cancers of the lung. A variety of nonmalignant diseases, trauma and medications are associated with SIADH. Antineoplastics including vincristine, vinblastine, cisplatin, and cyclophosphamide, as well as morphine stimulate ADH secretion, which promotes conservation and reabsorption of water by the kidneys. As more fluid is absorbed, the circulatory volume increases, ANF is released, and sodium is actively excreted by the kidneys in compensation (Clancey, 2006)</p>	<p>Clinical</p> <p><i>Serum sodium levels lower than 125 mEq/L (125 mmol/L):</i> symptoms of hyponatremia including personality changes, irritability, nausea, anorexia, vomiting, weight gain, fatigue, muscular pain (myalgia), headache, lethargy, and confusion</p> <p><i>Serum sodium levels lower than 115 mEq/L (11 mmol/L):</i> seizure, abnormal reflexes and gait, papilledema, coma, and death; edema is rare</p> <p>Diagnostic</p> <ul style="list-style-type: none"> • Decreased serum sodium level • Increased urine osmolality • Increased urinary sodium level • Decreased blood urea nitrogen (BUN), creatinine, and serum albumin levels secondary to dilution • Abnormal water load test results 	<p>Medical</p> <ul style="list-style-type: none"> • Treat underlying disease process or eliminate contributing medications • Fluid intake range limited to 500–1000 mL/day to increase the serum sodium level and decrease fluid overload. If water restriction alone is not effective in correcting or controlling serum sodium levels, demeclocycline is often prescribed to interfere with the antidiuretic action of ADH and ANF; if neurologic symptoms are severe, parenteral sodium replacement and diuretic therapy are indicated; electrolyte levels are monitored carefully to detect secondary magnesium, potassium, and calcium imbalances; after the symptoms of SIADH are controlled, the underlying cancer is treated; if water excess continues despite treatment, pharmacologic intervention (urea and furosemide) may be indicated (Clancey, 2006) <p>Nursing</p> <ul style="list-style-type: none"> • Recognize individuals at risk • Maintain intake and output measurements as often as hourly for severe hyponatremia (Clancey, 2006) • Assess level of consciousness, lung and heart sounds, vital signs, daily weight, and urine specific gravity; also assess for nausea, vomiting, anorexia, edema, fatigue, and lethargy • Monitor laboratory test results, including serum electrolyte levels, osmolality, and BUN, creatinine, and urinary sodium levels • Minimize the patient's activity; provide appropriate oral hygiene; maintain environmental safety; and restrict fluid intake if necessary • Reorient the patient and provide instruction and encouragement as needed
<p>Tumor Lysis Syndrome</p> <p>Potentially fatal complication associated with radiation, biotherapy, or chemotherapy-induced cell destruction of large or rapidly growing cancers such as leukemia, lymphoma, and small cell lung cancer (Higdon & Higdon, 2006). The release of intracellular contents from the tumor cells leads to electrolyte imbalances—hyperkalemia, hypocalcemia, hyperphosphatemia, and hyperuricemia—because the kidneys can no longer excrete large volumes of the released intracellular metabolites.</p>	<p>Clinical</p> <p>Clinical manifestations depend on the extent of metabolic abnormalities</p> <ul style="list-style-type: none"> • <i>Neurologic:</i> Fatigue, weakness, memory loss, altered mental status, muscle cramps, tetany, paresthesias (numbness and tingling), seizures • <i>Cardiac:</i> Elevated blood pressure, shortened QT complexes, widened QRS waves, altered T waves, dysrhythmias, cardiac arrest • <i>GI:</i> Anorexia, nausea, vomiting, abdominal cramps, diarrhea, increased bowel sounds • <i>Renal:</i> Flank pain, oliguria, anuria, renal failure, acidic urine pH <p>Other: Gout, malaise, pruritus</p> <p>Diagnostic</p> <p>Electrolyte imbalances identified by serum electrolyte measurement and urinalysis; EKG necessary to monitor cardiac abnormalities (Gobel, 2006)</p>	<p>Medical</p> <ul style="list-style-type: none"> • To prevent renal failure and restore electrolyte balance, aggressive fluid hydration is initiated 24–48 hours before and after the initiation of cytotoxic therapy to increase urine volume and eliminate uric acid and electrolytes; urine is alkalized by adding sodium bicarbonate to intravenous fluid to maintain a urine pH of 7 to 7.5; this prevents renal failure secondary to uric acid precipitation in the kidneys (Gobel, 2006) • Diuresis with a loop diuretic or osmotic diuretic if urine output is not sufficient (Gobel, 2006) • Allopurinol therapy to inhibit the conversion of nucleic acids to uric acid or rasburicase to oxidizes uric acid to allantoin that has higher solubility than uric acid (Gobel, 2006) • Administration of a cation-exchange resin, such as sodium polystyrene sulfonate (Kayexalate) to treat hyperkalemia by binding and eliminating potassium through the bowel • Administration of intravenous sodium bicarbonate, hypertonic dextrose, and regular insulin temporarily shifts potassium into cells and lowers serum potassium levels • Administration of phosphate-binding gels, such as aluminum hydroxide, to treat hyperphosphatemia by promoting phosphate excretion in the feces • Hemodialysis when patients are unresponsive to the standard approaches for managing uric acid and electrolyte abnormalities

Continued

Table 16-10 ONCOLOGIC EMERGENCIES: MANIFESTATIONS AND MANAGEMENT (Continued)

Emergency	Clinical Manifestations and Diagnostic Findings	Management
		<p>Nursing</p> <ul style="list-style-type: none"> Identify at-risk patients, including those in whom tumor lysis syndrome may develop up to 1 week after therapy has been completed Institute essential preventive measures (eg, fluid hydration, allopurinol) Assess patient for signs and symptoms of electrolyte imbalances Assess urine pH to confirm alkalinization Monitor serum electrolyte and uric acid levels for evidence of fluid volume overload secondary to aggressive hydration Instruct patients to report symptoms indicating electrolyte disturbances

Because of the high costs associated with maintaining free-standing hospices, care is often delivered through coordination of services provided by hospitals, home care programs, and the community. The view that palliative care services are necessary only in extreme circumstances prevents appropriate and timely consultation with palliative care specialists (MacDonald, 2005; Pavlish & Ceronsky, 2007). Patients should be referred to palliative care and hospice services in a timely fashion so that complex patient needs can be addressed. Although physicians, social workers, clergy, dietitians, pharmacists, physical therapists, and volunteers are involved in patient care, nurses often coordinate hospice services.

Hospice programs strive to facilitate clear communication among family members and health care providers. Most patients and families are informed of the prognosis and are encouraged to participate in decisions regarding pursuing or terminating cancer treatment. Through collaboration with other support disciplines, the nurse helps the patient and family cope with changes in role identity, family structure, grief, and loss. Hospice nurses are actively involved in bereavement counseling. See Chapter 17 for detailed discussion of end-of-life care.

Cancer Survivorship

The National Cancer Institute (2007) estimates that over 10 million individuals are alive today who have been previously diagnosed with cancer. Largely as a result of increased screening programs for breast, cervical, and prostate cancers and advances in treatment, the numbers of cancer survivors has tripled over the past 37 years. Cancer survivorship refers to a distinct phase of cancer care that follows primary treatment for cancer and lasts until cancer recurrence or end of life (Hewitt, Greenfield & Stovall, 2006). Although individuals vary and there are many types of cancers and treatments, the acute, long-term, and late effects of cancer and its treatment may have multiple physical and psychosocial consequences.

Approaches to survivorship care are often based on expert opinion and experiences rather than evidence-based interventions. Knowledge regarding survivorship concerns continues to evolve. The Institute of Medicine identified four components of survivorship care (Hewitt, et al., 2006), listed in Table 16-11. Multiple professional and advocacy

organizations across the country have recommended that a survivorship care plan be provided to all cancer patients and their primary care physician at the completion of treatment. The survivorship care plan includes a summary of cancer diagnosis and treatment, recommendations for follow-up and care, including approaches to treat symptoms, rehabilitative needs, monitoring for late effects, and surveillance and screening for new and recurrent cancer. Referrals for specific services such as lymphedema therapy, support groups, and genetic counseling are also provided. Nurses assist in the development of the survivorship care plan and provide education and care for cancer survivors. Nurses, other health care providers, public health professionals, and patient advocates design and conduct research in order to identify needs of cancer survivors and evidence-based approaches to care.

Table 16-11 COMPONENTS OF SURVIVORSHIP CARE

Component	Examples of Care
Prevention and detection of new and recurrent cancer.	<ul style="list-style-type: none"> Mammography (per ACS guidelines) Papanicolaou (Pap) smears (per ACS guidelines) Smoking cessation programs Nutrition counseling
Surveillance for cancer spread, recurrence or second cancers	<ul style="list-style-type: none"> Colonoscopy post-colon cancer Mammography post-breast cancer Liver function tests post-colon cancer Prostate specific antigen post-prostate cancer
Intervention for consequences of cancer and its treatments	<ul style="list-style-type: none"> Lymphedema therapy Pain management Enterostomal therapy Fertility care
Coordination between specialists and primary care providers to meet health needs	<ul style="list-style-type: none"> Care for comorbidities (eg, diabetes) Influenza vaccination Bone densitometry

The National Academies Press. Components of survivorship care provided by the Institute of Medicine report on cancer survivorship.

CRITICAL THINKING EXERCISES

EBP 1 Your patient has just completed treatment planning for receiving external beam radiation for an aggressive nasopharyngeal cancer. The patient has expressed concerns about what side effects of this treatment can be anticipated. What would your response be to him? What evidence-based nursing interventions would you implement to minimize side effects? Are there any preventive measures to protect the patient's oral mucosa? What nutritional needs would this patient experience and what approaches should be used to address them? What is the evidence for the interventions you identified? How strong is that evidence, and what criteria did you use to assess the strength of that evidence?

2 A 58-year-old patient with bone metastasis from an unknown primary cancer has been receiving an opioid through a continuous subcutaneous infusion of analgesia with an infusion pump to relieve his severe pain. His wife tells you that both she and her husband fear that he will become addicted to the opioid; his adult children report that his pain remains severe and unrelieved. As a home care nurse, what assessments would be of highest priority to you during your initial visit to this patient? What nursing interventions would be indicated for the patient and his wife?

3 A 33-year-old man has presented to the cancer center for treatment of colorectal cancer. In reviewing his family history, you note that his father and grandfather (who are both deceased) had metastatic colon cancer and his father's sister had endometrial cancer at age 45. You also note that he has two younger sisters. What information is important in this family history and why? What type of referral would be appropriate for this man and his family? How would you best advise this man and his family regarding cancer risks and screening practices?

4 Your 28-year-old patient with acute leukemia, hospitalized for high-dose chemotherapy, has developed tumor lysis syndrome and acute renal failure. Describe the underlying pathology that can lead to the signs and symptoms of tumor lysis syndrome. What patient monitoring will be essential during this patient's care? Describe the medical and nursing management strategies that will be used for this patient.

The Smeltzer suite offers these additional resources to enhance learning and facilitate understanding of this chapter:

- thePoint on line resource, thepoint.lww.com/Smeltzer12E
- Student CD-ROM included with the book
- *Study Guide to Accompany Brunner & Suddarth's Textbook of Medical-Surgical Nursing*
- *Handbook for Brunner & Suddarth's Textbook of Medical-Surgical Nursing*

chapter 17

End-of-Life Care

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Discuss the historical, legal, and sociocultural perspectives of palliative and end-of-life care in the United States.
- 2 Define palliative care.
- 3 Compare and contrast the settings where palliative care and end-of-life care are provided.
- 4 Describe the principles and components of hospice care.
- 5 Identify barriers to improving care at the end of life.
- 6 Reflect on personal experience with and attitudes toward death and dying.
- 7 Apply skills for communicating with terminally ill patients and their families.
- 8 Provide culturally and spiritually sensitive care to terminally ill patients and their families.
- 9 Implement nursing measures to manage physiologic responses to terminal illness.
- 10 Support actively dying patients and their families.
- 11 Identify components of uncomplicated grief and mourning and implement nursing measures to support patients and families.

GLOSSARY

assisted suicide: use of pharmacologic agents to hasten the death of a terminally ill patient; illegal in most states

autonomy: self-determination; in the health care context, the right of the individual to make choices about the use and discontinuation of medical treatment

bereavement: period during which mourning for a loss takes place

euthanasia: Greek for “good death”; has evolved to mean the intentional killing by act or omission of a dependent human being for his or her alleged benefit

grief: the personal feelings that accompany an anticipated or actual loss

hospice: a coordinated program of interdisciplinary care and services provided primarily in the home to terminally ill patients and their families

interdisciplinary collaboration: communication and cooperation among members of diverse health care disciplines jointly to plan, implement, and evaluate care

Medicare Hospice Benefit: a Medicare entitlement that provides for comprehensive, interdisciplinary palliative care and services for eligible beneficiaries who have a terminal illness and a life expectancy of less than 6 months

mourning: individual, family, group, and cultural expressions of grief and associated behaviors

palliative care: comprehensive care for patients whose disease is not responsive to cure; care also extends to patients’ families

palliative sedation: use of pharmacologic agents, at the request of the terminally ill patient, to induce sedation when symptoms have not responded to other management measures; the purpose is not to hasten the patient’s death but to relieve intractable symptoms

prognosis: the expected course of an illness and the chance for recovery

spirituality: personal belief systems that focus on a search for meaning and purpose in life, intangible elements that impart meaning and vitality to life, and a connectedness to a higher or transcendent dimension

terminal illness: progressive, irreversible illness that despite cure-focused medical treatment will result in the patient’s death

Nursing and End-of-Life Care

Nurses can have a significant and lasting effect on the way in which patients live until they die, the manner in which the death occurs, and the enduring memories of that death for the families. Nursing has a long history of holistic, person-centered and family-centered care. Indeed, the definition of nursing highlights nursing's commitment to the diagnosis and treatment of *human responses to illness* (American Nurses Association [ANA], 2003). There may be no setting or circumstance in which nursing care—that is, attention to human responses—is more important than in caring for dying patients.

Knowledge about end-of-life principles of care and patients' and families' unique responses to illness are essential to supporting their unique values and goals. There is an opportunity to bring research, education, and practice together to change the culture of dying, bringing much-needed improvement to care that is relevant across practice settings, age groups, cultural backgrounds, and illnesses. The National Institute for Nursing Research (NINR) has taken the lead in coordinating research related to end-of-life care within the National Institutes of Health (NIH) and included end-of-life care in its strategic plan (see References and Selected Readings). In its 2004 State-of-the-Science conference aimed at improvement of end-of-life care, the NIH concluded that patient and family needs at end of life are neither appreciated nor well understood (NIH, 2005).

Death and Dying in America

The focus on care of the dying has been motivated by the aging of the population, the prevalence of and publicity surrounding life-threatening illnesses (eg, cancer and AIDS), and the increasing likelihood of a prolonged period of chronic illness prior to death. Although there are more opportunities than ever before to allow peaceful death, the knowledge and technologies available to health care providers have made the process of dying anything but peaceful. Patients and clinicians may view death as what happens when medicine fails. This attitude has placed the issue of death and improvement of the dying process outside the focus of modern medicine and health care. Numerous initiatives aimed at improving end-of-life care have been launched in recent years, spurred by a widespread call for substantive change in the way Americans deal with death.

The National Consensus Project for Quality Palliative Care (NCP, 2009) identified the following eight key domains underlying a more comprehensive and humane approach to care of the dying. These include:

- *Structure and processes of care.* The timely plan of care is based on a comprehensive interdisciplinary assessment of the patient and family.
- *Physical aspects of care.* Pain, other symptoms, and side effects are managed based on the best available evidence, with attention to disease-specific pain and symptoms, which is skillfully and systematically applied.
- *Psychological and psychiatric aspects of care.* Psychological status is assessed and managed based on the best available evidence, which is skillfully and systematically applied. When necessary, psychiatric issues are addressed and treated.

- *Social aspects of care.* Comprehensive interdisciplinary assessment identifies the social needs of patients and their families, and a plan of care is developed to respond to these needs as effectively as possible.
- *Spiritual, religious, and existential aspects of care.* Spiritual and existential dimensions are assessed and responded to based on the best available evidence, which is skillfully and systematically applied.
- *Cultural aspects of care.* The palliative care program assesses and attempts to meet the needs of the patient, family, and community in a culturally sensitive manner.
- *Care of the imminently dying patient.* Signs and symptoms of impending death are recognized and communicated in developmentally appropriate language for children and patients with cognitive disabilities with respect to family preferences. Care appropriate for this phase of illness is provided to the patient and family.
- *Ethical and legal aspects of care.* The patient's goals, preferences, and choices are respected within the limits of applicable state and federal law, within current accepted standards of medical care, and form the basis for the plan of care.

Major organizations, such as the National Hospice and Palliative Care Organization, National Quality Forum, and others have used the NCP clinical guidelines to structure quality palliative and end-of-life programs.

Technology and End-of-Life Care

In the 20th century, chronic, degenerative diseases replaced communicable diseases as the major causes of death. In the earlier part the 20th century, most deaths occurred at home. Most families had direct experience with death, providing care to family members at the end of life and then mourning their losses. As the place of death shifted from home to hospitals, families became increasingly distanced from the death experience.

The application of technology to prolong life has raised several ethical issues. The major question is: Because we *can* prolong life through increasingly sophisticated technology, does it necessarily follow that we *must* do so? In the later half of the 20th century, a “technologic imperative” practice pattern among health care professionals emerged, along with an expectation among patients and families that every available means to extend life must be tried. By the early 1970s, when hospice care was just beginning in this country, technology had become an expected companion of the critically and terminally ill. The implications of technologic intervention at the end of life are profound and affect how clinicians care for the dying, how family and friends participate in care, how patients and families understand and choose among end-of-life care options, how families prepare for **terminal illness** and death, and how they heal after the death of a loved one.

Sociocultural Context

Although each person experiences terminal illness uniquely, terminal illness is also shaped by the broader social and cultural contexts in which it occurs. The approach in the United States to serious illness has been described as “death-denying”; that is, the health care system has been built on management of acute illness and the use of technology to

cure (when possible) and to extend life. As a result, life-threatening illness, life-sustaining treatment decisions, dying, and death occur in a social environment in which illness is largely considered an enemy. Many common expressions reflect this dominant sociocultural view. For example, people talk about the “war” against cancer, “fighting” illness, and when patients choose not to pursue the most aggressive course of medical treatment to fight their diseases, many health care providers perceive this as “giving up.” A care/cure dichotomy has emerged in which health care providers may view cure as the ultimate good and care as second best, a good only when cure is no longer possible. In such a model, alleviating suffering is not as valued as curing disease. Patients who cannot be cured feel distanced from the health care team, and when curative treatments have failed, they feel that they too have failed. Patients and families may fear that any shift from curative goals to comfort-focused care will result in no care or lower-quality care, and that the clinicians on whom they have come to rely will abandon them if they withdraw from a focus on cure.

This is exemplified by the statement in late-stage illness that “nothing more can be done.” This all-too-frequently used statement communicates the belief of many clinicians that there is nothing of value to offer patients beyond cure; however, in a care-focused perspective, there is always more that can be done. This expanded notion of healing implies that healing can take place throughout life. There are many opportunities for physical, spiritual, emotional, and social healing, even as body systems begin to fail at the end of life.

Clinicians’ Attitudes Toward Death

Clinicians’ attitudes toward the terminally ill and dying remain the greatest barrier to improving care at the end of life. Kübler-Ross illuminated the concerns of the seriously ill and dying in her seminal work, *On Death and Dying*, in 1969. At that time, it was common for patients to be kept uninformed about life-threatening diagnoses, particularly cancer, and for physicians and nurses to avoid open discussion of death and dying with their patients. Her work revealed that, given open discussion, adequate time, and some help in working through the process, patients could reach a stage of acceptance in which they were neither angry nor depressed about their fate.

Clinicians’ reluctance to discuss disease and death openly with patients stems from their own anxieties about death as well as misconceptions about what and how much patients want to know about their illnesses. In an early study of care of the dying in hospital settings, sociologists Glaser and Strauss (1965) discovered that health care professionals in hospital settings avoided direct communication about dying in hopes that the patient would discover it on his or her own. They identified four “awareness contexts”:

1. *Closed awareness*: The patient is unaware of his or her terminal state, whereas others are aware. Closed awareness may be characterized as a conspiracy between the family and health care professionals to guard the “secret,” fearing that the patient may not be able to cope with full disclosure about his or her status, and the patient’s acceptance of others’ accounts of his or her “future biography” as long as the others give him or her no reason to be suspicious.

2. *Suspected awareness*: The patient suspects what others know and attempts to find out details about his or her condition. Suspected awareness may be triggered by inconsistencies in the family’s and the clinician’s communication and behavior, discrepancies between clinicians’ accounts of the seriousness of the patient’s illness, or a decline in the patient’s condition or other environmental cues.
3. *Mutual pretense awareness*: The patient, the family, and the health care professionals are aware that the patient is dying but all pretend otherwise.
4. *Open awareness*: The patient, the family, and the health care professionals are aware that the patient is dying and openly acknowledge that reality.

Glaser and Strauss (1965) also identified a pattern of clinician behavior in which those clinicians who feared or were uncomfortable discussing death developed and substituted “personal mythologies” for appraisals of what level of disclosure patients actually wanted. For example, clinicians avoided direct communication with patients about the seriousness of their illness based on their beliefs that (1) patients already knew the truth or would ask if they wanted to know, or (2) patients would subsequently lose all hope, give up, or be psychologically harmed by disclosure.

Although Glaser and Strauss’s findings were published decades ago, their observations remain valid today. A growing number of health care providers are becoming comfortable with assessing patients’ and families’ information needs and disclosing honest information about the seriousness of illness, but many still avoid the topic of death in hope that the patient will ask or find out on his or her own. Despite progress on many health care fronts, many who work with dying patients have identified the persistence of a conspiracy of silence about dying.

Patient and Family Denial

Patient and family denial about the seriousness of terminal illness also has been cited as a barrier to discussion about end-of-life treatment options. However, denial is a useful coping mechanism that enables the patient to gain temporary emotional distance from a situation that is too painful to contemplate fully (Buckman, 2005). Patients in denial may be using that strategy to preserve important interpersonal relationships, to protect others from the emotional effects of their illness, or to protect themselves because of fears of abandonment (Zimmerman & Wennberg, 2006). Denial may become a barrier to care if patients or families refuse to acknowledge a diagnosis or refuse to hear about treatment options. Nurses must accept patients regardless of the degree to which they are in denial about their illness and work with other health care providers to present the same message.

Patient and family awareness of **prognosis** is a key factor in acceptance of and planning for death. Even patients and families who have received clear and honest information may not fully accept the situation. For patients who have been informed about terminal illness, their understanding of treatment goals and prognosis is dynamic and may sometimes require reinforcement. Furthermore, patients’ and their caregivers’ understanding of treatment goals and prognosis can differ dramatically. In a study of patients with terminal cancer, researchers found that only 33% of patients and their caregivers understood that treatment goals were

not cure-focused and that there was discrepancy between patients' and caregivers' understanding in 39% of cases. Such misunderstandings can complicate both delivery of effective care and informed consent for care (Burns, Broom, Smith, et al., 2007). Patients with noncancer diagnoses, such as heart failure, chronic obstructive pulmonary disease (COPD), renal failure, dementia, or neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS), frequently do not receive adequate information and support to fully understand their prognosis, yet they often desire clear and honest information. For example, they may have troublesome symptoms and reduced quality of life paralleling or exceeding that of those patients with cancer. Patients may want but are unlikely to receive clear information about disease progression, advanced care planning, and prognosis (Stapleton & Curtis, 2007). Similarly, in a qualitative study of preferences for prognosis communication among patients with end-stage heart failure, researchers found a strong preference for physician disclosure about treatment possibilities and probable outcomes (ie, a balance of honest disclosure with hope) (Caldwell, Arthur & Demers, 2007). Clearly, further research is needed to examine the complex interactions between patients' misconceptions about advanced illness, their underlying psychological states, and clinicians' persistent lack of explanations of treatment expectations and prognosis.

The questions of how to communicate truthfully with patients and encourage patient **autonomy** in a way that acknowledges where they are on the continuum of acceptance remains a challenge. Despite the continued reluctance of health care providers to engage in open discussion about end-of-life issues, studies have confirmed that patients want information about their illness and end-of-life choices and that they are not harmed by open discussion about death. Timing of sensitive discussion takes experience, but speaking the truth can be a relief to patients and families, enhancing their autonomy by making way for truly informed consent as the basis for decision making.

Assisted Suicide

The assisted suicide debate has aimed a spotlight on the adequacy and quality of end-of-life care in the United States. **Assisted suicide** refers to providing another person the means to end his or her own life. Physician-assisted suicide involves the prescription by a physician of a lethal dose of medication for the purpose of ending someone's life (not to be confused with the ethically and legally supported practice of withholding or withdrawing medical treatment in accordance with the wishes of the terminally ill person).

Although assisted suicide is expressly prohibited under statutory or common law in the overwhelming majority of states, calls for legalized assisted suicide have highlighted inadequacies in the care of the dying. Public support for physician-assisted suicide has resulted in a number of state ballot initiatives. In 1994, Oregon voters approved the Oregon Death With Dignity Act, the first and—until 2008—only such legislative initiative to pass. This law provides for access to physician-assisted suicide by terminally ill patients under very controlled circumstances. After numerous challenges the law was enacted in 1997. The number of Oregonians who have self-administered physician-prescribed lethal

medication has remained small, totaling 341 persons who have died under the terms of the law since it was passed in 1997 (Oregon Department of Human Services, 2008).

In November 2008, voters approved the Washington Death with Dignity Act. Modeled after the Oregon Death With Dignity law, the act contains the same safeguards and will be administered through the State Department of Health (Compassion and Choices, 2008). Twenty-five other states have considered and rejected assisted suicide initiatives. It is likely the issue will be pursued in the courts and throughout ballot measures in other states.

Proponents of physician-assisted suicide argue that terminally ill people should have a legally sanctioned right to make independent decisions about the value of their lives and the timing and circumstances of their deaths, and its opponents argue for greater access to symptom management and psychosocial support for people approaching the end of life.

The ANA Position Statement on Assisted Suicide acknowledges the complexity of the assisted suicide debate but clearly states that nursing participation in assisted suicide is a violation of the Code for Nurses. The ANA Position Statement further stresses the important role of the nurse in supporting effective symptom management, contributing to the creation of environments for care that honor the patient's and family's wishes, as well as identifying their concerns and fears (ANA, 1994). The Hospice and Palliative Nurses Association (HPNA) opposes the legalization of assisted suicide (HPNA, 2006). The Oncology Nursing Society (ONS, 2007) takes a somewhat more neutral stance, stating that nurses follow the ethical mandates of the profession while seeking to understand the meaning behind the patient's request for hastening death. Similarly, the American Academy of Hospice and Palliative Medicine (AAHPM, 2007) has also recommended that clinicians carefully assess the fear and suffering that have led patients to request assisted suicide and to address these without hastening death (Chart 17-1).

Settings for End-of-Life Care

Palliative Care

Palliative care is an approach to care for the seriously ill that has long been a part of cancer care. More recently, it has been expanded to address the comprehensive symptom management, psychosocial care, and spiritual support needed to enhance the quality of life for patients with noncancer diagnoses. Although hospice care is considered by many to be the gold standard for palliative care, the term **hospice** is generally associated with palliative care that is delivered at home or in special facilities to patients who are approaching the end of life. Both palliative care and hospice care have been recognized as important bridges between cure-oriented treatment and the needs of the terminally ill patients and their families for comprehensive care in the final years, months, or weeks of life. Advocates for improved care for the dying have stated that acceptance, management, and understanding of death should become fully integrated concepts in mainstream health care.

“What If a Patient Asks You to Help Him End His Life?”

Situation

You are a hospice nurse visiting a 72-year-old man with prostate cancer and metastasis to the bone. He reports severe pain that is increasing and unrelieved by any of the pharmacologic and nonpharmacologic interventions that have been tried. He lives with his wife but has no other family members nearby or close friends. He has told his only surviving son, who lives across the country, that he wants to obtain assistance to help him die when the pain becomes unbearable. He asks if you can help him with this request.

Dilemma

The patient’s autonomy conflicts with the nurse’s obligation to respect and protect human life, to promote comfort and relieve suffering, and to “do no harm.”

Discussion

1. What should your follow-up consist of?
2. Should you discuss the patient’s request with his wife before you end the visit that day? Discuss the moral basis for your decision.
3. Should you discuss the patient’s request with the patient’s primary care physician? What is the basis for your decision?
4. What is the position of the American Nurses Association (ANA) on assisted suicide, and how does the ANA position relate to your understanding of your moral obligation?
5. What is your responsibility to the patient and his wife?
6. What ethical and legal issues are involved in taking action or not taking action in this situation?

Palliative care, which is conceptually broader than hospice care, is both an approach to care and a structured system for care delivery that aims to “prevent and relieve suffering and to support the best possible quality of life for patients and their families, regardless of the stage of the disease or the need for other therapies” (NCP, 2009, p. 6). Palliative care emphasizes management of psychological, social, and spiritual problems in addition to control of pain and other physical symptoms. As the definition suggests, palliative care does not begin when cure-focused treatment ends but is most beneficial when it is provided along with disease-remitting treatments (World Health Organization, 2008). The goal of palliative care is to improve the patient’s and family’s quality of life, and many aspects of this type of comprehensive, comfort-focused approach to care are applicable earlier in the process of life-threatening disease and in conjunction with cure-focused treatment.

In palliative care, **interdisciplinary collaboration** is necessary to bring about the desired outcomes for patients and their families. Interdisciplinary collaboration, which is different from multidisciplinary practice, is based on communication and cooperation among the various disciplines, each member of the team contributing to a single integrated care plan that addresses the needs of the patient and family.

Multidisciplinary care refers to participation of clinicians with varied backgrounds and skill sets but without coordination and integration.

Palliative Care at the End of Life

The broadening of the concept of palliative care actually followed the development of hospice services in the United States. All hospice care is palliative care; not all palliative care is hospice care. The difference is that hospice care is a type of palliative care delivered at the end of life. Hospice care focuses on quality of life, but by necessity, it usually includes realistic emotional, social, spiritual, and financial preparation for death. After hospice care was recognized as a distinct program of services under Medicare in the early 1980s (see Funding Hospice Costs), organizations providing hospice care were able to receive Medicare reimbursement if they could demonstrate that the hospice program met the Medicare “conditions of participation,” or regulations, for hospice providers.

Many chronic diseases do not have a predictable “end stage” that fits hospice eligibility criteria, and many patients die after a long, slow, and often painful decline, without the benefit of the coordinated palliative care that is unique to hospice programs. The palliative approach to care could benefit many more patients if it were available across care settings and earlier in the disease process. Palliative care programs are now being developed in other settings for patients who are either not eligible for hospice or who are “not ready” to enroll in a formal hospice program. As yet there is no dedicated reimbursement to providers for palliative care services when they are delivered outside the hospice setting, making the sustainability of such programs challenging.

Palliative Care in the Hospital Setting

Since the advent of diagnosis-related groups (DRGs) as the basis for prospective payment for hospital services in the 1980s, hospitals have had a financial incentive to transfer patients with terminal illnesses who are no longer in need of acute care to other settings, such as long-term care facilities and home, to receive care. Despite the economic and human costs associated with death in the hospital setting, as many as 50% of all deaths occur in acute care settings (MedPAC, 2006). The landmark Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments documented troubling deficiencies in the care of the dying in hospital settings (SUPPORT Principal Investigators, 1995). Other studies have demonstrated that the health care system continues to be challenged when meeting seriously ill patients’ needs for pain and symptom management and their families’ needs for information and support. However, numerous guidelines have been issued in recent years in an effort to improve care for seriously ill and dying patients across settings. For example, in its 2000 to 2001 standards, the Joint Commission recognized pain as the “fifth vital sign” to ensure that pain is assessed routinely (Phillips, 2000), and in 2006 the National Quality Forum (NQF) issued a consensus report on preferred practices for palliative and hospice care quality. The latter report builds on the NCP’s eight domains of quality palliative and hospice care to develop 38 preferred practices to serve as a foundation for quality monitoring and reporting in health care organizations.

It is clear that many patients will continue to opt for hospital care or will by default find themselves in hospital settings at the end of life. Increasingly, hospitals are conducting system-wide assessments of end-of-life care practices and outcomes and are developing innovative models for delivering high-quality, person-centered care to patients approaching the end of life. Hospitals cite considerable financial barriers to providing high-quality palliative care in acute care settings (Connor, 2007–2008). Public policy changes have been called for that would reimburse hospitals for care delivered via designated hospital-wide palliative care beds, clustered palliative care units, or palliative care consultation services in acute care settings. Resources are available for developing hospital–hospice partnerships to provide high-quality palliative care for hospitalized patients and for addressing the palliative care needs of other specialized populations, such as patients receiving such care in intensive care units (ICUs) and pediatric patients (Center to Advance Palliative Care, 2008).

Palliative Care in Long-Term Care Facilities

The total number of nursing home residents declined between 1985 and 2000 (Federal Interagency Forum on Aging-Related Statistics, 2006). However, experts estimate that 69% of people who now reach 65 years of age will need some form of long-term care in their lifetimes, whether in the community or in a residential care facility (American Association of Homes and Services for the Aging, 2007). As a result, the likely place of death for a growing number of Americans after age 65 will be a long-term care facility. A recent systematic review of available data revealed that nursing homes were the place of death for 25% to 40% of Americans (Gruneir, Mor, Weitzen, et al., 2007). These authors further noted that the trend toward care of dying patients in long-term care facilities will continue as the population ages and as managed care payers pressure health care providers to minimize costs.

Yet residents of long-term care facilities typically have poor access to high-quality palliative care. Regulations that govern how care in these facilities is organized and reimbursed tend to emphasize restorative measures and serve as a disincentive to palliative care. Since 1986, home hospice programs have been permitted to enroll long-term care facility residents in hospice programs and to provide interdisciplinary services to residents who qualify for hospice care. Of the more than 800,000 Medicare beneficiaries who received hospice services in 2005, 28% resided in long-term care facilities (Department of Health and Human Services [DHHS], 2007). These people were older, more likely to have noncancer diagnoses such as dementia, and to have spent more time in hospice care at a higher cost to Medicare (DHHS, 2007). In 1997, the Office of the Inspector General (OIG), an oversight arm of the federal government, questioned whether such services are an unnecessary duplication of services already provided by long-term care facility staff. In 2008, the OIG reported on the appropriateness of payments for hospice care in nursing homes. Meanwhile, long-term care facilities are under increasing public pressure to improve care of the dying and are beginning to develop palliative care units or services, to contract with home hospice programs to provide hospice

care in the facilities, and to educate staff, residents, and their families about pain and symptom management and end-of-life care.

Hospice Care

Hospice is a coordinated program of interdisciplinary services provided by professional caregivers and trained volunteers to patients with serious, progressive illnesses that are not responsive to cure. Hospice in the United States is not a place but a concept of care in which the end of life is viewed as a developmental stage. The root of the word hospice is *hospes*, meaning “host.” According to Cicely Saunders, who founded the world-renowned St. Christopher’s Hospice in London, the principles underlying hospice are as follows:

- Death must be accepted.
- The patient’s total care is best managed by an interdisciplinary team whose members communicate regularly with one another.
- Pain and other symptoms of terminal illness must be managed.
- The patient and family should be viewed as a single unit of care.
- Home care of the dying is necessary.
- Bereavement care must be provided to family members.
- Research and education should be ongoing.

Hospice Care in the United States

The hospice movement in the United States is based on the belief that meaningful living is achievable during terminal illness and that it is best supported in the home, free from technologic interventions to prolong physiologic dying. The concept of hospice care as an alternative to depersonalized death in institutions began in the early 1970s as a grassroots, volunteer-based, and spiritually centered movement. After the first hospice in the United States was founded in 1974 in Connecticut, the concept quickly spread, and the number of hospice programs in the United States increased dramatically. By 2007, there were 4,700 hospice programs in operation, serving an estimated 1.4 million patients (NHPCO, 2008).

Despite more than 30 years of existence in the United States, hospice remains an option for end-of-life care that has not been fully integrated into mainstream health care. Physicians are reluctant to refer patients to hospice, and patients are reluctant to accept this form of care. Reasons include the difficulties in making a terminal prognosis (especially for those patients with noncancer diagnoses), the strong association of hospice with death, advances in “curative” treatment options in late-stage illness, and financial pressures on health care providers that may cause them to retain rather than refer hospice-eligible patients. As a result, many patients and families do not fully benefit from the comprehensive, interdisciplinary support offered by hospice programs; the median length of stay in a hospice program is just under 20 days (NHPCO, 2008).

The goal of hospice is to enable the patient to remain at home, surrounded by the people and objects that have been important to him or her throughout life. The patient and family make up the unit of care. Hospice care does not seek

to hasten death or encourage the prolongation of life through artificial means. Hospice care hinges on the competent patient's full or "open" awareness of dying; it embraces realism about death and helps patients and families understand the dying process so that they can live each moment as fully as possible. Approximately 20% of hospice programs have developed inpatient facilities or residences (NHPCO, 2008) where terminally ill patients without family support and those who desire inpatient care may receive hospice services.

Funding Hospice Care

Since 1983, the **Medicare Hospice Benefit** has covered costs of hospice care for Medicare beneficiaries. State Medical Assistance (Medicaid) also provides coverage for hospice care, as do most commercial insurers. To receive Medicare payment for hospice services, programs are required to comply with rules known as "conditions of participation," which are enforced by the Centers for Medicare and Medicaid Services. In many aspects, Medicare standards have come to largely define hospice philosophy and services.

Eligibility criteria for hospice vary depending on the hospice program, but generally patients must have a progressive, irreversible illness and limited life expectancy and must opt for palliative care rather than cure-focused treatment. Chart 17-2 presents the eligibility criteria for hospice coverage under the Medicare Hospice Benefit. According to Medicare, the patient who wishes to use his or her Medicare Hospice Benefit must be certified by a physician as terminally ill, with a life expectancy of 6 months or less if the disease follows its natural course. Thus, hospice has come to be defined as care provided to terminally ill persons and their families in the last 6 months of the patient's life. Because of additional Medicare rules concerning completion of cure-focused medical treatment before the Medicare Hospice Benefit may be accessed, many patients delay

enrollment in hospice programs until very close to the end of life.

Federal rules for hospices require that patients' eligibility be reviewed periodically. Patients who live longer than 6 months under hospice care are not discharged if their physician and the hospice medical director continue to certify that the patient is terminally ill with a life expectancy of 6 months or less (assuming that the disease continues its expected course). Once a patient meets eligibility criteria and elects to use the benefit, the Medicare-certified hospice program assumes responsibility for providing and paying for the care and treatment related to the terminal illness for which hospice care was elected. The Medicare-certified hospice is paid a predetermined dollar amount for each day of hospice care that each patient receives. Four levels of hospice care are covered under Medicare and Medicaid hospice benefits:

- *Routine home care*: All services provided are included in the daily rate to the hospice.
- *Inpatient respite care*: A 5-day inpatient stay, provided on an occasional basis to relieve the family caregivers.
- *Continuous care*: Continuous nursing care provided in the home for management of a medical crisis. Care reverts to the routine home care level after the crisis is resolved. (For example, seizure activity develops and a nurse is placed in the home continuously to monitor the patient and administer medications. After 72 hours, the seizure activity is under control, the family has been instructed how to care for the patient, and the continuous nursing care is discontinued.)
- *General inpatient care*: Inpatient stay for symptom management that cannot be provided in the home. This is not subject to the guidelines for a standard hospital inpatient stay.

Most hospice care is provided at the "routine home care" level and includes the services described in Chart 17-3. According to federal guidelines, hospices may provide no more than 20% of the aggregate annual patient days at the inpatient level. Patients may "revoke" their hospice benefits at any time, resuming traditional coverage under Medicare or Medicaid for the terminal illness. Those who revoke their benefits may also elect to use them at a later time.

Chart 17-2 • Eligibility Criteria for Hospice Care

General

- Serious, progressive illness
- Limited life expectancy
- Informed choice of palliative care over cure-focused treatment

Hospice-Specific

- Presence of a family member or other caregiver continuously in the home when the patient is no longer able to safely care for him/herself (some hospices have created special services within their programs for patients who live alone, but this varies widely)

Medicare and Medicaid Hospice Benefits

- Medicare Part A; Medical Assistance eligibility
- Waiver of traditional Medicare/Medicaid benefits for the terminal illness
- Life expectancy of 6 months or less
- Physician certification of terminal illness
- Care must be provided by a Medicare-certified hospice program

Chart 17-3 • Home Hospice Services Covered Under the Medicare/Medicaid Hospice Benefit Routine Home Care Level

- Nursing care provided by or under the supervision of a registered nurse, available 24 hours a day
- Medical social services
- Physician's services
- Counseling services, including dietary counseling
- Home health aide/homemaker
- Physical/occupational/speech therapists
- Volunteers
- Bereavement follow-up (for up to 13 months after the death of the patient)
- Medical supplies for the palliation of the terminal illness
- Medical equipment for the palliation of the terminal illness
- Medications for the palliation of the terminal illness

Hospice programs are reaching out to patients with very advanced illness and seeking ways to provide them with hospice services while they are completing courses of treatment that many programs previously defined as “life-prolonging,” such as disease-modifying therapies for dementia, enteral or parenteral nutritional support, and certain types of chemotherapy. The hospice industry has begun to refer to more flexible policies concerning disease-modifying medical treatment at the time of admission as “open access.” The National Hospice and Palliative Care Organization acknowledges the concept of open access, stating that palliative care is “treatment that enhances comfort and improves the quality of an individual’s life during the last phase of life. No specific therapy is excluded from consideration” (NHPCO, 2006).

Hospice use has increased steadily since the inception of the Medicare Hospice Benefit. Between 2000 and 2004, hospice use among Medicare beneficiaries increased by 50%, and within that period, the proportion of hospice enrollees with cancer diagnoses fell to 43% of the total. The most common primary hospice diagnoses among Medicare patients are neurodegenerative diseases (such as dementia and Parkinson’s disease) followed by cardiovascular diseases (MedPAC, 2006).

Although hospice utilization continues to increase, many patients who could benefit from hospice care do not receive it. Only slightly more than one third of Americans who died in 2007 had received hospice care (NHPCO, 2008). Most terminally ill patients who are not enrolled in hospice die in hospitals and long-term care facilities.

Nursing Care of Terminally Ill Patients

Many patients suffer unnecessarily when they do not receive adequate attention for the symptoms accompanying serious illness. Careful evaluation of the patient should include not only the physical problems but also the psychosocial and spiritual dimensions of the patient’s and family’s experience of serious illness. This approach contributes to a more comprehensive understanding of how the patient’s and family’s life has been affected by illness and leads to nursing care that addresses their needs in every dimension.

Psychosocial Issues

Nurses are responsible for educating patients about their illness and for supporting them as they adapt to life with the illness. Nurses can assist patients and families with life review, values clarification, treatment decision making, and end-of-life closure. The only way to do this effectively is to try to appreciate and understand the illness from the patient’s perspective.

Nurses should be both culturally aware and sensitive in their approaches to communication with patients and families about death. Attitudes toward open disclosure about terminal illness vary widely among different cultures, and direct communication with patients about such matters may be viewed as harmful (Barclay, Blackwell & Tulsy, 2007). To provide effective patient-centered and family-centered care at the end of life, nurses must be willing to set

aside their own assumptions and attitudes so that they can discover what type and amount of disclosure is most meaningful to each patient and family within their unique belief systems (Table 17-1).

The social and legal evolution of advance directive documents represents some progress in people’s willingness to both contemplate and communicate their wishes concerning the end of life (Chart 17-4). Now legally sanctioned in every state and federally sanctioned through the Patient Self-Determination Act of 1991, advance directives are written documents that allow competent people to document their preferences regarding the use or nonuse of medical treatment at the end of life, specify their preferred setting for care, and communicate other valuable insights into their values and beliefs. The addition of a proxy directive (the appointment and authorization of another person to make medical decisions on behalf of the person who created the advance directive when he or she can no longer speak for himself or herself) is an important addition to the “living will” or medical directive that specifies the signer’s preferences. These documents are widely available from health care providers, community organizations, bookstores, and the Internet. However, their underuse reflects society’s continued discomfort with openly confronting the subject of death. Furthermore, the existence of a properly executed advance directive does not reduce the complexity of end-of-life decisions.

The Patient Self-Determination Act requires that health care entities receiving Medicare or Medicaid reimbursement must ask if patients have advance directives, provide information about advance directives, and incorporate advance directives into the medical record. However, advance directives should not be considered a substitute for ongoing

Chart 17-4 • Methods of Stating End-of-Life Preferences

Advance directives—written documents that allow the individual of sound mind to document preferences regarding end-of-life care that should be followed when the signer is terminally ill and unable to verbally communicate his/her wishes. The documents are generally completed in advance of serious illness, but may be completed after a diagnosis of serious illness if the signer is still of sound mind. The most common types are the durable power of attorney for health care and the living will.

Durable power of attorney for health care—a legal document through which the signer appoints and authorizes another individual to make medical decisions on his/her behalf when he/she is no longer able to speak for him/herself. This is also known as a health care power of attorney or a proxy directive.

Living will—a type of advance directive in which the individual documents treatment preferences. It provides instructions for care in the event that the signer is terminally ill and not able to communicate his/her wishes directly and often is accompanied by a durable power of attorney for health care. This is also known as a medical directive or treatment directive.

Information about the advance care planning and state-specific advance directive documents and instructions are available at www.caringinfo.org

Table 17-1 OVERVIEW OF RELIGIOUS AND CULTURAL BELIEFS AND VIEWS ON DEATH AND DYING

Religion	General Religious/Cultural Beliefs	Views About Death/Preparing for Death
Hinduism	<ul style="list-style-type: none"> Each caste has a different view of death. This life is a transition between the previous life and the next. Bodies are cremated. During the first 10 days after death, relatives must create a new ethereal body. Good <i>karma</i> leads to good rebirth or release, and bad <i>karma</i> leads to bad rebirth. 	<ul style="list-style-type: none"> Many elderly people withdraw into their homes, where they prepare for death through prayer and meditation. A “good death” is timely, in the right place (on the ground at home), conscious and prepared, with the mind on God. All affairs should be in order. A “bad death” is untimely, violent, and unprepared. The worst death is suicide.
Judaism	<ul style="list-style-type: none"> Human beings are mortal, and their bodies belong to God. Although the physician has the authority to determine the appropriate course of treatment, ultimately the patient has the right to choose, as long as the medical regimen follows Jewish law. Disclosure is important. Most patients want to know the truth. Jews are obligated to visit the sick. 	<ul style="list-style-type: none"> Traditional criteria for death are cessation of breathing and heartbeat. Conservative rabbis have accepted brain death as fulfilling these criteria. Advance directives for health care are permissible. Views on the use of artificial nutrition and hydration vary, depending on the particular sect/movement. Most rabbis maintain that Jews may enroll in hospice.
Buddhism	<ul style="list-style-type: none"> There is no central authority in the Buddhist religion. Taboo and religious purity play little, if any, role, and religious law imposes no special requirements for medical treatment. Treatment by someone of the same gender is preferable. Cremation is the most common way of disposing of the dead. Some Buddhists may be unwilling to take pain-relieving medications or strong sedatives. It is believed that an unclouded mind can lead to a better rebirth. Buddhists believe that after death there is either rebirth or nirvana—the latter being enlightenment that frees the soul from the cycle of death and rebirth. 	<ul style="list-style-type: none"> Teachings emphasize the inevitability of death; therefore, Buddhists tend to be psychologically prepared to accept impending death with calmness and dignity. Death occurs when a body is bereft of vitality, heat, and sentience. Brain death is disputed as meeting the requirements for death. It is often appropriate to decide that the patient is beyond medical help and to allow events to take their course. In these cases, it is justifiable to refuse or withdraw treatment in light of the overall prognosis. Buddhism supports the use of hospice.
Islam	<ul style="list-style-type: none"> Muslims believe in one God. God revealed the message of God to Muhammad, the prophet, in the Qur’an (Koran). The Qur’an states that Muslims should maintain a balanced diet and exercise. Muslim patients may wish to engage in ritual prayer, practiced five times during the day. Fasting during the month of Ramadan is a pillar of Islam. Completion of the pilgrimage (<i>hajj</i>) to Mecca (money and health permitting), at least once, is also a pillar of Islam. 	<ul style="list-style-type: none"> Everyone will face death, and the way a person dies is of great individual importance. Death cannot happen except by God’s permission. However, it is recognized that diseases and trauma cause death. There is a belief that health care providers must do everything possible to prevent a premature death. Pain is a cleansing instrument of God. Pain can also be viewed as having an educational purpose (pain can compensate for sin). The killing of a terminally ill person is an act of disobedience against God. However, pain relief or withholding or withdrawing of life support when there is no doubt that the person’s disease is causing untreatable suffering is permissible as long as there is formal agreement among all parties concerned.
Traditional Christianity	<ul style="list-style-type: none"> Christians believe in one God. The belief in eternal salvation sets Christianity apart. Beliefs vary. Some Christians hope to attain eternal salvation, and some view the religion more as a culture. Even within a family, religious views can differ. Some family members may not follow the religion at all. 	<ul style="list-style-type: none"> Intentionally bringing about death by either omission or commission is prohibited. The appropriateness of analgesia and sedation to avoid terminal suffering and despair is acceptable, if it does not, by clouding consciousness, take away the final opportunity for repentance. There is no obligation to postpone death; the attempt to save life at all costs is forbidden. However, there could be a duty to use high-technology medicine to gain a last opportunity for repentance. Impending death offers a final chance to become reconciled with those whom one has harmed and to ask God’s forgiveness. Liturgical (ceremonial) Christians generally regard last rites as integral to the relationship with God. Repentance can include confessing formally and receiving Communion and final anointing. This often involves particular ministers. Christians who follow the religion at a cultural level are likely to have secular approaches to end-of-life decisions. Advance directives allow patients to appoint decision makers and to provide instructions that ensure that their wishes are followed.

communication among the health care provider, patient, and family as the end of life approaches (Tulsky, 2005).

Communication

As previously discussed, remarkable strides have been made in the ability to prolong life, but attention to care for the dying lags behind. On one level, this should come as no surprise. Each of us will eventually face death, and most would agree that one's own demise is a subject he or she would prefer not to contemplate. Confronting death in our patients uncovers our own deeply rooted fears.

To develop a level of comfort and expertise in communicating with seriously and terminally ill patients and their families, nurses must first consider their own experiences with and values concerning illness and death. Reflection, reading, and talking with family members, friends, and colleagues can help nurses examine beliefs about death and dying. Talking with people from different cultural and religious backgrounds can help nurses view personally held beliefs through a different lens and can increase their sensitivity to death-related beliefs and practices in other cultures. Discussion with nursing and nonnursing colleagues can also be useful; it may reveal the values shared by many health care professionals and may also identify diversity in the values of patients in their care. Values clarification and personal death awareness exercises can provide a starting point for self-discovery and discussion.

Skills for Communicating With the Seriously Ill

Nurses need to develop skill and comfort in assessing patients' and families' responses to serious illness and planning interventions that support their values and choices throughout the continuum of care. Throughout the course of a serious illness, patients and their families encounter complicated treatment decisions and bad news about disease progression. They may have to make difficult decisions at the time of diagnosis, when disease-focused treatment fails, when the effectiveness of a particular intervention is being discussed, and when decisions about hospice care are presented. These critical points on the treatment continuum demand patience, empathy, and honesty from nurses. Discussing sensitive issues such as serious illness, hopes for survival, and fears associated with death is never easy. However, the art of therapeutic communication can be learned and, like other skills, must be practiced to gain expertise. Like other skills, communication should be practiced in a "safe" setting, such as a classroom or clinical skills laboratory with other students or clinicians.

Communication with each patient and family should be tailored to their particular level of understanding and values concerning disclosure. Before disclosing any health information about a patient to family members, nurses should follow their agency's policy for obtaining patient consent in accordance with Health Insurance Portability and Accountability Act (HIPAA) rules.

Nursing Interventions When Patients and Families Receive Bad News

Communicating about a life-threatening diagnosis or about disease progression is best accomplished by the interdisciplinary team in any setting: a physician, nurse, social worker,

and chaplain should be present whenever possible to provide information, facilitate discussion, and address concerns. Most important, the presence of the team conveys caring and respect for the patient and family. If the patient wishes to have family present for the discussion, arrangements should be made to have the discussion at a time that is best for everyone. Creating the right setting is particularly important. A quiet area with a minimum of disturbances should be used. All clinicians present should turn off pagers, cell phones, and other communication devices for the duration of the meeting and should allow sufficient time for the patient and family to absorb and respond to the news. Finally, the space in which the meeting takes place should be conducive to seating all participants at eye level. It is difficult enough for the patient and family to be the recipients of bad news without having an array of clinicians standing uncomfortably over them at the foot of the patient's bed.

After the initial discussion of a life-threatening illness or progression of a disease, the patient and family will probably have many questions and may need to be reminded of factual information. Coping with news about a serious diagnosis or poor prognosis is an ongoing process. The nurse should be sensitive to these ongoing needs and may need to repeat previously provided information or simply be present while the patient and family react emotionally. The most important intervention the nurse can provide is listening empathetically. Seriously ill patients and their families need time and support to cope with the changes brought about by serious illness and the prospect of impending death. The nurse who is able to listen without judging and without trying to solve the patient's and family's problems provides an invaluable intervention. Keys to effective listening include the following:

- Resist the impulse to fill the "empty space" in communication with talk.
- Allow the patient and family sufficient time to reflect and respond after asking a question.
- Prompt gently: "Do you need more time to think about this?"
- Avoid distractions (noise, interruptions).
- Avoid the impulse to give advice.
- Avoid canned responses: "I know just how you feel."
- Ask questions.
- Assess understanding—your own and the patient's—by restating, summarizing, and reviewing.

Responding With Sensitivity to Difficult Questions

Patients often direct questions or concerns to nurses before they have been able to fully discuss the details of their diagnosis and prognosis with their physicians or the entire health care team. Using open-ended questions allows the nurse to elicit the patient's and family's concerns, explore misconceptions and needs for information, and form the basis for collaboration with physicians and other team members.

For example, a seriously ill patient may ask the nurse, "Am I dying?" The nurse should avoid making unhelpful responses that dismiss the patient's real concerns or defer the issue to another care provider. Nursing assessment and intervention are always possible, even when a need for further discussion with a physician is clearly indicated. Whenever possible,

discussions in response to a patient's concerns should occur when the patient expresses a need, although that may be the least convenient time for the nurse. Creating an uninterrupted space of just 5 minutes can do much to identify the source of the concern, allay anxieties, and plan for follow-up.

In response to the question, "Am I dying?," the nurse could establish eye contact and follow with a statement acknowledging the patient's fears ("This must be very difficult for you") and an open-ended statement or question ("Tell me more about what is on your mind"). The nurse then needs to listen intently, ask additional questions for clarification, and provide reassurance only when it is realistic. In this example, the nurse might quickly ascertain that the patient's question emanates from a need for specific information—about diagnosis and prognosis from the physician, about the physiology of the dying process from the nurse, or perhaps about financial implications for the family from the social worker. The chaplain may also be called to talk with the patient about existential concerns.

As a member of the interdisciplinary team caring for the patient at the end of life, the nurse plays an important role in facilitating the team's understanding of the patient's values and preferences, family dynamics concerning decision making, and the patient's and family's response to treatment and changing health status. Many dilemmas in patient care at the end of life are related to poor communication between team members and the patient and family, as well as to failure of team members to communicate with one another effectively. Regardless of the care setting, the nurse can ensure a proactive approach to the psychosocial care of the patient and family. Periodic, structured assessments provide an opportunity for all parties to consider their priorities and plan for an uncertain future. The nurse can help the patient and family clarify their values and preferences concerning end-of-life care by using a structured approach. Sufficient time must be devoted to each step, so that the patient and family have time to process new information, formulate questions, and consider their options. The nurse may need to plan several meetings to accomplish the steps described in Chart 17-5.

Providing Culturally Sensitive Care at the End of Life

Although death, grief, and mourning are universally accepted aspects of living, the values, expectations, and practices during serious illness, as death approaches and after death are culturally bound and expressed. Health care providers may share very similar values concerning end-of-life care and may find that they are inadequately prepared to assess for and implement care plans that support culturally diverse perspectives. Historical mistrust of the health care system and unequal access to even basic medical care may underlie the beliefs and attitudes among ethnically diverse populations (see Table 17-1). In addition, lack of education or knowledge about end-of-life care treatment options and language barriers influence decisions among many socioeconomically disadvantaged groups.

The nurse's role is to assess the values, preferences, and practices of every patient, regardless of ethnicity, socioeconomic status, or background. The nurse can share knowledge about a patient's and family's cultural beliefs and practices

Chart 17-5 • Breaking Bad News: The S-P-I-K-E-S Strategy

Setting (S)

- Arrange for a private setting.
- Involve significant others: Identify who will be the spokesperson (if applicable).
- Sit down.
- Communicate that you are listening, using silence and repetition.
- Remain available for the duration of the meeting.

Perception (P)

- Identify what the patient and family understand.
- Use the same vocabulary that they do.

Invitation (I)

- Obtain permission for the depth and breadth of information to be shared.

Knowledge (K)

- Provide a warning that bad news is going to be shared.
- Avoid technical language.
- Give the information in small chunks.
- Tailor the rate at which information is provided.

Empathy (E)

- Listen for and identify the emotion (or mix of emotions).
- Identify the source or cause of the emotion.
- Show the patient that you have made the connection between emotion and cause.

Strategy and Summary (S)

- Check for understanding.
- Summarize the discussion.
- Reiterate the plan.

Adapted with permission from Buckman, R. A. (2005). Breaking bad news: The S-P-I-K-E-S strategy. *Community Oncology*, 2(2), 138-142.

with the health care team and facilitate the adaptation of the care plan to accommodate these practices. For example, a nurse may find that a male patient prefers to have his eldest son make all of his care decisions. Institutional practices and laws governing informed consent are also rooted in the Western notion of autonomous decision making and informed consent. If a patient wishes to defer decisions to his son, the nurse can work with the team to negotiate informed consent, respecting the patient's right not to participate in decision making and honoring his family's cultural practice.

The nurse should assess and document the patient's and family's specific beliefs, preferences, and practices regarding end-of-life care, preparation for death, and after-death rituals. Chart 17-6 identifies topics that the nurse should cover and questions the nurse may use to elicit the information.

The nurse must use judgment and discretion about the timing and setting for eliciting this information. Some patients may wish to have a family member speak for them or may be unable to provide information because of advanced illness. The nurse should give the patient and family a context for the discussion, such as, "It is very important to us to provide care that addresses your needs and the needs of your

CHART
17-6

Assessing End-of-Life Care Beliefs, Preferences, and Practices

Disclosure/truth telling: “Tell me how you/your family talk about very sensitive or serious matters.”

- Content: “Are there any topics that you or your family are uncomfortable discussing?”
- Person responsible for disclosure: “Is there one person in the family who assumes responsibility for obtaining and sharing information?”
- Disclosure practices regarding children: “What kind of information may be shared with children in your family, and who is responsible for communicating with the children?”
- Sharing of information within the family or community group: “What kind/how much information should be shared with your immediate family? Your extended family? Others in the community (for example, members of a religious community)?”

Decision-making style: “How are decisions made in your family? Who would you like to be involved in decisions about your treatment or care?”

- Individual
- Family-centered
- Family elder or patriarch/matriarch
- Deference to authority (such as the physician)

Symptom management: “How would you like us to help you to manage the physical effects of your illness?”

- Acceptability of medications used for symptom relief
- Beliefs regarding expression of pain and other symptoms
- Degree of symptom management desired

Life-sustaining treatment expectations: “Have you thought about what type of medical treatment you or your loved one would want as the end of life is nearing? Do you have an advance directive (living will and/or durable power of attorney)?”

- Nutrition/hydration at the end of life
- Cardiopulmonary resuscitation
- Ventilator
- Dialysis
- Antibiotics
- Medications to treat infection

Desired location of dying: “Do you have a preference about being at home or in some other location when you die?”

- Desired role for family members in providing care: “Who do you want to be involved in caring for you at the end of life?”
- Gender-specific prohibitions: “Are you uncomfortable having either males or females provide your care or your loved one’s personal care?”

Spiritual/religious practices and rituals: “Is there anything that we should know about your spiritual or religious beliefs about death? Are there any practices that you would like us to observe as death is nearing?”

Care of the body after the death: “Is there anything that we should know about how a body/your body should be treated after death?”

Expression of grief: “What types of losses have you and your family experienced? How do you and your family express grief?”

Funeral and burial practices: “Are there any rituals or practices associated with funerals or burial that are especially important to you?”

Mourning practices: “How have you and your family carried on after a loss in the past? Are their particular behaviors or practices that are expected or required?”

family. We want to honor and support your wishes, and want you to feel free to tell us how we are doing, and what we could do to better meet your needs. I’d like to ask you some questions; what you tell me will help me to understand and support what is most important to you at this time. You don’t need to answer anything that makes you uncomfortable. Is it all right to ask some questions?” The assessment of end-of-life beliefs, preferences, and practices should be carried out in short segments over a period of time (for example, across multiple days of an inpatient hospital stay or in conjunction with multiple patient visits to an outpatient setting). The discomfort of novice nurses with asking questions and discussing this type of sensitive content can be reduced by prior practice in a classroom or clinical skills laboratory, observation of interviews conducted by experienced nurses, and partnering with experienced nurses during the first few assessments.

Goal Setting in Palliative Care at the End of Life

As treatment goals begin to shift in the direction of comfort care over aggressive disease-focused treatment, symptom relief and patient/family-defined quality of life assume greater prominence in treatment decision making. Throughout the course of the illness, and especially as the patient’s functional status and symptoms indicate approaching death, the

clinician should help the patient and family weigh the benefits of continued diagnostic testing and disease-focused medical treatment against the costs of those activities. The patient and family may be extremely reluctant to forgo monitoring that has become routine throughout the illness (eg, blood testing, x-rays) but that may contribute little to a primary focus on comfort. Likewise, health care providers may have difficulty discontinuing such diagnostic testing or medical treatment.

Specifically, the nurse should collaborate with other members of the interdisciplinary team to share assessment findings and develop a coordinated plan of care (Fig. 17-1). In addition, the nurse should help the patient and family clarify their goals, expected outcomes, and values as they consider treatment options (Chart 17-7). The nurse should work with colleagues in other disciplines to ensure that the patient and family are referred for continuing psychosocial support, symptom management, and assistance with other care-related challenges (eg, arrangements for home care or hospice support, referrals for financial assistance).

Spiritual Care

Attention to the spiritual component of the illness experienced by the patient and family is not new within the context of nursing care, yet many nurses lack the comfort or skills to assess and intervene in this dimension. **Spirituality**

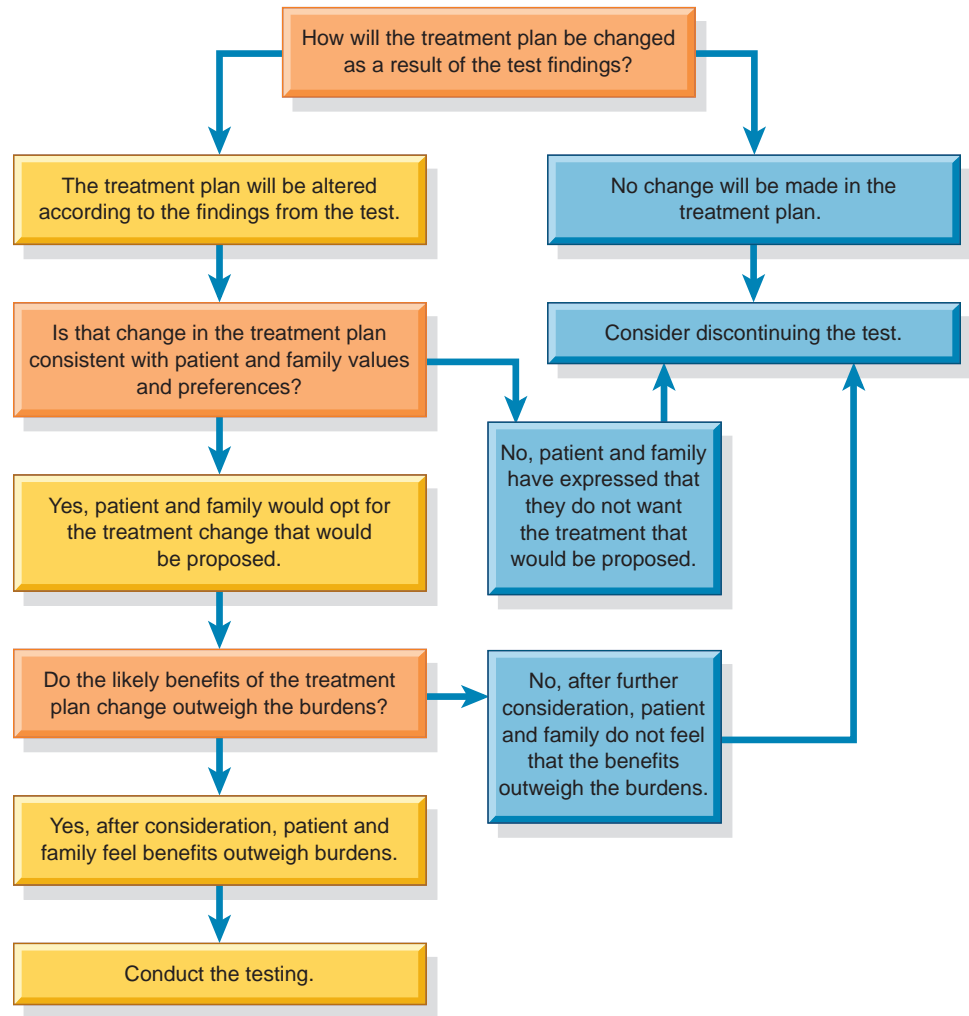

Figure 17-1 An algorithm for decision making about diagnostic testing at the end of life.

CHART
17-7

Assessing the Patient and Family Perspective: Goal Setting in Palliative Care

Patient and family

- **Awareness of diagnosis, illness stage, and prognosis:** “Tell me your understanding of your illness right now.”
- **Values:** “Tell me what is most important to you as you are thinking about the treatment options available to you/your loved one.”
- **Preferences:** “You’ve said that being comfortable and pain-free is most important to you right now. Where would you like to receive care (home, hospital, long-term care facility, doctor’s office), and how can I help?”
- **Expected/desired outcomes:** “What are your hopes and expectations for this (diagnostic test [eg, CT scan] or treatment)?”
- **Benefits and burdens:** “Is there a point at which you would say that the testing or treatment is outweighed by the burdens it is causing you (eg, getting from home to the hospital, pain, nausea, fatigue, interference with other important activities)?”

contains features of religiosity, but the two concepts are not interchangeable (Puchalski, Lunsford, Marris, et al., 2006). Spirituality refers to “one’s relationship with the transcendent questions that confront one as a human being and how one relates to those questions” (Sulmasy, 2006, p. 1386). For most people, contemplating one’s own death raises many issues, such as the meaning of existence, the purpose of suffering, and the existence of an afterlife. A survey on end-of-life issues conducted by the American Association of Retired Persons (AARP, 2005) revealed the following:

- Total physical dependency was worse than death (87%).
- Dying painfully (49%), dying from a long-term illness (36%), dying in an institution (30%), and dying alone (21%) made many people “very afraid.”
- Being free from pain (74%), being at peace spiritually (69%), and knowing how to say goodbye were “very important” (67%).

The spiritual assessment is a key component of comprehensive nursing assessment for terminally ill patients and their families. Although the nursing assessment should include religious affiliation, spiritual assessment is conceptually much

broader than religion and therefore is relevant regardless of a patient's expression of religious preference or affiliation. In addition to assessment of the role of religious faith and practices, important religious rituals, and connection to a religious community (see Table 17-1), the nurse should further explore:

- The harmony or discord between the patient's and the family's beliefs
- Other sources of meaning, hope, and comfort
- The presence or absence of a sense of peace of mind and purpose in life
- Spiritual or religious beliefs about illness, medical treatment, and care of the sick

Puchalski (2007–2008) created a four-step spiritual assessment process using the acronym FICA, which involves asking the following questions:

- **Faith and belief:** Do you consider yourself to be a spiritual or religious person? What is your *faith* or belief? What gives your life meaning?
- **Importance and Influence:** What *importance* does faith have in your life? Have your beliefs influenced the way you take care of yourself and your illness? What role do your beliefs play in regaining your health?
- **Community:** Are you a part of a spiritual or religious *community*? Is this of support to you and how? Is there a group of people you really love or who are important to you?
- **Address in care:** How would you like me to *address* these issues in your health care?

Hope

Clinicians and researchers have observed that although specific hopes may change over time, hope generally persists in some form across every stage of illness. In terminal illness, hope represents the patient's imagined future, forming the basis of a positive, accepting attitude and providing the patient's life with meaning, direction, and optimism. When hope is viewed in this way, it is not limited to cure of the disease; instead, it focuses on what is achievable in the time remaining. Many patients find hope in working on important relationships and creating legacies. Terminally ill patients can be extremely resilient, reconceptualizing hope repeatedly as they approach the end of life.

Numerous nurse researchers have studied the concept of hope, and they have related its presence to spirituality, quality of life, and transcendence. Hope is a multidimensional construct that provides comfort as a person endures life threats and personal challenges. Buckley and Herth (2004) identified the following categories of hope-fostering and hope-hindering activities among terminally ill hospice patients with various diagnoses:

- **Hope-fostering categories:** love of family and friends, spirituality/faith, setting goals and maintaining independence, positive relationships with clinicians, humor, personal characteristics, and uplifting memories
- **Hope-hindering categories:** abandonment and isolation, uncontrollable pain/discomfort, and devaluation of personhood

Nurses can support hope for the patient and family by using effective listening and communication skills, thus encouraging realistic hope that is specific to their needs for informa-

tion, expectations for the future, and values and preferences concerning the end of life. It is important for the nurse to engage in self-reflection and to identify his or her own biases and fears concerning illness, life, and death. As the nurse becomes more skilled in working with seriously ill patients, he or she can become less determined to “fix” and more willing to listen; more comfortable with silence, grief, anger, and sadness; and more fully present with patients and their families.

Nursing interventions for enabling and supporting hope include the following:

- Listening attentively
- Encouraging sharing of feelings
- Providing accurate information
- Encouraging and supporting the patient's control over his or her circumstances, choices, and environment whenever possible
- Assisting patients to explore ways for finding meaning in their lives
- Encouraging realistic goals
- Facilitating effective communication within families
- Making referrals for psychosocial and spiritual counseling
- Assisting with the development of supports in the home or community when none exist

Managing Physiologic Responses to Terminal Illness

Patients approaching the end of life experience many of the same symptoms, regardless of their underlying disease processes. Symptoms in terminal illness may be caused by the disease, either directly (eg, dyspnea due to chronic obstructive lung disease) or indirectly (eg, nausea and vomiting related to pressure in the gastric area), by the treatment for the disease, or by a coexisting disorder that is unrelated to the disease. Symptoms should be carefully and systematically assessed and managed. Questions that guide the assessment of symptoms are listed in Chart 17-8. Also, see the Nursing Research Profile presented in Chart 17-9.

CHART
17-8

Assessing Symptoms Associated With Terminal Illness

- How is this symptom affecting the patient's life?
- What is the meaning of the symptom to the patient? To the family?
- How does the symptom affect physical functioning, mobility, comfort, sleep, nutritional status, elimination, activity level, and relationships with others?
- What makes the symptom better?
- What makes it worse?
- Is it worse at any particular time of the day?
- What are the patient's expectations and goals for managing the symptom? The family's?
- How is the patient coping with the symptom?
- What is the economic effect of the symptom and its management?

17-9

NURSING RESEARCH PROFILE

Symptoms in Hospice Patients With End-Stage Heart Disease

McMillan, S. C., Dunbar, S. B. & Zhang, W. (2007). The prevalence of symptoms in hospice patients with end-stage heart disease. *Journal of Hospice and Palliative Nursing*, 9(3), 124–131.

Purpose

Heart disease is the leading cause of death in the United States. After cancer, it is the second most frequent diagnosis in hospice patients; however, little is known about how to guide patient care as patients with heart disease approach the end of life. The purpose of this study was to evaluate the type and frequency of symptoms in patients with end-stage heart failure newly enrolled in hospices. Such research is needed so that effective interventions for this group of patients can be developed.

Design

In this study, researchers conducted a retrospective review of medical records of patients with end-stage heart failure as the primary diagnosis who were admitted to a large, not-for-profit hospice program in 2004. They collected data from 51 eligible patients, using a medical record audit form to guide data collection. The form addressed demographic data, physical symptoms, and psychosocial assessment data. Psychosocial data included 10 depressive symptoms. Researchers also assessed satisfaction with social support in a subset of patients and caregivers.

Findings

The average length of stay (LOS) in the hospice was 127.5 days, with a range of 1 to 195 days and a median of 31 days.

The average patient age was 80.3 years and 57.1 years for caregivers. The majority of the subjects were Caucasian, and the number of men and women was about equal. Caregivers were more likely to be women.

Patients reported 1 to 28 symptoms, with an average of 11.9 symptoms. The most prevalent symptom was fatigue or weakness (82.4%) followed by shortness of breath (76.5%). (Shortness of breath was noted at rest in 52.9% of medical records.) Swelling or edema was subjectively reported in 56.9% of patients. Slightly more than 41% reported weight loss with decreased appetite reported by 49%. Nearly 40% reported difficulty concentrating and many reported chest pain (37.3%) and chest pressure (25.5%). “Worst pain in the past 24 hours” averaged 6.9 on a scale of 0 to 10, which was nearly in the severe range.

Nursing Implications

The LOS in the hospice program for patients with end-stage heart failure exceeded national norms for hospice patients (all diagnoses combined). This may reflect difficulty predicting life expectancy in patients with noncancer diagnoses.

In the patients, fatigue or weakness and shortness of breath were very common. These subjective symptoms need to be assessed by the health care team; patients can rate their intensity and associated distress on a scale of 0 to 10. Health care team members need to accept as valid patients’ reports about these symptoms and to identify interventions to address them. The findings of this study can be used to develop and test specific interventions that can be tested in future research.

The patient’s goals should guide symptom management. Medical interventions may be aimed at treating the underlying causes of the symptoms or reducing the impact of symptoms. For example, a medical intervention such as thoracentesis (an invasive procedure in which fluid is drained from the pleural space) may be performed to temporarily relieve dyspnea in a patient with pleural effusion secondary to lung cancer. Pharmacologic and nonpharmacologic methods of symptom management may be used in combination with medical interventions to modify the physiologic causes of symptoms. In addition, pharmacologic management with low-dose oral morphine is very effective in relieving dyspnea (Lorenz, Lynn, Dy, et al., 2008), and guided relaxation may reduce the anxiety associated with the sensation of breathlessness. As is true with pain, the principles of pharmacologic symptom management are use of the smallest dose of the medication to achieve the desired effect, avoidance of polypharmacy, anticipation and management of adverse effects, and creation of a therapeutic regimen that is acceptable to the patient based on his or her goals for maximizing quality of life.

The patient’s goals take precedence over the clinicians’ goals to relieve all symptoms at all costs. Although clini-

cians may believe that symptoms must be completely relieved whenever possible, the patient might choose instead to decrease symptoms to a tolerable level rather than to relieve them completely if the side effects of medications are unacceptable to him or her. This often allows the patient to have greater independence, mobility, and alertness and to devote attention to issues he or she considers of higher priority and greater importance.

Anticipating and planning interventions for symptoms is a cornerstone of end-of-life care. Both patients and family members cope more effectively with new symptoms and exacerbations of existing symptoms when they know what to expect and how to manage them. Hospice programs typically provide “emergency kits” containing ready-to-administer doses of a variety of medications that are useful to treat symptoms in advanced illness. For example, a kit might contain small doses of oral morphine liquid for pain or shortness of breath, a benzodiazepine for restlessness, and an acetaminophen suppository for fever. Family members can be instructed to administer a prescribed dose from the emergency kit, often avoiding prolonged suffering for the patient as well as rehospitalization for symptom management.

Pain

In the final stages of illnesses such as cancer, acquired immunodeficiency syndrome (AIDS), heart disease, COPD, and renal disease, pain and other symptoms are common (Solano, Gomes & Higginson, 2006). Pain results from both the diseases and the modalities used to treat them. A recent analysis of the research literature revealed that despite abundant literature and World Health Organization guidelines for pain management, prevalence of pain is as high as 50% in patients with cancer of any type (van den Beuken-van Everdingen, de Rijke, Kessels, et al., 2007) as well as in terminally ill patients with common noncancer diagnoses (Solano, et al., 2006). Chapter 13 presents the importance of pain assessment, assessment principles for pain that include identifying the effect of the pain on the patient's life, and the importance of believing the patient's report of the pain and its effect. Although the means to relieve pain have existed for many years, the continued, pervasive undertreatment of pain has been well documented. Poorly managed pain affects the psychological, emotional, social, and financial well-being of patients. Despite studies demonstrating the negative effects of inadequate pain management, practice has been slow to change (Gordon, Dahl, Miaskowski, et al., 2005).

Patients who are receiving an established regimen of analgesics should continue to receive those medications as they approach the end of life. Inability to communicate pain should not be equated with the absence of pain. Although most pain can be managed effectively using the oral route, as the end of life nears, patients may be less able to swallow oral medications due to somnolence or nausea. Patients who have been receiving opioids should continue to receive equianalgesic doses via rectal or sublingual routes. Concentrated morphine solution can be very effectively delivered by the sublingual route, because the small liquid volume is well tolerated even if swallowing is not possible. As long as the patient continues to receive opioids, a regimen to combat constipation must be implemented. If the patient cannot swallow laxatives or stool softeners, rectal suppositories or enemas may be necessary.

The nurse should teach the family about continuation of comfort measures as the patient approaches the end of life, how to administer analgesics via alternative routes, and how to assess for pain when the patient cannot verbally report pain intensity. Because the analgesics administered orally or rectally are short-acting and typically scheduled as frequently as every 3 to 4 hours around the clock, there is always a strong possibility that a patient approaching the end of life will die in close proximity to the time of analgesic administration. If the patient is at home, family members administering analgesics should be prepared for this possibility. They need reassurance that they did not "cause" the death of the patient by administering a dose of analgesic medication.

Dyspnea

Dyspnea is an uncomfortable awareness of breathing that is common in patients approaching the end of life (Weissman, 2005). A highly subjective symptom, dyspnea often is not associated with visible signs of distress, such as tachypnea,

diaphoresis, or cyanosis. Patients with primary lung tumors, lung metastases, pleural effusion, or restrictive lung disease may experience significant dyspnea. Although the underlying cause of the dyspnea can be identified and treated in some cases, the burdens of additional diagnostic evaluation and treatment aimed at the physiologic problem may outweigh the benefits. The treatment of dyspnea varies depending on the patient's general physical condition and imminence of death. For example, a blood transfusion may provide temporary symptom relief for a patient with anemia earlier in the disease process; however, as the patient approaches the end of life, the benefits are typically short-lived or absent.

Nursing Assessment and Intervention

As with assessment and management of pain, reports of dyspnea by patients must be believed. As is true for physical pain, the meaning of dyspnea to an individual patient may increase his or her suffering. For example, the patient may interpret increasing dyspnea as a sign that death is approaching. For some patients, sensations of breathlessness may invoke frightening images of drowning or suffocation, and the resulting cycle of fear and anxiety may increase the sensation of breathlessness. Therefore, the nurse should conduct a careful assessment of the psychosocial and spiritual components of the dyspnea. Physical assessment parameters include symptom intensity, distress, and interference with activities; auscultation of lung sounds; assessment of fluid balance, including measurement of dependent edema (circumference of lower extremities) and abdominal girth; temperature; skin color; sputum quantity and character; and cough.

To determine the intensity of dyspnea and its interference with daily activities, the patient can be asked to report the severity of the dyspnea using a scale of 0 to 10, where 0 is no dyspnea and 10 is the worst imaginable dyspnea. The patient's baseline rating before treatment and subsequent measurements taken during exacerbation of the symptom, periodically during treatment, and whenever the treatment plan changes provide ongoing objective evidence for the efficacy of the treatment plan. In addition, physical assessment findings may assist in locating the source of the dyspnea and selecting nursing interventions to relieve the symptom. The components of the assessment change as the patient's condition changes. For example, when the patient who has been on daily weights can no longer get out of bed, the goal of comfort may outweigh the benefit of continued weights. Like other symptoms at the end of life, dyspnea can be managed effectively in the absence of assessment and diagnostic data (eg, arterial blood gases) that are standard when a patient's illness or symptom is reversible.

Nursing management of dyspnea at the end of life is directed toward administering medical treatment for the underlying pathology, monitoring the patient's response to treatment, helping the patient and family manage anxiety (which exacerbates dyspnea), altering the perception of the symptom, and conserving energy (Chart 17-10). Pharmacologic intervention is aimed at modifying lung physiology and improving performance as well as altering the perception of the symptom. Bronchodilators and corticosteroids are used to treat underlying obstructive pathology, thereby improving overall lung function. Low doses of opioids are very effective in relieving dyspnea, although the mechanism of relief is not

Chart 17-10 • Palliative Nursing Interventions for Dyspnea

Decrease Anxiety

- Administer prescribed anxiolytic medications as indicated for anxiety or panic associated with dyspnea.
- Assist with relaxation techniques, guided imagery.
- Provide patient with a means to call for assistance (call bell/light within reach in a hospital or long-term care facility; handheld bell or other device for home).

Treat Underlying Pathology

- Administer prescribed bronchodilators and corticosteroids (obstructive pathology).
- Administer blood products, erythropoietin as prescribed (typically not beneficial in advanced disease).
- Administer prescribed diuretics and monitor fluid balance.

Alter Perception of Breathlessness

- Administer prescribed oxygen therapy via nasal cannula, if tolerated; masks may not be well tolerated.
- Administer prescribed low-dose opioids via oral route (morphine sulfate is used most commonly).
- Provide air movement in the patient's environment with a portable fan.

Reduce Respiratory Demand

- Teach patient and family to implement energy conservation measures.
- Place needed equipment, supplies, and nourishment within reach.
- For home or hospice care, offer bedside commode, electric bed (with head that elevates).

entirely clear. Although dyspnea in terminal illness is typically not associated with diminished blood oxygen saturation, low-flow oxygen often provides psychological comfort to both patients and families, particularly in the home setting.

As previously mentioned, dyspnea may be exacerbated by anxiety, and anxiety may trigger episodes of dyspnea, setting off a respiratory crisis in which the patient and family may panic. For patients receiving care at home, patient and family instruction should include anticipation and management of crisis situations and a clearly communicated emergency plan. The patient and family should be instructed about medication administration, condition changes that should be reported to the physician and nurse, and strategies for coping with diminished reserves and increasing symptomatology as the disease progresses. The patient and family need reassurance that the symptom can be effectively managed at home without the need for activation of the emergency medical services or hospitalization and that a nurse will be available at all times via telephone or to make a visit.

Nutrition and Hydration at the End of Life

Anorexia

Anorexia and cachexia are common in the seriously ill. The profound changes in the patient's appearance and a lack of interest in the socially important rituals of mealtime are particularly disturbing to families. The approach to the

problem varies depending on the patient's stage of illness, level of disability associated with the illness, and desires. The anorexia-cachexia syndrome is characterized by disturbances in carbohydrate, protein, and fat metabolism; endocrine dysfunction; and anemia. The syndrome results in severe asthenia (loss of energy).

Although causes of anorexia may be controlled for a period of time, progressive anorexia is an expected and natural part of the dying process. Anorexia may be related to or exacerbated by situational variables (eg, the ability to have meals with the family versus eating alone in the "sick room"), progression of the disease, treatment for the disease, or psychological distress. The patient and family should be instructed in strategies to manage the variables associated with anorexia (Table 17-2).

Use of Pharmacologic Agents to Stimulate Appetite. A number of pharmacologic agents are commonly used to stimulate appetite in patients with anorexia. These include dexamethasone (Decadron), megestrol acetate (Megace), and dronabinol (Marinol). Although these agents may result in temporary weight gain, their use is not associated with an increase in lean body mass in terminally ill patients. Therapy should be tapered or discontinued after 4 to 8 weeks if there is no response (Wrede-Seaman, 2008).

Dexamethasone initially increases appetite and may provide short-term weight gain in some patients. It should be considered for those patients whose life expectancy is less than 6 weeks because the beneficial effects may be limited to the first few weeks of therapy and side effects increase over time (Del Fabbro, Dalal & Bruera, 2006). Therapy may need to be discontinued in patients with a longer life expectancy; after 3 to 4 weeks, corticosteroids interfere with the synthesis of muscle protein.

Megestrol acetate produces temporary weight gain of primarily fatty tissue, with little effect on protein balance. Because of the time required to see any effect from this agent, therapy should not be initiated if life expectancy is less than 30 days. With long-term use, megestrol acetate may have fewer side effects than dexamethasone (Del Fabbro, et al., 2006).

Dronabinol is a psychoactive compound found in cannabis that may be helpful in reducing nausea and vomiting, appetite loss, pain, and anxiety, thereby improving food and fluid intake in some patients. However, in most patients, it is not as effective as other agents for appetite stimulation. Although dronabinol may have beneficial effects on appetite in patients with advanced cancer, it has not been shown to be more effective than megestrol. In addition, it possesses undesirable central nervous system side effects (Del Fabbro, et al., 2006).

Cachexia

Cachexia refers to severe muscle wasting and weight loss associated with illness. Although anorexia may exacerbate cachexia, it is not the primary cause. Cachexia is associated with anabolic and catabolic changes in metabolism that relate to activity of neurohormones and proinflammatory cytokines, resulting in profound protein loss. These processes appear to be similar at the end stages of both cancer and

Table 17-2 MEASURES FOR MANAGING ANOREXIA

Nursing Interventions	Patient and Family Teaching Tips
<p>Initiate measures to ensure adequate dietary intake without adding stress to the patient at mealtimes.</p> <p>Assess the impact of medications (eg, chemotherapy, antiretrovirals) or other therapies (radiation therapy, dialysis) that are being used to treat the underlying illness.</p> <p>Administer and monitor effects of prescribed treatment for nausea, vomiting, and delayed gastric emptying.</p> <p>Encourage patient to eat when effects of medications have subsided.</p> <p>Assess and modify environment to eliminate unpleasant odors and other factors that cause nausea, vomiting, and anorexia.</p> <p>Remove items that may reduce appetite (soiled tissues, bedpans, emesis basins, clutter).</p> <p>Assess and manage anxiety and depression to the extent possible.</p>	<p>Reduce the focus on “balanced” meals; offer the same food as often as the patient desires it.</p> <p>Increase the nutritional value of meals. For example, add dry milk powder to milk, and use this fortified milk to prepare cream soups, milkshakes, and gravies.</p> <p>Allow and encourage the patient to eat when hungry, regardless of usual meal times.</p> <p>Eliminate or reduce noxious cooking odors, pet odors, or other odors that may precipitate nausea, vomiting, or anorexia.</p> <p>Keep patient’s environment clean, uncluttered, and comfortable.</p>
<p>Position to enhance gastric emptying.</p>	<p>Make mealtime a shared experience away from the “sick” room whenever possible.</p> <p>Reduce stress at mealtimes.</p> <p>Avoid confrontations about the amount of food consumed.</p> <p>Reduce or eliminate routine weighing of the patient.</p> <p>Encourage patient to eat in a sitting position; elevate the head of the patient’s bed.</p>
<p>Assess for constipation and/or intestinal obstruction.</p>	<p>Plan meals (food selection and portion size) that the patient desires.</p> <p>Provide small frequent meals if they are easier for patient to eat.</p> <p>Ensure that patient and family understand that prevention of constipation is essential, even when the patient’s intake is minimal.</p> <p>Encourage adequate fluid intake, dietary fiber, and use of bowel program to prevent constipation.</p>
<p>Prevent and manage constipation on an ongoing basis, even when the patient’s intake is minimal.</p> <p>Provide frequent mouth care, particularly following nourishment.</p>	<p>Assist the patient to rinse after every meal. Avoid mouthwashes that contain alcohol or glycerine, which dry mucous membranes.</p> <p>Weight loss may cause dentures to loosen and cause irritation. Remove them to inspect the gums and to provide oral care.</p>
<p>Ensure that dentures fit properly.</p>	<p>The patient’s comfort may be enhanced if medications for pain relief given on an as-needed basis for breakthrough pain are administered before mealtimes.</p>
<p>Administer and monitor effects of topical and systemic treatment for oropharyngeal pain.</p>	

some noncancer illnesses, such as heart disease (Siddiqui, Pandya, Harvey, et al., 2006; von Haehling, Doehner & Anker, 2007). However, the pathophysiology of cachexia in terminal illness is not well understood. In terminal illness, the severity of tissue wasting is greater than would be expected from reduced food intake alone, and typically increasing appetite or food intake does not reverse cachexia.

Anorexia and cachexia differ from starvation (simple food deprivation) in several important ways. Appetite is lost early in the process, the body becomes catabolic in a dysfunctional way, and supplementation by gastric feeding (tube feeding) or parenteral nutrition in advanced disease does not replenish lean body mass that has been lost. At one time it was believed that cancer patients with rapidly growing tumors developed cachexia because the tumor created an excessive nutritional demand and diverted nutrients from the rest of the body. Research links cytokines produced by the body in response to a tumor to a complex inflammatory-immune response present in patients whose tumors have metastasized, leading to anorexia, weight loss, and altered metabolism. An increase in cytokines occurs not only in cancer but also in AIDS and many other chronic diseases (Del Fabbro, et al., 2006).

Artificial Nutrition and Hydration

Along with breathing, eating and drinking are essential to survival throughout life. Near the end of life, the body’s nutritional needs change, and the desire for food and fluid

may diminish. People may no longer be able to use, eliminate, or store nutrients and fluids adequately. Eating and sharing meals are important social activities in families and communities, and food preparation and enjoyment are linked to happy memories, strong emotions, and hopes for survival. For patients with serious illness, food preparation and mealtimes often become battlegrounds in which well-meaning family members argue, plead, and cajole to encourage ill people to eat. It is not unusual for seriously ill patients to lose their appetites entirely, to develop strong aversions to foods they have enjoyed in the past, or to crave a particular food to the exclusion of all other foods.

Although nutritional supplementation may be an important part of the treatment plan in early or chronic illness, unintended weight loss and dehydration are expected characteristics of progressive illness. As illness progresses, patients, families, and clinicians may believe that, without artificial nutrition and hydration, terminally ill patients will “starve,” causing profound suffering and hastened death. However, starvation should not be viewed as the failure to insert tubes for nutritional supplementation or hydration of terminally ill patients with irreversible progression of disease. Studies have demonstrated that terminally ill patients with cancer who were hydrated did not have improved biochemical parameters and exhibited lower serum albumin levels, leading to fluid retention (Morita, Hyodo, Yoshimi, et al., 2006). The use of artificial nutrition and hydration (tube and intravenous [IV]

fluids and feeding) carry considerable risks and do not contribute to comfort at end of life (Casarett, Kapo & Kaplan, 2005). Similarly, survival is not increased when terminally ill patients with advanced dementia receive enteral feeding (Chernoff, 2006), and no data support an association between tube feeding and improved quality of life in these patients (Kapo, Morrison & Liao, 2007). Furthermore, in patients who are close to death, symptoms associated with dehydration such as dry mouth, confusion, and diminished alertness are common and typically do not respond to artificial nutrition. Dry mouth can generally be managed through nursing measures such as mouth care and environmental changes with medications to diminish confusion.

As the patient approaches the end of life, the family and health care providers should offer the patient what he or she prefers and can most easily tolerate. The nurse should instruct the family how to separate feeding from caring, demonstrating love, sharing, and caring by being with the loved one in other ways. Preoccupation with appetite, feeding, and weight loss diverts energy and time that the patient and family could use in other meaningful activities. In addition to those give in Table 17-2, the following are tips to promote nutrition for terminally ill patients:

- Offer small portions of favorite foods.
- Cool foods may be better tolerated than hot foods.
- Offer cheese, eggs, peanut butter, mild fish, chicken, or turkey. Meat (especially beef) may taste bitter and unpleasant.
- Add milk shakes, Instant Breakfast drinks, or other liquid supplements.
- Place nutritious foods at the bedside (fruit juices, milk shakes in insulated drink containers with straws).
- Schedule meals when family members can be present to provide company and stimulation.
- Offer ice chips made from frozen fruit juices.
- Allow the patient to refuse foods and fluids.

Delirium

Many patients remain alert, arousable, and able to communicate until very close to death. Others sleep for long intervals and awaken only intermittently, with eventual somnolence until death. Delirium refers to concurrent disturbances in level of consciousness, psychomotor behavior, memory, thinking, attention, and sleep-wake cycle (Breitbart & Alici, 2008). In some patients, a period of agitated delirium precedes death, sometimes causing families to be hopeful that suddenly active patients may be getting better. Confusion may be related to underlying, treatable conditions such as medication side effects or interactions, pain or discomfort, hypoxia or dyspnea, or a full bladder or impacted stool. In patients with cancer, confusion may be secondary to brain metastases. Delirium may also be related to metabolic changes, infection, and organ failure.

Patients with delirium may become hypoactive or hyperactive, restless, irritable, and fearful. Sleep deprivation and hallucinations may occur. If treatment of the underlying factors contributing to these symptoms brings no relief, a combination of pharmacologic intervention with neuroleptics or benzodiazepines may be effective in decreasing distressing symptoms. Haloperidol (Haldol) may reduce hallucinations

and agitation. Benzodiazepines (eg, lorazepam [Ativan]) can reduce anxiety but do not clear the sensorium and may contribute to worsening cognitive impairment if used alone.

Nursing interventions are aimed at identifying the underlying causes of delirium; acknowledging the family's distress over its occurrence; reassuring family members about what is normal; teaching family members how to interact with and ensure safety for the patient with delirium; and monitoring the effects of medications used to treat severe agitation, paranoia, and fear. Confusion may mask the patient's unmet spiritual needs and fears about dying. Spiritual intervention, music therapy, gentle massage, and therapeutic touch may provide some relief. Reduction of environmental stimuli, avoidance of harsh lighting or very dim lighting (which may produce disturbing shadows), presence of familiar faces, and gentle reorientation and reassurance are also helpful.

Depression

Clinical depression should neither be accepted as an inevitable consequence of dying nor confused with sadness and anticipatory grieving, which are normal reactions to the losses associated with impending death. Emotional and spiritual support and control of disturbing physical symptoms are appropriate interventions for situational depression associated with terminal illness. Researchers have linked the psychological effects of cancer pain to suicidal thought and, less frequently, to carrying out a planned suicide (Maytal & Stern, 2006). Patients and their families must be given space and time to experience sadness and to grieve, but patients should not have to endure untreated depression at the end of their lives. An effective combined approach to clinical depression includes relief of physical symptoms, attention to emotional and spiritual distress, and pharmacologic intervention with psychostimulants, selective serotonin reuptake inhibitors, and tricyclic antidepressants (Lorenz, et al., 2008).

Palliative Sedation at the End of Life

Effective control of symptoms can be achieved under most conditions, but some patients may experience distressing, intractable symptoms. Although **palliative sedation** remains controversial, it is offered in some settings to patients who are close to death or who have symptoms that do not respond to conventional pharmacologic and nonpharmacologic approaches, resulting in unrelieved suffering. Palliative sedation is distinguished from **euthanasia** and physician-assisted suicide in that the intent of palliative sedation is to relieve symptoms, not to hasten death. Palliative sedation is most commonly used when the patient exhibits intractable pain, dyspnea, seizures, or delirium, and it is generally considered appropriate in only the most difficult situations. Before implementing palliative sedation, the health care team should assess for the presence of underlying and treatable causes of suffering, such as depression or spiritual distress. Finally, the patient and family should be fully informed about the use of this treatment and alternatives.

Palliative sedation is accomplished through infusion of a benzodiazepine or barbiturate in doses adequate to induce sleep and eliminate signs of discomfort (De Graeff & Dean, 2007). Nurses act as collaborating members of the

interdisciplinary health care team, providing emotional support to patients and families, facilitating clarification of values and preferences, and providing comfort-focused physical care. Once sedation has been induced, the nurse should continue to comfort the patient, monitor the physiologic effects of the sedation, support the family during the final hours or days of their loved one's life, and ensure communication within the health care team and between the team and family.

Nursing Care of Patients Who Are Close to Death

Providing care to patients who are close to death and being present at the time of death can be one of the most rewarding experiences a nurse can have. Patients and their families are understandably fearful of the unknown, and the approach of death may prompt new concerns or cause previous fears or issues to resurface. Family members who have always had difficulty communicating or who are part of families in which there are old resentments and hurts may experience heightened difficulty as their loved one nears death. However, the time at the end of life can also afford opportunities to resolve old hurts and learn new ways of being a family. Regardless of the setting, skilled practitioners can make dying patients comfortable, make space for their loved ones to remain present if they wish, and can give family members the opportunity to experience growth and healing. Likewise, patients and family members may be less apprehensive near the time of death if they know what to expect and how to respond.

Expected Physiologic Changes

As death approaches and organ systems begin to fail, observable, expected changes in the body take place. Nursing care measures aimed at patient comfort, such as pain medications (administered rectally or sublingually), turning, mouth care, eye care, positioning to facilitate draining of secretions, and measures to protect the skin from urine or feces (if the patient is incontinent), should be continued. The nurse should consult with the physician about discontinuing measures that no longer contribute to patient comfort, such as drawing blood, administering tube feedings, suctioning (in most cases), and invasive monitoring. The nurse should prepare the family for the normal, expected changes that accompany the period immediately preceding death. Although the exact time of death cannot be predicted, it is often possible to identify when the patient is very close to death. Hospice programs frequently provide written information for families so they know what to expect and what to do as death nears (Chart 17-11).

If family members have been prepared for the time of death, they are less likely to panic and are better able to be with their loved ones in a meaningful way. Noisy, gurgling breathing or moaning is generally most distressing to family members. In most cases, the sounds of breathing at the end of life are related to oropharyngeal relaxation and diminished awareness. Family members may have difficulty believing that the patient is not in pain or that the patient's breathing could not be improved by suctioning secretions.

Patient positioning and family reassurance are the most helpful responses to these symptoms.

When death is imminent, patients may become increasingly somnolent and unable to clear sputum or oral secretions, which may lead to further impairment of breathing from pooled or dried and crusted secretions. The sound (terminal bubbling) and appearance of the secretions are often more distressing to family members than is the presence of the secretions to the patient. Family distress over the changes in the patient's condition may be eased by supportive nursing care. Continuation of comfort-focused interventions and reassurance that the patient is not in any distress can do much to ease family concerns. Gentle mouth care with a moistened swab or very soft toothbrush helps maintain the integrity of the patient's mucous membranes. In addition, gentle oral suctioning, positioning to enhance drainage of secretions, and sublingual or transdermal administration of anticholinergic drugs (Table 17-3) reduce the production of secretions and provide comfort to the patient and support to the family. Deeper suctioning may cause significant discomfort to the dying patient and is rarely of any benefit because secretions reaccumulate rapidly.

The Death Vigil

Although each death is unique, it is often possible for experienced clinicians to assess that the patient is "actively" or imminently dying and to prepare the family in the final days or hours leading to death. As death nears, the patient may withdraw, sleep for longer intervals, or become somnolent. Death is generally preceded by a period of gradual diminishment of bodily functions, increased intervals between respirations, a weakened and irregular pulse, diminished blood pressure, and skin color changes or mottling may occur. Family members should be encouraged to be with the patient, to speak and reassure the patient of their presence, to stroke or touch the patient, or to lie alongside the patient (even in the hospital or long-term care facility) if the family members are comfortable with this degree of closeness and can do so without causing discomfort to the patient.

The family may have gone to great lengths to ensure that their loved one will not die alone. However, despite the best intentions and efforts of the family and clinicians, the patient may die at a time when no one is present. In any setting, it is unrealistic for family members to be at the patient's bedside 24 hours a day. Experienced hospice clinicians have observed and reported that some patients appear to "wait" until family members are away from the bedside to die, perhaps to spare their loved ones the pain of being present at the time of death. Nurses can reassure family members throughout the death vigil by being present intermittently or continuously, modeling behaviors (such as touching and speaking to the patient), providing encouragement in relation to family care giving, providing reassurance about normal physiologic changes, and encouraging family rest breaks. If a patient dies while family members are away from the bedside, they may express feelings of guilt and profound grief and may need emotional support.

After-Death Care

For patients who have received adequate management of symptoms and for families who have received adequate preparation and support, the actual time of death is

Chart 17-11 • Educating the Family: Signs of Approaching Death

The person shows less interest in eating and drinking.

For many patients, refusal of food is an indication that they are ready to die. Fluid intake may be limited to that which will keep their mouths from feeling too dry.

- What you can do: Offer, but do not force, fluids and medication. Sometimes pain or other symptoms that have required medication in the past may no longer be present. For most patients, pain medications are still needed, and they can be provided by concentrated oral solutions placed under the tongue or by rectal suppository.

Urinary output may decrease in amount and frequency.

- What you can do: No response is needed unless the patient expresses a desire to urinate and cannot. Call the hospice nurse for advice if you are not sure.

As the body weakens, the patient will sleep more and begin to detach from the environment. He or she may refuse your attempts to provide comfort.

- What you can do: Allow your loved one to sleep. You may wish to sit with him or her, play soft music, or hold hands. Your loved one's withdrawal is normal and is not a rejection of your love.

Mental confusion may become apparent because less oxygen is available to supply the brain. The patient may report strange dreams or visions.

- What you can do: As he or she awakens from sleep, remind him or her of the day and time, where he or she is, and who is present. This is best done in a casual, conversational way.

Vision and hearing may become somewhat impaired, and speech may be difficult to understand.

- What you can do: Speak clearly but no more loudly than necessary. Keep the room as light as the patient wishes, even at night. Carry on all conversations as if they can be heard, because hearing may be the last of the senses to cease functioning.
- Many patients are able to talk until minutes before death and are reassured by the exchange of a few words with a loved one.

Secretions may collect in the back of the throat and rattle or gurgle as the patient breathes through the mouth.

He or she may try to cough, and his or her mouth may become dry and encrusted with secretions.

- What you can do: If the patient is trying to cough up secretions and is experiencing choking or vomiting, call the hospice nurse for assistance.
- Secretions may drain from the mouth if you place the patient on his or her side and provide support with pillows.

- Cleansing the mouth with moistened mouth swabs will help to relieve the dryness that occurs with mouth breathing.
- Offer water in small amounts to keep the mouth moist. A straw with one finger placed over the end can be used to transfer sips of water to the patient's mouth.

Breathing may become irregular with periods of no breathing (apnea). The patient may be working very hard to breathe and may make a moaning sound with each breath. As the time of death nears, the breathing remains irregular and may become more shallow and mechanical.

- What you can do: Raising the head of the bed may help the patient to breathe more easily. The moaning sound does not mean that the patient is in pain or other distress; it is the sound of air passing over very relaxed vocal cords.

As the oxygen supply to the brain decreases, the patient may become restless. It is not unusual to pull at the bed linens, to have visual hallucinations, or even to try to get out of bed at this point.

- What you can do: Reassure the patient in a calm voice that you are there. Prevent him or her from falling by trying to get out of bed. Soft music or a back rub may be soothing.

The patient may feel hot one moment and cold the next as the body loses its ability to control temperature. As circulation slows, the arms and legs may become cool and bluish. The underside of the body may darken. It may be difficult to feel a pulse at the wrist.

- What you can do: Provide and remove blankets as needed. Avoid using electric blankets, which may cause burns because the patient cannot tell you if he or she is too warm.
- Sponge the patient's head with a cool cloth if this provides comfort.

Loss of bladder and bowel control may occur around the time of death.

- What you can do: Protect the mattress with waterproof padding and change the padding as needed to keep the patient comfortable.

As people approach death, many times they report seeing gardens, libraries, or family or friends who have died.

They may ask you to pack their bags and find tickets or a passport. Sometimes they may become insistent and attempt to do these chores themselves. They may try getting out of bed (even if they have been confined to bed for a long time) so that they can "leave."

- What you can do: Reassure the patient that it is all right; he or she can "go" without getting out of bed. Stay close, share stories, and be present.

Table 17-3  **PHARMACOLOGIC MANAGEMENT OF EXCESS ORAL/RESPIRATORY SECRETIONS WHEN DEATH IS IMMINENT**

Medication	Dose
Atropine sulfate drops 1%	1 or 2 drops 1% oral/sublingual q4–6h prn or around the clock (ATC) up to 12 drops/d
Atropine injection	0.4–0.6 mg intravenous/subcutaneous/intramuscular q4–6h prn or ATC (if oral therapy is ineffective)
Glycopyrrolate (Robinul)	1–2 mg oral/rectal/sublingual TID prn or ATC (maximum dose 6 mg/d)
Hyoscyamine (Levsin)	0.125–0.25 mg oral/sublingual q4–6h prn or ATC (maximum dose 1.5 mg/d)
Scopolamine (Transderm Scop)	1–3 patches q3d (maximum dose 3 patches every 72 h)*

Note: There is no evidence that one agent is more effective than another; therefore, selection should be based on the agent's side-effect profile, onset of action, duration of action, and route of administration. Adverse effects include central nervous system changes (eg, irritability, disorientation, hallucination, delirium), cardiac changes (eg, tachycardia or bradycardia, dysrhythmias), blurred vision, urinary retention, constipation, dry mouth, flushing, and confusion.

*The patch may take up to 12 hours before an effect is observed; it may be of little benefit if initiated in a patient who is imminently dying.

commonly peaceful and occurs without struggle. Nurses may or may not be present at the time of a patient's death. In many states, nurses are authorized to make the pronouncement of death and sign the death certificate when death is expected. The determination of death is made through a physical examination that includes auscultation for the absence of breathing and heart sounds. Home care or hospice programs in which nurses make the time-of-death visit and pronouncement of death have policies and procedures to guide the nurse's actions during this visit. Immediately on cessation of vital functions, the body begins to change. It becomes dusky or bluish, waxen-appearing, and cool; blood darkens and pools in dependent areas of the body (eg, the back and sacrum if the body is in a supine position); and urine and stool may be evacuated.

Immediately after death, family members should be allowed and encouraged to spend time with the deceased. Normal responses of family members at the time of death vary widely and range from quiet expressions of grief to overt expressions that include wailing and prostration. The family's desire for privacy during their time with the deceased should be honored. Family members may wish to independently manage or assist with care of the body after death. In the home, after-death care of the body frequently includes culturally specific rituals such as bathing the body. Home care agencies and hospices vary in the policies surrounding removal of tubes. In the absence of specific guidance from the organization, the nurse should shut off infusions of any kind (IV or tube feeding) and leave IV access devices, feeding tubes, catheters, and wound dressings in place. When an expected death occurs in the home setting, the family generally will have received assistance with

funeral arrangements in advance of the death. The funeral director often transports the body directly to the funeral home. In the hospital or long-term care facility, nurses follow the facility's procedure for preparation of the body and transportation to the facility's morgue. However, the needs of families to remain with the deceased, to wait until other family members arrive before the body is moved, and to perform after-death rituals should be honored.

Grief, Mourning, and Bereavement

A wide range of feelings and behaviors are normal, adaptive, and healthy reactions to the loss of a loved one. **Grief** refers to the personal feelings that accompany an anticipated or actual loss. **Mourning** refers to individual, family, group, and cultural expressions of grief and associated behaviors. **Bereavement** refers to the period of time during which mourning takes place. Both grief reactions and mourning behaviors change over time as people learn to live with the loss. Although the pain of the loss may be tempered by the passage of time, loss is an ongoing developmental process, and time does not heal the bereaved individual completely. That is, the bereaved do not get over a loss entirely, nor do they return to who they were before the loss. Rather, they develop a new sense of who they are and where they fit in a world that has changed dramatically and permanently.

Anticipatory Grief and Mourning

Denial, sadness, anger, fear, and anxiety are normal grief reactions in people with life-threatening illness and those close to them. Kübler-Ross (1969) described five common emotional reactions to dying that are applicable to the experience of any loss (Table 17-4). Not every patient or family member

Table 17-4 KÜBLER-ROSS'S FIVE STAGES OF DYING

Stage	Nursing Implications
Denial: "This cannot be true." Feelings of isolation. May search for another health care professional who will give a more favorable opinion. May seek unproven therapies.	Denial can be an adaptive response, providing a buffer after bad news. It allows time to mobilize defenses but can be maladaptive when it prevents the patient or family from seeking help or when denial behaviors cause more pain or distress than the illness or interfere with everyday functions. Nurses should assess the patient's and family's coping style, information needs, and understanding of the illness and treatment to establish a basis for empathetic listening, education, and emotional support. Rather than confronting the patient with information he or she is not ready to hear, the nurse can encourage him or her to share fears and concerns. Open-ended questions or statements such as "Tell me more about how you are coping with this new information about your illness" can provide a springboard for expression of concerns.
Anger: "Why me?" Feelings of rage, resentment or envy directed at God, health care professionals, family, others.	Anger can be very isolating, and loved ones or clinicians may withdraw. Nurses should allow the patient and family to express anger, treating them with understanding, respect, and knowledge that the root of the anger is grief over impending loss.
Bargaining: "I just want to see my grandchild's birth, then I'll be ready. . . ." Patient and/or family plead for more time to reach an important goal. Promises are sometimes made with God.	Terminally ill patients are sometimes able to outlive prognoses and achieve some future goal. Nurses should be patient, allow expression of feelings, and support realistic and positive hope.
Depression: "I just don't know how my kids are going to get along after I'm gone." Sadness, grief, mourning for impending losses.	Normal and adaptive response. Clinical depression should be assessed and treated when present. Nurses should encourage the patient and family to fully express their sadness. Insincere reassurance or encouragement of unrealistic hopes should be avoided.
Acceptance: "I've lived a good life, and I have no regrets." Patient and/or family are neither angry nor depressed.	The patient may withdraw as his or her circle of interest diminishes. The family may feel rejected by the patient. Nurses need to support the family's expression of emotions and encourage them to continue to be present for the patient.

experiences every stage; many patients never reach a stage of acceptance, and patients and families fluctuate on a sometimes daily basis in their emotional responses. Furthermore, although impending loss stresses the patient, people who are close to him or her, and the functioning of the family unit, awareness of dying also provides a unique opportunity for family members to reminisce, resolve relationships, plan for the future, and say goodbye.

Individual and family coping with the anticipation of death is complicated by the varied and conflicting trajectories that grief and mourning may assume in families. For example, the patient may be experiencing sadness while contemplating role changes that have been brought about by the illness and the patient's spouse or partner may be expressing or suppressing feelings of anger about the current changes in role and impending loss of the relationship. Others in the family may be engaged in denial (eg, "Dad will get better; he just needs to eat more"), fear ("Who will take care of us?" or "Will I get sick too?"), or profound sadness and withdrawal. Although each of these behaviors is normal, tension may arise when one or more family members perceive that others are less caring, too emotional, or too detached.

The nurse should assess the characteristics of the family system and intervene in a manner that supports and enhances the cohesion of the family unit. Parameters for assessing the family facing life-threatening illness are identified in Chart 17-12. The nurse can suggest that family members talk about their feelings and understand them in the broader context of anticipatory grief and mourning. Acknowledging and expressing feelings, continuing to interact with the patient in meaningful ways, and planning for the time of death and bereavement are adaptive family behaviors. Professional support provided by grief counselors, whether in the community, at a local hospital, in the long-term care facility, or associated with a hospice program, can help both the patient and the family sort out and acknowledge feelings and make the end of life as meaningful as possible.

Grief and Mourning After Death

When a loved one dies, the family members enter a new phase of grief and mourning as they begin to accept the loss, feel the pain of permanent separation, and prepare to live a life without the deceased. Even if the loved one died after a long illness, preparatory grief experienced during the terminal illness does not preclude the grief and mourning that follow the death. With a death after a long or difficult illness, family members may experience conflicting feelings of relief that the loved one's suffering has ended, compounded by guilt and grief related to unresolved issues or the circumstances of death. Grief work may be especially difficult if a patient's death was painful, prolonged, accompanied by unwanted interventions, or unattended. Families who had no preparation or support during the period of imminence and death may have a more difficult time finding a place for the painful memories.

Although some family members may experience prolonged or complicated mourning, most grief reactions fall within a "normal" range. The feelings are often profound, but bereaved people eventually reconcile the loss and find

CHART 17-12

Assessing for Anticipatory Mourning in the Family Facing Life-Threatening Illness

Family Constellation

- Identify the members who constitute the patient's family. Who is important to the patient?
- Identify roles and relationships among the family members.
 - Who is the primary caregiver?
 - By what authority is this person the primary caregiver?

Cohesion and Boundaries

- How autonomous/interdependent are family members?
 - Degree of involvement with each other as individuals and as a family
 - Degree of bonding between family members
 - Degree of "teamwork" in the family
 - Degree of reliance on individual family members for specific tasks/roles
- How do family members differ in
 - Personality?
 - Worldview?
 - Priorities?
- What are the implicit and explicit expectations or "rules" for behavior within the family?

Flexibility and Adaptability

- What is the family's ability to integrate new information?
- How does the family manage change?
- How able are the family members to assume new roles and responsibilities?

Communication

- What is the style of communication in the family, in terms of
 - Openness?
 - Directness?
 - Clarity?
- What are the constraints on communication?
- What topics are avoided?

a way to reengage with their lives. Grief and mourning are affected by several factors, including individual characteristics, coping skills, and experiences with illness and death; the nature of the relationship to the deceased; factors surrounding the illness and the death; family dynamics; social support; and cultural expectations and norms. Uncomplicated grief and mourning are characterized by emotional feelings of sadness, anger, guilt, and numbness; physical sensations such as hollowness in the stomach and tightness in the chest, weakness, and lack of energy; cognitions that include preoccupation with the loss and a sense of the deceased as still present; and behaviors such as crying, visiting places that are reminders of the deceased, social withdrawal, and restless overactivity (Zhang, El-Jawahri & Prigerson, 2006).

After-death rituals, including preparation of the body, funeral practices, and burial rituals, are socially and culturally significant ways in which family members begin to accept

the reality and finality of death. Preplanning of funerals is becoming increasingly common, and hospice professionals in particular help the family make plans for death, often involving the patient, who may wish to play an active role. Preplanning of the funeral relieves the family of the burden of making decisions in the intensely emotional period after a death.

In general, the period of mourning is an adaptive response to loss during which mourners come to accept the loss as real and permanent, acknowledge and experience the painful emotions that accompany the loss, experience life without the deceased, overcome impediments to adjustment, and find a new way of living in a world without the loved one. Particularly immediately after the death, mourners begin to recognize the reality and permanence of the loss by talking about the deceased and telling and retelling the story of the illness and death. Societal norms in the United States are frequently at odds with the normal grieving processes of people; time excused from work obligations is typically measured in days, and mourners are often expected to get over the loss quickly and get on with life.

In reality, the work of grief and mourning takes time, and avoiding grief work after the death often leads to long-term adjustment difficulties. According to Rando (2000), mourning for a loss involves the “undoing” of psychosocial ties that bind mourners to the deceased, personal adaptation to the loss, and learning to live in the world without the deceased. Six key processes of mourning allow people to accommodate to the loss in a healthy way:

1. Recognition of the loss
2. Reaction to the separation, and experiencing and expressing the pain of the loss
3. Recollection and reexperiencing the deceased, the relationship, and the associated feelings
4. Relinquishing old attachments to the deceased
5. Readjustment to adapt to the new world without forgetting the old
6. Reinvestment (Rando, 2000)

Although many people complete the work of mourning with the informal support of families and friends, many find that talking with others who have had a similar experience, such as in formal support groups, normalizes the feelings and experiences and provides a framework for learning new skills to cope with the loss and create a new life. Hospitals, hospices, religious organizations, and other community organizations often sponsor bereavement support groups. Groups for parents who have lost a child, children who have lost a parent, widows, widowers, and gay men and lesbians who have lost a life partner are some examples of specialized support groups available in many communities. Nursing interventions for those experiencing grief and mourning are identified in Chart 17-13.

Complicated Grief and Mourning

Complicated grief and mourning are characterized by prolonged feelings of sadness and feelings of general worthlessness or hopelessness that persist long after the death, prolonged symptoms that interfere with activities of daily living (anorexia, insomnia, fatigue, panic), or self-destructive behaviors such as alcohol or substance abuse and suicidal ideation or attempts. Complicated grief and mourning require

Chart 17-13 • Nursing Interventions for Grief and Mourning

Support the Expression of Feelings

- Encourage the telling of the story using open-ended statements or questions (eg, “Tell me about your husband”).
- Assist the mourner to find an outlet for his or her feelings: talking, attending a support group, keeping a journal, finding a safe outlet for angry feelings (writing letters that will not be mailed, physical activity).
- Assess emotional affect and reinforce the normalcy of feelings.
- Assess for guilt and regrets.
 - Are you especially troubled by a certain memory or thought?
 - How do you manage those memories?

Assess for the Presence of Social Support

- Do you have someone to whom you can talk about your husband?
- May I help you to find someone you can talk to?

Assess Coping Skills

- How are you managing day to day?
- Have you experienced other losses? How did you manage those?
- Are there things you are having trouble doing?
- Do you have/need help with specific tasks?

Assess for Signs of Complicated Grief and Mourning and Offer Professional Referral

professional assessment and can be treated with psychological interventions, and in some cases, with medications.

Coping With Death and Dying: Professional Caregiver Issues

Whether practicing in a trauma center, ICU or other acute care setting, home care, hospice, long-term care, or the many locations where patients and their families receive ambulatory services, the nurse is closely involved with complex and emotionally laden issues surrounding loss of life. To be most effective and satisfied with the care he or she provides, the nurse should attend to his or her own emotional responses to the losses witnessed every day. Well before the nurse exhibits symptoms of stress or burnout, he or she should acknowledge the difficulty of coping with others’ pain on a daily basis and put healthy practices in place that guard against emotional exhaustion. In hospice settings, where death, grief, and loss are expected outcomes of patient care, interdisciplinary colleagues rely on one another for support, using meeting time to express frustration, sadness, anger, and other emotions; to learn coping skills from one another; and to speak about how they were affected by the lives of those patients who have died since the last meeting. In many settings, staff members organize or attend memorial services to support families and other caregivers,

who find comfort in joining one another to remember and celebrate the lives of patients. Finally, healthy personal habits, including diet, exercise, stress reduction activities (eg, dance, yoga, tai chi, meditation), and sleep, help guard against the detrimental effects of stress.

CRITICAL THINKING EXERCISES

EBP 1 You are making follow-up telephone calls to the primary caregivers (family members) for all the patients who have died in the past 3 months in the hospital unit where you are a primary nurse. What questions could you ask to screen for complicated grief and bereavement? What activities or strategies would you consider to help families deal with their loss (before and after the death)? What is the evidence base for your selection of those activities and strategies? What resources are available in the community? What bereavement services are indicated for the staff? What would you suggest to a staff member who continues to have problems in coping with death of her patients?

2 You are caring for a 68-year-old man with end-stage heart failure in a hospital-based palliative care unit. You observe that he has peripheral edema and cachexia. He reports dyspnea at rest, profound fatigue, and activity intolerance. He tells you that he would like to return home, but his wife becomes very anxious when he has pain or shortness of breath, causing him to become anxious as well. What additional assessments would you conduct? What strategies would you implement to (1) relieve the patient's symptoms and discomfort, (2) prepare his wife to manage his care at home, and (3) initiate conversations to prepare both of them for his inevitable death?

EBP 3 A 33-year-old married mother of two young children has been referred for hospice care. She has advanced breast cancer with metastases to the bone, liver, and lung. During your initial visit to the patient's home, you assess that she is experiencing severe pain in her ribs and pelvis (she reports a score of 8 on a 0 to 10 pain intensity scale). In addition, she reports that she has no appetite. Her physician has prescribed morphine for her pain, but you assess that she has used very few doses of the morphine. Her husband tells you privately that he has discouraged her use of the medicine because it has made her very sleepy and nauseated in the past, and he believes this is the reason for her poor appetite. The interdisciplinary team is meeting to discuss the patient's treatment plan. What additional assessment data are needed to determine the wishes and expectations of the patient as well as the husband? What factors might be contributing to her anorexia? What interventions, both pharmacologic and nonpharmacologic, would you consider? What is the evidence base for each selection?

4 You have been assigned to make a home visit to an 87-year-old widow who has end-stage COPD. She lives in an assisted living facility. The staff has made a referral for

inpatient palliative care because the patient can no longer perform her activities of daily living (ADLs) in her apartment without assistance. She has no family living nearby; her son lives about 1 hour away and he visits her once a month. During your assessment visit, she tearfully states, "I don't know why I am still here. I want God to take me before I become a complete burden." Discuss how you would carry out additional assessment and the recommendations that you might make based on findings from your assessment. Give examples of questions you would ask to further assess the patient. What types of palliative care services may be helpful for this case. Why?

Perioperative Concepts and Nursing Management

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient Recovering From Abdominal Surgery

Mr. Dickson, a 60-year-old smoker, was admitted to the surgical unit 5 hours ago after colon resection for cancer. He is groggy but easily arousable. He can move all extremities with equal strength, but feels better lying still. In the last 4 hours, 125 mL of greenish material has drained from his nasogastric tube, which is connected to low intermittent suction. His abdomen is mildly distended; bowel sounds are absent. The large abdominal dressing has a reconstitutable bulb drain with 30 mL of serosanguineous drainage; the dressing's minimal visible drainage has not increased in several hours. A peripheral IV of D5W 12NS with 20 mEq of KCl is infusing at 125 mL/h. Mr. Dickson has voided 600 mL of clear urine. Vital signs are: Temp 97°F; HR 82, B/P 112/70; Resp 12 and shallow. Lung auscultation reveals scattered crackles throughout and a weak cough. After a 50-mg morphine injection, Mr. Dickson rates his pain at 3 (down from 7). He is reluctant to use his incentive spirometer for fear of more pain.

Visit the Point to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
RISK FOR IMPAIRED GAS EXCHANGE —At risk for excess or deficit in oxygenation and/or carbon dioxide elimination at the alveolar-capillary membrane	RESPIRATORY MONITORING — Collection and analysis of patient data to ensure airway patency and adequate gas exchange	ANXIETY CONTROL — Personal actions to eliminate or reduce feelings of apprehension and tension from an unidentifiable source
RISK FOR INEFFECTIVE AIRWAY CLEARANCE — At risk for inability to clear secretions or obstructions from the respiratory tract to maintain a clear airway	COUGH ENHANCEMENT — Promotion of deep inhalation by the patient with subsequent generation of high intrathoracic pressures and compression of underlying lung parenchyma for the forceful expulsion of air	RESPIRATORY STATUS: GAS EXCHANGE — The alveolar exchange of O ₂ and CO ₂ to maintain arterial blood gas concentrations
ACUTE PAIN — Unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage	PAIN MANAGEMENT — Alleviation of pain or reduction in pain to a level of comfort that is acceptable to the patient	PAIN LEVEL — Severity of observed or reported pain
IMPAIRED PHYSICAL MOBILITY — Limitation in independent, purposeful physical movement of the body or of one or more extremities	TEACHING: PRESCRIBED ACTIVITY/EXERCISE — Preparing a patient to achieve and/or maintain a prescribed level of activity	MOBILITY — Ability to move purposefully in own environment independently with or without assistive device

Preoperative Nursing Management

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Define the three phases of perioperative patient care.
- 2 Describe a comprehensive preoperative assessment to identify surgical risk factors.
- 3 Identify health factors that affect patients preoperatively.
- 4 Identify legal and ethical considerations related to obtaining informed consent for surgery.
- 5 Describe preoperative nursing measures that decrease the risk for infection and other postoperative complications.
- 6 Describe the immediate preoperative preparation of the patient.
- 7 Develop a preoperative teaching plan designed to promote the patient's recovery from anesthesia and surgery, thus preventing postoperative complications.

GLOSSARY

ambulatory surgery: includes outpatient, same-day, or short-stay surgery that does not require an overnight hospital stay

informed consent: the patient's autonomous decision about whether to undergo a surgical procedure, based on the nature of the condition, the treatment options, and the risks and benefits involved

intraoperative phase: period of time that begins with transfer of the patient to the operating room table and continues until the patient is admitted to the postanesthesia care unit

perioperative phase: period of time that constitutes the surgical experience; includes the preoperative, intraoperative, and postoperative phases of nursing care

postoperative phase: period of time that begins with the admission of the patient to the postanesthesia care unit and ends after follow-up evaluation in the clinical setting or home

preadmission testing: diagnostic testing performed before admission to the hospital

preoperative phase: period of time from when the decision for surgical intervention is made to when the patient is transferred to the operating room table

Surgery, whether elective or emergent, is a stressful, complex event. In the past decades, the patient scheduled for elective surgery was admitted to the hospital at least 1 day before surgery for evaluation and preparation. Today, as a result of advances in technology, surgical techniques and instrumentation, and anesthesia, many surgical procedures take place in outpatient or ambulatory settings in which the patient returns home after recovering from the anesthesia in the postanesthesia care unit (PACU). Often, surgical patients who require hospital stays are trauma patients, acutely ill patients, patients undergoing major surgery, patients who require emergency surgery, and patients with concurrent medical disorders. As a result, the acuity and complexity of surgical patients and procedures have increased in the inpatient setting. Although each setting (ambulatory, outpatient, or inpatient) offers its own unique advantages for the delivery of patient care, all patients require a comprehensive preoperative nursing assessment and nursing interventions to prepare for surgery.

Perioperative Nursing

The field of perioperative and perianesthesia nursing includes a wide variety of nursing functions. The **perioperative period** consists of three phases that begin and end at a particular point in the sequence of events in the surgical experience. The **preoperative phase** begins when the decision to proceed with surgical intervention is made and ends with the transfer of the patient onto the operating room (OR) table. The **intraoperative phase** begins when the patient is transferred onto the OR table and ends with admission to the PACU. Nursing duties involve acting as scrub nurse, circulating nurse, or registered nurse first assistant (RNFA) (see Chapter 19 for a description of these roles). The **postoperative phase** begins with the admission of the patient to the PACU and ends with a follow-up evaluation in the clinical setting or home (see Chapter 20).

Each perioperative phase includes a wide range of activities the nurse performs using the nursing process and based on the standards of practice of the American Society of PeriAnesthesia Nurses (2007). Chart 18-1 presents nursing activities characteristic of the three perioperative phases of care. Each phase of the surgical experience is reviewed in more detail in this chapter and in the other chapters in this unit.

A conceptual model of patient care, published by the Association of Perioperative Registered Nurses, formerly known as the Association of Operating Room Nurses (still abbreviated AORN), helps delineate the relationships between various components of nursing practice and patient outcomes. The Perioperative Nursing Data Set (PNDS) categorizes the practice of perioperative nursing practice into four domains: safety, physiologic responses, behavioral responses, and health care systems. The first three domains reflect phenomena of concern to perioperative nurses and are composed of nursing diagnoses, interventions, and outcomes. The fourth domain, the health care system, consists of structural data elements and focuses on clinical processes and outcomes. The model is used to depict the relationship of nursing process components to the achievement of optimal patient outcomes (Phillips, 2007).

Advances in Technology and Anesthesia

Advances in technology have led to more complex procedures, more complicated microsurgical and laser technology, more sophisticated bypass equipment, increased use of laparoscopic and minimally invasive surgery, and more sensitive monitoring devices. Surgery today can involve the transplantation of multiple human organs, the implantation of mechanical devices, the reattachment of body parts, and the use of robots and minimally invasive procedures in the OR.

Advances in anesthesia have kept pace with these surgical technologies. More sophisticated monitoring and new pharmacologic agents, such as short-acting anesthetics and more effective antiemetics, have improved postoperative pain management, reduced postoperative nausea and vomiting, and shortened procedure and recovery times.

Surgical Classifications

Surgery may be performed for various reasons. A surgical procedure may be diagnostic (eg, biopsy, exploratory laparotomy), curative (eg, excision of a tumor or an inflamed appendix), or reparative (eg, multiple wound repair). It may be reconstructive or cosmetic (eg, mammoplasty or a facelift) or palliative (eg, to relieve pain or correct a problem—for instance, a gastrostomy tube may be inserted to compensate for the inability to swallow food). Surgery may also be classified according to the degree of urgency involved: emergent, urgent, required, elective, and optional (Table 18-1).

Preadmission Testing

Concurrent with the increase in ambulatory surgeries have been changes in the delivery of and payment for health care. The pressure to reduce hospital stays and contain costs has resulted in diagnostic **preadmission testing (PAT)** and preoperative preparation prior to admission. Many facilities have a presurgical services department to facilitate PAT and to initiate the nursing assessment process, which focuses on admission data such as patient demographics, health history, and other information pertinent to the surgical procedure (ie, appropriate consent forms, diagnostic and laboratory tests) (Rothrock, 2007). The increasing use of ambulatory, same-day, or short-stay surgery means that patients leave the hospital sooner, which increases the need for teaching, discharge planning, preparation for self-care, and referral for home care and rehabilitation services.

Special Considerations During the Perioperative Period

Gerontologic Considerations

The hazards of surgery for the elderly are proportional to the number and severity of coexisting health problems and the nature and duration of the operative procedure. The

Chart 18-1 • Examples of Nursing Activities in the Perioperative Phases of Care**Preoperative Phase****Preadmission Testing (PAT)**

1. Initiates initial preoperative assessment
2. Initiates teaching appropriate to patient's needs
3. Involves family in interview
4. Verifies completion of preoperative diagnostic testing.
5. Verifies understanding of surgeon-specific preoperative orders (eg, bowel preparation, preoperative shower)
6. Discusses and reviews advanced directive document
7. Begins discharge planning by assessing patient's need for postoperative transportation and care

Admission to Surgical Center

1. Completes preoperative assessment
2. Assesses for risks for postoperative complications
3. Reports unexpected findings or any deviations from normal
4. Verifies that operative consent has been signed
5. Coordinates patient teaching and plan of care with nursing staff and other health team members
6. Reinforces previous teaching
7. Explains phases in perioperative period and expectations
8. Answers patient's and family's questions

In the Holding Area

1. Assesses patient's status, baseline pain, and nutritional status
2. Reviews chart
3. Identifies patient
4. Verifies surgical site and marks site per institutional policy
5. Establishes intravenous line
6. Administers medications if prescribed
7. Takes measures to ensure patient's comfort
8. Provides psychological support
9. Communicates patient's emotional status to other appropriate members of the health care team

Intraoperative Phase**Maintenance of Safety**

1. Maintains aseptic, controlled environment
2. Effectively manages human resources, equipment, and supplies for individualized patient care
3. Transfers patient to operating room bed or table
4. Positions patient based on functional alignment and exposure of surgical site
5. Applies grounding device to patient
6. Ensures that the sponge, needle, and instrument counts are correct
7. Completes intraoperative documentation

Physiologic Monitoring

1. Calculates effects on patient of excessive fluid loss or gain
2. Distinguishes normal from abnormal cardiopulmonary data
3. Reports changes in patient's vital signs
4. Institutes measures to promote normothermia

Psychological Support (Before Induction and When Patient Is Conscious)

1. Provides emotional support to patient

2. Stands near or touches patient during procedures and induction
3. Continues to assess patient's emotional status

Postoperative Phase**Transfer of Patient to Postanesthesia Care Unit**

1. Communicates intraoperative information
 - a. Identifies patient by name
 - b. States type of surgery performed
 - c. Identifies type and amounts of anesthetic and analgesic agents used
 - d. Reports patient's vital signs and response to surgical procedure and anesthesia
 - e. Describes intraoperative factors (eg, insertion of drains or catheters, administration of blood, medications during surgery, or occurrence of unexpected events)
 - f. Describes physical limitations
 - g. Reports patient's preoperative level of consciousness
 - h. Communicates necessary equipment needs
 - i. Communicates presence of family or significant others

Postoperative Assessment Recovery Area

1. Determines patient's immediate response to surgical intervention
2. Monitors patient's vital signs and physiologic status
3. Assesses patient's pain level and administers appropriate pain relief measures
4. Maintains patient's safety (airway, circulation, prevention of injury)
5. Administers medications, fluid, and blood component therapy, if prescribed
6. Provides oral fluids if prescribed for ambulatory surgery patient
7. Assesses patient's readiness for transfer to in-hospital unit or for discharge home based on institutional policy (eg, Alderete score, see Chapter 20)

Surgical Nursing Unit

1. Continues close monitoring of patient's physical and psychological response to surgical intervention
2. Assesses patient's pain level and administers appropriate pain relief measures
3. Provides teaching to patient during immediate recovery period
4. Assists patient in recovery and preparation for discharge home
5. Determines patient's psychological status
6. Assists with discharge planning

Home or Clinic

1. Provides follow-up care during office or clinic visit or by telephone contact
2. Reinforces previous teaching and answers patient's and family's questions about surgery and follow-up care
3. Assesses patient's response to surgery and anesthesia and their effects on body image and function
4. Determines family's perception of surgery and its outcome

underlying principle that guides the preoperative assessment, surgical care, and postoperative care is that elderly patients have less physiologic reserve (the ability of an organ to return to normal after a disturbance in its equilibrium) than younger patients. Respiratory and cardiac com-

plications are the leading causes of postoperative morbidity and mortality in older adults (Stanley, Blair & Beare, 2005). Cardiac reserves are lower, renal and hepatic functions are depressed, and gastrointestinal activity is likely to be reduced. Dehydration, constipation, and malnutrition may

Table 18-1 CATEGORIES OF SURGERY BASED ON URGENCY

Classification	Indications for Surgery	Examples
I. Emergent—Patient requires immediate attention; disorder may be life-threatening	Without delay	Severe bleeding Bladder or intestinal obstruction Fractured skull Gunshot or stab wounds Extensive burns
II. Urgent—Patient requires prompt attention	Within 24–30 hours	Acute gallbladder infection Kidney or ureteral stones
III. Required—Patient needs to have surgery	Plan within a few weeks or months	Prostatic hyperplasia without bladder obstruction Thyroid disorders Cataracts
IV. Elective—Patient should have surgery	Failure to have surgery not catastrophic	Repair of scars Simple hernia Vaginal repair
V. Optional—Decision rests with patient	Personal preference	Cosmetic surgery

occur. Sensory limitations, such as impaired vision or hearing and reduced tactile sensitivity, are often the reasons for falls (Meiner & Lueckenolte, 2006). Therefore, the nurse must be alert to maintaining a safe environment. Arthritis is common in older people and may affect mobility, making it difficult for the patient to turn from one side to the other or ambulate without discomfort. Protective measures include adequate padding for tender areas, moving the patient slowly, protecting bony prominences from prolonged pressure, and providing gentle massage to promote circulation.

As the body ages, its ability to perspire decreases. Because decreased perspiration leads to dry, itchy skin that becomes fragile and is easily abraded, precautions are taken when moving an elderly person. Decreased subcutaneous fat makes older people more susceptible to temperature changes. A lightweight cotton blanket is an appropriate cover when an elderly patient is moved to and from the OR.

Because the elderly patient may have greater risks during the perioperative period, the following factors are critical: (1) skillful preoperative assessment and treatment (Kazmieriski, Kowman, Banach, et al., 2006), (2) skillful anesthesia and surgery, and (3) meticulous and competent postoperative and postanesthesia management. In addition, the nurse should incorporate pain management information and pain communication skills when teaching the elderly patient how to obtain greater postoperative pain relief (see Providing Patient Teaching).

Patients Who Are Obese

Like age, obesity increases the risk and severity of complications associated with surgery. During surgery, fatty tissues are especially susceptible to infection. In addition, obesity increases technical and mechanical problems related to surgery. Therefore, dehiscence (wound separation) and wound infections are more common. Moreover, the obese patient may be more difficult to care for because of the excessive weight. It has been estimated that for each 30 pounds of excess weight, about 25 additional miles of blood vessels are needed, and this places increased demands on the heart. The patient tends to have shallow respirations when supine, which increases the risk of hypoventilation and postoperative pulmonary complications. Short thick necks, large tongues, and redundant pharyngeal tissue, along with an increased demand

for oxygen and decreased reserves, can make intubation difficult (Marley, Hoyle & Ries, 2005). The anesthesiologist or anesthetist also assesses for obstructive sleep apnea that is often diagnosed and treated with continuous positive airway pressure (CPAP) preoperatively. The use of CPAP should continue throughout the perioperative period, especially when sleep is likely, for example, in the recovery room or at night (McGlinch, Que, Nelson, et al., 2006). As the incidence of obesity continues to grow, nurses will be called on to be part of multidisciplinary teams that will develop and implement clinical plans for patients who are obese.

Patients With Disabilities

Special considerations for patients with mental or physical disabilities include the need for appropriate assistive devices, modifications in preoperative teaching, and additional assistance with and attention to positioning or transferring. Assistive devices include hearing aids, eyeglasses, braces, prostheses, and other devices. People who are hearing-impaired may need a sign interpreter or some alternative communication system perioperatively. If the patient relies on signing or speech (lip) reading and his or her eyeglasses or contact lenses are removed or the health care staff wears surgical masks, an alternative method of communication will be needed. These needs must be identified in the preoperative evaluation and clearly communicated to personnel. Specific strategies for accommodating the patient's needs must be identified in advance. Ensuring the security of assistive devices is important, because these devices are expensive and are likely to be lost.

Most patients are directed to move from the stretcher to the OR table and back again. In addition to being unable to see or hear instructions, the patient with a disability may be unable to move without special devices or a great deal of assistance. The patient with a disability that affects body position (eg, cerebral palsy, postpolio syndrome, and other neuromuscular disorders) may need special positioning during surgery to prevent pain and injury. Moreover, these patients may be unable to sense whether their extremities are positioned incorrectly.

Patients with respiratory problems related to a disability (eg, multiple sclerosis, muscular dystrophy) may experience difficulties unless the problems are made known to the anesthesiologist or anesthetist and adjustments are made. These

factors need to be clearly identified in the preoperative period and communicated to the appropriate personnel.

Patients Undergoing Ambulatory Surgery

Ambulatory surgery includes outpatient, same-day, or short-stay surgery that does not require an overnight hospital stay but may entail an admission to an inpatient hospital setting for less than 24 hours. During the brief time the patient and family spend in the ambulatory setting, the nurse must quickly and comprehensively assess and anticipate the patient's needs and at the same time begin planning for discharge and follow-up home care.

The nurse needs to be sure that the patient and family understand that the patient will first go to the preoperative holding area before going to the OR for the surgical procedure and then will spend some time in the PACU before being discharged home with the family later that day. Other preoperative teaching content should also be verified and reinforced as needed (see later discussion). The nurse should ensure that any plans for follow-up home care are in place if needed.

Patients Undergoing Emergency Surgery

Emergency surgeries are unplanned and occur with little time for preparation for the patient or the perioperative team. See Chapter 19 for the duties of the members of the perioperative team. The unpredictable nature of trauma and emergency surgery poses unique challenges to the nurse throughout the perioperative period. It is important for the nurse to communicate with the patient and team members as calmly and effectively as possible in these situations.

Factors that affect patients preparing to undergo surgery also apply to patients undergoing emergency surgery, but usually in a very condensed time frame. The only opportunity for preoperative assessment may take place at the same time as resuscitation in the emergency department. For the unconscious patient, informed consent and essential information, such as pertinent past medical history and allergies, need to be obtained from a family member, if one is available. A quick visual survey of the patient is essential to identify all sites of injury if the emergency surgery is due to trauma (see Chapter 71 for more information). The patient, who may have undergone a traumatic experience, may need extra support and explanation of the surgery.

Informed Consent

Informed consent is the patient's autonomous decision about whether to undergo a surgical procedure. Voluntary and written informed consent from the patient is necessary before nonemergent surgery can be performed in order to protect the patient from unsanctioned surgery and protect the surgeon from claims of an unauthorized operation. Consent is a legal mandate, but it also helps the patient to prepare psychologically, because it helps to ensure that the patient understands the surgery to be performed (Rothrock, 2007).

While the nurse may ask the patient to sign the consent form and witness the signature, it is the surgeon's responsibility to provide a clear and simple explanation of what the surgery will entail prior to the patient giving consent. The sur-

geon must also inform the patient of the benefits, alternatives, possible risks, complications, disfigurement, disability, and removal of body parts as well as what to expect in the early and late postoperative periods. The nurse clarifies the information provided and if the patient requests additional information, the nurse notifies the physician. The nurse ascertains that the consent form has been signed before administering psychoactive premedication, because consent is not valid if it is obtained while the patient is under the influence of medications that can affect judgment and decision-making capacity.

NURSING ALERT

The signed consent form is placed in a prominent place on the patient's chart and accompanies the patient to the OR.

Many ethical principles are integral to informed consent (see Chapter 3). Informed consent is necessary in the following circumstances:

- Invasive procedures, such as a surgical incision, a biopsy, a cystoscopy, or paracentesis
- Procedures requiring sedation and/or anesthesia (see Chapter 19 for a discussion of anesthesia)
- A nonsurgical procedure, such as an arteriography, that carries more than a slight risk to the patient
- Procedures involving radiation

The patient personally signs the consent if of legal age and mentally capable. Permission is otherwise obtained from a surrogate, who most often is a responsible family member (preferably next of kin) or legal guardian. See Chart 18-2 for criteria for valid informed consent. State regulations and agency policy must be followed. In an emergency, it may be necessary for the surgeon to operate as a lifesaving measure without the patient's informed consent. However, every effort must be made to contact the patient's family. In such a situation, contact can be made by telephone, fax, or other electronic means.

If the patient has doubts and has not had the opportunity to investigate alternative treatments, a second opinion may be requested. No patient should be urged or coerced to give informed consent. Refusing to undergo a surgical procedure is a person's legal right and privilege. However, such information must be documented and relayed to the surgeon so that other arrangements can be made. For example, additional explanations may be provided to the patient and family, or the surgery may be rescheduled. Consents for specific procedures such as sterilization, therapeutic abortion, disposal of severed body parts, organ donation, and blood product administration provide additional protection for the patient (Rothrock, 2007).

The consent process can be improved by providing audiovisual materials to supplement discussion, by ensuring that the wording of the consent form is understandable, and by using other strategies and resources as needed to help the patient understand its content (see Chart 18-2) (Sallady, 2005).

Preoperative Assessment

The goal in the preoperative period is for the patient to be as healthy as possible. Every attempt is made to address risk factors that otherwise lead to postoperative complications

Chart 18-2 • Valid Informed Consent**Voluntary Consent**

Valid consent must be freely given, without coercion. Patient must be at least 18 years of age (unless an emancipated minor), consent must be obtained by a physician, and patient's signature must be witnessed by a professional staff member.

Incompetent Patient

Legal definition: individual who is *not* autonomous and cannot give or withhold consent (eg, individuals who are cognitively impaired, mentally ill, or neurologically incapacitated).

Informed Subject

Informed consent should be in writing. It should contain the following:

- Explanation of procedure and its risks
- Description of benefits and alternatives
- An offer to answer questions about procedure
- Instructions that the patient may withdraw consent
- A statement informing the patient if the protocol differs from customary procedure

Patient Able to Comprehend

If the patient is non-English speaking, it is necessary to provide consent (written and verbal) in a language that is understandable to the client. A trained medical interpreter may be consulted. Alternative formats of communication (eg, Braille, large print, sign interpreter) may be needed if the patient has a disability that affects vision or hearing. Questions must be answered to facilitate comprehension if material is confusing.

and hinder recovery (Chart 18-3). Before any surgical treatment is initiated, a health history is obtained, a physical examination is performed during which vital signs are noted, and a database is established for future comparisons. During the physical examination, many factors that have the potential to affect the patient undergoing surgery are considered. Genetic considerations are also taken into account during assessment to prevent complications with anesthesia (Chart 18-4).

Health care providers should be alert for signs of abuse, which can occur at all ages and to men and women from all socioeconomic, ethnic, and cultural groups (Weber & Kelley, 2007). Findings need to be reported accordingly (see Chapter 5 for further discussion of signs of abuse). Blood tests, x-rays, and other diagnostic tests are prescribed when indicated by information obtained from the history and physical examination.

Nutritional and Fluid Status

Optimal nutrition is an essential factor in promoting healing and resisting infection and other surgical complications. Assessment of a patient's nutritional status identifies factors that can affect the patient's surgical course, such as obesity weight loss, malnutrition, deficiencies in specific nutrients, metabolic abnormalities, and the effects of medications on nutrition. Nutritional needs may be determined by measurement of body mass index and waist cir-

CHART
18-3**Risk Factors for Surgical Complications**

 - Hepatitis
- Preexisting mental or physical disability

cumference (U.S. Department of Health and Human Services, 2007). See Chapter 5 for further discussion of nutritional assessment.

Any nutritional deficiency, such as malnutrition, should be corrected before surgery to provide adequate protein for tissue repair. The nutrients needed for wound healing are summarized in Table 18-2.

Dehydration, hypovolemia, and electrolyte imbalances can lead to significant problems in patients with comorbid medical conditions or in patients who are elderly. The severity of fluid and electrolyte imbalances is often difficult to determine. Mild volume deficits may be treated during surgery; however, additional time may be needed to correct pronounced fluid and electrolyte deficits to promote the best possible preoperative condition.

Dentition

The condition of the mouth is an important health factor to assess. Dental caries, dentures, and partial plates are particularly significant to the anesthesiologist or anesthesiologist, because decayed teeth or dental prostheses may become dislodged during intubation and occlude the airway. This is

CHART
18.4GENETICS IN NURSING PRACTICE
Perioperative Nursing

Nurses who are caring for patients undergoing surgery need to take various genetic considerations into account when assessing patients throughout the perioperative experience. For example, surgical outcomes may be altered by genetic conditions that may cause complications with anesthesia, including the following:

- Malignant hyperthermia
- Central core disease (CCD)
- Duchenne muscular dystrophy
- Hyperkalemic periodic paralysis
- King-Denborough syndrome

Nursing Assessments**Preoperative Family History Assessment**

- Obtain a thorough assessment of personal and family history, inquiring about prior problems with surgery or anesthesia with specific attention to complications such as fever, rigidity, dark urine, and unexpected reactions.
- Inquire about any history of musculoskeletal complaints, history of heat intolerance, fevers of unknown origin, or unusual drug reaction.
- Assess for family history of any sudden or unexplained death, especially during participation in athletic events.

Patient Assessment

- Assess for subclinical muscle weakness.
- Assess for other physical features suggestive of an underlying genetic condition, such as contractures, kyphoscoliosis, and pterygium with progressive weakness.

Management Issues Specific to Genetics

- Inquire whether DNA mutation or other genetic testing has been performed on an affected family member.

- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of diagnostic/genetic testing.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed malignant hyperthermia.
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

Genetics Resources for Nurses and Their Patients on the Web

Genetic Alliance—a directory of support groups for patients and families with genetic conditions, www.geneticalliance.org

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information, www.geneclinics.org

International Council of Nurses (ICN)—ICN's statement re: genetics and nursing, www.icn.ch/matters_genetics.htm

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders, www.rarediseases.org

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions, www.ncbi.nlm.nih.gov/entrez/query.fcgi?db-OMIM

especially important for elderly patients, as well as those from underserved communities or who are uninsured or do not have regular dental care.

Drug or Alcohol Use

People who abuse drugs or alcohol frequently deny or attempt to hide it. In such situations, the nurse who is obtaining the patient's health history needs to ask frank questions with patience, care, and a nonjudgmental attitude. See Chapter 5 for an assessment of alcohol and drug use.

Because acutely intoxicated people are susceptible to injury, surgery is postponed if possible. If emergency surgery is required, local, spinal, or regional block anesthesia is used for minor surgery. Otherwise, to prevent vomiting and potential aspiration, a nasogastric tube is inserted before general anesthesia is administered.

The person with a history of chronic alcoholism often suffers from malnutrition and other systemic problems that increase surgical risk. Alcohol withdrawal syndrome (ie, delirium tremens) may be anticipated between 48 and 72 hours after alcohol withdrawal and is associated with a significant mortality rate when it occurs postoperatively. This increase in mortality rate can be contributed to cardiac dysrhythmias, cardiomyopathy, and bleeding tendencies seen in long-term alcohol abuse (Lussier-Cushing, Repper-DeLisi, Mitchell, et al., 2007).

Respiratory Status

The goal for surgical patients is optimal respiratory function. The patient is taught breathing exercises and the use of an incentive spirometer if indicated. Because ventilation is potentially compromised during all phases of surgical treatment, surgery is usually postponed if the patient has a respiratory infection. Patients with underlying respiratory disease (eg, asthma, chronic obstructive pulmonary disease) are assessed carefully for current threats to their pulmonary status. Patients also need to be assessed for comorbid conditions such as human immunodeficiency virus (HIV) infection and Parkinson's disease, which may affect respiratory function (West, 2008).

Patients who smoke are urged to stop 4 to 8 weeks before surgery to significantly reduce pulmonary and wound healing complications. Preoperative smoking cessation interventions can be effective in changing smoking behavior and reducing the incidence of postoperative complications (Moller & Villebro, 2007).

Cardiovascular Status

The goal in preparing any patient for surgery is to ensure a well-functioning cardiovascular system to meet the oxygen, fluid, and nutritional needs of the perioperative period. If the patient has uncontrolled hypertension, surgery may be postponed until the blood pressure is under control. At

Table 18-2 NUTRIENTS IMPORTANT FOR WOUND HEALING

Nutrient	Rationale for Increased Need	Possible Deficiency Outcome
Protein	To allow collagen deposition and wound healing to occur	Collagen deposition leading to impaired/delayed wound healing Decreased skin and wound strength Increased wound infection rates Impaired wound healing
Arginine (amino acid)	To provide necessary substrate for collagen synthesis and nitric oxide (crucial for wound healing) at wound site To increase wound strength and collagen deposition To stimulate T-cell response Associated with a variety of essential reactions of intermediary metabolism	
Carbohydrates and fats	Primary source of energy in the body and consequently in the wound healing process To meet the demand for increased essential fatty acids needed for cellular function after an injury To spare protein To restore normal weight	Signs and symptoms of protein deficiency due to use of protein to meet energy requirements Extensive weight loss
Water	To replace fluid lost through vomiting, hemorrhage, exudates, fever, drainage, diuresis To maintain homeostasis	Signs, symptoms, and complications of dehydration, such as poor skin turgor, dry mucous membranes, oliguria, anuria, weight loss, increased pulse rate, decreased central venous pressure
Vitamin C	Important for capillary formation, tissue synthesis, and wound healing through collagen formation Needed for antibody formation	Impaired/delayed wound healing related to impaired collagen formation and increased capillary fragility and permeability Increased risk for infection related to decreased antibodies
Vitamin B complex	Indirect role in wound healing through their influence on host resistance	Decreased enzymes available for energy metabolism
Vitamin A	Increases inflammatory response in wounds, reduces anti-inflammatory effects of corticosteroids on wound healing	Impaired/delayed wound healing related to decreased collagen synthesis; impaired immune function Increased risk for infection
Vitamin K	Important for normal blood clotting Impaired intestinal synthesis associated with the use of antibiotics	Prolonged prothrombin time Hematomas contributing to impaired healing and predisposition to wound infections
Magnesium	Essential cofactor for many enzymes that are involved in the process of protein synthesis and wound repair	Impaired/delayed wound healing (impaired collagen production)
Copper	Required cofactor in the development of connective tissue	Impaired wound healing
Zinc	Involved in DNA synthesis, protein synthesis, cellular proliferation needed for wound healing Essential to immune function	Impaired immune response

Information from Dudek, S. G. (2006). *Nutrition essentials for nursing practice* (5th ed.). Philadelphia: Lippincott Williams & Wilkins; and Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

times, surgical treatment can be modified to meet the cardiac tolerance of the patient. For example, in a patient with obstruction of the descending colon and coronary artery disease, a temporary simple colostomy may be performed rather than a more extensive colon resection that would require a prolonged period of anesthesia.

Hepatic and Renal Function

The presurgical goal is optimal function of the liver and urinary systems so that medications, anesthetic agents, body wastes, and toxins are adequately metabolized and removed from the body.

The liver is important in the biotransformation of anesthetic compounds. Therefore, any disorder of the liver has an effect on how anesthetic agents are metabolized. Because acute liver disease is associated with high surgical mortality, preoperative improvement in liver function is a goal. Careful assessment may include various liver function tests (see Chapter 39).

The kidneys are involved in excreting anesthetic medications and their metabolites; therefore, surgery is contraindicated if a patient has acute nephritis, acute renal insufficiency with oliguria or anuria, or other acute renal problems (see Chapter 44). Exceptions include surgeries performed as lifesaving measures or those necessary to improve urinary function (ie, obstructive uropathy).

Endocrine Function

The patient with diabetes who is undergoing surgery is at risk for hypoglycemia and hyperglycemia. Hypoglycemia may develop during anesthesia or postoperatively from inadequate carbohydrates or excessive administration of insulin. Hyperglycemia, which can increase the risk for surgical wound infection, may result from the stress of surgery, which can trigger increased levels of catecholamine. Other risks are acidosis and glucosuria. Although the surgical risk in the patient with controlled diabetes is no

greater than in the patient without diabetes, strict glycemic control (80 to 110 mg/dL) leads to better outcomes (Plank, Blaha, Cordingley, et al., 2006). Frequent monitoring of blood glucose levels is important before, during, and after surgery (see Chapter 41 for a discussion of the patient with diabetes).

Patients who have received corticosteroids are at risk for adrenal insufficiency. Therefore, the use of corticosteroids for any purpose during the preceding year must be reported to the anesthesiologist or anesthesiologist and surgeon. The patient is monitored for signs of adrenal insufficiency.

Patients with uncontrolled thyroid disorders are at risk for thyrotoxicosis (with hyperthyroid disorders) or respiratory failure (with hypothyroid disorders). Therefore, the patient is assessed for a history of these disorders.

Immune Function

An important function of the preoperative assessment is to determine the presence of allergies. It is especially important to identify and document any sensitivity to medications and past adverse reactions to these agents. The patient is asked to identify any substances that precipitated previous allergic reactions, including medications, blood transfusions, contrast agents, latex, and food products, and to describe the signs and symptoms produced by these substances. A sample latex allergy screening questionnaire is shown in Figure 18-1.

Immunosuppression is common with corticosteroid therapy, renal transplantation, radiation therapy, chemotherapy, and disorders affecting the immune system, such as acquired immunodeficiency syndrome (AIDS) and leukemia. The mildest symptoms or slightest temperature elevation must be investigated. Because patients who are immunosuppressed are highly susceptible to infection, great care is taken to ensure strict asepsis.

Previous Medication Use

A medication history is obtained because of the possible effects of medications on the patient's perioperative course, including the possibility of drug interactions. Any medication the patient is using or has used in the past is documented, including over-the-counter (OTC) preparations, herbal agents, and the frequency with which they are used. Many medications have an effect on physiologic functions; interactions of such medications with anesthetic agents can cause serious problems, such as arterial hypotension and circulatory collapse. Medications that cause particular concern are listed in Table 18-3.

The anesthesiologist or anesthesiologist evaluates the potential effects of prior medication therapy, considering the length of time the patient has used the medication, the physical condition of the patient, and the nature of the proposed surgery (D'Arcy, 2007).

Many patients take self-prescribed or OTC medications. Aspirin is a common OTC medication that inhibits platelet aggregation; therefore, it is prudent to stop aspirin at least 7 to 10 days before surgery if possible, especially for surgeries in which excess bleeding would cause significant complications, such as brain or spinal cord surgeries (Rothrock, 2007). Any use of aspirin or other OTC medications is noted in the patient's chart and conveyed to the anesthesiologist or anesthesiologist and surgeon.

Latex Allergy Assessment

Ask the patient the following questions. Check "Yes" or "No" in the box.	YES	NO
1. Has a doctor ever told you that you are allergic to latex?		
2. Do you have on-the-job exposure to latex?		
3. Were you born with problems involving your spinal cord?		
4. Have you ever had allergies, asthma, hay fever, eczema, or problems with rashes?		
5. Have you ever had respiratory distress, rapid heart rate, or swelling?		
6. Have you ever had swelling, itching, hives, or other symptoms after contact with a balloon?		
7. Have you ever had swelling, itching, hives, or other symptoms after a dental examination or procedure?		
8. Have you ever had swelling, itching, hives, or other symptoms following a vaginal or rectal examination or after contact with a diaphragm or condom?		
9. Have you ever had swelling, itching, hives, or other symptoms during or within 1 hour after wearing rubber gloves?		
10. Have you ever had a rash on your hands that lasted longer than 1 week?		
11. Have you ever had swelling, itching, hives, runny nose, eye irritation, wheezing, or asthma after contact with any latex or rubber product?		
12. Have you ever had swelling, itching, hives, or other symptoms after being examined by someone wearing rubber or latex gloves?		
13. Are you allergic to bananas, avocados, kiwi, or chestnuts?		
14. Have you ever had an unexplained anaphylactic episode?

NURSING ALERT

Because of possible adverse interactions, the nurse must assess and document the patient's use of prescription medications, OTC medications (especially aspirin), herbal agents, and the frequency with which medications are used. The nurse must clearly communicate this information to the anesthesiologist or anesthesiologist.

The use of herbal medications is widespread among patients; approximately 40% of Americans report taking some

Table 18-3  **EXAMPLES OF MEDICATIONS WITH THE POTENTIAL TO AFFECT THE SURGICAL EXPERIENCE**

Agent	Effect of Interaction With Anesthetics
Corticosteroids Prednisone (Deltasone)	Cardiovascular collapse can occur if discontinued suddenly. Therefore, a bolus of corticosteroid may be administered intravenously immediately before and after surgery.
Diuretics Hydrochlorothiazide (HydroDIURIL)	During anesthesia, may cause excessive respiratory depression resulting from an associated electrolyte imbalance
Phenothiazines Chlorpromazine (Thorazine)	May increase the hypotensive action of anesthetics
Tranquilizers Diazepam (Valium)	May cause anxiety, tension, and even seizures if withdrawn suddenly
Insulin	Interaction between anesthetics and insulin must be considered when a patient with diabetes is undergoing surgery. Intravenous insulin may need to be administered to keep the blood glucose within the normal range.
Antibiotics Erythromycin (Ery-Tab)	When combined with a curariform muscle relaxant, nerve transmission is interrupted and apnea from respiratory paralysis may result.
Anticoagulants Warfarin (Coumadin)	Can increase the risk of bleeding during the intraoperative and postoperative periods; should be discontinued in anticipation of elective surgery. The surgeon will determine how long before the elective surgery the patient should stop taking an anticoagulant, depending on the type of planned procedure and the medical condition of the patient.
Antiseizure Medications	Intravenous administration of medication may be needed to keep the patient seizure-free in the intraoperative and postoperative periods.
Thyroid Hormone Levothyroxine sodium (Levothroid)	Intravenous administration may be needed during the postoperative period to maintain thyroid levels.
Opioids	Long-term use of opioids for chronic pain (6 mo or greater) in the preoperative period may alter the patient's response to analgesic agents.

Adapted from D'Arcy, Y. (2007). Managing pain in a patient who is drug dependent. *Nursing*, 37(3), 36–41.

form of these substances (Messina, 2006). The most commonly used herbal medications are echinacea, ephedra, garlic (*Allium sativum*), ginkgo biloba, ginseng, kava kava (*Piper methysticum*), St. John's wort (*Hypericum perforatum*), licorice extract (*Glycyrrhizic acid*), and valerian (*Valeriana officinalis*). Many patients fail to report using herbal medicines to their health care providers; therefore, the nurse must ask surgical patients specifically about the use of these agents. Any use of herbal medications is noted in the patient's chart and conveyed to the anesthesiologist or anesthesiologist and surgeon because of the potential effects on coagulation and potentially lethal interactions with other medications. Currently, it is recommended that the use of herbal products be discontinued 2 to 3 weeks before surgery (Rothrock, 2007).

Psychosocial Factors

Most patients have some type of emotional reaction before any surgical procedure, be it obvious or hidden, normal or abnormal. Fears may be related to fear of the unknown or of death, anesthesia, pain, complications, or cancer. Preoperative anxiety may be an anticipatory response to an experience viewed by the patient as a threat to his or her customary role in life, permanent incapacity, body integrity, increased responsibilities or burden on family members, or life itself. Less obvious concerns may occur because of previous experiences with the health care system and people the patient has known with the same condition. Psycholog-

ical distress directly influences body functioning. Therefore, it is imperative to identify any anxiety the patient is experiencing (Kain, Caldwell-Andrews, Mayes, et al., 2007).

People express fear in different ways. For example, some patients may repeatedly ask many questions, even though answers were given previously. Others may withdraw, deliberately avoiding communication, perhaps by reading, watching television, or talking about trivialities. Consequently, the nurse must be empathetic, listen well, and provide information that helps alleviate concerns.

An important outcome of the psychosocial assessment is the determination of the extent and role of the patient's support network. The value and reliability of available support systems are assessed. Other information, such as usual level of functioning and typical daily activities, may assist in the patient's care and recovery. Assessing the patient's readiness to learn and determining the best approach to maximize comprehension provides the basis for preoperative patient education. This is of particular importance in patients who are developmentally delayed and those who are cognitively impaired, where the approach to patient education and consent will include the legal guardian.

Spiritual and Cultural Beliefs

Spiritual beliefs play an important role in how people cope with fear and anxiety. Regardless of the patient's religious affiliation, spiritual beliefs can be as therapeutic as medication.

Every attempt must be made to help the patient obtain the spiritual support that he or she requests. Therefore, the nurse must respect and support the beliefs of each patient. Some nurses may avoid the subject of a clergy visit lest the suggestion alarm the patient. Asking whether the patient's spiritual advisor knows about the impending surgery is a caring, nonthreatening approach.

Showing respect for a patient's cultural values and beliefs facilitates rapport and trust. Some areas of assessment include identifying the ethnic group to which the patient relates and the customs and beliefs the patient holds about illness and health care providers. For example, patients from some cultural groups are unaccustomed to expressing feelings openly. Nurses need to consider this pattern of communication when assessing pain. As a sign of respect, people from some cultural groups may not make direct eye contact with others (Andrews & Boyle, 2008). The nurse should know that this lack of eye contact is not avoidance or a lack of interest.

Perhaps the most valuable skill at the nurse's disposal is listening carefully to the patient, especially when obtaining the history. Invaluable information and insights may be gained through effective communication and interviewing skills. An unhurried, understanding, and caring nurse promotes confidence on the part of the patient.

General Preoperative Nursing Interventions

There are a wide range of interventions used to prepare the patient physically and psychologically and to maintain safety.

Providing Patient Teaching

Nurses have long recognized the value of preoperative instruction (Rothrock, 2007). Each patient is taught as an individual, with consideration for any unique concerns or learning needs. Multiple teaching strategies should be used (eg, verbal, written, return demonstration), depending on the patient's needs and abilities.

Preoperative teaching is initiated as soon as possible, beginning in the physician's office, in the clinic, or at the time of PAT when diagnostic tests are performed. During PAT, the nurse or health care provider makes resources available related to patient teaching such as written instructions (designed to be copied and given to patients), audiovisual resources, and telephone numbers to ensure that teaching continues until the patient arrives for the surgical intervention. When possible, instruction is spaced over a period of time to allow the patient to assimilate information and ask questions as they arise.

Frequently, teaching sessions are combined with various preparation procedures to allow for an easy and timely flow of information. The nurse should guide the patient through the experience and allow ample time for questions. Teaching should go beyond descriptions of the procedure and should include explanations of the sensations the patient will experience. For example, telling the patient only that preoperative medication will cause relaxation before the operation is not as effective as also noting that the medication may result in lightheadedness and drowsiness. Knowing what to expect will help the patient anticipate these re-

actions and thus attain a higher degree of relaxation than might otherwise be expected. For some patients, overly detailed descriptions may increase anxiety; therefore, the nurse should be sensitive to this and provide less detail based on the individual patient's needs.

Deep Breathing, Coughing, and Incentive Spirometry

One goal of preoperative nursing care is to teach the patient how to promote optimal lung expansion and resulting blood oxygenation after anesthesia. The patient assumes a sitting position to enhance lung expansion. The nurse then demonstrates how to take a deep, slow breath and how to exhale slowly. After practicing deep breathing several times, the patient is instructed to breathe deeply, exhale through the mouth, take a short breath, and cough from deep in the lungs (Chart 18-5). The nurse or respiratory therapist also demonstrates how to use an incentive spirometer, a device that provides measurement and feedback related to breathing effectiveness (see Chapter 25). In addition to enhancing respiration, these exercises may help the patient relax. Research indicates that some patients benefit from intensive inspiratory muscle training in the preoperative period (Hulzebos, Helders, Favie, et al., 2006).

If a thoracic or abdominal incision is anticipated, the nurse demonstrates how to splint the incision to minimize pressure and control pain. The patient should put the palms of both hands together, interlacing the fingers snugly. Placing the hands across the incisional site acts as an effective splint when coughing. In addition, the patient is informed that medications are available to relieve pain and should be taken regularly for pain relief so that effective deep-breathing and coughing exercises can be performed. The goal in promoting coughing is to mobilize secretions so that they can be removed. Deep breathing before coughing stimulates the cough reflex. If the patient does not cough effectively, atelectasis (collapse of the alveoli), pneumonia, or other lung complications may occur.

Mobility and Active Body Movement

The goals of promoting mobility postoperatively are to improve circulation, prevent venous stasis, and promote optimal respiratory function. The patient should be taught that early and frequent ambulation immediately postoperative as tolerated will help to prevent complications.

The nurse explains the rationale for frequent position changes after surgery and then shows the patient how to turn from side to side and how to assume the lateral position without causing pain or disrupting intravenous (IV) lines, drainage tubes, or other equipment. Any special position the patient needs to maintain after surgery (eg, adduction or elevation of an extremity) is discussed, as is the importance of maintaining as much mobility as possible despite restrictions. Reviewing the process before surgery is helpful, because the patient may be too uncomfortable or drowsy after surgery to absorb new information.

Exercise of the extremities includes extension and flexion of the knee and hip joints (similar to bicycle riding while lying on the side) unless contraindicated by type of surgical procedure (eg, hip replacement). The foot is rotated as though tracing the largest possible circle with the great toe

CHART
18-5

PATIENT EDUCATION

Preoperative Instructions to Prevent Postoperative Complications

Diaphragmatic Breathing

Diaphragmatic breathing refers to a flattening of the dome of the diaphragm during inspiration, with resultant enlargement of the upper abdomen as air rushes in. During expiration, the abdominal muscles contract.

1. Practice in the same position you would assume in bed after surgery: a semi-Fowler's position, propped in bed with the back and shoulders well supported with pillows.
2. With your hands resting lightly on the front of the lower ribs, and fingertips against lower chest to feel the movement.

Diaphragmatic breathing

3. Breathe out gently and fully as the ribs sink down and inward toward midline.
4. Then take a deep breath through your nose and mouth, letting the abdomen rise as the lungs fill with air.
5. Hold this breath for a count of five.
6. Exhale and let out *all* the air through your nose and mouth.
7. Repeat this exercise 15 times with a short rest after each group of five.
8. Practice this twice a day preoperatively.

Coughing

1. Lean forward slightly from a sitting position in bed, interlace your fingers together, and place your hands across the incisional site to act as a splintlike support when coughing.

Splinting of chest when coughing

2. Breathe with the diaphragm as described under "Diaphragmatic Breathing."

3. With your mouth slightly open, breathe in fully.
4. "Hack" out sharply for three short breaths.
5. Then, keeping your mouth open, take in a quick deep breath and immediately give a strong cough once or twice. This helps clear secretions from your chest. It may cause some discomfort but will not harm your incision.

Leg Exercises

1. Lie in a semi-Fowler's position and perform the following simple exercises to improve circulation.
2. Bend your knee and raise your foot—hold it a few seconds, then extend the leg and lower it to the bed.

Leg exercises

3. Do this five times with one leg, then repeat with the other leg.
4. Then trace circles with the feet by bending them down, in toward each other, up, and then out.
5. Repeat these movements five times.

Foot exercises

Turning to the Side

1. Turn on your side with the uppermost leg flexed most and supported on a pillow.
2. Grasp the side rail as an aid to maneuver to the side.
3. Practice diaphragmatic breathing and coughing while on your side.

Getting Out of Bed

1. Turn on your side.
2. Push yourself up with one hand as you swing your legs out of bed.

(see Chart 18-5). The elbow and shoulder are also put through their range of motion. At first, the patient is assisted and reminded to perform these exercises. Later, the patient is encouraged to do them independently. Muscle tone is maintained so that ambulation will be easier. The nurse should remember to use proper body mechanics and to instruct the patient to do the same. Whenever the patient is positioned, his or her body needs to be properly aligned.

Pain Management

A pain assessment should include differentiation between acute and chronic pain. A pain intensity scale should be introduced and explained to the patient to promote more effective postoperative pain management. Chapter 13 contains several examples of pain scales. Preoperative patient teaching also needs to include the difference between acute and chronic pain, so that the patient is prepared to differentiate acute postoperative pain from a chronic condition such as back pain. Preoperative pain assessment and teaching for the elderly patient may require additional attention (Chart 18-6).

Postoperatively, medications are administered to relieve pain and maintain comfort without suppressing respiratory function. The patient is instructed to take the medication as frequently as prescribed during the initial postoperative period for pain relief. Anticipated methods of administration of analgesic agents for inpatients include patient-controlled analgesia (PCA), epidural catheter bolus or infusion, or patient-controlled epidural analgesia (PCEA). A patient who is expected to go home will likely receive oral analgesic agents. These methods are discussed with the patient before surgery, and the patient's interest and willingness to use them are assessed.

Cognitive Coping Strategies

Cognitive strategies may be useful for relieving tension, overcoming anxiety, decreasing fear, and achieving relaxation. Examples of such strategies include the following:

- Imagery: The patient concentrates on a pleasant experience or restful scene.
- Distraction: The patient thinks of an enjoyable story or recites a favorite poem or song.
- Optimistic self-recitation: The patient recites optimistic thoughts ("I know all will go well").
- Music therapy: The patient listens to soothing music (an easy-to-administer, inexpensive, noninvasive intervention).

Instruction for Patients Undergoing Ambulatory Surgery

Preoperative education for the same-day or ambulatory surgical patient comprises all previously discussed patient teaching as well as collaborative planning with the patient and family for discharge and follow-up home care. The major difference in outpatient preoperative education is the teaching environment.

Preoperative teaching content may be presented in a group class, on a videotape, at PAT, or by telephone in conjunction with the preoperative interview. In addition to answering questions and describing what to expect, the nurse tells the patient when and where to report, what to bring (insurance card, list of medications and allergies), what to leave at home (jewelry, watch, medications, contact lenses), and what to wear (loose-fitting, comfortable clothes; flat shoes). The nurse in the surgeon's office may initiate teaching before the perioperative telephone contact.

During the final preoperative telephone call, teaching is completed or reinforced as needed, and last-minute instructions are given. The patient is reminded not to eat or drink as directed.

Providing Psychosocial Interventions

Reducing Anxiety and Decreasing Fear

During the preoperative assessment of psychological factors and spiritual and cultural beliefs, the nurse assists the patient to identify coping strategies that he or she has previously used to decrease fear. Discussions with the patient to help determine the source of fears can help with expression of concerns. The patient benefits from knowing when family and friends will be able to visit after surgery and that a spiritual advisor will be available if desired. The general preoperative teaching and cognitive strategies addressed earlier in this section help decrease preoperative anxiety in many patients. Knowing ahead of time about the possible need for a ventilator, drainage tubes, or other types of equipment helps decrease anxiety related to the postoperative period. Chart 18-7 addresses patient teaching as a means of reducing emotional distress.

Respecting Cultural, Spiritual, and Religious Beliefs

Psychosocial interventions include identifying and showing respect for cultural, spiritual, and religious beliefs. In some cultures, for example, people are stoic in regard to pain,

CHART
18-6

Preoperative Pain Assessment and Teaching for the Elderly

The older person undergoing surgery may have a combination of chronic illnesses and health issues in addition to the specific one for which surgery is indicated. The elderly frequently do not report symptoms, perhaps because they fear a serious illness may be diagnosed or because they accept such symptoms as part of the aging process. Subtle clues alert the nurse to underlying problems. Some older patients believe that pain is inevitable with aging and is meant

to be endured; therefore, nurses must teach the patient about the benefits of controlling pain (Linton & Lach, 2007). Older patients also report higher levels of preoperative anxiety; therefore, the nurse should be prepared to spend additional time, increase the amount of therapeutic touch utilized, and encourage family members to be present to decrease anxiety (Stanley, et al., 2005).

CHART
18-7
NURSING RESEARCH PROFILE
Nursing Intervention Following Day Surgery for Breast Cancer

Allard, N. C. (2007). Day surgery for breast cancer: Effects of a psychoeducational telephone intervention on functional status and emotional distress. *Oncology Nursing Forum*, 34(1), 133–141.

Purpose

Breast cancer causes significant physical and emotional distress in the approximately 400 women in Canada diagnosed each week. The purpose of this study was to determine if a nursing intervention based on a self-regulation theory known as Attentional Focus and Symptom Management Intervention (AFSMI) was effective in enhancing functional status and relieving emotional distress in women who underwent day surgery for breast cancer as part of their initial treatment.

Design

A convenience sample of 117 women with primary breast cancer who were scheduled for day surgery were randomized into two groups. The control group ($n = 56$) received usual care, while the experimental group ($n = 61$) received AFSMI during two phone sessions. Functional status was measured with the Sickness Impact Profile (SIP) and emotional distress was measured using the short form of the Profile of Mood States (POMS). The SIP and POMS were measured preoperatively and at 3 to 4 days and 10 to 11 days after surgery.

Findings

The mean age of the total sample was 54 years; 37% had a secondary level of education, and 46% were married. More women in the group who received the AFSMI had a greater number of chronic health conditions (37%) compared to the control group (22%) ($X^2 = 4.55$; $p = 0.03$). Significant differences were found between the two groups on home management, total mood disturbance, confusion, and tension scores. The group that received AFSMI had more effective home management, as measured by a subscale of the SIP, compared to the usual care group ($F[1,98] = 4.9$; $p = 0.03$). Those who received AFSMI also had lower scores on the POMS compared to the usual care group ($F[1,93] = 3.98$; $p = 0.05$).

Nursing Implications

During preoperative assessment and teaching, nurses should be aware that AFSMI was effective in reducing emotional distress and enhancing physical functioning in this study. More research is needed, but this may be a low-cost and effective nursing strategy to consider implementing, especially with women who exhibit high levels of stress in the preoperative period before day surgery for breast cancer.

whereas in others they are more expressive. These responses should be recognized as normal for those patients and families and should be respected by perioperative personnel (Andrews & Boyle, 2008). If patients decline blood transfusions for religious reasons (Jehovah's Witnesses), this information needs to be clearly identified in the preoperative period, documented, and communicated to the appropriate personnel.

Maintaining Patient Safety

Protecting patients from injury is one of the major roles of the perioperative nurse. Adherence to AORN recommended practices, The Joint Commission patient safety goals (Chart 18-8), and national patient safety goals are crucial (Rothrock, 2007). These apply to hospitals as well as to ambulatory surgery centers and office-based surgery facilities (The Joint Commission, 2008).

Managing Nutrition and Fluids

The major purpose of withholding food and fluid before surgery is to prevent aspiration. Until recently, fluid and food were restricted preoperatively overnight and often longer. However, the American Society of Anesthesiologists reviewed this practice and has made new recommendations for people undergoing elective surgery who are otherwise healthy. Specific recommendations depend on the age of the patient and the type of food eaten. For example, adults may be advised to fast for 8 hours after eating fatty food and 4 hours after ingesting milk products. Many patients are currently allowed clear liquids up to 2 hours before an elective procedure (Spry, 2005).

Preparing the Bowel

Enemas are not commonly prescribed preoperatively unless the patient is undergoing abdominal or pelvic surgery. In this case, a cleansing enema or laxative may be prescribed

Chart 18-8 • 2009 National Patient Safety Goals

- Improve the accuracy of patient identification
- Improve effectiveness of communication among caregivers
- Improve safety of using medications
- Reduce the risk of health care–associated infections
- Accurately and completely reconcile medications across continuum of care
- Reduce the risk of patient harm resulting from falls
- Reduce the risk of influenza and pneumococcal disease in institutionalized older adults
- Reduce the risk of surgical fires
- Implement applicable National Patient Safety Goals and associated requirements by components and practitioner sites
- Encourage patients' active involvement in their own care as a patient safety strategy
- Prevent health care–associated pressure ulcers (decubitus ulcers)
- Identify safety risks inherent in the organization's patient population
- Improve recognition and response to changes in a patient's condition

From The Joint Commission. (2008). *2009 National patient safety goals*. Available at: www.jointcommission.org/PatientSafety/NationalPatientSafetyGoals/09_npsg_facts.htm

the evening before surgery and may be repeated the morning of surgery. The goals of this preparation are to allow satisfactory visualization of the surgical site and to prevent trauma to the intestine or contamination of the peritoneum by fecal material. Unless the condition of the patient presents some contraindication, the toilet or bedside commode, rather than the bedpan, is used for evacuating the enema if the patient is hospitalized during this time. In addition, antibiotics may be prescribed to reduce intestinal flora.

Preparing the Skin

The goal of preoperative skin preparation is to decrease bacteria without injuring the skin. If the surgery is not performed as an emergency, the patient may be instructed to use a soap containing a detergent-germicide to cleanse the skin area for several days before surgery to reduce the number of skin organisms; this preparation may be carried out at home.

Generally, hair is not removed preoperatively unless the hair at or around the incision site is likely to interfere with the operation. If hair must be removed, electric clippers are used for safe hair removal immediately before the operation. To ensure the correct site, the surgical site is typically marked by the patient and the surgeon in the preoperative waiting area.

Immediate Preoperative Nursing Interventions

Immediately prior to the procedure the patient changes into a hospital gown that is left untied and open in the back. The patient with long hair may braid it, remove hairpins, and cover the head completely with a disposable paper cap. The mouth is inspected, and dentures or plates are removed. If left in the mouth, these items could easily fall to the back of the throat during induction of anesthesia and cause respiratory obstruction.

Jewelry is not worn to the OR; wedding rings and jewelry or body piercings should be removed to prevent injury. If a patient objects to removing a ring, some institutions allow the ring to be securely fastened to the finger with tape. All articles of value, including assistive devices, dentures, glasses, and prosthetic devices, are given to family members or are labeled clearly with the patient's name and stored in a safe and secure place according to the institution's policy.

All patients (except those with urologic disorders) should void immediately before going to the OR. This is particularly important in promoting continence during low abdominal surgery and to make abdominal organs more accessible. Urinary catheterization is performed in the OR as necessary.

Administering Preanesthetic Medication

The use of preanesthetic medication is minimal with ambulatory or outpatient surgery. If prescribed, it is usually administered in the preoperative holding area. If a preanesthetic medication is administered, the patient is kept in bed with the side rails raised, because the medication can cause

lightheadedness or drowsiness. During this time, the nurse observes the patient for any untoward reaction to the medications. The immediate surroundings are kept quiet to promote relaxation.

Often, surgery is delayed or OR schedules are changed, and it becomes impossible to request that a medication be given at a specific time. In these situations, the preoperative medication is prescribed "on call to OR." The nurse can have the medication ready to administer as soon as a call is received from the OR staff. It usually takes 15 to 20 minutes to prepare the patient for the OR. If the nurse gives the medication before attending to the other details of preoperative preparation, the patient will have at least partial benefit from the preoperative medication and will have a smoother anesthetic and operative course.

Maintaining the Preoperative Record

Preoperative checklists contain critical elements that must be checked and verified preoperatively (Rothrock, 2007). The nurse completes the preoperative checklist (Fig. 18-2). The completed chart (with the preoperative checklist and verification form) accompanies the patient to the OR with the surgical consent form attached, along with all laboratory reports and nurses' records. Any unusual last-minute observations that may have a bearing on anesthesia or surgery are noted prominently at the front of the chart.

Transporting the Patient to the Presurgical Area

The patient is transferred to the holding area or presurgical suite in a bed or on a stretcher about 30 to 60 minutes before the anesthetic is to be given. The stretcher should be as comfortable as possible, with a sufficient number of blankets to prevent chilling in an air-conditioned room. A small head pillow is usually provided.

The patient is taken to the preoperative holding area, greeted by name, and positioned comfortably on the stretcher or bed. The surrounding area should be kept quiet if the preoperative medication is to have maximal effect. Unpleasant sounds or conversation should be avoided, because they may be misinterpreted by a sedated patient.

Patient safety in the preoperative area is a priority. Use of a standard process or procedure to verify patient identification, the surgical procedure, and the surgical site is imperative to maximize patient safety (World Health Organization, 2008). This allows for prompt intervention if any discrepancies are identified.

Attending to Family Needs

Most hospitals and ambulatory surgery centers have a waiting room where family members and significant others can wait while the patient is undergoing surgery. This room may be equipped with comfortable chairs, televisions, telephones, and light refreshments. Volunteers may remain with the family, offer them coffee, and keep them informed of the patient's progress. After surgery, the surgeon may meet the family in the waiting room and discuss the outcome.

Preoperative Checklist

1. Patient's name: _____ Date: _____ Height: _____ Weight: _____		
Identification band present: _____		
2. Informed consent signed: _____ Special permits signed: _____		
3. Surgical site: _____ (Ex: Sterilization)		
4. History & physical examination report present: _____ Date: _____		
5. Laboratory records present: _____		
CBC: _____ Hgb: _____ Urinalysis: _____ Hct: _____		
6.	<u>Item</u>	<u>Present</u>
		<u>Removed</u>
a.	Natural teeth	_____
	Dentures; upper, lower, partial	_____
	Bridge, fixed; crown	_____

Figure 18-2 Example of a preoperative checklist.

The family and significant others should never judge the seriousness of an operation by the length of time the patient is in the OR. A patient may be in the OR much longer than the actual operating time for several reasons:

- Patients are routinely transported well in advance of the actual operating time.
- The anesthesiologist or anesthesiologist often makes additional preparations that may take 30 to 60 minutes.
- The surgeon may take longer than expected with the preceding case, which delays the start of the next surgical procedure.

After surgery, the patient is taken to the PACU to ensure safe emergence from anesthesia. Family members and significant others waiting to see the patient after surgery should be informed that the patient may have certain

equipment or devices (eg, IV lines, indwelling urinary catheter, nasogastric tube, oxygen lines, monitoring equipment, blood transfusion lines) in place when he or she returns from surgery. When the patient returns to the room, the nurse provides explanations regarding the frequent postoperative observations that will be made. However, it is the responsibility of the surgeon, not the nurse, to relay the surgical findings and the prognosis, even when the findings are favorable.

Expected Patient Outcomes

Expected patient outcomes in the preoperative phase of care are summarized in Chart 18-9.

Chart 18-9 • Expected Patient Outcomes in the Preoperative Phase of Care

Relief of anxiety, evidenced when the patient

- Discusses with the anesthesiologist, anesthesiologist, or nurse anesthetist concerns related to types of anesthesia and induction
- Verbalizes an understanding of the preanesthetic medication and general anesthesia
- Discusses last-minute concerns with the nurse or physician
- Discusses financial concerns with the social worker, when appropriate
- Requests visit with spiritual advisor when appropriate
- Appears relaxed when visited by health care team members

Decreased fear, evidenced when the patient

- Discusses fears with health care professionals or a spiritual advisor, or both

- Verbalizes an understanding of any expected bodily changes, including expected duration of bodily changes

Understanding of the surgical intervention, evidenced when the patient

- Participates in preoperative preparation
- Demonstrates and describes exercises he or she is expected to perform postoperatively
- Reviews information about postoperative care
- Accepts preanesthetic medication, if prescribed
- Remains in bed once premedicated
- Relaxes during transportation to the OR or unit
- States rationale for use of side rails
- Discusses postoperative expectations

No evidence of preoperative complications

CRITICAL THINKING EXERCISES

1 During your preoperative assessment of your patient, a 42-year-old female who is alert and oriented reports that she is having her right breast removed for cancer. The OR schedule indicates that she is having a left mastectomy (breast removal). What preoperative assessments are indicated? What nursing interventions are warranted? What should your initial action be?

2 A morbidly obese 55-year-old patient with diabetes and a history of high blood pressure who takes insulin, antihypertensive medication, aspirin, and several herbal supplements daily is scheduled for major abdominal surgery. What preoperative assessments would be appropriate? What instructions would you anticipate for the patient regarding medications and their rationale? What additional preoperative teaching should be undertaken with this patient?

EBP 3 A patient is admitted to the same-day surgery unit with a known allergy to latex. What resources would you use to identify evidence-based practices during the perioperative period? Identify the evidence for and the criteria used to evaluate the strength of the evidence for the practices identified for this patient.

Intraoperative Nursing Management

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the interdisciplinary approach to the care of the patient during surgery.
- 2 Describe the principles of surgical asepsis.
- 3 Describe the roles of the surgical team members during the intraoperative phase of care.
- 4 Identify adverse effects of surgery and anesthesia.
- 5 Identify the surgical risk factors related to age-specific populations and nursing interventions to reduce those risks.
- 6 Compare types of anesthesia with regard to uses, advantages, disadvantages, and nursing responsibilities.
- 7 Use the nursing process to optimize patient outcomes during the intraoperative period.
- 8 Describe the role of the nurse in ensuring patient safety during the intraoperative period.

GLOSSARY

anesthesia: a state of narcosis, analgesia, relaxation, and loss of reflexes

anesthesiologist: physician trained to deliver anesthesia and to monitor the patient's condition during surgery

anesthetic agent: the substance, such as a chemical or gas, used to induce anesthesia

anesthetist: health care professional, such as a nurse anesthetist, who is trained to deliver anesthesia and to monitor the patient's condition during surgery

circulating nurse (or circulator): registered nurse who coordinates and documents patient care in the operating room

epidural anesthesia: state of narcosis, analgesia, relaxation, and loss of reflexes achieved by injecting an anesthetic agent into the epidural space of the spinal cord

general anesthesia: state of narcosis, analgesia, relaxation, and loss of reflexes produced by pharmacologic agents

local anesthesia: injection of a solution containing the anesthetic agent into the tissues at the planned incision site

GLOSSARY (Continued)

malignant hyperthermia: a rare life-threatening condition triggered by exposure to most anesthetic agents inducing a drastic and uncontrolled increase in skeletal muscle oxidative metabolism that can overwhelm the body's capacity to supply oxygen, remove carbon dioxide, and regulate body temperature, eventually leading to circulatory collapse and death if untreated. Malignant hyperthermia is often inherited as an autosomal dominant disorder

moderate sedation: previously referred to as conscious sedation, involves use of sedation to depress the level of consciousness without altering the patient's ability to maintain a patent airway and to respond to physical stimuli and verbal commands

monitored anesthesia care: moderate sedation administered by an anesthesiologist or anesthetist

regional anesthesia: an anesthetic agent is injected around nerves so that the area supplied by these nerves is anesthetized

restricted zone: area in the operating room where scrub attire and surgical masks are required; includes operating room and sterile core areas

scrub role: registered nurse, licensed practical nurse, or surgical technologist who scrubs and dons sterile surgical attire, prepares instruments and supplies, and hands instruments to the surgeon during the procedure

semirestricted zone: area in the operating room where scrub attire is required; may include areas where surgical instruments are processed

spinal anesthesia: achieved when a local anesthetic agent is introduced into the subarachnoid space of the spinal cord

surgical asepsis: absence of microorganisms in the surgical environment to reduce the risk for infection

unrestricted zone: area in the operating room that interfaces with other departments; includes patient reception area and holding area

The intraoperative experience has undergone many changes and advances that make it safer and less disturbing to patients. Even with these advances, anesthesia and surgery still place the patient at risk for several complications or adverse events. Consciousness or full awareness, mobility, protective biologic functions, and personal control are totally or partially relinquished by the patient when entering the operating room (OR). Staff from the departments of anesthesia, nursing, and surgery work collaboratively to implement professional standards of care, to control iatrogenic and individual risks, to prevent complications, and to promote high-quality patient outcomes.

The Surgical Team

The surgical team consists of the patient, the anesthesiologist or anesthesiologist, the surgeon, nurses, and the surgical technologists (or assistants). The anesthesiologist or anesthesiologist (often a nurse anesthetist) administers the **anesthetic agent** and monitors the patient's physical status throughout the surgery. The surgeon, nurses, and assistants scrub and perform the surgery. The person in the scrub role, either a nurse or a surgical technologist, provides sterile instruments and supplies to the surgeon during the procedure. The circulating nurse coordinates the care of the patient in the OR. Care provided by the circulating nurse includes assisting with patient positioning, preparing the patient's skin for surgery, managing surgical specimens, anticipating the needs of the surgical team, and documenting intraoperative events. Collaboration of the surgical team using evidence-based practice tailored to the specific case results in optimum patient care and improved outcomes.

The Patient

As the patient enters the OR, he or she may feel either relaxed and prepared or fearful and highly stressed. These feelings depend to a large extent on the amount and timing of preoperative sedation and the individual patient. Fears about loss of control, the unknown, pain, death, changes in body structure or function, and disruption of lifestyle all contribute to anxiety. These fears can increase the amount of anesthetic medication needed, the level of postoperative pain, and overall recovery time. See Chapter 7 for more information on stress.

The patient is also subject to several risks. Infection, failure of the surgery to relieve symptoms or correct a deformity, temporary or permanent complications related to the procedure or the anesthetic agent, and death are uncommon but potential outcomes of the surgical experience (Chart 19-1). In addition to fears and risks, the patient undergoing sedation and anesthesia temporarily loses both cognitive function and biologic self-protective mechanisms. Loss of pain sense, reflexes, and ability to communicate subjects the intraoperative patient to possible injury.

Gerontologic Considerations

Elderly patients face higher risks from anesthesia and surgery compared to younger adult patients (Rothrock, 2007). There is a progressive loss of skeletal muscle mass in conjunction with an increase in adipose tissue. About one-third of surgical

Chart 19-1 • Potential Adverse Effects of Surgery and Anesthesia

Anesthesia and surgery disrupt all major body systems. Although most patients can compensate for surgical trauma and the effects of anesthesia, all patients are at risk during the operative procedure. These risks include the following:

- Allergic reactions
- Cardiac dysrhythmia from electrolyte imbalance or adverse effect of anesthetic agents
- Myocardial depression, bradycardia, and circulatory collapse
- Central nervous system agitation, seizures, and respiratory arrest
- Oversedation or undersedation
- Agitation or disorientation, especially in elderly patients
- Hypoxemia or hypercarbia from hypoventilation and inadequate respiratory support during anesthesia
- Laryngeal trauma, oral trauma, and broken teeth from difficult intubation
- Hypothermia from cool operating room temperatures, exposure of body cavities, and impaired thermoregulation secondary to anesthetic agents
- Hypotension from blood loss or adverse effect of anesthesia
- Infection
- Thrombosis from compression of blood vessels or stasis
- Malignant hyperthermia secondary to adverse effect of anesthesia
- Nerve damage and skin breakdown from prolonged or inappropriate positioning
- Electrical shock or burns
- Laser burns
- Drug toxicity, faulty equipment, and human error

patients are 65 years of age or older. These numbers will increase with prolongation of the lifespan (Barash, Cullen & Stoelting, 2006; Brady, Noorily & Dillman, 2007). Even in the healthiest older adult perioperative management is considerably more complex because of comorbidities, more advanced disease, and increased susceptibility to nosocomial illnesses. Age alone confers enough surgical risk that it is a clinical predictor of cardiovascular complications (Duthie, Katz & Malone, 2007).

Biologic variations of particular importance include age-related cardiovascular and pulmonary changes. The aging heart and blood vessels have decreased ability to respond to stress. Reduced cardiac output and limited cardiac reserve make the elderly patient vulnerable to changes in circulating volume and blood oxygen levels. Excessive or rapid administration of intravenous (IV) solutions can cause pulmonary edema. A sudden or prolonged decline in blood pressure may lead to cerebral ischemia, thrombosis, embolism, infarction, and anoxia. Reduced gas exchange can result in cerebral hypoxia.

Lower doses of anesthetic agents are required in elderly patients due to decreased tissue elasticity (lung and cardiovascular systems) and reduced lean tissue mass. Elderly patients often experience an increase in the duration of clinical effects of medications. With decreased plasma proteins, more of the anesthetic agent remains free or unbound, and the result is more potent action (Barash, et al., 2006).

In addition, body tissues of the older adult are made up predominantly of water, and those tissues with a rich blood supply, such as skeletal muscle, liver, and kidneys, shrink as the body ages. Reduced liver size decreases the rate at which the liver can inactivate many anesthetic agents, and decreased kidney function slows the elimination of waste products and anesthetic agents. Other factors that affect the elderly surgical patient in the intraoperative period include the following:

- Impaired ability to increase metabolic rate and impaired thermoregulatory mechanisms increase susceptibility to hypothermia.
- Bone loss (25% in women, 12% in men) necessitates careful manipulation and positioning during surgery.
- Reduced ability to adjust rapidly to emotional and physical stress influences surgical outcomes and requires meticulous observation of vital functions.

All of these factors lead to a higher likelihood of perioperative mortality and morbidity in elderly patients (Barash, et al., 2006). Further discussion of age-related physiologic changes can be found in Chapter 12.

Nursing Care

Throughout surgery, nursing responsibilities include providing for the safety and well-being of the patient, coordinating the OR personnel, and performing scrub and circulating activities. Because the patient's emotional state remains a concern, the care initiated by preoperative nurses is continued by the intraoperative nursing staff that provides the patient with information and reassurance. The nurse supports coping strategies and reinforces the patient's ability to influence outcomes by encouraging active participation in the plan of care incorporating cultural, ethnic, and religious considerations as appropriate.

As patient advocates, intraoperative nurses monitor factors that can cause injury, such as patient position, equipment malfunction, and environmental hazards, and they protect the patient's dignity and interests while the patient is anesthetized. Additional responsibilities include maintaining surgical standards of care and identifying and minimizing risks and complications.

Cultural Diversity

Cultural, ethnic, and religious diversity are important considerations for all health care professionals. Nurses in the perioperative area should be aware of medications that may be prohibited by certain groups (ie, Muslims and those of the Jewish faith cannot use porcine-based products [heparin (porcine or bovine)], Buddhists may choose not to use bovine products). In certain cultures, the head is a sacred area and staff should allow patients to apply their own surgical cap in this case. When English is the second language of the patient having surgery under local anesthesia, personnel can be provided who speak the patient's native language (DeFazio-Quinn, 2006; Miller, 2009).

The Circulating Nurse

The **circulating nurse**, a qualified registered nurse (Phillips, 2007), works in collaboration with surgeons, anesthesia providers, and other health care providers to plan the best course of action for each patient (Rothrock, 2007). In this leadership role the circulating nurse manages the OR and

protects the patient's safety and health by monitoring the activities of the surgical team, checking the OR conditions, and continually assessing the patient for signs of injury and implementing appropriate interventions. Main responsibilities include verifying consent; coordinating the team; and ensuring cleanliness, proper temperature, humidity, lighting, safe function of equipment, and the availability of supplies and materials. The circulating nurse monitors aseptic practices to avoid breaks in technique while coordinating the movement of related personnel (medical, x-ray, and laboratory), as well as implementing fire safety precautions. The circulating nurse also monitors the patient and documents specific activities throughout the operation to ensure the patient's safety and well-being.

In addition, the circulating nurse is responsible for ensuring that the second verification of the surgical procedure and site takes place and is documented (Fig. 19-1). In some institutions, this is referred to as a "time out" that takes place among the surgical team prior to induction of anesthesia. Every member of the surgical team verifies the patient's name, procedure, and surgical site using objective documentation and data before beginning the surgery (World Health Organization, 2008). Proper patient identification is one of the 2009 National Patient Safety Goals (see Chart 18-8 in Chapter 18). Research suggests use of a surgical safety checklist reduces morbidity and mortality (Haynes, Weiser, Berry, et al., 2009).

NURSING ALERT

It is imperative that the correct patient identity, surgical procedure, and surgical site be verified prior to surgery.

The Scrub Role

The registered nurse, licensed practical nurse, or surgical technologist (or assistant) performs the activities of the **scrub role**, including performing a surgical hand scrub; setting up the sterile tables; preparing sutures, ligatures, and special equipment (eg, laparoscope); and assisting the surgeon and the surgical assistants during the procedure by anticipating the instruments and supplies that will be required, such as sponges, drains, and other equipment. As the surgical incision is closed, the scrub person and the circulator count all needles, sponges, and instruments to be sure they are accounted for and not retained as a foreign body in the patient (AORN, 2007; Rothrock, 2007). Standards call for all sponges to be visible on x-ray and for sponge counts to take place at the beginning of surgery and twice at the end. Tissue specimens obtained during surgery are labeled by the person in the scrub role and sent to the laboratory by the circulator.

The Surgeon

The surgeon performs the surgical procedure, heads the surgical team, and is a licensed physician (MD), osteopath (DO), oral surgeon (DDS or DMD), or podiatrist (DPM) who is specially trained and qualified. Qualifications and training must adhere to the Joint Commission standards, hospital standards, and local and state admitting practices and procedures (Phillips, 2007).

The Registered Nurse First Assistant

The registered nurse first assistant (RNFA) is another member of the OR team. Although the scope of practice of the RNFA depends on each state’s nurse practice act, the RNFA practices under the direct supervision of the surgeon. RNFA responsibilities may include handling tissue, providing exposure at the operative field, suturing, and maintaining hemostasis (Rothrock, 2007). The role requires a thorough understanding of anatomy and physiology, tissue handling, and the principles of surgical asepsis. The RNFA must be aware of the objectives of the surgery, must have the knowledge and ability to anticipate needs and to work as a skilled member of a team, and must be able to handle any emergency situation in the OR.

The Anesthesiologist and Anesthetist

An **anesthesiologist** is a physician specifically trained in the art and science of anesthesiology. An **anesthetist** is also a qualified and specifically trained health care professional who administers anesthetic medications. Most anesthetists are nurses who have graduated from an accredited nurse anesthesia program and have passed examinations sponsored by the American Association of Nurse Anesthetists to become a certified registered nurse anesthetist (CRNA).

The anesthesiologist or anesthetist assesses the patient before surgery, selects the anesthesia, administers it, intubates the patient if necessary, manages any technical problems related to the administration of the anesthetic agent, and supervises the patient’s condition throughout the surgical procedure. Before the patient enters the OR, often at preadmission testing, the anesthesiologist or anesthetist visits the patient to perform an assessment, supply information, and answer questions. The type of anesthetic agent to be administered, previous reactions to anesthetic medications, and known anatomic abnormalities that would make airway management difficult are among the topics discussed.

The anesthesiologist or anesthetist uses the American Society of Anesthesiologists (ASA) Physical Status Classification System to determine the patient’s status. A patient who is classified as P2, P3, or P4 has a systemic disease that may or may not be related to the cause of surgery. If a patient with a classification of P1, P2, P3, P4, or P5 requires emergency surgery, an E is added to the physical status designation (eg, P1E, P2E). P6 refers to a patient who is brain dead and is undergoing surgery as an organ donor. The abbreviations ASA1 through ASA6 are often used interchangeably with P1 to P6 to designate physical status (Phillips, 2007).

When the patient arrives in the OR, the anesthesiologist or anesthetist reassesses the patient's physical condition immediately prior to initiating anesthesia. The anesthetic agent is administered, and the patient's airway is maintained through either an intranasal intubation, oral intubation, or a laryngeal mask airway. During surgery, the anesthesiologist or anesthetist monitors the patient's blood pressure, pulse, and respirations as well as the electrocardiogram (ECG), blood oxygen saturation level, tidal volume, blood gas levels, blood pH, alveolar gas concentrations, and body temperature. Monitoring by electroencephalography is sometimes required. Levels of anesthetic medications in the body can also be determined; a mass spectrometer can provide instant readouts of critical concentration levels on display terminals. This information is used to assess the patient's ability to breathe unassisted or the need for mechanical assistance if ventilation is poor and the patient is not breathing well independently.

The Surgical Environment

The surgical environment is known for its stark appearance and cool temperature. The surgical suite is behind double doors, and access is limited to authorized personnel. External precautions include adherence to principles of surgical asepsis; strict control of the OR environment is required, including traffic pattern restrictions. Policies governing this environment address such issues as the health of the staff; the cleanliness of the rooms; the sterility of equipment and surfaces; processes for scrubbing, gowning, and gloving; and OR attire.

To provide the best possible conditions for surgery, the OR is situated in a location that is central to all supporting services (eg, pathology, x-ray, and laboratory). The OR has special air filtration devices to screen out contaminating particles, dust, and pollutants.

The National Patient Safety Goals all pertain to the perioperative areas (see Chart 18-8 in Chapter 18), but the one with the most direct relevance to the OR is the reduction of the risk of surgical fires. The risk of fire in the OR is ever present due to three factors: a source of fuel, an oxygen source, and a mechanism to ignite a fire (AORN, 2007). All surgical services personnel must familiarize themselves with the department fire emergency response plan and be competent in the use and safeguards of all combustible materials and equipment in the surgical environment (Rothrock, 2007). Surgical drapes provide an opportunity for oxygen to concentrate; a stray spark could more easily ignite a fire. This occurs most commonly in ambulatory surgery settings (Joint Commission, 2005). To further improve safety, electrical hazards, emergency exit clearances, and storage of equipment and anesthetic gases are monitored periodically by official agencies, such as the state department of health and the Joint Commission.

To help decrease microbes, the surgical area is divided into three zones: the **unrestricted zone**, where street clothes are allowed; the **semirestricted zone**, where attire consists of scrub clothes and caps; and the **restricted zone**, where scrub clothes, shoe covers, caps, and masks are worn. The surgeons and other surgical team members wear additional sterile clothing and protective devices during surgery.

The Association of PeriOperative Registered Nurses (AORN), recommends specific practices for personnel wearing surgical attire to promote a high level of cleanliness in a particular practice setting (AORN, 2007). OR attire includes close-fitting cotton dresses, pantsuits, jumpsuits, and gowns. Knitted cuffs on sleeves and pant legs prevent organisms shed from the perineum, legs, and arms from being released into the immediate surroundings. Shirts and waist drawstrings should be tucked inside the pants to prevent accidental contact with sterile areas and to contain skin shedding. Wet or soiled garments should be changed.

Masks are worn at all times in the restricted zone of the OR. High-filtration masks decrease the risk of postoperative wound infection by containing and filtering microorganisms from the oropharynx and nasopharynx. Masks should fit tightly; should cover the nose and mouth completely; and should not interfere with breathing, speech, or vision. Masks must be adjusted to prevent venting from the sides. Disposable masks have a filtration efficiency exceeding 95%. Masks are changed between patients and should not be worn outside the surgical department. The mask must be either on or off; it must not be allowed to hang around the neck.

Headgear should completely cover the hair (head and neckline, including beard) so that hair, bobby pins, clips, and particles of dandruff or dust do not fall on the sterile field.

Shoes should be comfortable and supportive. Shoe covers are worn when it is anticipated that spills or splashes will occur. If worn, the covers should be changed whenever they become wet, torn, or soiled (Phillips, 2007; Rothrock, 2007).

Barriers such as scrub attire and masks do not entirely protect the patient from microorganisms. Upper respiratory tract infections, sore throats, and skin infections in staff and patients are sources of pathogens and must be reported.

Because artificial fingernails harbor microorganisms and can cause nosocomial infections, a ban on artificial nails by OR personnel is supported by the Centers for Disease Control and Prevention (CDC), AORN, and the Association of Professionals in Infection Control. Research provides support for policies prohibiting artificial nails for health care workers (Gordin, Schultz, Huber, et al., 2007). Short, natural fingernails are encouraged.

Principles of Surgical Asepsis

Surgical asepsis prevents the contamination of surgical wounds. The patient's natural skin flora or a previously existing infection may cause postoperative wound infection. Rigorous adherence to the principles of surgical asepsis by OR personnel is basic to preventing surgical site infections.

All surgical supplies, instruments, needles, sutures, dressings, gloves, covers, and solutions that may come in contact with the surgical wound or exposed tissues must be sterilized before use (Rothrock, 2007). Traditionally, the surgeon, surgical assistants, and nurses prepared themselves by scrubbing their hands and arms with antiseptic soap and water, but this practice is being challenged by research investigating the optimal length of time to scrub and the best preparation to use.

In some institutions, an alcohol-based product or scrubless soap is used to prepare for surgery (Rothrock, 2007).

Surgical team members wear long-sleeved, sterile gowns and gloves. Head and hair are covered with a cap, and a mask is worn over the nose and mouth to minimize the possibility that bacteria from the upper respiratory tract will enter the wound. During surgery, only personnel who have scrubbed, gloved, and gowned touch sterilized objects. Non-scrubbed personnel refrain from touching or contaminating anything sterile.

An area of the patient's skin larger than that requiring exposure during the surgery is meticulously cleansed, and an antiseptic solution is applied (Phillips, 2007). If hair needs to be removed, this is done immediately before the procedure with clippers (not shaved) to minimize the risk of infection (Celik & Kara, 2007). The remainder of the patient's body is covered with sterile drapes.

Environmental Controls

In addition to the protocols described previously, surgical asepsis requires meticulous cleaning and maintenance of the OR environment. Floors and horizontal surfaces are cleaned between cases with detergent, soap and water or a detergent germicide. Sterilized equipment is inspected regularly to ensure optimal operation and performance.

All equipment that comes into direct contact with the patient must be sterile. Sterilized linens, drapes, and solutions are used. Instruments are cleaned and sterilized in a unit near the OR. Individually wrapped sterile items are used when additional individual items are needed.

Airborne bacteria are a concern. To decrease the amount of bacteria in the air, standard OR ventilation provides 15 air exchanges per hour, at least three of which are fresh air (Phillips, 2007). A room temperature of 20°C to 24°C (68°F to 73°F), humidity between 30% and 60%, and positive pressure relative to adjacent areas are maintained. Staff members shed skin scales, resulting in about 1000 bacteria-carrying particles (or colony-forming units [CFUs]) per cubic foot per minute. With the standard air exchanges, air counts of bacteria are reduced to 50 to 150 CFUs per cubic foot per minute. Systems with high-efficiency particulate air (HEPA) filters are needed to remove particles larger than 0.3 μm (Rothrock, 2007). Unnecessary personnel and physical movement may be restricted to minimize bacteria in the air and achieve an OR infection rate no greater than 3% to 5% in clean, infection-prone surgery.

Some ORs have laminar airflow units. These units provide 400 to 500 air exchanges per hour (Phillips, 2007). When used appropriately, laminar airflow units result in fewer than 10 CFUs per cubic foot per minute during surgery. The goal for a laminar airflow–equipped OR is an infection rate of less than 1%. An OR equipped with a laminar airflow unit is frequently used for total joint replacement or organ transplant surgery.

Even using all precautions, wound contamination may inadvertently occur resulting in a nosocomial infection and a prolonged hospitalization. Constant surveillance and conscientious technique in carrying out aseptic practices are necessary to reduce the risk of contamination and infection.

Basic Guidelines for Maintaining Surgical Asepsis

All practitioners involved in the intraoperative phase have a responsibility to provide and maintain a safe environment. Adherence to aseptic practice is part of this responsibility. The basic principles of aseptic technique follow:

- All materials in contact with the surgical wound or used within the sterile field must be sterile. Sterile surfaces or articles may touch other sterile surfaces or articles and remain sterile; contact with unsterile objects at any point renders a sterile area contaminated.
- Gowns of the surgical team are considered sterile in front from the chest to the level of the sterile field. The sleeves are also considered sterile from 2 inches above the elbow to the stockinette cuff.
- Sterile drapes are used to create a sterile field (Fig. 19-2). Only the top surface of a draped table is considered sterile. During draping of a table or patient, the sterile drape is held well above the surface to be covered and is positioned from front to back.
- Items are dispensed to a sterile field by methods that preserve the sterility of the items and the integrity of the sterile field. After a sterile package is opened, the edges are considered unsterile. Sterile supplies, including solutions, are delivered to a sterile field or handed to a scrubbed person in such a way that the sterility of the object or fluid remains intact.
- The movements of the surgical team are from sterile to sterile areas and from unsterile to unsterile areas. Scrubbed people and sterile items contact only sterile areas; circulating nurses and unsterile items contact only unsterile areas.
- Movement around a sterile field must not cause contamination of the field. Sterile areas must be kept in view during movement around the area. At least a 1-foot distance from the sterile field must be maintained to prevent inadvertent contamination.
- Whenever a sterile barrier is breached, the area must be considered contaminated. A tear or puncture of the drape permitting access to an unsterile surface underneath renders the area unsterile. Such a drape must be replaced.

Figure 19-2 Proper draping exposes only the surgical site, which decreases the risk for infection.

- Every sterile field is constantly monitored and maintained. Items of doubtful sterility are considered unsterile. Sterile fields are prepared as close as possible to the time of use.
- The routine administration of hyperoxia (high levels of oxygen) is *not* recommended to reduce surgical site infections.

Health Hazards Associated With the Surgical Environment

Faulty equipment, improper use of equipment, exposure to toxic substances, as well as infectious waste, cuts, needlestick injuries, and lasers are some of the associated hazards in the surgical environment (Kiffmeyer & Hadstein, 2007; Phillips, 2007). Internal monitoring of the OR includes the analysis of surface swipe samples and air samples for infectious and toxic agents. In addition, policies and procedures for minimizing exposure to body fluids and reducing the dangers associated with lasers and radiation have been established.

Regardless of the size or location of an incision, unintentional retention of an object (eg, sponge, instrument) can occur. A retained object can cause wound infection or disruption, an abscess can form, and fistulas may develop between organs (Phillips, 2007).

Laser Risks

The AORN has recommended practices for laser safety (Phillips, 2007). When lasers are in use, warning signs must be clearly posted to alert personnel. Safety precautions are implemented to reduce the possibility of exposing the eyes and skin to laser beams, to prevent inhalation of the laser plume (smoke and particulate matter), and to protect the patient and personnel from fire and electrical hazards. Several types of lasers are available for clinical use; perioperative personnel should be familiar with the unique features, specific operation, and safety measures for each type of laser used in the practice setting and wear appropriate laser goggles for the type of laser beam in use.

Smoke evacuators are used in some procedures to remove the laser plume from the operative field. In recent years, this technology has been used to protect the surgical team from the potential hazards associated with the generalized smoke plume generated by standard electrocautery units.

Exposure to Blood and Body Fluids

OR attire has changed dramatically since the advent of acquired immunodeficiency syndrome (AIDS). Double-gloving is routine in trauma and other types of surgery where sharp bone fragments are present. In addition to the routine scrub suit and double gloves, some surgical personnel wear rubber boots, a waterproof apron, and sleeve protectors. Goggles, or a wrap-around face shield, are worn to protect against splashing when the surgical wound is irrigated or when bone drilling is performed. In hospitals where numerous total joint procedures are performed, a complete bubble mask may be used. This mask provides full-barrier protection from bone fragments and splashes. Ventilation is accomplished through an accompanying hood with a separate air filtration system.

The Surgical Experience

During the surgical procedure, the patient will need sedation, anesthesia, or some combination of these.

Types of Anesthesia and Sedation

Research estimates anesthesia-related death rates in the United States to be less than 1 per 10,000 surgeries (Barash, et al., 2006). For the patient, the anesthesia experience consists of having an IV line inserted, if it was not inserted earlier; receiving a sedating agent prior to induction with an anesthetic agent; losing consciousness; being intubated, if indicated; and then receiving a combination of anesthetic agents. Typically the experience is a smooth one, and the patient has no recall of the events. The main types of anesthesia are general anesthesia, regional anesthesia, moderate sedation, monitored anesthesia care, and local anesthesia.

General Anesthesia

Anesthesia is a state of narcosis (severe central nervous system depression produced by pharmacologic agents), analgesia, relaxation, and reflex loss. Patients under **general anesthesia** are not arousable, not even to painful stimuli. They lose the ability to maintain ventilatory function and require assistance in maintaining a patent airway. Cardiovascular function may be impaired as well.

The Joint Commission has issued an alert regarding the phenomenon of patients being partially awake while under general anesthesia (referred to as anesthesia awareness). Patients at greatest risk of anesthesia awareness are cardiac, obstetric, and major trauma patients. The entire surgical team must be aware of this phenomenon and help prevent or manage it (Joint Commission, 2008).

General anesthesia consists of four stages, each associated with specific clinical manifestations (Rothrock, 2007):

- *Stage I: beginning anesthesia.* As the patient breathes in the anesthetic mixture, warmth, dizziness, and a feeling of detachment may be experienced. The patient may have a ringing, roaring, or buzzing in the ears and, although still conscious, may sense an inability to move the extremities easily. During this stage, noises are exaggerated; even low voices or minor sounds seem loud and unreal. For this reason, unnecessary noises and motions are avoided when anesthesia begins.
- *Stage II: excitement.* The excitement stage, characterized variously by struggling, shouting, talking, singing, laughing, or crying, is often avoided if the anesthetic agent is administered smoothly and quickly. The pupils dilate, but they contract if exposed to light; the pulse rate is rapid, and respirations may be irregular. Because of the possibility of uncontrolled movements of the patient during this stage, the anesthesiologist or anesthetist must always be assisted by someone ready to help restrain the patient. Manipulation increases circulation to the operative site and thereby increases the potential for bleeding.
- *Stage III: surgical anesthesia.* Surgical anesthesia is reached by continued administration of the anesthetic vapor or gas. The patient is unconscious and lies quietly on the table. The pupils are small but contract when

exposed to light. Respirations are regular, the pulse rate and volume are normal, and the skin is pink or slightly flushed. With proper administration of the anesthetic agent, this stage may be maintained for hours in one of several planes, ranging from light (1) to deep (4), depending on the depth of anesthesia needed.

- *Stage IV: medullary depression.* This stage is reached if too much anesthesia has been administered. Respirations become shallow, the pulse is weak and thready, and the pupils become widely dilated and no longer contract when exposed to light. Cyanosis develops and, without prompt intervention, death rapidly follows. If this stage develops, the anesthetic agent is discontinued immediately and respiratory and circulatory support is initiated to prevent death. Stimulants, although rarely used, may be administered; narcotic antagonists can be used if the overdosage is due to opioids.

When opioid agents (narcotics) and neuromuscular blockers (relaxants) are administered, several of the stages are absent. During smooth administration of an anesthetic agent, there is no sharp division between stages I, II, and III, and there is no stage IV. The patient passes gradually from one stage to another, and it is through close observation of the signs exhibited by the patient that an anesthesiologist or anesthetist controls the situation. The responses of the pupils, the blood pressure, and the respiratory and cardiac rates are among the most reliable guides to the patient's condition.

Anesthetic agents used in general anesthesia are inhaled or administered by IV. Anesthetic medications produce anesthesia because they are delivered to the brain at a high partial pressure that enables them to cross the blood–brain barrier. Relatively large amounts of anesthetic medication must be administered during induction and the early maintenance phases because the anesthetic agent is recirculated and deposited in body tissues. As these sites become saturated, smaller amounts of the anesthetic agent are required to maintain anesthesia because equilibrium or near equilibrium has been achieved between brain, blood, and other tissues. When possible, the anesthesia induction (initiation) begins with IV anesthesia and is then maintained at the desired stage by inhalation methods, achieving a smooth transition and eliminating the obvious stages of anesthesia.

Any condition that diminishes peripheral blood flow, such as vasoconstriction or shock, may reduce the amount of anesthetic medication required. Conversely, when peripheral blood flow is unusually high, as in a muscularly active or apprehensive patient, induction is slower, and greater quantities of anesthetic agents are required because the brain receives a smaller quantity of anesthetic agent.

Inhalation

Inhaled anesthetic agents include volatile liquid agents and gases. Volatile liquid anesthetic agents produce anesthesia when their vapors are inhaled. Some commonly used inhalation agents are included in Table 19-1. All are administered

Table 19-1  **INHALATION ANESTHETIC AGENTS**

Agent	Administration	Advantages	Disadvantages	Implications/Considerations
Volatile Liquids				
Halothane (Fluothane)	Inhalation; special vaporizer	Not explosive or flammable Induction rapid and smooth Useful in almost every type of surgery Low incidence of postoperative nausea and vomiting	Requires skillful administration to prevent overdosage May cause liver damage May produce hypotension Requires special vaporizer for administration	In addition to observation of pulse and respiration postoperatively, blood pressure must be monitored frequently.
Enflurane (Ethrane)	Inhalation	Rapid induction and recovery Potent analgesic agent Not explosive or flammable	Respiratory depression may develop rapidly, along with ECG abnormalities. Not compatible with epinephrine	Observe for possible respiratory depression. Administration with epinephrine may cause ventricular fibrillation.
Isoflurane (Forane)	Inhalation	Rapid induction and recovery Muscle relaxants are markedly potentiated.	A profound respiratory depressant	Monitor respirations closely and support when necessary.
Sevoflurane* (Ultrane)	Inhalation	Rapid induction and excretion; minimal side effects	Coughing and laryngospasm; trigger for malignant hyperthermia	Monitor for malignant hyperthermia.
Desflurane (Suprane)	Inhalation	Rapid induction and emergence; rare organ toxicity	Respiratory irritation; trigger for malignant hyperthermia	Monitor for malignant hyperthermia and dysrhythmias.
Gases				
Nitrous oxide (N ₂ O)	Inhalation (semi-closed method)	Induction and recovery rapid Nonflammable Useful with oxygen for short procedures Useful with other agents for all types of surgery	Poor relaxant Weak anesthetic May produce hypoxia	Most useful in conjunction with other agents with longer action. Monitor for chest pain, hypertension, and stroke.
Oxygen (O ₂)	Inhalation	Can increase O ₂ available to tissues	High concentrations are hazardous.	Increased fire risk when used with lasers

*Currently most popular choice.

Figure 19-3 Anesthetic delivery methods. **A**, laryngeal mask airway (LMA). **B**, Nasal endotracheal catheter (in position with cuff inflated). **C**, Oral endotracheal intubation (tube is in position with cuff inflated).

in combination with oxygen and usually nitrous oxide as well.

Gas anesthetic agents are administered by inhalation and are always combined with oxygen. Nitrous oxide is the most commonly used gas anesthetic agent. When inhaled, the anesthetic agents enter the blood through the pulmonary capillaries and act on cerebral centers to produce loss of consciousness and sensation. When anesthetic administration is discontinued, the vapor or gas is eliminated through the lungs.

The vapor from inhalation anesthetic agents can be administered to the patient by several methods. The inhalation anesthetic agent may be administered through a laryngeal mask airway (Fig. 19-3A), a flexible tube with an inflatable silicone ring and cuff that can be inserted into the larynx. The endotracheal technique for administering anesthetic medications consists of introducing a soft rubber or plastic endotracheal tube into the trachea, usually by means of a laryngoscope. The endotracheal tube may be inserted through either the nose (see Fig. 19-3B) or mouth (see Fig. 19-3C). When in place, the tube seals off the lungs from the esophagus so that, if the patient vomits, stomach contents do not enter the lungs.

Intravenous Administration

General anesthesia can also be produced by the IV administration of various substances, such as barbiturates, benzodiazepines, nonbarbiturate hypnotics, dissociative agents, and opioid agents. Table 19-2 lists commonly used IV anesthetic and analgesic agents, including IV medications used as muscle relaxants in the intraoperative period. These medications may be administered to induce or maintain anesthesia. Although they are often used in combination with inhalation anesthetic agents, they may be used alone. They may also be used to produce moderate sedation, as discussed later in this chapter.

An advantage of IV anesthesia is that the onset of anesthesia is pleasant; there is none of the buzzing, roaring, or dizziness known to follow administration of an inhalation anesthetic agent. The duration of action is brief, and the patient awakens with little nausea or vomiting.

The IV anesthetic agents are nonexplosive, require little equipment, and are easy to administer. The low incidence

of postoperative nausea and vomiting makes the method useful in eye surgery, because in this setting vomiting would increase intraocular pressure and endanger vision in the operated eye. IV anesthesia is useful for short procedures but is used less often for the longer procedures of abdominal surgery. It is not indicated for children who have small veins or for those who require intubation because of their susceptibility to respiratory obstruction.

IV neuromuscular blockers (muscle relaxants) block the transmission of nerve impulses at the neuromuscular junction of skeletal muscles. Muscle relaxants are used to relax muscles in abdominal and thoracic surgery, relax eye muscles in certain types of eye surgery, facilitate endotracheal intubation, treat laryngospasm, and assist in mechanical ventilation.

Regional Anesthesia

In **regional anesthesia**, an anesthetic agent is injected around nerves so that the region supplied by these nerves is anesthetized. The effect depends on the type of nerve involved. Motor fibers are the largest fibers and have the thickest myelin sheath. Sympathetic fibers are the smallest and have a minimal covering. Sensory fibers are intermediate. A local anesthetic agent blocks motor nerves least readily and sympathetic nerves most readily. An anesthetic agent cannot be regarded as having worn off until all three systems (motor, sensory, and autonomic) are no longer affected.

The patient receiving regional anesthesia is awake and aware of his or her surroundings unless medications are given to produce mild sedation or to relieve anxiety. The health care team must avoid careless conversation, unnecessary noise, and unpleasant odors; these may be noticed by the patient in the OR and may contribute to a negative response to the surgical experience. A quiet environment is therapeutic. The diagnosis must not be stated aloud if the patient is not to know it at this time.

Epidural Anesthesia

Epidural anesthesia is achieved by injecting a local anesthetic agent into the epidural space that surrounds the dura mater of the spinal cord (Fig. 19-4). The administered medication diffuses across the layers of the spinal cord to provide anesthesia and pain relief (Schwartz, 2006). In contrast,

Table 19-2 COMMONLY USED INTRAVENOUS MEDICATIONS

Medication	Common Usage	Advantages	Disadvantages	Comments
Opioid Analgesic Agents				
Alfentanil (Alfenta)	Surgical analgesia in ambulatory patients	Ultra-short (5–10 min) acting analgesic agent; duration of action 0.5 h; bolus or infusion		Potency: 750 µg; half-life 1.6 h
Fentanyl (Sublimaze)	Surgical analgesia: epidural infusion for postoperative analgesia; add to SAB	Good cardiovascular stability; duration of action 0.5 h	May cause muscle or chest wall rigidity	Most commonly used opioid; potency: 100 µg = 10 mg morphine sulfate; elimination half-life 3.6 h
Morphine sulfate (MS)	Preoperative pain; premedication; postoperative pain	Inexpensive; duration of action 4–5 h; euphoria; good cardiovascular stability	Nausea and vomiting; histamine release; postural ↓ BP and ↓ SVR	Epidural and intrathecal administration for postoperative pain; elimination half-life 3 h
Remifentanyl (Ultiva)	IV infusion for surgical analgesia; small boluses for brief, intense pain	Easily titratable; very short duration; good cardiovascular stability Ultiva is rapidly metabolized by hydrolysis of the propanoic acid–methyl ester linkage by nonspecific blood and tissue esterases.	New; expensive; requires mixing; may cause muscle rigidity	Potency: 25 µg = 10 mg morphine sulfate; 20–30 times potency of alfentanil; elimination half-life 3–10 min
Sufentanil (Sufenta)	Surgical analgesia	Duration of action 0.5 h; prolonged analgesia exceptionally potent (5–10 times more than fentanyl); provides good stability in cardiovascular surgery	Prolonged respiratory depression	Potency: 15 µg = 10 mg morphine sulfate; elimination half-life 2.7 h
Depolarizing Muscle Relaxants				
Succinylcholine	Relax skeletal muscles for surgery and orthopedic manipulations; short procedures; intubation	Short duration; rapid onset	No known effect on consciousness, pain threshold, or cerebation; fasciculations, postoperative myalgias, dysrhythmias; raises serum K ⁺ in tissue trauma, muscular disease, paralysis, burns; histamine release is slight; requires refrigeration	Prolonged muscle relaxation with serum cholinesterase deficiency and some antibiotics; may trigger malignant hyperthermia
Nondepolarizing Muscle Relaxants—Intermediate Onset and Duration				
Atracurium besylate (Tracrium)	Intubation; maintenance of skeletal muscle relaxation	No significant cardiovascular or cumulative effects; good with renal failure	Requires refrigeration; slight histamine release; pregnancy risk category C; do not mix with lactated Ringer's solution or alkaline solutions such as barbiturates	Rapid IV bolus; use cautiously with geriatric and debilitated patients
Cisatracurium besylate (Nimbex)	Intubation; maintenance of skeletal muscle relaxation	Similar to atracurium	No histamine release	Similar to atracurium
Mivacurium (Mivacron)	Intubation; maintenance of skeletal muscle relaxation	Short acting; rapid metabolism by plasma cholinesterase; used as bolus or infusion	Expensive in longer cases	Competes with acetylcholine for receptor sites at the motor end plate, blocking neuromuscular transmission; new; rarely need to reverse; prolonged effect with plasma cholinesterase deficiency
Rocuronium (Zemuron)	Intubation; maintenance of relaxation	Rapid onset (dose dependent); elimination via kidney and liver	No known effect on consciousness, pain threshold, or cerebation; vagolytic; may ↑ HR	Duration similar to atracurium and vecuronium

Continued on following page

Table 19-2 COMMONLY USED INTRAVENOUS MEDICATIONS (Continued)				
Medication	Common Usage	Advantages	Disadvantages	Comments
Vecuronium (Norcuron)	Intubation; maintenance of relaxation	No significant cardiovascular or cumulative effects; no histamine release	Requires mixing	Mostly eliminated in bile, some in urine
Nondepolarizing Muscle Relaxants—Longer Onset and Duration				
<i>d</i> -Tubocurarine	Adjunct to anesthesia; maintenance of relaxation		No known effect on consciousness, pain threshold, or cerebation; might cause histamine release and transient ganglionic blockade	Mostly used for pretreatment with succinylcholine
Metocurine (Metubine)	Maintenance of relaxation	Good cardiovascular stability	Slight histamine release	Most commonly used opioid; potency: 100 µg = 10 mg morphine sulfate; elimination half-life 3.6 h
Pancuronium (Pavulon)	Maintenance of relaxation		May cause ↑ HR and ↑ BP	Used intrathecally and epidurally for postoperative pain; elimination half-life 3 h
Intravenous Anesthetic Agents				
Diazepam (Valium, Dizac)	Amnesia; hypnotic; relieves anxiety; preoperative	Good sedation	Long acting	Residual effects for 20–90 h; increased effect with alcohol
Etomidate (Amidate)	Induction of general anesthesia; indicated to supplement low-potency anesthetic agents	Short-acting hypnotic; good cardiovascular stability; fast, smooth induction and recovery	May cause brief period of apnea; pain with injection and myotonic movements	
Ketamine (Ketalar)	Induction; occasional maintenance (IV or IM)	Short acting; profound analgesia; patient maintains airway; good in small children and burn patients	Large doses may cause hallucinations and respiratory depression; chest wall rigidity; laryngeal spasm	Need darkened, quiet room for recovery; often used in trauma cases
Midazolam (Versed)	Hypnotic; anxiolytic; sedation; often used as adjunct to induction	Excellent amnesia; water soluble (no pain with IV injection); short acting	Slower induction than thiopental	Often used for amnesia with insertion of invasive monitors or regional anesthesia; depresses all levels of CNS, including limbic and reticular formation, probably through increased action of GABA, which is major inhibitory neurotransmitter in brain
Propofol (Diprivan)	Induction and maintenance; sedation with regional anesthesia or MAC	Rapid onset; awakening in 4–8 min; produces sedation/hypnosis rapidly (within 40 sec) and smoothly with minimal excitation; decreases intraocular pressure and systemic vascular resistance; rarely is associated with malignant hyperthermia and histamine release	May cause pain when injected; suppresses cardiac output and respiratory drive	Short elimination half-life (34–64 min)
Sodium methohexital (Brevital)	Induction; methohexital slows the activity of brain and nervous system	Ultra-short-acting barbiturate	May cause hiccups	Can be given rectally
Thiopental sodium (Pentothal)	Induction; stops seizures		May cause laryngospasm; can be given rectally	Large doses may cause apnea and cardiovascular depression

BP, blood pressure; CNS, central nervous system; GABA, gamma-aminobutyric acid; HR, heart rate; IM, intramuscular; IV, intravenous; MAC, monitored anesthesia care; SAB, subarachnoid block; SVR, stroke volume ratio.

Figure 19-4 A, Injection sites for spinal and epidural anesthesia. B, Cross-section of injection sites for peripheral nerve, epidural, and spinal blocks.

spinal anesthesia involves injection through the dura mater into the subarachnoid space surrounding the spinal cord. Epidural anesthesia blocks sensory, motor, and autonomic functions; it differs from spinal anesthesia by the site of the injection and the amount of anesthetic agent used. Epidural doses are much higher because the epidural anesthetic agent does not make direct contact with the spinal cord or nerve roots.

An advantage of epidural anesthesia is the absence of headache that can result from spinal anesthesia. A disadvantage is the greater technical challenge of introducing the anesthetic agent into the epidural rather than the subarachnoid space. If inadvertent puncture of the dura occurs during epidural anesthesia and the anesthetic agent travels toward the head, high spinal anesthesia can result; this can produce severe hypotension and respiratory depression and arrest. Treatment of these complications includes airway support, IV fluids, and use of vasopressors.

Spinal Anesthesia

Spinal anesthesia is an extensive conduction nerve block that is produced when a local anesthetic agent is introduced into the subarachnoid space at the lumbar level, usually between L4 and L5 (see Fig. 19-4). It produces anesthesia of the lower extremities, perineum, and lower abdomen. For the lumbar puncture procedure, the patient usually lies on the side in a knee-chest position. Sterile technique is used as a spinal puncture is made and the medication is injected through the needle. As soon as the injection has been made, the patient is positioned on his or her back. If a relatively high level of block is sought, the head and shoulders are lowered.

The spread of the anesthetic agent and the level of anesthesia depend on the amount of fluid injected, the speed with which it is injected, the positioning of the patient after the injection, and the specific gravity of the agent. If the specific gravity is greater than that of cerebrospinal fluid (CSF), the agent moves to the dependent position of the subarachnoid space. If the specific gravity is less than that of CSF, the anesthetic agent moves away from the dependent position. The anesthesiologist or anesthetist controls the administration of the agent. Table 19-3 presents types of regional anesthesia agents.

A few minutes after induction of a spinal anesthetic agent, anesthesia and paralysis affect the toes and perineum and then gradually the legs and abdomen. If the anesthetic agent reaches the upper thoracic and cervical spinal cord in high concentrations, a temporary partial or complete respiratory paralysis results. Paralysis of the respiratory muscles is managed by mechanical ventilation until the effects of the anesthetic agent on the cranial and thoracic nerves have worn off.

Nausea, vomiting, and pain may occur during surgery when spinal anesthesia is used. As a rule, these reactions result from manipulation of various structures, particularly those within the abdominal cavity. Adequate hydration and the IV administration of appropriate medications may prevent such reactions (Fetzer, 2008).

Headache may be an after-effect of spinal anesthesia. Several factors are related to the incidence of headache: the size of the spinal needle used, the leakage of fluid from the subarachnoid space through the puncture site, and the patient's hydration status. Measures that increase cerebrospinal pressure are helpful in relieving headache. These

**Table 19-3** SELECTED REGIONAL AND LOCAL ANESTHETIC AGENTS

Agent	Administration	Advantages	Disadvantages	Implications/Considerations
Lidocaine (Xylocaine)	Epidural, spinal, peripheral intravenous anesthesia, and local infiltration	Rapid Longer duration of action (compared with procaine) Free from local irritative effect	Occasional idiosyncrasy	Useful topically for cystoscopy Observe for untoward reactions—drowsiness, depressed respiration, seizures
Bupivacaine (Marcaine, Sensoricaine)	Epidural, spinal, peripheral intravenous anesthesia, and local infiltration	Duration is 2–3 times longer than lidocaine	Use cautiously in patients with known drug allergies or sensitivities.	A period of analgesia persists after return of sensation; therefore, need for strong analgesics agents is reduced. Greater potency and longer action than lidocaine
Tetracaine (Pontocaine)	Topical, infiltration, and nerve block	Long acting, produces good relaxation	Occasional allergic reaction	More than 10 times as potent as procaine (Novocaine)
Procaine (Novocaine)	Local infiltration		Occasional allergic reaction	Commonly used in oral or dental surgery

include maintaining a quiet environment, keeping the patient lying flat, and keeping the patient well hydrated.

In continuous spinal anesthesia, the tip of a plastic catheter remains in the subarachnoid space during the surgical procedure so that more anesthetic medication may be injected as needed. This technique allows greater control of the dosage, but there is greater potential for postanesthetic headache because of the large-gauge needle used.

Local Conduction Blocks

Examples of common local conduction blocks are:

- Brachial plexus block, which produces anesthesia of the arm
- Paravertebral anesthesia, which produces anesthesia of the nerves supplying the chest, abdominal wall, and extremities
- Transsacral (caudal) block, which produces anesthesia of the perineum and, occasionally, the lower abdomen

Moderate Sedation

Moderate sedation, previously referred to as conscious sedation, is a form of anesthesia that involves the IV administration of sedatives or analgesic medications to reduce patient anxiety and control pain during diagnostic or therapeutic procedures. It is being used increasingly for specific short-term surgical procedures in hospitals and ambulatory care centers (Rothrock, 2007). The goal is to depress a patient's level of consciousness to a moderate level to enable surgical, diagnostic, or therapeutic procedures to be performed while ensuring the patient's comfort during and cooperation with the procedures. With moderate sedation, the patient is able to maintain a patent airway, retain protective airway reflexes, and respond to verbal and physical stimuli.

Moderate sedation can be administered by an anesthesiologist, anesthesiologist, or other specially trained and credentialed physician or nurse. The patient receiving moderate sedation is never left alone and is closely monitored by a physician or nurse who is knowledgeable and skilled in detecting dysrhythmias, administering oxygen, and performing resuscitation. The continual assessment of the

patient's vital signs, level of consciousness, and cardiac and respiratory function is an essential component of moderate sedation. Pulse oximetry, ECG monitor, and frequent measurement of vital signs are used to monitor the patient. The regulations for use and administration of moderate sedation differ from state to state, and its administration is addressed by standards issued by the Joint Commission and by institutional policies and nursing specialty organizations, including the Association of PeriAnesthesia Nurses.

Monitored Anesthesia Care

Monitored anesthesia care (MAC), also referred to as monitored sedation, is moderate sedation administered by an anesthesiologist or anesthesiologist who must be prepared and qualified to convert to general anesthesia if necessary. The skills of an anesthesiologist or anesthesiologist may be necessary to manage the effects of a level of deeper sedation to return the patient to the appropriate level of sedation (Barash, et al., 2006). MAC may be used for healthy patients undergoing relatively minor surgical procedures and for some critically ill patients who may be unable to tolerate anesthesia without extensive invasive monitoring and pharmacologic support (Rothrock, 2007).

Local Anesthesia

Local anesthesia is the injection of a solution containing the anesthetic agent into the tissues at the planned incision site. Often it is combined with a local regional block by injecting around the nerves immediately supplying the area. Advantages of local anesthesia are as follows:

- It is simple, economical, and nonexplosive.
- Equipment needed is minimal.
- Postoperative recovery is brief.
- Undesirable effects of general anesthesia are avoided.
- It is ideal for short and minor surgical procedures.

Local anesthesia is often administered in combination with epinephrine. Epinephrine constricts blood vessels, which prevents rapid absorption of the anesthetic agent and thus prolongs its local action. Rapid absorption of the anesthetic agent into the bloodstream, which could cause

seizures, is also prevented. Agents that can be used as local anesthetic agents are listed in Table 19-3; some of the same agents used in regional anesthesia are used as local anesthetic agents.

Local anesthesia is the preferred method in any surgical procedure in which it can be used. However, contraindications include high preoperative levels of anxiety, because surgery with local anesthesia may increase anxiety. A patient who requests general anesthesia rarely does well under local anesthesia. For some surgical procedures, local anesthesia is impractical because of the number of injections and the amount of anesthetic medication that would be required (eg, breast reconstruction).

The skin is prepared as for any surgical procedure, and a small-gauge needle is used to inject a modest amount of the anesthetic medication into the skin layers. This produces blanching or a wheal. Additional anesthetic medication is then injected into the skin until an area the length of the proposed incision is anesthetized. A larger, longer needle then is used to infiltrate deeper tissues with the anesthetic agent. The action of the agent is almost immediate, so surgery may begin as soon as the injection is complete. Anesthesia lasts 45 minutes to 3 hours, depending on the anesthetic agent and the simultaneous use of epinephrine.

Potential Intraoperative Complications

The surgical patient is subject to several risks. Potential intraoperative complications include nausea and vomiting, anaphylaxis, hypoxia, hypothermia, and malignant hyperthermia. The national Surgical Care Improvement Project (SCIP) set a national goal of a 25% reduction in surgical complications by 2010. Targeted areas include surgical site infections, as well as cardiac, respiratory, and venous thromboembolic complications (SCIP, 2005).

NAUSEA AND VOMITING

Nausea and vomiting, or regurgitation, may affect patients during the intraoperative period. If gagging occurs, the patient is turned to the side, the head of the table is lowered, and a basin is provided to collect the vomitus. Suction is used to remove saliva and vomited gastric contents. The advent of new anesthetic agents has reduced the incidence; however, there is no single way to prevent nausea and vomiting. An interdisciplinary approach involving the surgeon, anesthesiologist or anesthetist, and nurse is best (Fetzer, 2008).

In some cases, the anesthesiologist or anesthetist administers antiemetics preoperatively or intraoperatively to counteract possible aspiration. If the patient aspirates vomitus, an asthmalike attack with severe bronchial spasms and wheezing is triggered. Pneumonitis and pulmonary edema can subsequently develop, leading to extreme hypoxia. Increasing medical attention is being paid to silent regurgitation of gastric contents (not related to preoperative fasting times), which occurs more frequently than previously realized. The volume and acidity of the aspirate determine the extent of damage to the lungs. Patients may be given citric acid and sodium citrate (Bicitra), a clear, nonparticulate antacid to

increase gastric fluid pH or a histamine-2 (H_2) receptor antagonist such as cimetidine (Tagamet), ranitidine (Zantac), or famotidine (Pepcid) to decrease gastric acid production (Rothrock, 2007).

ANAPHYLAXIS

Any time the patient comes into contact with a foreign substance, there is the potential for an anaphylactic reaction. Because medications are the most common cause of anaphylaxis, intraoperative nurses must be aware of the type and method of anesthesia used as well as the specific agents. An anaphylactic reaction can occur in response to many medications, latex, or other substances. The reaction may be immediate or delayed. Anaphylaxis is a life-threatening acute allergic reaction.

Fibrin sealants are used in a variety of surgical procedures, and cyanoacrylate tissue adhesives are used to close wounds without the use of sutures. These sealants have been implicated in allergic reactions and anaphylaxis (Phillips, 2007). Although these reactions are rare, the nurse must be alert to the possibility and observe the patient for changes in vital signs and symptoms of anaphylaxis when these products are used. See Chapters 15 and 53 for more details about the signs, symptoms, and treatment of anaphylaxis and anaphylactic shock.

HYPOXIA AND OTHER RESPIRATORY COMPLICATIONS

Inadequate ventilation, occlusion of the airway, inadvertent intubation of the esophagus, and hypoxia are significant potential complications associated with general anesthesia. Many factors can contribute to inadequate ventilation. Respiratory depression caused by anesthetic agents, aspiration of respiratory tract secretions or vomitus, and the patient's position on the operating table can compromise the exchange of gases. Anatomic variation can make the trachea difficult to visualize and result in insertion of the artificial airway into the esophagus rather than into the trachea. In addition to these dangers, asphyxia caused by foreign bodies in the mouth, spasm of the vocal cords, relaxation of the tongue, or aspiration of vomitus, saliva, or blood can occur. Brain damage from hypoxia occurs within minutes; therefore, vigilant monitoring of the patient's oxygenation status is a primary function of the anesthesiologist or anesthetist and the circulating nurse. Peripheral perfusion is checked frequently, and pulse oximetry values are monitored continuously.

HYPOTHERMIA

During anesthesia, the patient's temperature may fall. Glucose metabolism is reduced, and, as a result, metabolic acidosis may develop. This condition is called hypothermia and is indicated by a core body temperature that is lower than normal (36.6°C [98.0°F] or less). Inadvertent hypothermia may occur as a result of a low temperature in the OR, infusion of cold fluids, inhalation of cold gases, open body wounds or cavities, decreased muscle activity, advanced age, or the pharmaceutical agents used (eg, vasodilators, phenothiazines, general anesthetic medications). Hypothermia can depress neuronal activity and decrease

cellular oxygen requirements below the minimum levels normally required for continued cell viability. As a result, it is used to protect function during some surgical procedures (eg, carotid endarterectomy, cardiopulmonary bypass) (Barash, et al., 2006).

Unintentional hypothermia needs to be avoided. If it occurs, it must be minimized or reversed. If hypothermia is intentional, the goal is safe return to normal body temperature. Environmental temperature in the OR can temporarily be set at 25°C to 26.6°C (78°F to 80°F). IV and irrigating fluids are warmed to 37°C (98.6°F). Wet gowns and drapes are removed promptly and replaced with dry materials, because wet materials promote heat loss. Whatever methods are used to rewarm the patient, warming must be accomplished gradually, not rapidly. Conscientious monitoring of core temperature, urinary output, ECG, blood pressure, arterial blood gas levels, and serum electrolyte levels is required.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is a rare inherited muscle disorder that is chemically induced by anesthetic agents (Rothrock, 2007). MH can be triggered by myopathies, emotional stress, heatstroke, neuroleptic malignant syndrome, strenuous exercise exertion, and trauma. It occurs in 1 in 50,000 to 100,000 adults. Mortality from MH was reported to be as high as 70%, but with prompt recognition and rapid treatment, it has fallen to less than 10% (Hommertzheim & Steinke, 2006). Susceptible people include those with strong and bulky muscles, a history of muscle cramps or muscle weakness and unexplained temperature elevation, and an unexplained death of a family member during surgery that was accompanied by a febrile response (Litman & Rosenberg, 2005).

Pathophysiology

During anesthesia, potent agents such as inhalation anesthetic agents (halothane, enflurane) and muscle relaxants (succinylcholine) may trigger the symptoms of malignant hyperthermia (Rothrock, 2007). Stress and some medications, such as sympathomimetics (epinephrine), theophylline, aminophylline, anticholinergics (atropine), and cardiac glycosides (digitalis), can induce or intensify such a reaction.

The pathophysiology of MH is related to a hypermetabolic condition that involves altered mechanisms of calcium function in skeletal muscle cells. This disruption of calcium causes clinical symptoms of hypermetabolism, which in turn increases muscle contraction (rigidity) and causes hyperthermia and subsequent damage to the central nervous system.

Clinical Manifestations

The initial symptoms of malignant hyperthermia are related to cardiovascular and musculoskeletal activity. Tachycardia (heart rate greater than 150 bpm) is often the earliest sign. Sympathetic nervous stimulation also leads to ventricular dysrhythmia, hypotension, decreased cardiac output, oliguria, and, later, cardiac arrest. With the abnormal transport of calcium, rigidity or tetanuslike movements occur, often in the jaw. Generalized muscle rigidity is one of the earliest signs. The rise in temperature is actually a late sign that develops rapidly; body temperature can increase 1°C to 2°C (2°F to 4°F)

every 5 minutes and core body temperature can exceed 42°C (107°F) (Hommertzheim & Steinke, 2006; Rothrock, 2007).

Medical Management

Recognizing symptoms early and discontinuing anesthesia promptly are imperative. Goals of treatment are to decrease metabolism, reverse metabolic and respiratory acidosis, correct dysrhythmias, decrease body temperature, provide oxygen and nutrition to tissues, and correct electrolyte imbalance. The Malignant Hyperthermia Association of the United States (MHAUS) publishes a treatment protocol that should be posted in the OR and be readily available on a malignant hyperthermia cart.

Anesthesia and surgery should be postponed. However, if end-tidal CO₂ monitoring and dantrolene sodium (Dantrium) are available and the anesthesiologist is experienced in managing MH, the surgery may continue using a different anesthetic agent (Barash, et al., 2006). Although malignant hyperthermia usually manifests about 10 to 20 minutes after induction of anesthesia, it can also occur during the first 24 hours after surgery.

Nursing Management

Although malignant hyperthermia is uncommon, the nurse must identify patients at risk, recognize the signs and symptoms, have the appropriate medication and equipment available, and be knowledgeable about the protocol to follow. This preparation may be lifesaving for the patient.

NURSING PROCESS

THE PATIENT DURING SURGERY

Intraoperative nurses focus on nursing diagnoses, interventions, and outcomes that surgical patients and their families experience. Additional priorities include collaborative problems and expected goals.

Assessment

Nursing assessment of the intraoperative patient involves obtaining data from the patient and the patient's medical record to identify factors that can affect care. These serve as guidelines for an individualized plan of patient care. The intraoperative nurse uses the focused preoperative nursing assessment documented on the patient record. This includes assessment of physiologic status (eg, health–illness level, level of consciousness), psychosocial status (eg, anxiety level, verbal communication problems, coping mechanisms), physical status (eg, surgical site, skin condition, and effectiveness of preparation; mobility of joints), and ethical concerns (Chart 19-2).

Diagnosis

Nursing Diagnoses

Based on the assessment data, some major nursing diagnoses may include the following:

- Anxiety related to surgical or environmental concerns
- Risk of latex allergy response due to possible exposure to latex in OR environment

Ethics and Related Issues

To Resuscitate or Not?

Situation

Your ambulatory care center has developed a policy, authorized through the medical staff, that allows for patients to have a do-not-resuscitate order (DNR) in place during a surgical procedure. This policy follows the American Society of Anesthesiologists guidelines for DNR in the OR. You are preparing a patient for surgery, and the anesthesiologist who will be administering the anesthetic agent writes an order for the DNR to be rescinded during surgery. The physician is refusing to talk to the patient concerning the DNR.

Problem

The patient believes his wishes will be followed with regard to resuscitation in the event of a cardiac arrest and the physician does not believe he can administer anesthesia if the DNR is in place.

Discussion

- What are the rights of the patient with regard to advance directives?
- What can you do to advocate for the patient?
- Should you contact the ethics committee of the hospital?
- How do you contact the ethics committee?

- Risk for perioperative positioning injury related to positioning in the OR
- Risk for injury related to anesthesia and surgical procedure
- Disturbed sensory perception (global) related to general anesthesia or sedation

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include the following:

- Nausea and vomiting
- Anaphylaxis
- Hypoxia
- Unintentional hypothermia
- Malignant hyperthermia
- Infection

Planning and Goals

The major goals for care of the patient during surgery include reduced anxiety, absence of latex exposure, absence of positioning injuries, freedom from injury, maintenance of the patient's dignity, and absence of complications.

Nursing Interventions

Reducing Anxiety

The OR environment can seem cold, stark, and frightening to the patient, who may be feeling isolated and apprehensive. Introducing yourself, addressing the patient by name warmly and frequently, verifying details, providing explanations, and encouraging and answering questions provide a sense of professionalism and friendliness that can help the patient feel safe and secure. When discussing what the patient can expect

in surgery, the nurse uses basic communication skills, such as touch and eye contact, to reduce anxiety. Attention to physical comfort (warm blankets, padding, and position changes) helps the patient feel more comfortable. Telling the patient who else will be present in the OR, how long the procedure is expected to take, and other details helps the patient prepare for the experience and gain a sense of control.

Reducing Latex Exposure

Patients with latex allergies require early identification and communication to all personnel about the presence of the allergy. The AORN (2007) has recommended standards of care for patients with latex allergy. In most ORs, there are few latex items currently in use, but because there still remain some instances of latex use, maintenance of latex allergy precautions throughout the perioperative period must be observed. For safety, manufacturers and hospital materials managers need to take responsibility for identifying the latex content in items used by patients and health care personnel. (See Chapters 18 and 53 for assessment for latex allergy.)

NURSING ALERT

It is the responsibility of all nurses, and particularly perianesthesia and perioperative nurses, to be aware of latex allergies, necessary precautions, and products that are latex-free. Hospital staff is also at risk for development of a latex allergy secondary to repeated exposure to latex products.

Preventing Intraoperative Positioning Injury

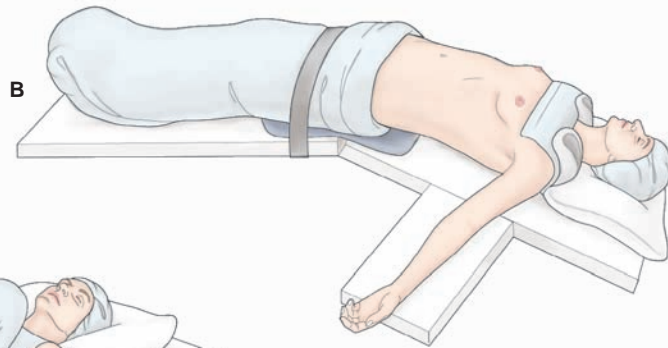

The patient's position on the operating table depends on the surgical procedure to be performed as well as on the patient's physical condition (Fig. 19-5). The potential for transient discomfort or permanent injury is present, because many positions are awkward. Hyperextending joints, compressing arteries, or pressing on nerves and bony prominences usually results in discomfort simply because the position must be sustained for a long period of time (Rothrock, 2007). Factors to consider include the following:

- The patient should be in as comfortable a position as possible, whether conscious or unconscious.
- The operative field must be adequately exposed.
- An awkward position, undue pressure on a body part, or use of stirrups or traction should not obstruct the vascular supply.
- Respiration should not be impeded by pressure of arms on the chest or by a gown that constricts the neck or chest.
- Nerves must be protected from undue pressure. Improper positioning of the arms, hands, legs, or feet can cause serious injury or paralysis. Shoulder braces must be well padded to prevent irreparable nerve injury, especially when the Trendelenburg position is necessary.
- Precautions for patient safety must be observed, particularly with thin, elderly, or obese patients and those with a physical deformity.
- The patient may need light restraint before induction in case of excitement.

- A. Patient in position on the operating table for a laparotomy. Note the strap above the knees.

- B. Patient in Trendelenburg position on operating table. Note padded shoulder braces in place. Be sure that brace does not press on brachial plexus.

- C. Patient in lithotomy position. Note that the hips extend over the edge of the table.

- D. Patient lies on unaffected side for kidney surgery. Table is spread apart to provide space between the lower ribs and the pelvis. The upper leg is extended; the lower leg is flexed at the knee and hip joints; a pillow is placed between the legs.

Figure 19-5 Positions on the operating table. Captions call attention to safety and comfort features. All surgical patients wear caps to cover the hair completely.

The usual position for surgery, called the dorsal recumbent position, is flat on the back. Both arms are positioned at the side of the table, one with the hand placed palm down; the other is carefully positioned on an armboard to facilitate IV infusion of fluids, blood, or medications. This position is used for most abdominal surgeries except for surgery of the gallbladder or pelvis (see Fig. 19-5A).

The Trendelenburg position usually is used for surgery on the lower abdomen and pelvis to obtain good exposure by displacing the intestines into the upper abdomen. In this position, the head and body are lowered. The patient is held in position by padded shoulder braces (see Fig. 19-5B).

The lithotomy position is used for nearly all perineal, rectal, and vaginal surgical procedures (see Fig. 19-5C). The patient is positioned on the back with the legs and thighs flexed. The position is maintained by placing the feet in stirrups.

The Sims or lateral position is used for renal surgery. The patient is placed on the nonoperative side with an air

pillow 12.5 to 15 cm (5 to 6 inches) thick under the loin, or on a table with a kidney or back lift (see Fig. 19-5D).

Protecting the Patient From Injury

A variety of activities are used to address the diverse patient safety issues that arise in the OR. The nurse protects the patient from injury by providing a safe environment. Verifying information, checking the chart for completeness, and maintaining surgical asepsis and an optimal environment are critical nursing responsibilities. Verification that all required documentation is completed is an important function of the intraoperative nurse. A surgical checklist is used prior to induction of anesthesia, before the skin incision is made, and before the patient leaves the OR (see Fig. 19-1). It is important to review the patient's record for the following:

- Correct informed surgical consent, with patient's signature
- Completed records for health history and physical examination

- Results of diagnostic studies
- Allergies (including latex)

In addition to checking that all necessary patient data are complete, the perioperative nurse obtains the necessary equipment specific to the procedure. The need for nonroutine medications, blood components, instruments, and other equipment and supplies is assessed, and the readiness of the room, completeness of physical setup, and completeness of instrument, suture, and dressing setups are determined. Any aspects of the OR environment that may negatively affect the patient are identified. These include physical features, such as room temperature and humidity; electrical hazards; potential contaminants (dust, blood, and discharge on floor or surfaces; uncovered hair; nonsterile attire of personnel; jewelry worn by personnel; chipped or artificial fingernails); and unnecessary traffic. The circulating nurse also sets up and maintains suction equipment in working order, sets up invasive monitoring equipment, assists with insertion of vascular access and monitoring devices (arterial, Swan-Ganz, central venous pressure, IV lines), and initiates appropriate physical comfort measures for the patient.

Preventing physical injury includes using safety straps and side rails and not leaving the sedated patient unattended. Transferring the patient from the stretcher to the OR table requires safe transferring practices. Other safety measures include properly positioning a grounding pad under the patient to prevent electrical burns and shock, removing excess antiseptic solution from the patient's skin, and promptly and completely draping exposed areas after the sterile field has been created to decrease the risk for hypothermia.

Nursing measures to prevent injury from excessive blood loss include blood conservation using equipment such as a cell-saver (a device for recirculating the patient's own blood cells) and administration of blood products (Phillips, 2007). Few patients undergoing an elective procedure require blood transfusion, but those undergoing high-risk procedures (such as orthopedic or cardiac surgeries) may require an intraoperative transfusion. The circulating nurse anticipates this need, checks that blood has been cross-matched and held in reserve, and is prepared to administer blood.

Serving as Patient Advocate

The patient undergoing general anesthesia or moderate sedation experiences temporary sensory or perceptual alteration or loss, and has an increased need for protection and advocacy. Patient advocacy in the OR entails maintaining the patient's physical and emotional comfort, privacy, rights, and dignity. Patients, whether conscious or unconscious, should not be subjected to excess noise, inappropriate conversation, or, most of all, derogatory comments. Banter in the OR should not include comments about the patient's physical appearance, job, personal history, and so forth. Cases have been reported in which seemingly deeply anesthetized patients recalled the entire surgical experience, including disparaging personal remarks made by OR personnel. As an advocate, the nurse never engages in such conversation and discourages others from doing so. Other advocacy activities include minimizing the clinical, dehumanizing aspects of being a surgical patient by making sure the patient is treated as a person, respecting cultural and spiritual values, providing physical privacy, and maintaining confidentiality.

Monitoring and Managing Potential Complications

It is the responsibility of the surgeon and the anesthesiologist or anesthetist to monitor and manage complications. However, intraoperative nurses also play an important role. Being alert to and reporting changes in vital signs, cardiac dysrhythmias, symptoms of nausea and vomiting, anaphylaxis, hypoxia, hypothermia, and malignant hyperthermia and assisting with their management are important nursing functions. Each of these complications was discussed earlier. Maintaining asepsis and preventing infection are responsibilities of all members of the surgical team (Phillips, 2007; Rothrock, 2007). Evidence-based interventions to decrease surgical site infections include appropriate skin preparation and antibiotic administration. Using clippers to remove hair from the surgical site as needed instead of shaving the site is recommended (Celik & Kara, 2007; SCIP, 2005).

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Exhibits low level of anxiety while awake during the intraoperative phase of care
2. Has no symptoms of latex allergy
3. Remains free of perioperative positioning injury
4. Experiences no unexpected threats to safety
5. Has dignity preserved throughout OR experience
6. Is free of complications (eg, nausea and vomiting, anaphylaxis, hypoxia, hypothermia, malignant hyperthermia, or deep vein thrombosis) or experiences successful management of adverse effects of surgery and anesthesia should they occur

CRITICAL THINKING EXERCISES

1 An 80-year-old patient with Parkinson's disease and decreased hearing is scheduled for surgery. Identify factors that have the potential to affect this elderly surgical patient in the intraoperative period. Develop a plan of care for safe intraoperative care of this patient.

2 **EBP** A patient has an identified latex allergy and is undergoing surgery. What resources would you use to identify the current guidelines for avoiding latex exposure for the patient? What is the evidence base for current latex allergy practices? Identify the criteria used to evaluate the strength of the evidence for these practices.

3 A patient has an unintentional temperature of 36°C (96°F) halfway through surgery. Describe the actions you would take and what parameters you would monitor. How would your actions differ if the patient is at the very end of the surgical procedure?

4 **EBP** A patient is scheduled for spinal surgery. Develop an evidence-based plan of care that will reduce the risk of infection. What is the evidence base for infection control practices? Identify the criteria used to evaluate the strength of the evidence for these practices.

Postoperative Nursing Management

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the responsibilities of the postanesthesia care unit nurse in the prevention of immediate postoperative complications.
- 2 Compare postoperative care of the ambulatory surgery patient with that of the hospitalized surgery patient.
- 3 Identify common postoperative problems and their management.
- 4 Describe the gerontologic considerations related to postoperative management.
- 5 Describe variables that affect wound healing.
- 6 Demonstrate postoperative dressing techniques.
- 7 Identify assessment parameters appropriate for the early detection of postoperative complications.

GLOSSARY

dehiscence: partial or complete separation of wound edges

visceration: protrusion of organs through the surgical incision

first-intention healing: method of healing in which wound edges are surgically approximated and integumentary continuity is restored without granulation

Phase I PACU: area designated for care of surgical patients immediately after surgery and for patients whose condition warrants close monitoring

Phase II PACU: area designated for care of surgical patients who have been transferred from a phase I PACU because their condition no longer requires the close monitoring provided in a phase I PACU

Phase III PACU: setting in which the patient is cared for in the immediate postoperative period and then prepared for discharge from the facility

postanesthesia care unit (PACU): area where postoperative patients are monitored as they recover from anesthesia; formerly referred to as the recovery room or postanesthesia recovery room

second-intention healing: method of healing in which wound edges are not surgically approximated and integumentary continuity is restored by the process known as granulation

third-intention healing: method of healing in which surgical approximation of wound edges is delayed and integumentary continuity is restored by apposing areas of granulation

The postoperative period extends from the time the patient leaves the operating room (OR) until the last follow-up visit with the surgeon. This may be as short as a day or two or as long as several months. During the postoperative period, nursing care focuses on reestablishing the patient's physiologic equilibrium, alleviating pain, preventing complications, and teaching the patient self-care. Careful assessment and immediate intervention assist the patient in returning to optimal function quickly, safely, and as comfortably as possible. Ongoing care in the community through home care, clinic visits, office visits, or telephone follow-up facilitates an uncomplicated recovery.

Care of the Patient in the Postanesthesia Care Unit

The postanesthesia care unit (PACU), also called the recovery room or postanesthesia recovery room, is located adjacent to the operating rooms suite. Patients still under anesthesia or recovering from anesthesia are placed in this unit for easy access to experienced, highly skilled nurses, anesthesiologists or anesthesiologists, surgeons, advanced hemodynamic and pulmonary monitoring and support, special equipment, and medications.

Phases of Postanesthesia Care

In some hospitals and ambulatory surgical centers, postanesthesia care is divided into three phases (Phillips, 2007). In the **phase I PACU**, used during the immediate recovery phase, intensive nursing care is provided. In the **phase II PACU**, the patient is prepared for self-care or care in the hospital or an extended care setting. In **phase III PACU**, the patient is prepared for discharge. Recliners rather than stretchers or beds are standard in many phase III units, which may also be referred to as step-down, sit-up, or progressive care units. Patients may remain in a PACU unit for as long as 4 to 6 hours, depending on the type of surgery and any preexisting conditions. In facilities without separate phase I, II, and III units, the patient remains in the PACU and may be discharged home directly from this unit.

Admitting the Patient to the PACU

Transferring the postoperative patient from the OR to the PACU is the responsibility of the anesthesiologist or anesthesiologist. During transport from the OR to the PACU, the anesthesia provider remains at the head of the stretcher (to maintain the airway), and a surgical team member remains at the opposite end. Transporting the patient involves special consideration of the incision site, potential vascular changes, and exposure. The surgical incision is considered every time the postoperative patient is moved; many wounds are closed under considerable tension, and every effort is made to prevent further strain on the incision. The patient is positioned so that he or she is not lying on and obstructing drains or drainage tubes. Orthostatic hypotension may occur when a patient is moved too quickly from one position to another (eg, from a lithotomy position to a horizontal position or from a lateral to a

Chart 20-1 • Anesthesia Provider-to-Nurse Report and Nurse-to-Nurse Report: Information to Convey

Patient name, gender, age
Surgical procedure
Anesthetic options (agents and reversal agents used)
Estimated blood loss/fluid loss
Fluid/blood replacement
Vital signs—significant problems
Complications encountered (anesthetic or surgical)
Preoperative medical diagnosis (eg, diabetes, hypertension, allergies)
Considerations for immediate postoperative period (pain management, reversals, ventilator settings)
Language barrier
Location of patient's family

Ideally, the anesthesia provider should not leave the patient until the nurse is satisfied with the patient's airway and immediate condition.

supine position), so the patient must be moved slowly and carefully. As soon as the patient is placed on the stretcher or bed, the soiled gown is removed and replaced with a dry gown. The patient is covered with lightweight blankets and warmed. Three side rails may be raised to prevent falls.

The nurse who admits the patient to the PACU reviews essential information with the anesthesiologist or anesthesiologist (Chart 20-1) and the circulating nurse. Monitoring equipment is attached and oxygen applied, and an immediate physiologic assessment is conducted.

Nursing Management in the PACU

The nursing management objectives for the patient in the PACU are to provide care until the patient has recovered from the effects of anesthesia (eg, until resumption of motor and sensory functions), is oriented, has stable vital signs, and shows no evidence of hemorrhage or other complications.

Assessing the Patient

Frequent, skilled assessments of the patient's airway, respiratory function, cardiovascular function, skin color, level of consciousness, and ability to respond to commands are the cornerstones of nursing care in the PACU. The nurse performs and documents a baseline assessment, then checks the surgical site for drainage or hemorrhage and makes sure that all drainage tubes and monitoring lines are connected and functioning. The nurse checks any intravenous (IV) fluids or medications currently infusing and verifies dosage and rate.

After the initial assessment, vital signs are monitored and the patient's general physical status is assessed and documented at least every 15 minutes (Barash, Cullen & Stoelting, 2006). The nurse must be aware of any pertinent information from the patient's history that may be significant (eg, patient is deaf or hard of hearing, has a history of seizures, has diabetes, or is allergic to certain medications or to latex). Administration of the patient's

Figure 20-1 A, A hypopharyngeal obstruction occurs when neck flexion permits the chin to drop toward the chest; obstruction almost always occurs when the head is in the midposition. B, Tilting the head back to stretch the anterior neck structure lifts the base of the tongue off the posterior pharyngeal wall. The direction of the arrows indicates the pressure of the hands. C, Opening the mouth is necessary to correct a valvelike obstruction of the nasal passage during expiration, which occurs in about 30% of unconscious patients. Open the patient's mouth (separate lips and teeth) and move the lower jaw forward so that the lower teeth are in front of the upper teeth. To regain backward tilt of the neck, lift with both hands at the ascending rami of the mandible.

postoperative analgesic requirements is a top priority (Barash, et al., 2006).

NURSING ALERT

A systolic blood pressure of less than 90 mm Hg is usually considered immediately reportable. However, the patient's preoperative or baseline blood pressure is used to make informed postoperative comparisons. A previously stable blood pressure that shows a downward trend of 5 mm Hg at each 15-minute reading should also be reported.

NURSING ALERT

The treatment of hypopharyngeal obstruction involves tilting the head back and pushing forward on the angle of the lower jaw, as if to push the lower teeth in front of the upper teeth (see Fig. 20-1B, C). This maneuver pulls the tongue forward and opens the air passages.

The anesthesiologist or anesthetist may leave a hard rubber or plastic airway in the patient's mouth to maintain a patent airway (Fig. 20-2). Such a device should not be

Maintaining a Patent Airway

The primary objective in the immediate postoperative period is to maintain ventilation and thus prevent hypoxemia (reduced oxygen in the blood) and hypercapnia (excess carbon dioxide in the blood). Both can occur if the airway is obstructed and ventilation is reduced (hypoventilation). Besides checking the physician's orders for and administering supplemental oxygen, the nurse assesses respiratory rate and depth, ease of respirations, oxygen saturation, and breath sounds.

Patients who have experienced prolonged anesthesia usually are unconscious, with all muscles relaxed. This relaxation extends to the muscles of the pharynx. When the patient lies on his or her back, the lower jaw and the tongue fall backward and the air passages become obstructed (Fig. 20-1A). This is called hypopharyngeal obstruction. Signs of occlusion include choking; noisy and irregular respirations; decreased oxygen saturation scores; and within minutes, a blue, dusky color (cyanosis) of the skin. Because movement of the thorax and the diaphragm does not necessarily indicate that the patient is breathing, the nurse needs to place the palm of the hand at the patient's nose and mouth to feel the exhaled breath.

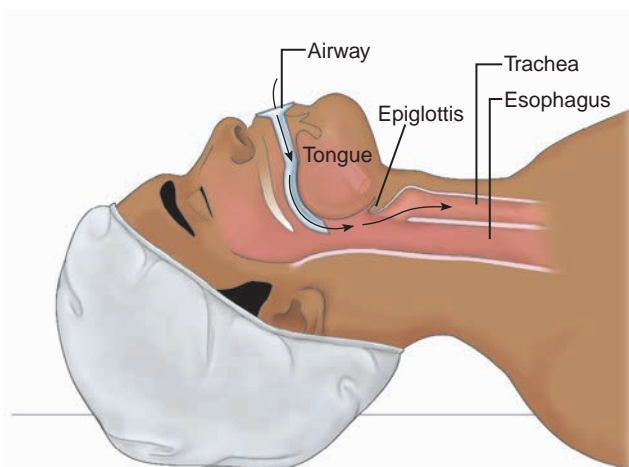

Figure 20-2 Use of an airway to maintain a patent airway after anesthesia. The airway passes over the base of the tongue and permits air to pass into the pharynx in the region of the epiglottis. Patients often leave the operating room with an airway in place. The airway should remain in place until the patient recovers sufficiently to breathe normally. As the patient regains consciousness, the airway usually causes irritation and should be removed.

removed until signs such as gagging indicate that reflex action is returning. Alternatively, the patient may enter the PACU with an endotracheal tube still in place and may require continued mechanical ventilation. The nurse assists in initiating the use of the ventilator and in the weaning and extubation processes. Some patients, particularly those who have had extensive or lengthy surgical procedures, may be transferred from the OR directly to the intensive care unit (ICU) or from the PACU to the ICU while still intubated and receiving mechanical ventilation. In most facilities the patient is awakened and extubated in the OR (except in cases of trauma or a critically ill patient) and arrives in the PACU breathing without support.

If the teeth are clenched, the mouth may be opened manually but cautiously with a padded tongue depressor. The head of the bed is elevated 15 to 30 degrees unless contraindicated, and the patient is closely monitored to maintain the airway as well as to minimize the risk of aspiration. If vomiting occurs, the patient is turned to the side to prevent aspiration and the vomitus is collected in the emesis basin. Mucus or vomitus obstructing the pharynx or the trachea is suctioned with a pharyngeal suction tip or a nasal catheter introduced into the nasopharynx or oropharynx to a distance of 15 to 20 cm (6 to 8 inches). Caution is necessary in suctioning the throat of a patient who has had a tonsillectomy or other oral or laryngeal surgery because of risk of bleeding and discomfort.

Maintaining Cardiovascular Stability

To monitor cardiovascular stability, the nurse assesses the patient's mental status; vital signs; cardiac rhythm; skin temperature, color, and moisture; and urine output. Central venous pressure, pulmonary artery pressure, and arterial lines are monitored if in place. The nurse also assesses the patency of all IV lines. The primary cardiovascular complications seen in the PACU include hypotension and shock, hemorrhage, hypertension, and dysrhythmias.

Hypotension and Shock

Hypotension can result from blood loss, hypoventilation, position changes, pooling of blood in the extremities, or side effects of medications and anesthetics. The most common cause is loss of circulating volume through blood and plasma loss. If the amount of blood loss exceeds 500 mL (especially if the loss is rapid), replacement is usually indicated.

Shock, one of the most serious postoperative complications, can result from hypovolemia and decreased intravascular volume. The types of shock are classified as hypovolemic, cardiogenic, neurogenic, anaphylactic, and septic shock. The classic signs of hypovolemic shock (the most common type of shock) are pallor; cool, moist skin; rapid breathing; cyanosis of the lips, gums, and tongue; rapid, weak, thready pulse; narrowing pulse pressure; low blood pressure; and concentrated urine. See Chapter 15 for a detailed discussion of shock.

Hypovolemic shock can be avoided largely by the timely administration of IV fluids, blood, blood products, and medications that elevate blood pressure. The primary intervention for hypovolemic shock is volume replacement, with an

infusion of lactated Ringer's solution, 0.9% sodium chloride solution, colloids, or blood component therapy (see Table 15-2 in Chapter 15). Oxygen is administered by nasal cannula, face mask, or mechanical ventilation. If fluid administration fails to reverse hypovolemic shock, then various cardiac, vasodilator, and corticosteroid medications may be prescribed to improve cardiac function and reduce peripheral vascular resistance.

The PACU bed provides easy access to the patient, is easily movable, can readily be positioned to facilitate use of measures to counteract shock, and has features that facilitate care, such as IV poles, side rails, and wheel brakes. The patient is placed flat with the legs elevated. Respiratory rate, pulse rate, blood pressure, blood oxygen concentration, urinary output, level of consciousness, central venous pressure, pulmonary artery pressure, pulmonary capillary wedge pressure, and cardiac output are monitored to provide information on the patient's respiratory and cardiovascular status. Vital signs are monitored continuously until the patient's condition has stabilized.

Other factors can contribute to hemodynamic instability, such as body temperature and pain. The PACU nurse implements measures to manage these factors. The nurse keeps the patient warm (while avoiding overheating to prevent cutaneous vessels from dilating and depriving vital organs of blood), avoids exposure, and maintains normothermia (to prevent vasodilation). Pain control measures are implemented, as discussed later in this chapter.

Hemorrhage

Hemorrhage is an uncommon yet serious complication of surgery that can result in hypovolemic shock and death. It can present insidiously or emergently at any time in the immediate postoperative period or up to several days after surgery (Table 20-1). The patient presents with hypotension; rapid, thready pulse; disorientation; restlessness; oliguria; and cold, pale skin. The early phase of shock will

Table 20-1 CLASSIFICATIONS OF HEMORRHAGE

Classification	Defining Characteristic
Time Frame	
Primary	Hemorrhage occurs at the time of surgery.
Intermediary	Hemorrhage occurs during the first few hours after surgery when the rise of blood pressure to its normal level dislodges insecure clots from untied vessels.
Secondary	Hemorrhage may occur some time after surgery if a suture slips because a blood vessel was not securely tied, became infected, or was eroded by a drainage tube.
Type of Vessel	
Capillary	Hemorrhage is characterized by a slow, general ooze.
Venous	Darkly colored blood bubbles out quickly.
Arterial	Blood is bright red and appears in spurts with each heartbeat.
Visibility	
Evident	Hemorrhage is on the surface and can be seen.
Concealed	Hemorrhage is in a body cavity and cannot be seen.

manifest in feelings of apprehension, decreased cardiac output, and vascular resistance. Breathing becomes labored and “air hunger” will be exhibited; the patient will feel cold (hypothermia) and may experience tinnitus. If shock symptoms are left untreated, the patient will continually grow weaker but can remain conscious until near death (Barash, et al., 2006; Rothrock, 2007).

Transfusing blood or blood products and determining the cause of hemorrhage are the initial therapeutic measures. The surgical site and incision should always be inspected for bleeding. If bleeding is evident, a sterile gauze pad and a pressure dressing are applied, and the site of the bleeding is elevated to heart level if possible. The patient is placed in the shock position (flat on back; legs elevated at a 20-degree angle; knees kept straight). If hemorrhage is suspected but cannot be visualized, the patient may be taken back to the OR for emergency exploration of the surgical site.

If hemorrhage is suspected, the nurse should be aware of any special considerations related to blood loss replacement. Certain patients may decline blood transfusions for religious or cultural reasons and may identify this request on their advance directives or living will.

Hypertension and Dysrhythmias

Hypertension is common in the immediate postoperative period secondary to sympathetic nervous system stimulation from pain, hypoxia, or bladder distention. Dysrhythmias are associated with electrolyte imbalance, altered respiratory function, pain, hypothermia, stress, and anesthetic agents. Both hypertension and dysrhythmias are managed by treating the underlying causes.

Relieving Pain and Anxiety

The PACU nurse monitors the patient’s physiologic status, manages pain, and provides psychological support in an effort to relieve the patient’s fears and concerns. The nurse checks the medical record for special needs and concerns of the patient. Opioid analgesics are administered mostly by IV in the PACU (Rothrock, 2007). IV opioids provide immediate pain relief and are short-acting, thus minimizing the potential for drug interactions or prolonged respiratory depression while anesthetics are still active in the patient’s system. When the patient’s condition permits, a close member of the family may visit in the PACU to decrease the family’s anxiety and make the patient feel more secure.

Controlling Nausea and Vomiting

Nausea and vomiting are common issues in the PACU (Chart 20-2). The nurse should intervene at the patient’s first report of nausea to control the problem rather than wait for it to progress to vomiting.

NURSING ALERT

At the slightest indication of nausea, the patient is turned completely to one side to promote mouth drainage and prevent aspiration of vomitus, which can cause asphyxiation and death.

Many medications are available to control postoperative nausea and vomiting (PONV) without oversedating the patient; they are commonly administered during surgery as

CHART
20-2

NURSING RESEARCH PROFILE

Preventing Postoperative Nausea and Vomiting

Forrester, C. M., Matern, C. E., Kelly, J., et al. (2007). Meclizine in combination with ondansetron for prevention of postoperative nausea and vomiting in high-risk patients. *AANA Journal*, 75(1), 27–33.

Purpose

Postoperative nausea and vomiting (PONV) are prevalent in surgical patients, especially those with known risks related to general anesthesia, female, nonsmoker, and history of motion sickness and PONV. This study investigated whether meclizine (Antivert), a medication commonly administered for motion sickness, given in the preoperative period to high-risk patients, would decrease PONV.

Design

This was a randomized, controlled trial in which 77 patients were studied, all of whom had four of five known risk factors for PONV. Patients who consented were randomly assigned to either the experimental group that received 50 mg of meclizine administered by mouth 15 to 30 minutes prior to surgery or usual care with no meclizine. All patients received a prophylactic dose of ondansetron 4 mg IV 15 to 30 minutes administered before the end of the surgical pro-

cedure. Severity of PONV was measured on a 0 (no nausea) to 10 (worst nausea) verbal numeric rating scale (VNRS) prior to surgery, in the postanesthesia care unit (PACU) 15 minutes before any antiemetic administration for nausea and every 15 minutes thereafter and on admission to the same day surgery unit.

Findings

There were no significant differences between the two groups in demographics, surgical or anesthesia time, analgesia requirements or overall nausea in the PACU. Patients who received meclizine ($n = 39$) and became nauseated had lower VNRS scores in the PACU at 15 ($p = .013$) and 45 ($p = .006$) minutes compared to the placebo group ($n = 38$).

Nursing Implications

Further study is needed, but in this small study, 50 mg of meclizine administered by mouth 15 to 30 minutes prior to surgery helped decrease the severity and incidence of PONV. Nurses working in the perioperative areas should be aware that meclizine is an inexpensive medication with a long duration of action and few side effects that may be helpful in the management of PONV.

Drug Classes	Name	Major Indications
GI stimulant	Metoclopramide (Reglan)	Relief of symptoms of acute and recurrent gastroparesis (ie, feelings of fullness after only a few bites of food, bloating, excessive belching nausea)
Phenothiazine Antiemetic	Prochlorperazine (Compazine)	Control of severe nausea and vomiting
Phenothiazine Antiemetic	Promethazine (Phenergan)	Prevention and control of nausea and vomiting associated with anesthesia and surgery
Antimotion sickness Antiemetic	Dimenhydrinate (Dramamine) Hydroxyzine (Vistaril, Atarax)	Prevention and treatment of nausea, vomiting, or vertigo of motion sickness Control of nausea and vomiting and as adjunct to analgesia preoperatively and postoperatively to allow decreased opioid dosage
Antiemetic Antimotion sickness Antiemetic	Scopolamine (Transderm-Scop)	Prevention and control of nausea and vomiting associated with motion sickness and recovery from surgery
Antiemetic	Ondansetron (Zofran)	Prevention of postoperative nausea and vomiting

well as in the PACU. Table 20-2 contains examples of medications commonly prescribed to control PONV (Fetzer, 2008; Karch, 2008). Ondansetron (Zofran) is an effective antiemetic with few side effects and is frequently the drug of choice.

The risk of PONV ranges from 30% in the general surgical population but increases to 80% with certain risk factors. These risks include general anesthesia, female gender, nonsmoker, history of PONV, and history of motion sickness (Forrester, Matern, Kelly, et al., 2007). Surgical risks are increased with PONV due to an increase in intra-abdominal pressure, elevated central venous pressure, the potential for aspiration, increased heart rate and systemic blood pressure, which increase the risk of myocardial ischemia and dysrhythmias. Postoperative pain is increased as well (Barash, et al., 2006). Ongoing research is investigating the most efficacious combination of medications for patients with different risk profiles (Board & Board, 2006; Bridges, Nettle, Dugirrala, et al., 2006; Forrester, et al., 2007).

Gerontologic Considerations

The elderly patient, like all patients, is transferred from the OR table to the bed or stretcher slowly and gently. The effects of this action on blood pressure and ventilation are monitored. Special attention is given to keeping the patient warm because elderly patients are more susceptible to hypothermia. The patient's position is changed frequently to stimulate respirations and to promote circulation and comfort.

Immediate postoperative care for the elderly patient is the same as for any surgical patient, but additional support is given if cardiovascular, pulmonary, or renal function is impaired. With careful monitoring, it is possible to detect cardiopulmonary deficits before signs and symptoms are apparent. Changes associated with the aging process, the prevalence of chronic diseases, alteration in fluid and nutrition status, and the increased use of medications result in postoperative requirements and slower recovery from anesthesia due to the prolonged time to eliminate sedatives and anesthetic agents. The elderly patient requires understanding of specific needs such as hypothermia, need for protection of fragile skin, padding and repositioning,

depleted energy levels, cardiac and pulmonary issues, postoperative pain, and the sensitivity and metabolic issues related to medication. Having less physiologic reserve, elderly patients require more frequent monitoring. Postoperative confusion and delirium affect as many as 51% of older patients. Acute confusion may be caused by pain, analgesic agents, hypotension, fever, hypoglycemia, fluid loss, fecal impaction, urinary retention, or anemia (Cofer, 2005; Litwack, 2006). Providing adequate hydration; reorienting to the environment; and reassessing the doses of sedatives, anesthetics, and analgesics may reduce the risk for confusion. Hypoxia can present as confusion and restlessness, as can blood loss and electrolyte imbalances. Exclusion of all other causes of confusion must precede the assumption that confusion is related to age, circumstances, and medications.

Determining Readiness for Discharge From the PACU

A patient remains in the PACU until fully recovered from the anesthetic agent. Indicators of recovery include stable blood pressure, adequate respiratory function, and adequate oxygen saturation level compared with baseline.

Many hospitals use a scoring system (eg, Aldrete score) to determine the patient's general condition and readiness for transfer from the PACU. Throughout the recovery period, the patient's physical signs are observed and evaluated by means of a scoring system based on a set of objective criteria. This evaluation guide allows an objective assessment of the patient's condition in the PACU (Fig. 20-3). The patient is assessed at regular intervals, and a total score is calculated and recorded on the assessment record. The Aldrete score is usually 8 to 10 before discharge from the PACU. Patients with a score of less than 7 must remain in the PACU until their condition improves or they are transferred to an intensive care area, depending on their preoperative baseline score (Rothrock, 2007).

The patient is discharged from the phase I PACU by the anesthesiologist or anesthesiologist to the critical care unit, the medical-surgical unit, the phase II PACU, or home with a responsible family member. In some hospitals and ambulatory care centers, patients are discharged to a phase III PACU, where they are prepared for discharge.

Preparing the Postoperative Patient for Direct Discharge

Ambulatory surgical centers frequently only have a step-down PACU similar to a phase II PACU. This type of patient is basically healthy and will be discharged directly to home. Prior to discharge the patient will require verbal

and written instructions and information about follow-up care.

Promoting Home and Community-Based Care

To ensure patient safety and recovery, expert patient teaching and discharge planning are necessary when a patient

CHART
20-3

HOME CARE CHECKLIST

Discharge After Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Name the procedure that was performed and identify any permanent changes in anatomic structure or function.	✓	✓
• Describe ongoing postoperative therapeutic regimen, including medications, diet, activities to perform (eg, walking and breathing exercises) and to avoid (eg, driving a car; contact sports), adjuvant therapies, dressing changes and wound care, and any other treatments.	✓	✓
• Describe signs and symptoms of complications.	✓	✓
• State time and date of follow-up appointments.	✓	✓
• Identify interventions and strategies to use in adapting to any permanent changes in structure or function.	✓	✓
• Relate how to reach health care provider with questions or complications.	✓	✓
• State understanding of community resources and referrals (if any).	✓	✓
• Describe pertinent health promotion activities (eg, weight reduction, smoking cessation, stress management).	✓	✓

undergoes same-day or ambulatory surgery. Because anesthetics cloud memory for concurrent events, verbal and written instructions should be given to both the patient and the adult who will be accompanying the patient home. Alternative formats (eg, large print, Braille) of instructions or use of a sign language interpreter may be required to ensure patient and family understanding. A translator may be required if the patient and family members do not understand English.

Teaching Patients Self-Care

The patient and caregiver (eg, family member or friend) are informed about expected outcomes and immediate postoperative changes anticipated. Chart 20-3 identifies important teaching points; before discharging the patient, the nurse provides written instructions covering each of those points. Prescriptions are given to the patient. The nurse's or surgeon's telephone number is provided, and the patient and caregiver are encouraged to call with questions and to schedule follow-up appointments.

Although recovery time varies depending on the type and extent of surgery and the patient's overall condition, instructions usually advise limited activity for 24 to 48 hours. During this time, the patient should not drive a vehicle, drink alcoholic beverages, or perform tasks that require energy or skill. Fluids may be consumed as desired and smaller-than-normal amounts may be eaten at mealtime. Patients are cautioned not to make important decisions at this time because the medications, anesthesia, and surgery may affect their decision-making ability.

Continuing Care

Although most patients who undergo ambulatory surgery recover quickly and without complications, some patients require referral for home care. These may be elderly or frail patients, those who live alone, and patients with other health care problems or disabilities that might interfere with self-care or resumption of usual activities. The home care nurse assesses the patient's physical status (eg, respiratory and cardiovascular status, adequacy of pain management, the surgical incision,

surgical complications) and the patient's and family's ability to adhere to the recommendations given at the time of discharge. Previous teaching is reinforced as needed. The home care nurse may change surgical dressings, monitor the patency of a drainage system, or administer medications. The patient and family are reminded about the importance of keeping follow-up appointments with the surgeon. Follow-up phone calls from the nurse or surgeon are also used to assess the patient's progress and to answer any questions.

Care of the Hospitalized Postoperative Patient

The majority of surgeries are now performed in ambulatory care centers, and surgical patients who require hospital stays include trauma patients, acutely ill patients, patients undergoing major surgery, patients who require emergency surgery, and patients with a concurrent medical disorder. Seriously ill patients and those who have undergone major cardiovascular, pulmonary, or neurologic surgery may be admitted to specialized ICUs for close monitoring and advanced interventions and support. The care required by these patients in the immediate postoperative period is discussed in specific chapters of this book. Patients admitted to the clinical unit for postoperative care have multiple needs and stay for a short period of time. Postoperative care for those surgical patients returning to the general medical-surgical unit is discussed later in this chapter.

Receiving the Patient in the Clinical Unit

The patient's room is readied by assembling the necessary equipment and supplies: IV pole, drainage receptacle holder, suction equipment, oxygen, emesis basin, tissues, disposable pads, blankets, and postoperative documentation forms. When the call comes to the unit about the patient's transfer from the PACU, the need for any additional items

**CHART
20-4**

Guidelines for Immediate Postoperative Nursing Interventions

Nursing Interventions

1. Assess breathing and administer supplemental oxygen, if prescribed.
2. Monitor vital signs and note skin warmth, moisture, and color.
3. Assess the surgical site and wound drainage systems. Connect all drainage tubes to gravity or suction as indicated and monitor closed drainage systems.
4. Assess level of consciousness, orientation, and ability to move extremities.
5. Assess pain level, pain characteristics (location, quality) and timing, type, and route of administration of last dose of analgesic.
6. Administer analgesics as prescribed and assess their effectiveness in relieving pain.
7. Place the call light, emesis basin, ice chips (if allowed), and bedpan or urinal within reach.
8. Position the patient to enhance comfort, safety, and lung expansion.
9. Assess IV sites for patency and infusions for correct rate and solution.
10. Assess urine output in closed drainage system or the patient's urge to void and bladder distention.
11. Reinforce the need to begin deep breathing and leg exercises.
12. Provide information to the patient and family.

Rationale

1. Assessment provides a baseline and helps identify signs and symptoms of respiratory distress early.
2. A careful baseline assessment helps identify signs and symptoms of shock early.
3. Assessment provides a baseline and helps identify signs and symptoms of hemorrhage early.
4. These parameters provide a baseline and help identify signs and symptoms of neurologic complications.
5. Assessment provides a baseline of current pain level and for assessment of effectiveness of pain management strategies.
6. Administration of analgesics helps decrease pain.
7. Attending to these needs provides for comfort and safety.
8. This promotes safety and reduces risk of postoperative complications.
9. Assessing IV sites and infusions helps detect phlebitis and prevents errors in rate and solution type.
10. Assessment provides a baseline and helps identify signs of urinary retention.
11. These activities help to prevent complications.
12. Patient teaching helps to decrease the patient's and family's anxiety.

is communicated. The PACU nurse reports relevant data about the patient to the receiving nurse (see Chart 20-1).

Usually the surgeon speaks to the family after surgery and relates the general condition of the patient. The receiving nurse reviews the postoperative orders, admits the patient to the unit, performs an initial assessment, and attends to the patient's immediate needs (Chart 20-4).

Nursing Management After Surgery

During the first 24 hours after surgery, nursing care of the hospitalized patient on the general medical-surgical unit involves continuing to help the patient recover from the effects of anesthesia, frequently assessing the patient's physiologic status, monitoring for complications, managing pain, and implementing measures designed to achieve the long-range goals of independence with self-care, successful management of the therapeutic regimen, discharge to home, and full recovery. In the initial hours after admission to the clinical unit, adequate ventilation, hemodynamic stability, incisional pain, surgical site integrity, nausea and vomiting, neurologic status, and spontaneous voiding are primary concerns. The pulse rate, blood pressure, and respiration rate are recorded at least every 15 minutes for the first hour and every 30 minutes for the next 2 hours. Thereafter, they are measured less frequently if they remain stable. The temperature is monitored every 4 hours for the first 24 hours.

Patients usually begin to return to their usual state of health several hours after surgery or after awaking the next morning. Although pain may still be intense, many patients feel more alert, less nauseous, and less anxious. They

have begun their breathing and leg exercises as appropriate for the type of surgery, and many will have dangled their legs over the edge of the bed, stood, and ambulated a few feet or been assisted out of bed to the chair at least once. Many will have tolerated a light meal and had IV fluids discontinued. The focus of care shifts from intense physiologic management and symptomatic relief of the adverse effects of anesthesia to regaining independence with self-care and preparing for discharge.

NURSING PROCESS

THE HOSPITALIZED PATIENT RECOVERING FROM SURGERY

Nursing care of the hospitalized patient recovering from surgery takes place in a compressed time frame, with much of the healing and recovery occurring after the patient is discharged to home or to a rehabilitation center.

Assessment

Assessment of the hospitalized postoperative patient includes monitoring vital signs and completing a review of systems upon the patient's arrival to the clinical unit (see Chart 20-4) and at regular intervals thereafter.

Respiratory status is important because pulmonary complications are among the most frequent and serious problems encountered by the surgical patient. The nurse

monitors for airway patency and any signs of laryngeal edema. The quality of respirations, including depth, rate, and sound, are assessed regularly. Chest auscultation verifies that breath sounds are normal (or abnormal) bilaterally, and the findings are documented as a baseline for later comparisons. Often, because of the effects of analgesic and anesthetic medications, respirations are slow. Shallow and rapid respirations may be caused by pain, constricting dressings, gastric dilation, abdominal distention, or obesity. Noisy breathing may be due to obstruction by secretions or the tongue. Another possible complication is flash pulmonary edema that occurs when protein and fluid accumulate in the alveoli unrelated to elevated pulmonary artery occlusive pressure. Signs and symptoms include agitation; tachypnea; tachycardia; decreased pulse oximetry readings; frothy, pink sputum; and crackles on auscultation.

The nurse assesses the patient's pain level using a verbal or visual analogue scale and assesses the characteristics of the pain. The patient's appearance, pulse, respirations, blood pressure, skin color (adequate or cyanotic), and skin temperature (cold and clammy, warm and moist, or warm and dry) are clues to cardiovascular function. When the patient arrives in the clinical unit, the surgical site is assessed for bleeding, type and integrity of dressings, and drains.

The nurse also assesses the patient's mental status and level of consciousness, speech, and orientation and compares them with the preoperative baseline. Although a change in mental status or postoperative restlessness may be related to anxiety, pain, or medications, it may also be a symptom of oxygen deficit or hemorrhage. These serious causes must be investigated and excluded before other causes are pursued.

General discomfort that results from laying in one position on the operating table, the handling of tissues by the surgical team, the body's reaction to anesthesia, and anxiety are also common causes of restlessness. These discomforts may be relieved by administering the prescribed analgesics, changing the patient's position frequently, and assessing and alleviating the cause of anxiety. If tight, drainage-soaked bandages are causing discomfort, reinforcing or changing the dressing completely as prescribed by the physician may make the patient more comfortable. The bladder is assessed for distention because urinary retention can also cause restlessness.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for ineffective airway clearance related to depressed respiratory function, pain, and bed rest
- Acute pain related to surgical incision
- Decreased cardiac output related to shock or hemorrhage
- Risk for activity intolerance related to generalized weakness secondary to surgery
- Impaired skin integrity related to surgical incision and drains
- Ineffective thermoregulation related to surgical environment and anesthetic agents

- Risk for imbalanced nutrition, less than body requirements related to decreased intake and increased need for nutrients secondary to surgery
- Risk for constipation related to effects of medications, surgery, dietary change, and immobility
- Risk for urinary retention related to anesthetic agents
- Risk for injury related to surgical procedure/positioning or anesthetic agents
- Anxiety related to surgical procedure
- Risk for ineffective management of therapeutic regimen related to wound care, dietary restrictions, activity recommendations, medications, follow-up care, or signs and symptoms of complications

Collaborative Problems or Potential Complications

Based on the assessment data, potential complications may include the following:

- Pulmonary infection/hypoxia
- Deep vein thrombosis (DVT)
- Hematoma or hemorrhage
- Infection
- Pulmonary embolism
- Wound dehiscence or evisceration

Planning and Goals

The major goals for the patient include optimal respiratory function, relief of pain, optimal cardiovascular function, increased activity tolerance, unimpaired wound healing, maintenance of body temperature, and maintenance of nutritional balance. Further goals include resumption of usual pattern of bowel and bladder elimination, identification of any perioperative positioning injury, acquisition of sufficient knowledge to manage self-care after discharge, and absence of complications.

Nursing Interventions

Preventing Respiratory Complications

Respiratory depressive effects of opioid medications, decreased lung expansion secondary to pain, and decreased mobility combine to put the patient at risk for common respiratory complications, particularly atelectasis (alveolar collapse; incomplete expansion of the lung), pneumonia, and hypoxemia (Rothrock, 2007). Atelectasis remains a risk for the patient who is not moving well or ambulating or who is not performing deep-breathing and coughing exercises or using an incentive spirometer. Signs and symptoms include decreased breath sounds over the affected area, crackles, and cough. Pneumonia is characterized by chills and fever, tachycardia, and tachypnea. Cough may or may not be present and may or may not be productive. Hypostatic pulmonary congestion, caused by a weakened cardiovascular system that permits stagnation of secretions at lung bases, may develop; this condition occurs most frequently in elderly patients who are not mobilized effectively. The symptoms are often vague, with perhaps a slight elevation of temperature, pulse, and respiratory rate, as well as a cough. Physical examination reveals dullness and crackles at the base of the lungs. If the condition progresses, the outcome may be fatal.

The types of hypoxemia that can affect postoperative patients are subacute and episodic. Subacute hypoxemia is a constant low level of oxygen saturation when breathing appears normal. Episodic hypoxemia develops suddenly, and the patient may be at risk for cerebral dysfunction, myocardial ischemia, and cardiac arrest. Risk for hypoxemia is increased in patients who have undergone major surgery (particularly abdominal), are obese, or have preexisting pulmonary problems. Hypoxemia is detected by pulse oximetry that measures blood oxygen saturation. Factors that may affect the accuracy of pulse oximetry readings include cold extremities, tremors, atrial fibrillation, acrylic nails, and black or blue nail polish (these colors interfere with the functioning of the pulse oximeter; other colors do not).

Preventive measures and timely recognition of signs and symptoms help avert pulmonary complications. Crackles indicate static pulmonary secretions that need to be mobilized by coughing and deep-breathing exercises. When a mucus plug obstructs one of the bronchi entirely, the pulmonary tissue beyond the plug collapses, resulting in atelectasis.

To clear secretions and prevent pneumonia, the nurse encourages the patient to turn frequently, take deep breaths, cough, and use the incentive spirometer at least every 2 hours. These pulmonary exercises should begin as soon as the patient arrives on the clinical unit and continue until the patient is discharged. Even if he or she is not fully awake from anesthesia, the patient can be asked to take several deep breaths. This helps expel residual anesthetic agents, mobilize secretions, and prevent atelectasis. Careful splinting of abdominal or thoracic incision sites helps the patient overcome the fear that the exertion of coughing might open the incision. Analgesic agents are administered to permit more effective coughing, and oxygen is administered as prescribed to prevent or relieve hypoxia. To encourage lung expansion, the patient is encouraged to yawn or take sustained maximal inspirations to create a negative intrathoracic pressure of -40 mm Hg and expand lung volume to total capacity. Chest physical therapy may be prescribed if indicated. See Chapter 25.

Coughing is contraindicated in patients who have head injuries or who have undergone intracranial surgery (because of the risk for increasing intracranial pressure), as well as in patients who have undergone eye surgery (because of the risk for increasing intraocular pressure) or plastic surgery (because of the risk for increasing tension on delicate tissues).

Early ambulation increases metabolism and pulmonary aeration and, in general, improves all body functions. The patient is encouraged to be out of bed as soon as possible (ie, on the day of surgery, or no later than the first postoperative day). This practice is especially valuable in preventing pulmonary complications in older patients.

Relieving Pain

Most patients experience some pain after a surgical procedure. Complete absence of pain in the area of the surgical incision may not occur for a few weeks, depending on the site and nature of the surgery, but the intensity of postoper-

ative pain gradually subsides on subsequent days. About one third of patients report severe pain, one third moderate pain, and one third little or no pain. This does not mean that the patients in the last group have no pain; rather, they appear to activate psychodynamic mechanisms that impair the registering of pain (“gate closing” theory and nociceptive transmission). See Chapter 13 for a more detailed discussion of pain.

Many factors (motivational, affective, cognitive, emotional, and cultural) influence the pain experience. The degree and severity of postoperative pain and the patient’s tolerance for pain depend on the incision site, the nature of the surgical procedure, the extent of surgical trauma, the type of anesthesia, and route of administration. The preoperative preparation received by the patient (including information about what to expect, reassurance, psychological support, and teaching specific communication techniques related to pain) is a significant factor in decreasing anxiety, apprehension, the amount of postoperative pain, and PONV (Barash, et al., 2006).

Intense pain stimulates the stress response, which adversely affects the cardiac and immune systems. When pain impulses are transmitted, both muscle tension and local vasoconstriction increase, further stimulating pain receptors. This increases myocardial demand and oxygen consumption. The hypothalamic stress response also results in an increase in blood viscosity and platelet aggregation, increasing the risk of thrombosis and pulmonary embolism.

Often the physician has prescribed different medications or dosages to cover various levels of pain. The nurse discusses these options with the patient to determine the best medication. The nurse assesses the effectiveness of the medication periodically, beginning 30 minutes after administration, or sooner if the medication is being delivered by patient-controlled analgesia (PCA).

OPIOID ANALGESICS. Opioid analgesics are commonly prescribed for pain and immediate postoperative restlessness. A preventive approach, rather than an “as needed” (PRN) approach, is more effective in relieving pain. With a preventive approach, the medication is administered at prescribed intervals rather than when the pain becomes severe or unbearable. Many patients (and some health care providers) are overly concerned about the risk of drug addiction in the postoperative patient. However, this risk is negligible with the use of opioid medications for short-term pain control (D’Arcy, 2007).

PATIENT-CONTROLLED ANALGESIA. The nurse’s goal is pain prevention rather than sporadic pain control. Patients recover more quickly when adequate pain relief measures are used, and PCA permits patients to administer their own pain medication when needed. Most patients are candidates for PCA. The two requirements for PCA are an understanding of the need to self-dose and the physical ability to self-dose. The amount of medication delivered by the IV or epidural route and the time span during which the opioid medication is released are controlled by the PCA device. PCA promotes patient participation in care, eliminates delayed administration of analgesics, maintains a therapeutic drug level, and enables the patient to move, turn, cough,

and take deep breaths with less pain, thus reducing postoperative pulmonary complications (Rothrock, 2007).

EPIDURAL INFUSIONS AND INTRAPLEURAL ANESTHESIA. Patients undergoing many types of procedures and surgeries benefit from the use of epidural infusion of opioids (Schwartz, 2006). Epidural infusions are used with caution in chest procedures because the analgesic may ascend along the spinal cord and affect respiration. Intrapleural anesthesia involves the administration of local anesthetic by a catheter between the parietal and visceral pleura. It provides sensory anesthesia without affecting motor function to the intercostal muscles. This anesthesia allows more effective coughing and deep breathing in conditions such as cholecystectomy, renal surgery, and rib fractures in which pain in the thoracic region would interfere with these exercises.

A local opioid or a combination anesthetic (opioid plus local anesthetic agent) is used in the epidural infusion.

OTHER PAIN RELIEF MEASURES. For pain that is difficult to control, a subcutaneous pain management system may be used. This is a silicone catheter that is inserted at the site of the affected area. The catheter is attached to a pump that delivers a continuous amount of local anesthetic at a specific amount determined and prescribed by the physician (Fig. 20-4).

Nonpharmacologic pain relief measures, such as guided imagery, music, and application of heat or cold (if prescribed) have been successful in decreasing pain (Rothrock, 2007). Changing the patient's position, using distraction, applying cool washcloths to the face, and providing back massage may be useful in relieving general

Figure 20-4 Subcutaneous pain management system consists of a pump, filter, and catheter that delivers a specific amount of prescribed local anesthetic at the rate determined by the physician. Redrawn from I-Flow Corporation, Lake Forest, CA.

discomfort temporarily, promoting relaxation, and rendering medication more effective when it is administered.

Promoting Cardiac Output

If signs and symptoms of shock or hemorrhage occur, treatment and nursing care are implemented as described in the discussion of care in the PACU.

Although most patients do not hemorrhage or go into shock, changes in circulating volume, the stress of surgery, and the effects of medications and preoperative preparations all affect cardiovascular function. IV fluid replacement may be prescribed for up to 24 hours after surgery or until the patient is stable and tolerating oral fluids. Close monitoring is indicated to detect and correct conditions such as fluid volume deficit, altered tissue perfusion, and decreased cardiac output, all of which can increase the patient's discomfort, place him or her at risk of complications, and prolong the hospital stay. Some patients are at risk of fluid volume excess secondary to existing cardiovascular or renal disease, advanced age, and other factors (Litwack, 2006). Consequently, fluid replacement must be carefully managed, and intake and output records must be accurate.

Nursing management includes assessing the patency of the IV lines and ensuring that the correct fluids are administered at the prescribed rate. Intake and output, including emesis and output from wound drainage systems, are recorded separately and totaled to determine fluid balance. If the patient has an indwelling urinary catheter, hourly outputs are monitored and rates of less than 30 mL/h are reported; if the patient is voiding, an output of less than 240 mL per 8-hour shift is reported. Electrolyte levels and hemoglobin and hematocrit levels are monitored. Decreased hemoglobin and hematocrit levels can indicate blood loss or dilution of circulating volume by IV fluids. If dilution is contributing to the decreased levels, the hemoglobin and hematocrit will rise as the stress response abates and fluids are mobilized and excreted.

Venous stasis from dehydration, immobility, and pressure on leg veins during surgery put the patient at risk for DVT. Leg exercises and frequent position changes are initiated early in the postoperative period to stimulate circulation. Patients should avoid positions that compromise venous return, such as raising the bed's knee gatch, placing a pillow under the knees, sitting for long periods, and dangling the legs with pressure at the back of the knees. Venous return is promoted by anti-embolism stockings and early ambulation.

Encouraging Activity

Early ambulation has a significant effect on recovery and the prevention of complications (eg, atelectasis, hypostatic pneumonia, gastrointestinal [GI] discomfort, circulatory problems) (Rothrock, 2007). Postoperative activity orders are checked before the patient is assisted to get out of bed, in many instances, on the evening following surgery. Sitting up at the edge of the bed for a few minutes may be all that the patient who has undergone a major surgical procedure can tolerate at first.

Ambulation reduces postoperative abdominal distention by increasing GI tract and abdominal wall tone and stimulating peristalsis. Early ambulation prevents stasis of blood, and thromboembolic events occur less frequently. Pain is often

decreased when early ambulation is possible, and the hospital stay is shorter and less costly.

Despite the advantages of early ambulation, patients may be reluctant to get out of bed on the evening of surgery. Reminding them of the importance of early mobility in preventing complications may help patients overcome their fears. When a patient gets out of bed for the first time, orthostatic hypotension, also called postural hypotension, is a concern. Orthostatic hypotension is an abnormal drop in blood pressure that occurs as the patient changes from a supine to a standing position. It is common after surgery because of changes in circulating blood volume and bed rest. Signs and symptoms include a decrease of 20 mm Hg in systolic blood pressure or 10 mm Hg in diastolic blood pressure, weakness, dizziness, and fainting. Older adults are at increased risk for orthostatic hypotension secondary to age-related changes in vascular tone. To detect orthostatic hypotension, the nurse assesses the patient's blood pressure first in the supine position, after the patient sits up, again after the patient stands, and 2 to 3 minutes later. Gradual position change gives the circulatory system time to adjust. If the patient becomes dizzy, he or she is returned to the supine position, and ambulation is delayed for several hours.

To assist the postoperative patient in getting out of bed for the first time after surgery, the nurse:

1. Helps the patient move gradually from the lying position to the sitting position by raising the head of the bed and encourages the patient to splint the incision when applicable.
2. Positions the patient completely upright (sitting) and turned so that both legs are hanging over the edge of the bed.
3. Helps the patient stand beside the bed.

After becoming accustomed to the upright position, the patient may start to walk. The nurse should be at the patient's side to give physical support and encouragement. Care must be taken not to tire the patient; the extent of the first few periods of ambulation varies with the type of surgical procedure and the patient's physical condition and age.

Whether or not the patient can ambulate early in the postoperative period, bed exercises are encouraged to improve circulation. Bed exercises consist of the following:

- Arm exercises (full range of motion, with specific attention to abduction and external rotation of the shoulder)
- Hand and finger exercises
- Foot exercises to prevent DVT, foot drop, and toe deformities and to aid in maintaining good circulation
- Leg flexion and leg-lifting exercises to prepare the patient for ambulation
- Abdominal and gluteal contraction exercises

Hampered by pain, dressings, IV lines, or drains, many patients cannot engage in activity without assistance. Helping the patient increase his or her activity level on the first postoperative day is important to prevent complications related to prolonged inactivity. One way to increase the patient's activity is to have the patient perform as much routine hygiene care as possible. Setting up the patient to bathe with a bedside

wash basin or, if possible, assisting the patient to the bathroom to sit in a chair at the sink not only gets the patient moving but helps restore a sense of self-control and prepares the patient for discharge.

For a safe discharge to home, patients need to be able to ambulate a functional distance (eg, length of the house or apartment), get in and out of bed unassisted, and be independent with toileting. Patients can be asked to perform as much as they can and then to call for assistance. The patient and the nurse can collaborate on a schedule for progressive activity that includes ambulating in the room and hallway and sitting out of bed in a chair. Assessing the patient's vital signs before, during, and after a scheduled activity helps the nurse and patient determine the rate of progression. By providing physical support, the nurse maintains the patient's safety; by communicating a positive attitude about the patient's ability to perform the activity, the nurse promotes the patient's confidence. The nurse encourages the patient to continue to perform bed exercises, wear pneumatic compression or prescribed anti-embolism stockings when in bed, and rest as needed. If the patient has had orthopedic surgery of the lower extremities or will require a mobility aid (ie, walker, crutches) at home, a physical therapist may be involved the first time the patient gets out of bed to teach him or her to ambulate safely or to use the mobility aid correctly.

Caring for Wounds

WOUND HEALING. Wounds heal by different mechanisms, depending on the condition of the wound. Surgical wound healing occurs in three phases: **first-intention**, **second-intention**, and **third-intention wound healing** (Chart 20-5) (Rothrock, 2007). With shorter hospital stays, much of the healing takes place at home, and both the hospital and home care nurse should be informed about the principles of wound healing (Hahler, 2006; Hunter, Thompson, Langemo, et al., 2007).

Ongoing assessment of the surgical site involves inspection for approximation of wound edges, integrity of sutures or staples, redness, discoloration, warmth, swelling, unusual tenderness, or drainage. The area around the wound should also be inspected for a reaction to tape or trauma from tight bandages. As a wound heals, many factors, such as adequate nutrition, cleanliness, rest, and position, determine how quickly healing occurs. These factors are influenced by nursing interventions. Specific nursing assessments and interventions that address these factors and help promote wound healing are presented in Table 20-3.

CARING FOR SURGICAL DRAINS. Nursing interventions to promote wound healing also include management of surgical drains. Drains are tubes that exit the peri-incisional area, either into a portable wound suction device (closed) or into the dressings (open). The principle involved is to allow the escape of fluids that could otherwise serve as a culture medium for bacteria. In portable wound suction, the use of gentle, constant suction enhances drainage of these fluids and collapses the skin flaps against the underlying tissue, thus removing "dead space." Types of wound drains include the Penrose, Hemovac, and Jackson-Pratt drains (Fig. 20-5). Output (drainage) from wound systems

Chart 20-5 • Wound Healing Mechanisms

First-Intention Healing

Wounds made aseptically with a minimum of tissue destruction that are properly closed heal with little tissue reaction by first intention (primary union). When wounds heal by first-intention healing, granulation tissue is not visible and scar formation is minimal. Postoperatively, many of these wounds are covered with a dry sterile dressing. If a cyanoacrylate tissue adhesive (Liquiband) was used to close the incision without sutures, a dressing is contraindicated.

Second-Intention Healing

Second-intention healing (granulation) occurs in infected wounds (abscess) or in wounds in which the edges have not been approximated. When an abscess is incised, it collapses partly, but the dead and dying cells forming its walls are still being released into the cavity. For this reason, a drainage tube or gauze packing is inserted into the abscess pocket to allow drainage to escape easily. Gradually, the necrotic material disintegrates and escapes, and the abscess cavity fills with a red, soft, sensitive tissue that bleeds easily. This tissue is composed of minute, thin-walled capillaries and buds that later form connective tissue. These buds, called granulations, enlarge until they fill the area left by the destroyed tissue. The cells surrounding the capillaries change their round shape to become long, thin, and intertwined to form a scar (cicatrix). Healing is complete when skin cells (epithelium) grow over these granulations. This method of repair is called healing by granulation, and it takes place whenever pus is formed or when loss of tissue has occurred for any reason. When the postoperative wound is to be allowed to heal by secondary intention, it is usually packed with saline-moistened sterile dressings and covered with a dry sterile dressing.

Third-Intention Healing

Third-intention healing (secondary suture) is used for deep wounds that either have not been sutured early or break down and are resutured later, thus bringing together two

opposing granulation surfaces. This results in a deeper and wider scar. These wounds are also packed postoperatively with moist gauze and covered with a dry sterile dressing.

is recorded. The amount of bloody drainage on the surgical dressing is assessed frequently. Spots of drainage on the dressings are outlined with a pen, and the date and time of the outline are recorded on the dressing so that increased drainage can be easily seen. A certain amount of bloody drainage in a wound drainage system or on the dressing is expected, but excessive amounts should be reported to the surgeon. Increasing amounts of fresh blood on the dressing should be reported immediately. Some wounds are irrigated heavily before closure in the OR, and open drains exiting the wound may be embedded in the dressings. These wounds may drain large amounts of blood-tinged fluid that saturate the dressing. The dressing can be reinforced with sterile gauze bandages; the time at which they were reinforced should be documented. If drainage continues, the surgeon should be notified so that the dressing can be changed. Multiple similar drains are numbered or otherwise labeled (eg, left lower quadrant, left upper quadrant)

so that output measurements can be reliably and consistently recorded.

CHANGING THE DRESSING. Although the first postoperative dressing is usually changed by a member of the surgical team, subsequent dressing changes in the immediate postoperative period are usually performed by the nurse. A dressing is applied to a wound for one or more of the following reasons: (1) to provide a proper environment for wound healing; (2) to absorb drainage; (3) to splint or immobilize the wound; (4) to protect the wound and new epithelial tissue from mechanical injury; (5) to protect the wound from bacterial contamination and from soiling by feces, vomitus, and urine; (6) to promote hemostasis, as in a pressure dressing; and (7) to provide mental and physical comfort for the patient.

The patient is told that the dressing is to be changed and that changing the dressing is a simple procedure associated

Table 20-3 FACTORS AFFECTING WOUND HEALING

Factors	Rationale	Nursing Interventions
Age of patient Handling of tissues Hemorrhage	The older the patient, the less resilient the tissues. Rough handling causes injury and delayed healing. Accumulation of blood creates dead spaces as well as dead cells that must be removed. The area becomes a growth medium for organisms.	Handle all tissues gently. Handle tissues carefully and evenly. Monitor vital signs. Observe incision site for evidence of bleeding and infection.
Hypovolemia	Insufficient blood volume leads to vasoconstriction and reduced oxygen and nutrients available for wound healing.	Monitor for volume deficit (circulatory impairment). Correct by fluid replacement as prescribed.
Local factors Edema Inadequate dressing technique Too small Too tight	Reduces blood supply by exerting increased interstitial pressure on vessels. Permits bacterial invasion and contamination. Reduces blood supply carrying nutrients and oxygen.	Elevate part; apply cool compresses. Follow guidelines for proper dressing technique.
Nutritional deficits	Protein-calorie depletion may occur. Insulin secretion may be inhibited, causing blood glucose to rise.	Correct deficits; this may require parenteral nutritional therapy. Monitor blood glucose levels. Administer vitamin supplements as prescribed.
Foreign bodies	Foreign bodies retard healing.	Keep wounds free of dressing threads and talcum powder from gloves.
Oxygen deficit (tissue oxygenation insufficient)	Insufficient oxygen may be due to inadequate lung and cardiovascular function as well as localized vasoconstriction.	Encourage deep breathing, turning, controlled coughing.
Drainage accumulation	Accumulated secretions hamper healing process.	Monitor closed drainage systems for proper functioning. Institute measures to remove accumulated secretions.
Medications Corticosteroids Anticoagulants Broad-spectrum and specific antibiotics	May mask presence of infection by impairing normal inflammatory response. May cause hemorrhage. Effective if administered immediately before surgery for specific pathology or bacterial contamination. If administered after wound is closed, ineffective because of intravascular coagulation.	Be aware of action and effect of medications patient is receiving.
Patient overactivity	Prevents approximation of wound edges. Resting favors healing.	Use measures to keep wound edges approximated: taping, bandaging, splints. Encourage rest.
Systemic disorders Hemorrhagic shock Acidosis Hypoxia Renal failure Hepatic disease Sepsis	These depress cell functions that directly affect wound healing.	Be familiar with the nature of the specific disorder. Administer prescribed treatment. Cultures may be indicated to determine appropriate antibiotic.
Immunosuppressed state	Patient is more vulnerable to bacterial and viral invasion; defense mechanisms are impaired.	Provide maximum protection to prevent infection. Restrict visitors with colds; institute mandatory hand hygiene by all staff.
Wound stressors Vomiting Valsalva maneuver Heavy coughing Straining	Produce tension on wounds, particularly of the torso.	Encourage frequent turning and ambulation and administer antiemetic medications as prescribed. Assist patient in splinting incision.

with little discomfort. The dressing change is performed at a suitable time (eg, not at mealtimes or when visitors are present). Privacy is provided, and the patient is not unduly exposed. The nurse should avoid referring to the incision as a scar because the term may have negative connotations for the patient. Assurance is given that the incision will shrink as it heals and that the redness will fade.

The nurse performs hand hygiene before and after the dressing change and wears disposable gloves (sterile or clean as needed) for the dressing change itself. Most dressing changes following surgery are sterile. In accordance with standard precautions, dressings are never touched by ungloved hands because of the danger of transmitting path-

ogenic organisms. The tape or adhesive portion of the dressing is removed by pulling it parallel with the skin surface and in the direction of hair growth, rather than at right angles. Alcohol wipes or nonirritating solvents aid in removing adhesive painlessly and quickly. The soiled dressing is removed and deposited in a container designated for disposal of biomedical waste.

Gloves are changed and a new dressing applied. If the patient is sensitive to adhesive tape, the dressing may be held in place with hypoallergenic tape. Many tapes are porous to prevent skin maceration. Some wounds become edematous after having been dressed, causing considerable tension on the tape. If the tape is not flexible, the stretching bandage

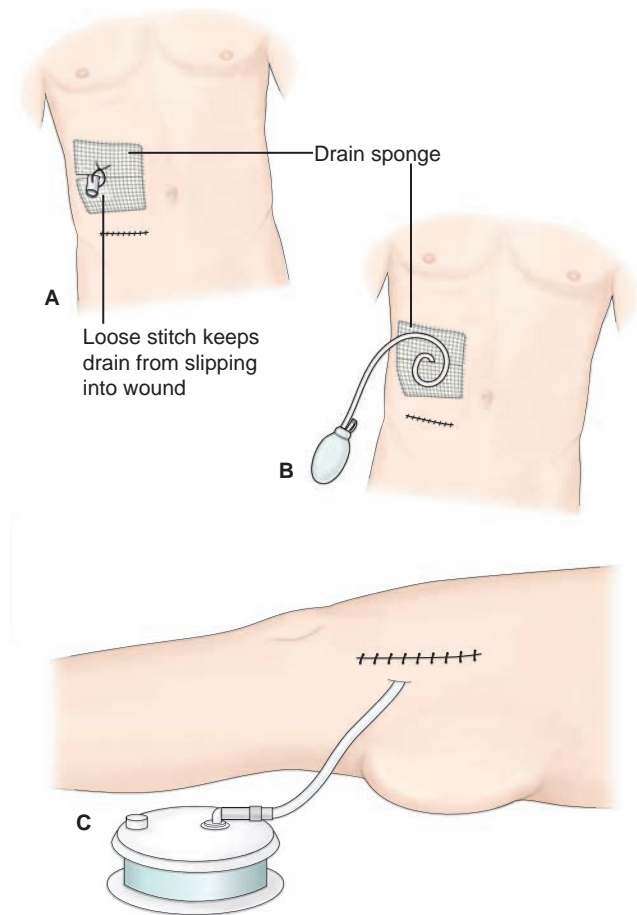

Figure 20-5 Types of surgical drains: **A**, Penrose, **B**, Jackson-Pratt, **C**, Hemovac.

will also cause a shear injury to the skin. This can result in denuded areas or large blisters and should be avoided. An elastic adhesive bandage (Elastoplast, Microfoam-3M) may be used to hold dressings in place over mobile areas, such as the neck or the extremities, or where pressure is required.

While changing the dressing, the nurse has an opportunity to teach the patient how to care for the incision and change the dressings at home. The nurse observes for indicators of the patient's readiness to learn, such as looking at the incision, expressing interest, or assisting in the dressing change. Information on self-care activities and possible signs of infection is summarized in Chart 20-6.

Maintaining Normal Body Temperature

The patient is still at risk for malignant hyperthermia and hypothermia in the postoperative period. Efforts are made to identify malignant hyperthermia and to treat it early and promptly (Rothrock, 2007). (See the discussion of malignant hyperthermia in Chapter 19.)

Patients who have received anesthesia are susceptible to chills and drafts. Hypothermia management, begun in the intraoperative period, extends into the postoperative period to prevent significant nitrogen loss and catabolism. Low body temperature is reported to the physician. The room is maintained at a comfortable temperature, and blankets are

provided to prevent chilling. Treatment includes oxygen administration, adequate hydration, and proper nutrition. The patient is also monitored for cardiac dysrhythmias. The risk of hypothermia is greater in the elderly and in patients who were in the cool OR environment for a prolonged period.

Managing Gastrointestinal Function and Resuming Nutrition

Discomfort of the GI tract (nausea, vomiting, and hiccups) and resumption of oral intake are issues for both the patient and the nurse. See the earlier discussion of nausea and vomiting in the PACU.

If risk of vomiting is high due to the nature of surgery, a nasogastric tube is inserted preoperatively and remains in place throughout the surgery and the immediate postoperative period. A nasogastric tube also may be inserted before surgery if postoperative distention is anticipated. In addition, a nasogastric tube may be inserted if a patient who has food in the stomach requires emergency surgery.

Hiccups, produced by intermittent spasms of the diaphragm secondary to irritation of the phrenic nerve, can occur after surgery. The irritation may be direct, such as from stimulation of the nerve by a distended stomach, subdiaphragmatic abscess, or abdominal distention; indirect, such as from toxemia or uremia that stimulates the nerve; or reflexive, such as irritation from a drainage tube or obstruction of the intestines. Usually these occurrences are mild, transitory attacks that cease spontaneously. If hiccups persist, they may produce considerable distress and serious effects such as vomiting, exhaustion, and wound dehiscence. The physician may prescribe phenothiazine medications (eg chlorpromazine [Thorazine]) for intractable hiccups (Zonderman & Doyle, 2006).

Once nausea and vomiting have subsided and the patient is fully awake and alert, the sooner he or she can tolerate a usual diet, and the more quickly normal GI function will resume. Taking food by mouth stimulates digestive juices and promotes gastric function and intestinal peristalsis. The return to normal dietary intake should proceed at a pace set by the patient. The nature of the surgery and the type of anesthesia directly affect the rate at which normal gastric activity resumes. Liquids are typically the first substances desired and tolerated by the patient after surgery. Water, juice, and tea may be given in increasing amounts. Cool fluids are tolerated more easily than those that are ice cold or hot. Soft foods (gelatin, custard, milk, and creamed soups) are added gradually after clear fluids have been tolerated. As soon as the patient tolerates soft foods well, solid food may be given.

Assessment and management of GI function are important after surgery because the GI tract is subject to uncomfortable or potentially life-threatening complications. Any postoperative patient may suffer from distention. Postoperative distention of the abdomen results from the accumulation of gas in the intestinal tract. Manipulation of the abdominal organs during surgery may produce a loss of normal peristalsis for 24 to 48 hours, depending on the type and extent of surgery. Even though nothing is given by mouth, swallowed air and GI tract secretions enter the stomach and intestines; if not propelled by peristalsis, they collect in the

CHART
20-6

PATIENT EDUCATION

Wound Care Instructions

Until Sutures Are Removed

- Keep the wound dry and clean.
 - If there is no dressing, ask your nurse or physician if you can bathe or shower.
 - If a dressing or splint is in place, do not remove it unless it is wet or soiled.
 - If wet or soiled, change dressing yourself if you have been taught to do so; otherwise, call your nurse or physician for guidance.
 - If you have been taught, instruction might be as follows:
 - Cleanse area *gently* with sterile normal saline once or twice daily.
 - Cover with a sterile Telfa pad or gauze square large enough to cover wound.
 - Apply hypoallergenic tape (Dermacel or paper). Adhesive is not recommended because it is difficult to remove without possible injury to the incisional site.
- Immediately report any of these signs of infection:
 - Redness, marked swelling exceeding ½ inch (2.5 cm) from incision site; tenderness; or increased warmth around wound
 - Red streaks in skin near wound
 - Pus or discharge, foul odor
 - Chills or temperature higher than 37.7°C (100°F)
- If soreness or pain causes discomfort, apply a dry cool pack (containing ice or cold water) or take prescribed acet-

aminophen tablets (2) every 4–6 hours. Avoid using aspirin without direction or instruction because bleeding can occur with its use.

- Swelling after surgery is common. To help reduce swelling, elevate the affected part to the level of the heart.
 - Hand or arm
 - Sleep—elevate arm on pillow at side
 - Sitting—place arm on pillow on adjacent table
 - Standing—rest affected hand on opposite shoulder; support elbow with unaffected hand
 - Leg or foot
 - Sitting—place a pillow on a facing chair; provide support underneath the knee
 - Lying—place a pillow under affected leg

After Sutures Are Removed

Although the wound appears to be healed when sutures are removed, it is still tender and will continue to heal and strengthen for several weeks.

- Follow recommendations of physician or nurse regarding extent of activity.
- Keep suture line clean; do not rub vigorously; pat dry. Wound edges may look red and may be slightly raised. This is normal.
- If the site continues to be red, thick, and painful to pressure after 8 weeks, consult the health care provider. (This may be due to excessive collagen formation and should be checked.)

intestines, producing distention and causing the patient to complain of fullness or pain in the abdomen. Most often, the gas collects in the colon. Abdominal distention is further increased by immobility, anesthetic agents, and the use of opioid medications.

After major abdominal surgery, distention may be avoided by having the patient turn frequently, exercise, and ambulate as early as possible. This also alleviates distention produced by swallowing air, which is common in anxious patients. A nasogastric tube inserted before surgery may remain in place until full peristaltic activity (indicated by the passage of flatus) has resumed. The nurse detects bowel sounds by listening to the abdomen with a stethoscope. Bowel sounds are documented so that diet progression can occur.

Paralytic ileus and intestinal obstruction are potential postoperative complications that occur more frequently in patients undergoing intestinal or abdominal surgery. Refer to Chapter 38 for discussion of treatment.

Promoting Bowel Function

Constipation is common after surgery and can be minor or a serious complication. Decreased mobility, decreased oral intake, and opioid analgesics contribute to difficulty having a bowel movement. In addition, irritation and trauma to the bowel during surgery may inhibit intestinal movement for several days. The combined effect of early ambulation, improved dietary intake, and a stool softener (if prescribed)

promotes bowel elimination. Until the patient reports return of bowel function, the nurse should assess the abdomen for distention and the presence and frequency of bowel sounds. If the abdomen is not distended and bowel sounds are present, and if the patient does not have a bowel movement by the second or third postoperative day, the physician should be notified so that a laxative can be administered.

Managing Voiding

Urinary retention after surgery can occur for various reasons. Anesthetics, anticholinergic agents, and opioids interfere with the perception of bladder fullness and the urge to void and inhibit the ability to initiate voiding and completely empty the bladder. Abdominal, pelvic, and hip surgery may increase the likelihood of retention secondary to pain. In addition, some patients find it difficult to use the bedpan or urinal in the recumbent position.

Bladder distention and the urge to void should be assessed at the time of the patient's arrival on the unit and frequently thereafter. The patient is expected to void within 8 hours after surgery (this includes time spent in the PACU). If the patient has an urge to void and cannot, or if the bladder is distended and no urge is felt or the patient cannot void, catheterization is not delayed solely on the basis of the 8-hour time frame. All methods to encourage the patient to void should be tried (eg, letting water run, applying heat to the perineum). The bedpan should be warm; a cold bedpan

causes discomfort and automatic tightening of muscles (including the urethral sphincter). If the patient cannot void on a bedpan, it may be possible to use a commode rather than resorting to catheterization. Male patients are often permitted to sit up or stand beside the bed to use the urinal, but safeguards should be taken to prevent the patient from falling or fainting due to loss of coordination from medications or orthostatic hypotension. If the patient cannot void in the specified time frame, the patient is catheterized and the catheter is removed after the bladder has emptied. Straight intermittent catheterization is preferred over indwelling catheterization because the risk of infection is increased with an indwelling catheter.

Even if the patient voids, the bladder may not necessarily be empty. The nurse notes the amount of urine voided and palpates the suprapubic area for distention or tenderness. A portable ultrasound device may also be used to assess residual volume. Intermittent catheterization may be prescribed every 4 to 6 hours until the patient can void spontaneously and the postvoid residual is less than 100 mL.

Maintaining a Safe Environment

During the immediate postoperative period, the patient recovering from anesthesia should have three side rails up, and the bed should be in the low position. The nurse assesses the patient's level of consciousness and orientation and determines whether the patient can resume wearing his or her eyeglasses or hearing aid, because impaired vision, inability to hear postoperative instructions, or inability to communicate verbally places the patient at risk for injury. All objects the patient may need should be within reach, especially the call light. Any immediate postoperative orders concerning special positioning, equipment, or interventions should be implemented as soon as possible. The patient is instructed to ask for assistance with any activity. Although restraints are occasionally necessary for the disoriented patient, they should be avoided if at all possible. Agency policy on the use of restraints must be consulted and followed.

Any surgical procedure has the potential for injury due to disrupted neurovascular integrity resulting from prolonged awkward positioning in the OR, manipulation of tissues, inadvertent severing of nerves or blood vessels, or tight bandages. Any orthopedic surgery or surgery involving the extremities carries a risk of peripheral nerve damage. Vascular surgeries, such as replacement of sections of diseased peripheral arteries or inserting an arteriovenous graft, put the patient at risk for thrombus formation at the surgi-

cal site and subsequent ischemia of tissues distal to the thrombus. Assessment includes having the patient move the hand or foot distal to the surgical site through a full range of motion, assessing all surfaces for intact sensation, and assessing peripheral pulses (Rothrock, 2007).

Providing Emotional Support to the Patient and Family

Although patients and families are undoubtedly relieved that surgery is over, anxiety levels may remain high in the immediate postoperative period. Many factors contribute to this anxiety: pain, being in an unfamiliar environment, inability to control one's circumstances or care for oneself, fear of the long-term effects of surgery, fear of complications, fatigue, spiritual distress, altered role responsibilities, ineffective coping, and altered body image are all potential reactions to the surgical experience. The nurse helps the patient and family work through their anxieties by providing reassurance and information and by spending time listening to and addressing their concerns. The nurse describes hospital routines and what to expect in the time until discharge and explains the purpose of nursing assessments and interventions. Informing patients when they will be able to drink fluids or eat, when they will be getting out of bed, and when tubes and drains will be removed helps them gain a sense of control and participation in recovery and engages them in the plan of care. Acknowledging family members' concerns and accepting and encouraging their participation in the patient's care assists them in feeling that they are helping their loved one. The nurse can modify the environment to enhance rest and relaxation by providing privacy, reducing noise, adjusting lighting, providing enough seating for family members, and encouraging a supportive atmosphere.

Managing Potential Complications

The postoperative patient is at risk for complications as outlined below and listed in Table 20-4.

DEEP VEIN THROMBOSIS. Serious potential complications of surgery include DVT and pulmonary embolism (PE) (Rothrock, 2007).

Prophylactic treatment is common for patients at risk for DVT and PE. Low-molecular-weight or low-dose heparin and low-dose warfarin (Coumadin) are other anticoagulants that may be used. External pneumatic compression and anti-embolism stockings can be used alone or in combination

Table 20-4 POTENTIAL POSTOPERATIVE COMPLICATIONS

Body System/Type	Complications
Respiratory	Atelectasis, pneumonia, PE aspiration
Cardiovascular	Shock, thrombophlebitis
Neurologic	Delirium, stroke
Skin/wound	Breakdown, infection, dehiscence, evisceration, delayed healing, hemorrhage, hematoma
Gastrointestinal	Constipation, paralytic ileus, bowel obstruction
Urinary	Acute urine retention, urinary tract infection
Functional	Weakness, fatigue, functional decline
Thromboembolic	DVT, PE

Table 20-5 WOUND CLASSIFICATION AND ASSOCIATED SURGICAL SITE INFECTION RISK

Surgical Category	Determinants of Category	Expected Risk of Postsurgical Infection (%)
Clean	Nontraumatic site Uninfected site No inflammation No break in aseptic technique No entry into respiratory, alimentary, genitourinary, or oropharyngeal tracts	1–3
Clean-contaminated	Entry into respiratory, alimentary, genitourinary or oropharyngeal tracts without unusual contamination Appendectomy Minor break in aseptic technique Mechanical drainage	3–7
Contaminated	Open, newly experienced traumatic wounds Gross spillage from gastrointestinal tract Major break in aseptic technique Entry into genitourinary or biliary tract when urine or bile is infected	7–16
Dirty	Traumatic wound with delayed repair, devitalized tissue, foreign bodies, or fecal contamination Acute inflammation and purulent drainage encountered during procedure	16–29

with low-dose heparin. The stress response that is initiated by surgery inhibits the fibrinolytic system, resulting in blood hypercoagulability. Dehydration, low cardiac output, blood pooling in the extremities, and bed rest add to the risk of thrombosis formation. Although all postoperative patients are at some risk, factors such as a history of thrombosis, malignancy, trauma, obesity, indwelling venous catheters, and hormone (eg, estrogen) use increase the risk. The first symptom of DVT may be a pain or cramp in the calf. Initial pain and tenderness may be followed by a painful swelling of the entire leg, often accompanied by fever, chills, and diaphoresis (Cawley, 2008).

The benefits of early ambulation and leg exercises in preventing DVT cannot be overemphasized, and these activities are recommended for all patients, regardless of their risk. It is important to avoid the use of blanket rolls, pillow rolls, or any form of elevation that can constrict vessels under the knees. Even prolonged “dangling” (having the patient sit on the edge of the bed with legs hanging over the side) can be dangerous and is not recommended in susceptible patients because pressure under the knees can impede circulation. Adequate hydration is also encouraged; the patient can be offered juices and water throughout the day to avoid dehydration. Refer to Chapter 31 for a complete discussion of DVT and to Chapter 23 for discussion of PE.

HEMATOMA. At times, concealed bleeding occurs beneath the skin at the surgical site. This hemorrhage usually stops spontaneously but results in clot (hematoma) formation within the wound. If the clot is small, it will be absorbed and need not be treated. If the clot is large, the wound usually bulges somewhat, and healing will be delayed unless the clot is removed. After several sutures are removed by the physician, the clot is evacuated and the wound is packed lightly with gauze. Healing occurs usually by granulation, or a secondary closure may be performed.

INFECTION (WOUND SEPSIS). The creation of a surgical wound disrupts the integrity of the skin, bypassing the body’s primary defense and protection against infection.

Exposure of deep body tissues to pathogens in the environment places the patient at risk for infection of the surgical site, and a potentially life-threatening complication such as infection increases hospital length of stay, costs of care, and risk of further complications. It is estimated that 14% to 16% of all health care–associated infections are surgical-site infections and 77% of surgical patients who die do so due to sepsis associated with infections (Phillips, 2007).

Multiple factors, including the type of wound, place the patient at risk of infection. Surgical wounds are classified according to the degree of contamination. Table 20-5 defines the terms used to describe surgical wounds and gives the expected rate of wound infection per category. Patient-related factors include age, nutritional status, diabetes, smoking, obesity, remote infections, endogenous mucosal microorganisms, altered immune response, length of preoperative stay, and severity of illness (Phillips, 2007). Factors related to the surgical procedure include the method of preoperative skin preparation, surgical attire of the team, method of sterile draping, duration of surgery, antimicrobial prophylaxis, aseptic technique, factors related to surgical technique, drains or foreign material, OR ventilation, length of procedure, and exogenous micro-organisms. Other risk factors for wound sepsis include wound contamination, foreign body, faulty suturing technique, devitalized tissue, hematoma, debilitation, dehydration, malnutrition, anemia, obesity, shock, duration of surgical procedure, and associated disorders (eg, diabetes mellitus) (Baugh, Zuelaer, Meador, et al., 2007; Litwack, 2006). Efforts to prevent wound infection are directed at reducing risks. Preoperative and intraoperative risks and interventions are discussed in Chapters 18 and 19. Postoperative care of the wound centers on assessing the wound, preventing contamination and infection before wound edges have sealed, and enhancing healing.

Wound infection may not be evident until at least postoperative day 5. Most patients are discharged before that time, and more than half of wound infections are diagnosed after discharge, highlighting the importance of patient education regarding wound care. Signs and symptoms of wound infection include increased pulse rate and

temperature; an elevated white blood cell count; wound swelling, warmth, tenderness, or discharge; and incisional pain. Local signs may be absent if the infection is deep. *Staphylococcus aureus* accounts for many postoperative wound infections. Other infections may result from *Escherichia coli*, *Proteus vulgaris*, *Aerobacter aerogenes*, *Pseudomonas aeruginosa*, and other organisms. Although they are rare, beta-hemolytic streptococcal or clostridial infections can be rapid and deadly and need strict infection control practices to prevent the spread of infection to others. Intensive medical and nursing care is essential if the patient is to survive.

When a wound infection is diagnosed in a surgical incision, the surgeon may remove one or more sutures or staples and, using aseptic precautions, separate the wound edges with a pair of blunt scissors or a hemostat. Once the incision is opened, a drain is inserted. If the infection is deep, an incision and drainage procedure may be necessary. Antimicrobial therapy and a wound care regimen are also initiated.

WOUND DEHISCENCE AND EVISCERATION. Wound dehiscence (disruption of surgical incision or wound) and evisceration (protrusion of wound contents) are serious surgical complications (Fig. 20-6). Dehiscence and evisceration are especially serious when they involve abdominal incisions or wounds. These complications result from sutures giving way, from infection, or, more frequently, from marked distention or strenuous cough. They may also occur because of increasing age, anemia, poor nutritional status, obesity, malignancy, jaundice, diabetes, use of steroids, and gender in patients undergoing abdominal surgery (Hahler, 2006; Hunter, et al., 2007).

When the wound edges separate slowly, the intestines may protrude gradually or not at all, and the earliest sign

may be a gush of bloody (serosanguineous) peritoneal fluid from the wound. When a wound ruptures suddenly, coils of intestine may push out of the abdomen. The patient may report that “something gave way.” The evisceration causes pain and may be associated with vomiting.

NURSING ALERT

If disruption of a wound occurs, the patient is placed in the low Fowler’s position and instructed to lie quietly. These actions minimize protrusion of body tissues. The protruding coils of intestine are covered with sterile dressings moistened with sterile saline solution, and the surgeon is notified at once.

An abdominal binder can provide support and guard against dehiscence and often is used along with the primary dressing, especially in patients with weak or pendulous abdominal walls or when rupture of a wound has occurred (Hahler, 2006).

GERONTOLOGIC CONSIDERATIONS. Elderly patients recover more slowly, have longer hospital stays, and are at greater risk for development of postoperative complications. Delirium, pneumonia, decline in functional ability, exacerbation of comorbid conditions, pressure ulcers, decreased oral intake, GI disturbance, and falls are all threats to recovery in the older adult (Litwack, 2006; Mentis, 2006). Expert nursing care can help the older adult avoid these complications or minimize their effects (Phillips, 2007).

Postoperative delirium, characterized by confusion, perceptual and cognitive deficits, altered attention levels, disturbed sleep patterns, and impaired psychomotor skills, is a significant problem for older adults (Cofer, 2005). Causes of delirium are multifactorial (Chart 20-7). Skilled and frequent assessment of mental status and of all physiologic factors influencing mental status helps the nurse plan for care because delirium may be the initial or only indicator of infection, fluid and electrolyte imbalance, or deterioration of respiratory or hemodynamic status in the elderly patient. Factors that determine whether a patient is at risk for delirium include age, history of alcohol abuse, preoperative cognitive function, physical function, serum chemistries, and type of surgery.

Recognizing postoperative delirium and identifying and treating its underlying cause are the goals of care. Postoperative delirium is sometimes mistaken for preexisting dementia or is attributed to age. In addition to monitoring and managing identifiable causes, the nurse implements supportive interventions. Keeping the patient in a well-lit room and close to the nurses’ station can reduce sensory deprivation. At the same time, distracting and unfamiliar noises should be minimized. Because pain can contribute to postoperative delirium, adequate pain control without oversedation is essential (Phillips, 2007).

The patient is reoriented as often as necessary, and staff should introduce themselves each time they come in contact with the patient. Engaging the patient in conversation

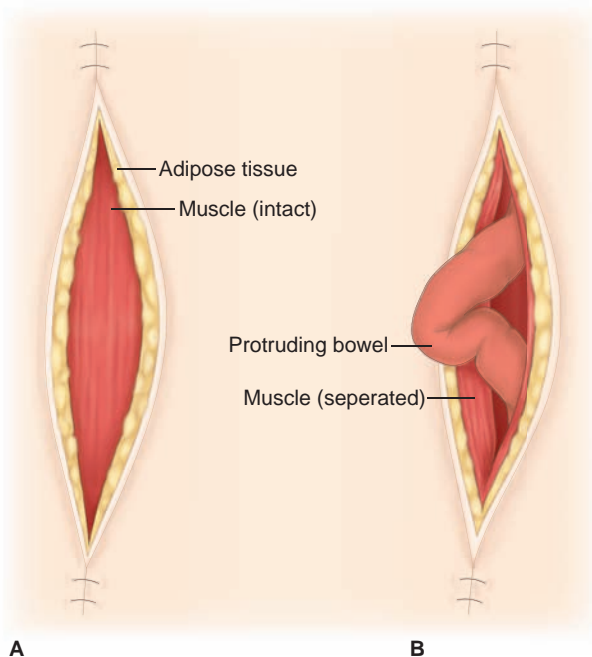

Figure 20-6 A, Wound dehiscence. B, Wound evisceration.

Chart 20-7 • Causes of Postoperative Delirium

- Acid–base disturbances
- Age greater than 80 years

- Unrelieved pain
- Blood loss
- Decreased cardiac output
- Cerebral hypoxia
- Heart failure
- Acute myocardial infarction
- Hypothermia or hyperthermia
- Unfamiliar surroundings and sensory deprivation
- Emergent surgery
- Alcohol withdrawal
- Urinary retention
- Fecal impaction
- Polypharmacy
- Presence of multiple diseases
- Sensory impairments
- High stress or anxiety levels

and care activities and placing a clock and calendar nearby may improve cognitive function. Physical activity should not be neglected while the patient is confused because physical deterioration can worsen delirium and place the patient at increased risk for other complications. Restraints should be avoided because they can worsen confusion. If possible, a family member or staff member is asked to stay with the patient instead. Haloperidol (Haldol) or lorazepam (Ativan) may be administered during episodes of acute confusion, but these medications should be discontinued as soon as possible to avoid side effects.

Other problems confronting the elderly postoperative patient, such as pneumonia, altered bowel function, DVT, weakness, and functional decline, often can be prevented by early and progressive ambulation. Prolonged sitting positions are avoided at they promote venous stasis in the lower extremities. Assistance with ambulation may be required to keep the patient from bumping into objects and falling. A physical therapy referral may be indicated to promote safe, regular exercise for the older adult.

Urinary incontinence can be prevented by providing easy access to the call bell and the commode and by prompting voiding. Early ambulation and familiarity with the room help the patient to become self-sufficient sooner.

Optimal nutritional status is important for wound healing, return of normal bowel function, and fluid and electrolyte balance. The nurse and patient can consult with the dietitian to plan appealing, high-protein meals that provide sufficient fiber, calories, and vitamins. Nutritional supplements, such as

Ensure or Sustacal, may be recommended. Multivitamins, iron, and vitamin C supplements may be prescribed to aid in tissue healing, formation of new red blood cells, and overall nutritional status.

In addition to monitoring and managing physiologic recovery of the older adult, the nurse identifies and addresses psychosocial needs. The older adult may require much encouragement and support to resume activities, and the pace may be slow. Sensory deficits may require frequent repetition of instructions, and decreased physiologic reserve may necessitate frequent rest periods. The older adult may require extensive discharge planning to coordinate both professional and family care providers, and the nurse, social worker, or nurse case manager may institute the plan for continuing care.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patients have always required detailed discharge instructions to become proficient in special self-care needs after surgery; however, shorter hospital stays have increased the amount of information needed while reducing the amount of time in which to provide it. Although needs are specific to individual patients and the procedures they have undergone, general patient education needs for postoperative care have been identified (see Chart 20-3).

CONTINUING CARE. Community-based services are frequently necessary after surgery. Older patients, patients who live alone, patients without family support, and patients with preexisting chronic illness or disabilities are often in greatest need. Planning for discharge involves arranging for necessary services early in the acute care hospitalization for wound care, drain management, catheter care, infusion therapy, and physical or occupational therapy. The home care nurse coordinates these activities and services.

During home care visits, the nurse assesses the patient for postoperative complications by assessment of the surgical incision, respiratory and cardiovascular status, adequacy of pain management, fluid and nutritional status, and the patient's progress in returning to preoperative status. The nurse evaluates the patient's and family's ability to manage dressing changes and drainage systems and other devices and to administer prescribed medications. The nurse may change dressings or catheters if needed. The nurse identifies any additional services that are needed and assists the patient and family to arrange for them. Previous teaching is reinforced, and the patient is reminded to keep follow-up appointments. The patient and family are instructed about signs and symptoms to be reported to the surgeon. In addition, the nurse provides information about how to obtain needed supplies and suggests resources or support groups.

Evaluation**Expected Patient Outcomes**

Expected patient outcomes may include the following:

1. Maintains optimal respiratory function
 - a. Performs deep-breathing exercises

- b. Displays clear breath sounds
 - c. Uses incentive spirometer as prescribed
 - d. Splints incisional site when coughing to reduce pain
2. Indicates that pain is decreased in intensity
 3. Increases activity as prescribed
 - a. Alternates periods of rest and activity
 - b. Progressively increases ambulation
 - c. Resumes normal activities within prescribed time frame
 - d. Performs activities related to self-care
 4. Wound heals without complication
 5. Maintains body temperature within normal limits
 6. Resumes oral intake
 - a. Reports absence of nausea and vomiting
 - b. Eats at least 75% of usual diet
 - c. Is free of abdominal distress and gas pains
 - d. Exhibits normal bowel sounds
 7. Reports resumption of usual bowel elimination pattern
 8. Resumes usual voiding pattern
 9. Is free of injury
 10. Exhibits decreased anxiety
 11. Acquires knowledge and skills necessary to manage therapeutic regimen
 12. Experiences no complications

CRITICAL THINKING EXERCISES

1 EBP A frail 86-year-old woman is admitted to PACU following a hemi-arthroplasty of her right hip. She has a history of osteoporosis. She is complaining of pain and difficulty taking a deep breath. How would you prioritize her needs, and what complications would you anticipate? Develop an evidence-based plan of care for her, addressing priorities from admission to the unit until discharge. What resources would you use to identify the current safe practice guidelines? Identify the criteria used to evaluate the strength of the evidence for these practices.

2 A 36-year-old woman who is obese and has had abdominal surgery is admitted to the phase II PACU. Identify what information is essential to obtain during report from the OR, describe the Aldrete scoring system, and explain how you will know when the patient is ready to be discharged from the PACU.

3 EBP A 45-year-old patient who is a smoker is admitted to the postoperative nursing unit after abdominal surgery and is complaining of severe pain. Develop an evidence-based plan of care for this patient, addressing pain relief from admission to the unit until discharge to home. What resources would you use to identify the current pain relief practices? Identify the criteria used to evaluate the strength of the evidence for these practices.

Gas Exchange and Respiratory Function

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Impaired Cough Reflex

Mr. Lewis, age 57 years, is admitted to the hospital for left lower lobe pneumonia. His vital signs are: Temp 100.6°F; HR 90 and regular; B/P: 142/74; Resp 28. He has a weak cough, diminished breath sounds over the lower left lung field, and coarse rhonchi over the midtracheal area. He can expectorate some sputum, which is thick and grayish-green. He has a history of stroke. Secondary to the stroke he has impaired gag and cough reflexes and mild weakness of the left side. He is allowed food and fluids because he can swallow safely if he uses the chin-tuck maneuver.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
INEFFECTIVE AIRWAY CLEARANCE —Inability to clear secretions or obstructions from the respiratory tract to maintain a clear airway	RESPIRATORY MONITORING —Collection and analysis of patient data to ensure airway patency and adequate gas exchange	RESPIRATORY STATUS: AIRWAY PATENCY —Extent to which the tracheobronchial passages remain open
IMPAIRED GAS EXCHANGE —Excess or deficit in oxygenation and/or carbon dioxide elimination at the alveolar-capillary membrane	AIRWAY MANAGEMENT —Facilitation of patency of air passages	RESPIRATORY STATUS: GAS EXCHANGE —The alveolar exchange of O ₂ and CO ₂ to maintain arterial blood gas concentrations
INEFFECTIVE BREATHING PATTERN —Inspiration and/or expiration that does not provide adequate ventilation	COUGH ENHANCEMENT —Promotion of deep inhalation by the patient with subsequent generation of high intrathoracic pressures and compression of underlying lung parenchyma for the forceful expulsion of air	RESPIRATORY STATUS: VENTILATION —Movement of air in and out of the lungs
RISK FOR ASPIRATION —At risk for entry of gastrointestinal secretions, oropharyngeal secretions, solids, or fluids into tracheobronchial passages	AIRWAY SUCTIONING —Removal of airway secretions by inserting a suction catheter into the patient's oral airway and/or trachea ASPIRATION PRECAUTIONS —Prevention or minimization of risk factors in the patient at risk for aspiration

Assessment of Respiratory Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the structures and functions of the upper and lower respiratory tracts.
- 2 Describe ventilation, perfusion, diffusion, shunting, and the relationship of pulmonary circulation to these processes.
- 3 Discriminate between normal and abnormal breath sounds.
- 4 Use assessment parameters appropriate for determining the characteristics and severity of the major symptoms of respiratory dysfunction.
- 5 Identify the nursing implications of procedures used for diagnostic evaluation of respiratory function.

GLOSSARY

- apnea:** temporary cessation of breathing
- bronchophony:** abnormal increase in clarity of transmitted voice sounds
- bronchoscopy:** direct examination of larynx, trachea, and bronchi using an endoscope
- cilia:** short hairs that provide a constant whipping motion that serves to propel mucus and foreign substances away from the lung toward the larynx
- compliance:** measure of the force required to expand or inflate the lungs
- crackles:** soft, high-pitched, discontinuous popping sounds during inspiration caused by delayed reopening of the airways
- diffusion:** exchange of gas molecules from areas of high concentration to areas of low concentration
- dyspnea:** labored breathing or shortness of breath
- egophony:** abnormal change in tone of voice that is heard when auscultating lungs
- fremitus:** vibrations of speech felt as tremors of chest wall during palpation
- hemoptysis:** expectoration of blood from the respiratory tract
- hypoxemia:** decrease in arterial oxygen tension in the blood
- hypoxia:** decrease in oxygen supply to the tissues and cells
- obstructive sleep apnea:** temporary absence of breathing during sleep secondary to transient upper airway obstruction
- orthopnea:** inability to breathe easily except in an upright position
- oxygen saturation:** percentage of hemoglobin that is bound to oxygen
- physiologic dead space:** portion of the tracheobronchial tree that does not participate in gas exchange
- pulmonary perfusion:** blood flow through the pulmonary vasculature
- respiration:** gas exchange between atmospheric air and the blood and between the blood and cells of the body
- rhonchi:** low-pitched wheezing or snoring sound associated with partial airway obstruction, heard on chest auscultation
- stridor:** harsh high-pitched sound heard on inspiration, usually without need of stethoscope, secondary to upper airway obstruction
- tachypnea:** abnormally rapid respirations
- tidal volume:** volume of air inspired and expired with each breath during normal breathing
- ventilation:** movement of air in and out of airways
- wheezes:** continuous musical sounds associated with airway narrowing or partial obstruction

Disorders of the respiratory system are common and are encountered by nurses in every setting from the community to the intensive care unit. Expert assessment skills must be developed and used to provide the best care for patients with acute and chronic respiratory problems. In order to differentiate between normal and abnormal assessment findings, an understanding of respiratory function and the significance of abnormal diagnostic test results is essential.

Anatomic and Physiologic Overview

The respiratory system is composed of the upper and lower respiratory tracts. Together, the two tracts are responsible for **ventilation** (movement of air in and out of the airways). The upper respiratory tract, known as the upper airway, warms and filters inspired air so that the lower respiratory tract (the lungs) can accomplish gas exchange. Gas exchange involves delivering oxygen to the tissues through the bloodstream and expelling waste gases, such as carbon dioxide, during expiration. The respiratory system works in concert with the cardiovascular system; the respiratory system is responsible for ventilation and diffusion, and the cardiovascular system is responsible for perfusion (Farquhar & Fantasia, 2005).

Anatomy of the Respiratory System

Upper Respiratory Tract

Upper airway structures consist of the nose, sinuses and nasal passages, pharynx, tonsils and adenoids, larynx, and trachea.

Nose

The nose serves as a passageway for air to pass to and from the lungs. It filters impurities and humidifies and warms the air as it is inhaled. The nose is composed of an external and an internal portion. The external portion protrudes from the face and is supported by the nasal bones and cartilage. The anterior nares (nostrils) are the external openings of the nasal cavities.

The internal portion of the nose is a hollow cavity separated into the right and left nasal cavities by a narrow vertical divider, the septum. Each nasal cavity is divided into three passageways by the projection of the turbinates from the lateral walls. The turbinate bones are also called conchae (the name suggested by their shell-like appearance). Because of their curves, these bones increase the mucous membrane surface of the nasal passages and slightly obstruct the air flowing through them (Fig. 21-1).

Air entering the nostrils is deflected upward to the roof of the nose, and it follows a circuitous route before it reaches the nasopharynx. It comes into contact with a large surface of moist, warm, highly vascular, ciliated mucous membrane (called nasal mucosa) that traps practically all the dust and organisms in the inhaled air. The air is moistened, warmed to body temperature, and brought into contact with sensitive nerves. Some of these nerves detect odors; others provoke sneezing to expel irritating dust. Mucus, secreted continuously by goblet cells, covers the surface of the nasal mucosa and is moved back to the nasopharynx by the action of the **cilia** (fine hairs).

Figure 21-1 Cross-section of nasal cavity.

Paranasal Sinuses

The paranasal sinuses include four pairs of bony cavities that are lined with nasal mucosa and ciliated pseudostratified columnar epithelium. These air spaces are connected by a series of ducts that drain into the nasal cavity. The sinuses are named by their location: frontal, ethmoidal, sphenoidal, and maxillary (Fig. 21-2). A prominent function of the sinuses is to serve as a resonating chamber in speech. The sinuses are a common site of infection.

Pharynx, Tonsils, and Adenoids

The pharynx, or throat, is a tubelike structure that connects the nasal and oral cavities to the larynx. It is divided into three regions: nasal, oral, and laryngeal. The nasopharynx is located posterior to the nose and above the soft palate. The oropharynx houses the faucial, or palatine, tonsils. The laryngopharynx extends from the hyoid bone to the cricoid cartilage. The epiglottis forms the entrance to the larynx.

Figure 21-2 The paranasal sinuses.

The adenoids, or pharyngeal tonsils, are located in the roof of the nasopharynx. The tonsils, the adenoids, and other lymphoid tissue encircle the throat. These structures are important links in the chain of lymph nodes guarding the body from invasion by organisms entering the nose and the throat. The pharynx functions as a passageway for the respiratory and digestive tracts.

Larynx

The larynx, or voice organ, is a cartilaginous epithelium-lined structure that connects the pharynx and the trachea. The major function of the larynx is vocalization. It also protects the lower airway from foreign substances and facilitates coughing. It is frequently referred to as the voice box and consists of the following:

- Epiglottis: a valve flap of cartilage that covers the opening to the larynx during swallowing
- Glottis: the opening between the vocal cords in the larynx
- Thyroid cartilage: the largest of the cartilage structures; part of it forms the Adam's apple
- Cricoid cartilage: the only complete cartilaginous ring in the larynx (located below the thyroid cartilage)
- Arytenoid cartilages: used in vocal cord movement with the thyroid cartilage
- Vocal cords: ligaments controlled by muscular movements that produce sounds; located in the lumen of the larynx

Trachea

The trachea, or windpipe, is composed of smooth muscle with C-shaped rings of cartilage at regular intervals. The cartilaginous rings are incomplete on the posterior surface and give firmness to the wall of the trachea, preventing it from collapsing. The trachea serves as the passage between the larynx and the bronchi.

Lower Respiratory Tract

The lower respiratory tract consists of the lungs, which contain the bronchial and alveolar structures needed for gas exchange.

Lungs

The lungs are paired elastic structures enclosed in the thoracic cage, which is an airtight chamber with distensible walls (Fig. 21-3). Ventilation requires movement of the walls of the thoracic cage and of its floor, the diaphragm. The effect of these movements is alternately to increase and decrease the capacity of the chest. When the capacity of the chest is increased, air enters through the trachea (inspiration) because of the lowered pressure within and inflates the lungs. When the chest wall and diaphragm return to their previous positions (expiration), the lungs recoil and force the air out through the bronchi and trachea. Inspiration occurs during the first third of the respiratory cycle, expiration during the later two thirds. The inspiratory phase of respiration normally requires energy; the expiratory phase is normally passive, requiring very little energy.

Figure 21-3 The respiratory system; **A**, upper respiratory structures and the structures of the thorax; **B**, alveoli, **C**, and a horizontal cross-section of the lungs.

In respiratory diseases, such as chronic obstructive pulmonary disease (COPD), expiration requires energy.

Pleura. The lungs and wall of the thorax are lined with a serous membrane called the pleura. The visceral pleura covers the lungs; the parietal pleura lines the thorax. The visceral and parietal pleura and the small amount of pleural fluid between these two membranes serve to lubricate the thorax and lungs and permit smooth motion of the lungs within the thoracic cavity with each breath.

Mediastinum. The mediastinum is in the middle of the thorax, between the pleural sacs that contain the two lungs. It extends from the sternum to the vertebral column and contains all the thoracic tissue outside the lungs (heart, thymus, certain large blood vessels [ie, aorta, vena cava], and esophagus).

Lobes. Each lung is divided into lobes. The right lung has upper, middle, and lower lobes, whereas the left lung consists of upper and lower lobes (Fig. 21-4). Each lobe is further subdivided into two to five segments separated by fissures, which are extensions of the pleura.

Bronchi and Bronchioles. There are several divisions of the bronchi within each lobe of the lung. First are the lobar bronchi (three in the right lung and two in the left lung). Lobar bronchi divide into segmental bronchi (10 on the right and 8 on the left), which are the structures identified when choosing the most effective postural drainage position for a given patient. Segmental bronchi then divide into subsegmental bronchi. These bronchi are surrounded by connective tissue that contains arteries, lymphatics, and nerves.

The subsegmental bronchi then branch into bronchioles, which have no cartilage in their walls. Their patency depends entirely on the elastic recoil of the surrounding smooth muscle and on the alveolar pressure. The bronchioles contain

submucosal glands, which produce mucus that covers the inside lining of the airways. The bronchi and bronchioles are also lined with cells that have surfaces covered with cilia. These cilia create a constant whipping motion that propels mucus and foreign substances away from the lungs toward the larynx.

The bronchioles then branch into terminal bronchioles, which do not have mucus glands or cilia. Terminal bronchioles then become respiratory bronchioles, which are considered to be the transitional passageways between the conducting airways and the gas exchange airways. Up to this point, the conducting airways contain about 150 mL of air in the tracheobronchial tree that does not participate in gas exchange; this is known as **physiologic dead space**. The respiratory bronchioles then lead into alveolar ducts and alveolar sacs and then alveoli. Oxygen and carbon dioxide exchange takes place in the alveoli.

Alveoli. The lung is made up of about 300 million alveoli, which are arranged in clusters of 15 to 20. These alveoli are so numerous that if their surfaces were united to form one sheet, it would cover 70 square meters—the size of a tennis court.

There are three types of alveolar cells. Type I alveolar cells are epithelial cells that form the alveolar walls. Type II alveolar cells are metabolically active. These cells secrete surfactant, a phospholipid that lines the inner surface and prevents alveolar collapse. Type III alveolar cell macrophages are large phagocytic cells that ingest foreign matter (eg, mucus, bacteria) and act as an important defense mechanism.

Function of the Respiratory System

The cells of the body derive the energy they need from the oxidation of carbohydrates, fats, and proteins. As with any type of combustion, this process requires oxygen. Certain vital tissues, such as those of the brain and the heart, cannot

Figure 21-4 Anterior view of the lungs. The lungs consist of five lobes. The right lung has three lobes (upper, middle, lower); the left has two (upper and lower). The lobes are further subdivided by fissures. The bronchial tree, another lung structure, inflates with air to fill the lobes.

survive for long without a continuous supply of oxygen. However, as a result of oxidation in the body tissues, carbon dioxide is produced and must be removed from the cells to prevent the buildup of acid waste products. The respiratory system performs this function by facilitating life-sustaining processes such as oxygen transport, respiration and ventilation, and gas exchange.

Oxygen Transport

Oxygen is supplied to, and carbon dioxide is removed from, cells by way of the circulating blood. Cells are in close contact with capillaries, the thin walls of which permit easy passage or exchange of oxygen and carbon dioxide. Oxygen diffuses from the capillary through the capillary wall to the interstitial fluid. At this point, it diffuses through the membrane of tissue cells, where it is used by mitochondria for cellular respiration. The movement of carbon dioxide occurs by diffusion in the opposite direction—from cell to blood.

Respiration

After these tissue capillary exchanges, blood enters the systemic veins (where it is called venous blood) and travels to the pulmonary circulation. The oxygen concentration in blood within the capillaries of the lungs is lower than in the lungs' air sacs (alveoli). Because of this concentration gradient, oxygen diffuses from the alveoli to the blood. Carbon dioxide, which has a higher concentration in the blood than in the alveoli, diffuses from the blood into the alveoli. Movement of air in and out of the airways (ventilation) continually replenishes the oxygen and removes the carbon dioxide from the airways and lungs. This whole process of gas exchange between the atmospheric air and the blood and between the blood and cells of the body is called **respiration**.

Ventilation

During inspiration, air flows from the environment into the trachea, bronchi, bronchioles, and alveoli. During expiration, alveolar gas travels the same route in reverse.

Physical factors that govern air flow in and out of the lungs are collectively referred to as the mechanics of ventilation and include air pressure variances, resistance to air flow, and lung compliance.

Air Pressure Variances

Air flows from a region of higher pressure to a region of lower pressure. During inspiration, movement of the diaphragm and other muscles of respiration enlarges the thoracic cavity and thereby lowers the pressure inside the thorax to a level below that of atmospheric pressure. As a result, air is drawn through the trachea and bronchi into the alveoli. During expiration, the diaphragm relaxes and the lungs recoil, resulting in a decrease in the size of the thoracic cavity. The alveolar pressure then exceeds atmospheric pressure, and air flows from the lungs into the atmosphere.

Airway Resistance

Resistance is determined chiefly by the radius or size of the airway through which the air is flowing. Any process that changes the bronchial diameter or width affects airway re-

Chart 21-1 • Causes of Increased Airway Resistance

Common phenomena that may alter bronchial diameter, which affects airway resistance, include the following:

- Contraction of bronchial smooth muscle—as in asthma
- Thickening of bronchial mucosa—as in chronic bronchitis
- Obstruction of the airway—by mucus, a tumor, or a foreign body
- Loss of lung elasticity—as in emphysema, which is characterized by connective tissue encircling the airways, thereby keeping them open during both inspiration and expiration

sistance and alters the rate of air flow for a given pressure gradient during respiration (Chart 21-1). With increased resistance, greater-than-normal respiratory effort is required to achieve normal levels of ventilation.

Compliance

Compliance, or distensibility, is the elasticity and expandability of the lungs and thoracic structures. Compliance allows the lung volume to increase when the difference in pressure between the atmosphere and thoracic cavity (pressure gradient) causes air to flow in. Factors that determine lung compliance are the surface tension of the alveoli (normally low with the presence of surfactant) and the connective tissue (ie, collagen and elastin) of the lungs.

Compliance is determined by examining the volume–pressure relationship in the lungs and the thorax. Compliance is normal (1.0 L/cm H₂O) if the lungs and thorax easily stretch and distend when pressure is applied. High or increased compliance occurs if the lungs have lost their elasticity and the thorax is overdistended (eg, in emphysema). Low or decreased compliance occurs if the lungs and thorax are “stiff.” Conditions associated with decreased compliance include morbid obesity, pneumothorax, hemothorax, pleural effusion, pulmonary edema, atelectasis, pulmonary fibrosis, and acute respiratory distress syndrome (ARDS), which are discussed in later chapters in this unit. Measurement of compliance is one method used to assess the progression and improvement in patients with ARDS. Lungs with decreased compliance require greater-than-normal energy expenditure by the patient to achieve normal levels of ventilation. Compliance is usually measured under static conditions.

Lung Volumes and Capacities

Lung function, which reflects the mechanics of ventilation, is viewed in terms of lung volumes and lung capacities. Lung volumes are categorized as tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume. Lung capacity is evaluated in terms of vital capacity, inspiratory capacity, functional residual capacity, and total lung capacity. These terms are described in Table 21-1.

Pulmonary Diffusion and Perfusion

Diffusion is the process by which oxygen and carbon dioxide are exchanged at the air–blood interface. The alveolar–capillary membrane is ideal for diffusion because of its

Table 21-1 LUNG VOLUMES AND LUNG CAPACITIES

Term	Symbol	Description	Normal Value*	Significance
Lung Volumes				
Tidal volume	VT or TV	The volume of air inhaled and exhaled with each breath	500 mL or 5–10 mL/kg	The tidal volume may not vary, even with severe disease.
Inspiratory reserve volume	IRV	The maximum volume of air that can be inhaled after a normal inhalation	3000 mL	
Expiratory reserve volume	ERV	The maximum volume of air that can be exhaled forcibly after a normal exhalation	1100 mL	Expiratory reserve volume is decreased with restrictive conditions, such as obesity, ascites, pregnancy.
Residual volume	RV	The volume of air remaining in the lungs after a maximum exhalation	1200 mL	Residual volume may be increased with obstructive disease.
Lung Capacities				
Vital capacity	VC	The maximum volume of air exhaled from the point of maximum inspiration $VC = TV + IRV + ERV$	4600 mL	A decrease in vital capacity may be found in neuromuscular disease, generalized fatigue, atelectasis, pulmonary edema, COPD, and obesity.
Inspiratory capacity	IC	The maximum volume of air inhaled after normal expiration $IC = TV + IRV$	3500 mL	A decrease in inspiratory capacity may indicate restrictive disease. May also be decreased in obesity.
Functional residual capacity	FRC	The volume of air remaining in the lungs after a normal expiration $FRV = ERV + RV$	2300 mL	Functional residual capacity may be increased with COPD and decreased in ARDS and obesity.
Total lung capacity	TLC	The volume of air in the lungs after a maximum inspiration $TLC = TV + IRV + ERV + RV$	5800 mL	Total lung capacity may be decreased with restrictive disease (atelectasis, pneumonia) and increased in COPD.

* Values for healthy men; women are 20–25% less.

ARDS, acute respiratory distress syndrome; COPD, chronic obstructed pulmonary disease.

thinness and large surface area. In the normal healthy adult, oxygen and carbon dioxide travel across the alveolar-capillary membrane without difficulty as a result of differences in gas concentrations in the alveoli and capillaries.

Pulmonary perfusion is the actual blood flow through the pulmonary circulation. The blood is pumped into the lungs by the right ventricle through the pulmonary artery. The pulmonary artery divides into the right and left branches to supply both lungs. These two branches divide further to supply all parts of each lung. Normally about 2% of the blood pumped by the right ventricle does not perfuse the alveolar capillaries. This shunted blood drains into the left side of the heart without participating in alveolar gas exchange.

The pulmonary circulation is considered a low-pressure system because the systolic blood pressure in the pulmonary artery is 20 to 30 mm Hg and the diastolic pressure is 5 to 15 mm Hg. Because of these low pressures, the pulmonary vasculature normally can vary its capacity to accommodate the blood flow it receives. However, when a person is in an upright position, the pulmonary artery pressure is not great enough to supply blood to the apex of the lung against the force of gravity. Thus, when a person is upright, the lung may be considered to be divided into three sections: an upper part with poor blood supply, a lower part with maximal blood supply, and a section between the two with an intermediate supply of blood. When a person who

is laying down turns to one side, more blood passes to the dependent lung.

Perfusion is also influenced by alveolar pressure. The pulmonary capillaries are sandwiched between adjacent alveoli. If the alveolar pressure is sufficiently high, the capillaries are squeezed. Depending on the pressure, some capillaries completely collapse, whereas others narrow.

Pulmonary artery pressure, gravity, and alveolar pressure determine the patterns of perfusion. In lung disease, these factors vary, and the perfusion of the lung may become very abnormal.

Ventilation and Perfusion Balance and Imbalance

Adequate gas exchange depends on an adequate ventilation-perfusion (\dot{V}/\dot{Q}) ratio. In different areas of the lung, the (\dot{V}/\dot{Q}) ratio varies. Alterations in perfusion may occur with a change in the pulmonary artery pressure, alveolar pressure, or gravity. Airway blockages, local changes in compliance, and gravity may alter ventilation.

(\dot{V}/\dot{Q}) imbalance occurs as a result of inadequate ventilation, inadequate perfusion, or both. There are four possible (\dot{V}/\dot{Q}) states in the lung: normal (\dot{V}/\dot{Q}) ratio, low (\dot{V}/\dot{Q}) ratio (shunt), high (\dot{V}/\dot{Q}) ratio (dead space), and absence of ventilation and perfusion (silent unit) (Chart 21-2). (\dot{V}/\dot{Q}) imbalance causes shunting of blood, resulting in **hypoxia** (low level of cellular oxygen). Shunting appears to be the main cause of hypoxia after thoracic or abdominal surgery

Chart 21-2 • Ventilation-Perfusion Ratios

Normal Ratio (A)

In the healthy lung, a given amount of blood passes an alveolus and is matched with an equal amount of gas (A). The ratio is 1:1 (ventilation matches perfusion).

Low Ventilation-Perfusion Ratio: Shunts (B)

Low ventilation-perfusion states may be called shunt-producing disorders. When perfusion exceeds ventilation, a shunt exists (B). Blood bypasses the alveoli without gas exchange occurring. This is seen with obstruction of the distal airways, such as with pneumonia, atelectasis, tumor, or a mucus plug.

High Ventilation-Perfusion Ratio: Dead Space (C)

When ventilation exceeds perfusion, dead space results (C). The alveoli do not have an adequate blood supply for gas exchange to occur. This is characteristic of a variety of disorders, including pulmonary emboli, pulmonary infarction, and cardiogenic shock.

Silent Unit (D)

In the absence of both ventilation and perfusion or with limited ventilation and perfusion, a condition known as a silent unit occurs (D). This is seen with pneumothorax and severe acute respiratory distress syndrome.

and most types of respiratory failure. Severe hypoxia results when the amount of shunting exceeds 20%. Supplemental oxygen may eliminate hypoxia, depending on the type of (\dot{V}/\dot{Q}) imbalance.

Gas Exchange

Partial Pressure of Gases

The air we breathe is a gaseous mixture consisting mainly of nitrogen (78.6%) and oxygen (20.8%), with traces of carbon dioxide (0.04%), water vapor (0.05%), helium, and argon. The atmospheric pressure at sea level is about 760 mm Hg. Partial pressure is the pressure exerted by each type of gas in a mixture of gases. The partial pressure of a gas is proportional to the concentration of that gas in the mixture. The total pressure exerted by the gaseous mixture, whether in the atmosphere or in the lungs, is equal to the sum of the partial pressures.

Based on these facts, the partial pressures of nitrogen and oxygen can be calculated. The partial pressure of nitrogen in the atmosphere at sea level is 78.6% of 760, or 597 mm Hg; that of oxygen is 20.8% of 760, or 158 mm Hg. Chart 21-3 identifies and defines terms and abbreviations related to partial pressure of gases.

Once the air enters the trachea, it becomes fully saturated with water vapor, which displaces some of the other gases. Water vapor exerts a pressure of 47 mm Hg when it fully saturates a mixture of gases at the body temperature of 37°C (98.6°F). Nitrogen and oxygen are responsible for almost all of the remaining 713 mm Hg pressure. Once this mixture enters the alveoli, it is further diluted by carbon dioxide. In the alveoli, the water vapor continues to exert a pressure of 47 mm Hg. The remaining 713 mm Hg pressure is now exerted as follows: nitrogen, 569 mm Hg (74.9%); oxygen, 104 mm Hg (13.6%); and carbon dioxide, 40 mm Hg (5.3%).

Chart 21-3 • Partial Pressure Abbreviations

P	= pressure
PO ₂	= partial pressure of oxygen
PCO ₂	= partial pressure of carbon dioxide
PAO ₂	= partial pressure of alveolar oxygen
PACO ₂	= partial pressure of alveolar carbon dioxide
PaO ₂	= partial pressure of arterial oxygen
PaCO ₂	= partial pressure of arterial carbon dioxide
PvO ₂	= partial pressure of venous oxygen
PvCO ₂	= partial pressure of venous carbon dioxide
P ₅₀	= partial pressure of oxygen when the hemoglobin is 50% saturated

When a gas is exposed to a liquid, the gas dissolves in the liquid until an equilibrium is reached. The dissolved gas also exerts a partial pressure. At equilibrium, the partial pressure of the gas in the liquid is the same as the partial pressure of the gas in the gaseous mixture. Oxygenation of venous blood in the lung illustrates this point. In the lung, venous blood and alveolar oxygen are separated by a very thin alveolar membrane. Oxygen diffuses across this membrane to dissolve in the blood until the partial pressure of oxygen in the blood is the same as that in the alveoli (104 mm Hg). However, because carbon dioxide is a by-product of oxidation in the cells, venous blood contains carbon dioxide at a higher partial pressure than that in the alveolar gas. In the lung, carbon dioxide diffuses out of venous blood into the alveolar gas. At equilibrium, the partial pressure of carbon dioxide in the blood and in alveolar gas is the same (40 mm Hg). The changes in partial pressure are shown in Figure 21-5.

Effects of Pressure on Oxygen Transport

Oxygen and carbon dioxide are transported simultaneously either dissolved in blood or combined with hemoglobin in red blood cells. Each 100 mL of normal arterial blood car-

ries 0.3 mL of oxygen physically dissolved in the plasma and 20 mL of oxygen in combination with hemoglobin. Large amounts of oxygen can be transported in the blood because oxygen combines easily with hemoglobin to form oxyhemoglobin:

The volume of oxygen physically dissolved in the plasma is measured by the partial pressure of oxygen in the arteries (PaO₂). The higher the PaO₂, the greater the amount of oxygen dissolved. For example, at a PaO₂ of 10 mm Hg, 0.03 mL of oxygen is dissolved in 100 mL of plasma. At PaO₂ of 20 mm Hg, twice this amount is dissolved in plasma, and at PaO₂ of 100 mm Hg, 10 times this amount is dissolved. Therefore, the amount of dissolved oxygen is directly proportional to the partial pressure, regardless of how high the oxygen pressure becomes.

The amount of oxygen that combines with hemoglobin depends on both the amount of hemoglobin in the blood and on PaO₂, but only up to a PaO₂ of about 150 mm Hg. This is measured as O₂ saturation (SaO₂), the percentage of the O₂ that could be carried if all the hemoglobin held the maximum possible amount of O₂. When the PaO₂ is 150 mm Hg, hemoglobin is 100% saturated and does not combine with any additional oxygen. When hemoglobin is 100% saturated, 1 g of hemoglobin combines with 1.34 mL of oxygen. Therefore, in a person with 14 g/dL of hemoglobin, each 100 mL of blood contains about 19 mL of oxygen associated with hemoglobin. If the PaO₂ is less than 150 mm Hg, the percentage of hemoglobin saturated with oxygen decreases. For example, at a PaO₂ of 100 mm Hg (normal value), saturation is 97%; at a PaO₂ of 40 mm Hg, saturation is 70%.

Oxyhemoglobin Dissociation Curve

The oxyhemoglobin dissociation curve (Chart 21-4) shows the relationship between the partial pressure of oxygen (PaO₂) and the percentage of saturation of oxygen (SaO₂). The percentage of saturation can be affected by carbon dioxide, hydrogen ion concentration, temperature, and 2,3-diphosphoglycerate. An increase in these factors shifts the curve to the right, so that less oxygen is picked up in the lungs, but more oxygen is released to the tissues, if PaO₂ is unchanged. A decrease in these factors causes the curve to shift to the left, making the bond between oxygen and hemoglobin stronger. If the PaO₂ is still unchanged, more oxygen is picked up in the lungs, but less oxygen is given up to the tissues. The unusual shape of the oxyhemoglobin dissociation curve is a distinct advantage to the patient for two reasons:

1. If the PaO₂ decreases from 100 to 80 mm Hg as a result of lung disease or heart disease, the hemoglobin of the arterial blood remains almost maximally saturated (94%), and the tissues do not suffer from hypoxia.
2. When the arterial blood passes into tissue capillaries and is exposed to the tissue tension of oxygen (about 40 mm Hg), hemoglobin gives up large quantities of oxygen for use by the tissues.

With a normal value for PaO₂ (80 to 100 mm Hg) and SaO₂ (95% to 98%), there is a 15% margin of excess oxygen

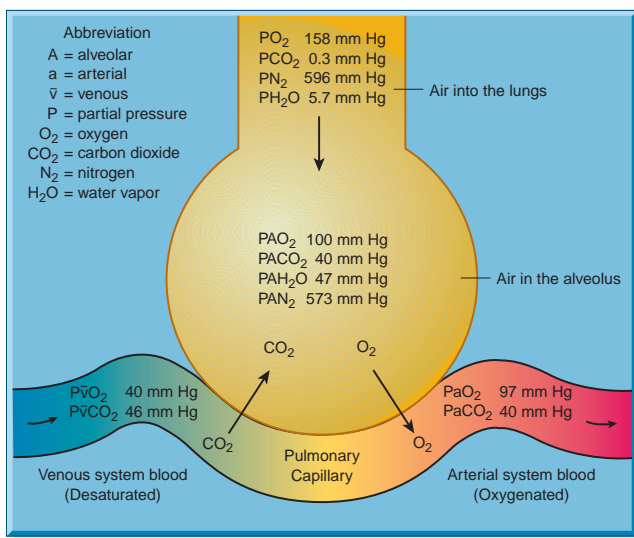

Figure 21-5 Changes occur in the partial pressure of gases during respiration. These values vary as a result of the exchange of oxygen and carbon dioxide and the changes that occur in their partial pressures as venous blood flows through the lungs.

Chart 21-4 • Oxyhemoglobin Dissociation Curve

The oxyhemoglobin dissociation curve is marked to show three oxygen levels:

1. Normal levels— PaO_2 above 70 mm Hg
 2. Relatively safe levels— PaO_2 45 to 70 mm Hg
 3. Dangerous levels— PaO_2 below 40 mm Hg
- The normal (middle) curve (N) shows that 75% saturation occurs at a PaO_2 of 40 mm Hg. If the curve shifts to the right (R), the same saturation (75%) occurs at the higher PaO_2 of 57 mm Hg. If the curve shifts to the left (L), 75% saturation occurs at a PaO_2 of 25 mm Hg.

available to the tissues. With a normal hemoglobin level of 15 mg/dL and a PaO_2 level of 40 mm Hg (SaO_2 75%), there is adequate oxygen available for the tissues but no reserve for physiologic stresses that increase tissue oxygen demand. If a serious incident occurs (eg, bronchospasm, aspiration, hypotension, or cardiac dysrhythmias) that reduces the intake of oxygen from the lungs, tissue hypoxia results.

An important consideration in the transport of oxygen is cardiac output, which determines the amount of oxygen delivered to the body and affects lung and tissue perfusion. If the cardiac output is normal (5 L/min), the amount of oxygen delivered to the body per minute is normal. Under normal conditions, only 250 mL of oxygen is used per minute, which is approximately 25% of available oxygen. The rest of the oxygen returns to the right side of the heart, and the PaO_2 of venous blood drops from 80 to 100 mm Hg to about 40 mm Hg. If cardiac output falls, however, the amount of oxygen delivered to the tissues also falls and may be inadequate to meet the body's needs.

Carbon Dioxide Transport

At the same time that oxygen diffuses from the blood into the tissues, carbon dioxide diffuses from tissue cells to blood and is transported to the lungs for excretion. The amount of carbon dioxide in transit is one of the major determinants of the acid–base balance of the body. Normally, only 6% of the venous carbon dioxide is removed in the lungs, and enough remains in the arterial blood to exert a pressure of

40 mm Hg. Most of the carbon dioxide (90%) is carried by red blood cells; the small portion (5%) that remains dissolved in the plasma (partial pressure of carbon dioxide [PCO_2]) is the critical factor that determines carbon dioxide movement in or out of the blood.

Although the many processes involved in respiratory gas transport seem to occur in intermittent stages, the changes are rapid, simultaneous, and continuous.

Neurologic Control of Ventilation

Resting respiration is the result of cyclic excitation of the respiratory muscles by the phrenic nerve. The rhythm of breathing is controlled by respiratory centers in the brain. The inspiratory and expiratory centers in the medulla oblongata and pons control the rate and depth of ventilation to meet the body's metabolic demands.

The apneustic center in the lower pons stimulates the inspiratory medullary center to promote deep, prolonged inspirations. The pneumotaxic center in the upper pons is thought to control the pattern of respirations.

Several groups of receptor sites assist in the brain's control of respiratory function. The central chemoreceptors, located in the medulla, respond to chemical changes in the cerebrospinal fluid, which result from chemical changes in the blood. These receptors respond to an increase or decrease in the pH and convey a message to the lungs to change the depth and then the rate of ventilation to correct the imbalance. The peripheral chemoreceptors are located in the aortic arch and the carotid arteries and respond first to changes in PaO_2 , then to partial pressure of carbon dioxide (PaCO_2) and pH. The Hering-Breuer reflex is activated by stretch receptors in the alveoli. When the lungs are distended, inspiration is inhibited; as a result, the lungs do not become overdistended. In addition, proprioceptors in the muscles and joints respond to body movements, such as exercise, causing an increase in ventilation. Thus, range-of-motion exercises in an immobile patient stimulate breathing. Baroreceptors, also located in the aortic and carotid bodies, respond to an increase or decrease in arterial blood pressure and cause reflex hypoventilation or hyperventilation.

**Gerontologic Considerations**

A gradual decline in respiratory function begins in early to middle adulthood and affects the structure and function of the respiratory system. The vital capacity of the lungs and strength of the respiratory muscles peak between 20 and 25 years of age and decrease thereafter. With aging (40 years and older), changes occur in the alveoli that reduce the surface area available for the exchange of oxygen and carbon dioxide. At approximately 50 years of age, the alveoli begin to lose elasticity. A decrease in vital capacity occurs with loss of chest wall mobility, which restricts the tidal flow of air. The amount of respiratory dead space increases with age. These changes result in a decreased diffusion capacity for oxygen with increasing age, producing lower oxygen levels in the arterial circulation. Elderly people have a decreased ability to rapidly move air in and out of the lungs.

Gerontologic changes in the respiratory system are summarized in Table 21-2. Despite these changes, in the absence of chronic pulmonary disease, elderly people are able

to carry out activities of daily living, but they may have decreased tolerance for, and require additional rest after, prolonged or vigorous activity.

Assessment

Health History

The health history focuses on the physical and functional problems and the effects of these problems on the patient, including the ability to carry out activities of daily living. Several common symptoms related to the respiratory system are discussed in detail below. If the patient is experiencing severe dyspnea, the nurse may need to modify or abbreviate the questions asked and the timing of the health history to avoid increasing the patient's breathlessness and anxiety.

In addition to identifying the chief reason why the patient is seeking health care, the nurse tries to determine when the health problem or symptom started, how long it lasted, if it was relieved at any time, and how relief was obtained. The nurse obtains information about precipitating factors, duration, severity, and associated factors or symptoms.

Common Symptoms

The major signs and symptoms of respiratory disease are dyspnea, cough, sputum production, chest pain, wheezing, and hemoptysis. The nurse also assesses the impact of signs and symptoms on the patient's ability to perform activities of daily living and to participate in usual work and family activities.

Dyspnea

Dyspnea (subjective feeling of difficult or labored breathing, breathlessness, shortness of breath) is a symptom common to many pulmonary and cardiac disorders, particularly when there is decreased lung compliance or increased airway resistance. The right ventricle of the heart is affected ultimately by lung disease because it must pump blood through the lungs against greater resistance. Dyspnea may also be associated with neurologic or neuromuscular disorders (eg, myasthenia gravis, Guillain-Barré syndrome, muscular dystrophy, postpolio syndrome) that affect respiratory function. Dyspnea can also occur after physical exercise in people without disease (Davis & Holliday, 2005; Porth & Matfin, 2009). It is also common at the end of life in patients with a variety of disorders.

In general, acute diseases of the lungs produce a more severe grade of dyspnea than do chronic diseases. Sudden dyspnea in a healthy person may indicate pneumothorax (air in the pleural cavity), acute respiratory obstruction, allergic reaction, or myocardial infarction. In immobilized patients, sudden dyspnea may denote pulmonary embolism. Dyspnea and **tachypnea** accompanied by progressive hypoxemia in a person who has recently experienced lung trauma, shock, cardiopulmonary bypass, or multiple blood transfusions may signal acute respiratory distress syndrome (ARDS). **Orthopnea** (inability to breathe easily except in an upright position) may be found in patients with heart disease and occasionally in patients with COPD; dyspnea with an expiratory wheeze occurs with COPD. Noisy breathing may result from a narrowing of the airway or localized obstruction of a major bronchus by a tumor or foreign body. The high-pitched

sound heard (usually on inspiration) when someone is breathing through a partially blocked upper airway is called **stridor**. The presence of both inspiratory and expiratory wheezing usually signifies asthma if the patient does not have heart failure. Because dyspnea can occur with other disorders (eg, cardiac disease, anaphylactic reactions, severe anemia), these disorders also need to be considered when obtaining the patient's health history (Davis & Holliday, 2005).

The circumstance that produces the dyspnea must be determined. Therefore, it is important to ask the patient the following questions:

- How much exertion triggers shortness of breath? Does it occur at rest? With exercise? Running? Climbing stairs?
- Is there an associated cough?
- Is the shortness of breath related to other symptoms?
- Was the onset of shortness of breath sudden or gradual?
- At what time of day or night does the shortness of breath occur?
- Is the shortness of breath worse when laying flat?
- Is the shortness of breath worse while walking? If so, when walking how far? How fast?
- How severe is the shortness of breath? On a scale of 1 to 10, if 1 is breathing without any effort and 10 is breathing that is as difficult as it could possibly be, how hard is it to breathe?

It is especially important to assess the patient's rating of the intensity of breathlessness, the effort required to breathe, and the severity of the breathlessness or dyspnea. Patients use a variety of terms and phrases to describe breathlessness, and the nurse needs to clarify what terms are most familiar to the patient and what these terms mean. Visual analogue or other scales can be used to assess changes in the severity of dyspnea over time (Dorman, Byrne & Edwards, 2007; Porth & Matfin, 2009).

Cough

Cough is a reflex that protects the lungs from the accumulation of secretions or the inhalation of foreign bodies. Its presence or absence can be a diagnostic clue because some disorders cause coughing and others suppress it. The cough reflex may be impaired by weakness or paralysis of the respiratory muscles, prolonged inactivity, the presence of a nasogastric tube, or depressed function of the medullary centers in the brain (eg, anesthesia, brain disorders) (Irwin, Baumann, Bolser, et al., 2006; Porth & Matfin, 2009).

Cough results from irritation of the mucous membranes anywhere in the respiratory tract. The stimulus that produces a cough may arise from an infectious process or from an airborne irritant, such as smoke, smog, dust, or a gas. A persistent and frequent cough can be exhausting and cause pain. Cough may indicate serious pulmonary disease or a variety of other problems as well, including cardiac disease, medication reactions (eg, amiodarone [Cordarone], angiotensin-converting enzyme [ACE] inhibitors), smoking, and gastroesophageal reflux disease (Irwin, et al., 2006).

To help determine the cause of the cough, the nurse describes the cough: dry, hacking, brassy, wheezing, loose, or severe. A dry, irritative cough is characteristic of an upper respiratory tract infection of viral origin, or it may be a side effect of ACE inhibitor therapy. An irritative, high-pitched cough can be caused by laryngotracheitis. A brassy cough is

the result of a tracheal lesion, while a severe or changing cough may indicate bronchogenic carcinoma. Pleuritic chest pain that accompanies coughing may indicate pleural or chest wall (musculoskeletal) involvement.

The nurse inquires about the onset and time of coughing. Coughing at night may indicate the onset of left-sided heart failure or bronchial asthma. A cough in the morning with sputum production may indicate bronchitis. A cough that worsens when the patient is supine suggests postnasal drip (rhinosinusitis). Coughing after food intake may indicate aspiration of material into the tracheobronchial tree. A cough of recent onset is usually from an acute infection.

A persistent cough may affect a patient's quality of life and may produce embarrassment, exhaustion, inability to sleep, and pain. Therefore, the nurse should explore the effect of a chronic cough on the patient and the patient's view about the significance of the cough and its effect on his or her life.

Violent coughing causes bronchial spasm, obstruction, and further irritation of the bronchi and may result in syncope (fainting). A severe, repeated, or uncontrolled cough that is nonproductive is exhausting and potentially harmful.

Sputum Production

A patient who coughs long enough almost invariably produces sputum. Sputum production is the reaction of the lungs to any constantly recurring irritant. It also may be associated with a nasal discharge. The nature of the sputum is often indicative of its cause. A profuse amount of purulent sputum (thick and yellow, green, or rust-colored) or a change in color of the sputum is a common sign of a bacterial infection. Thin, mucoid sputum frequently results from viral bronchitis. A gradual increase of sputum over time may occur with chronic bronchitis or bronchiectasis. Pink-tinged mucoid sputum suggests a lung tumor. Profuse, frothy, pink material, often welling up into the throat, may indicate pulmonary edema. Foul-smelling sputum and bad breath point to the presence of a lung abscess, bronchiectasis, or an infection caused by fusospirochetal or other anaerobic organisms.

Chest Pain

Chest pain or discomfort may be associated with pulmonary or cardiac disease. Chest pain associated with pulmonary conditions may be sharp, stabbing, and intermittent, or it may be dull, aching, and persistent. The pain usually is felt on the side where the pathologic process is located, but it may be referred elsewhere—for example, to the neck, back, or abdomen.

Chest pain may occur with pneumonia, pulmonary embolism with lung infarction, pleurisy, or as a late symptom of bronchogenic carcinoma. In carcinoma, the pain may be dull and persistent because the cancer has invaded the chest wall, mediastinum, or spine.

Lung disease does not always cause thoracic pain because the lungs and the visceral pleura lack sensory nerves and are insensitive to pain stimuli. However, the parietal pleura has a rich supply of sensory nerves that are stimulated by inflammation and stretching of the membrane. Pleuritic pain from irritation of the parietal pleura is sharp and seems to "catch" on inspiration; patients often describe it as being

“like the stabbing of a knife.” Patients are more comfortable when they lay on the affected side because this splints the chest wall, limits expansion and contraction of the lung, and reduces the friction between the injured or diseased pleurae on that side. Pain associated with cough may be reduced manually by splinting the rib cage.

The nurse assesses the quality, intensity, and radiation of pain and identifies and explores precipitating factors and their relationship to the patient’s position. In addition, it is important to assess the relationship of pain to the inspiratory and expiratory phases of respiration.

Wheezing

Wheezing is a high-pitched, musical sound heard mainly on expiration (asthma) or inspiration (bronchitis). It is often the major finding in a patient with bronchoconstriction or airway narrowing. **Rhonchi** are low pitched continuous sounds heard over the lungs in partial airway obstruction. Depending on their location and severity, these sounds may be heard with or without a stethoscope.

Hemoptysis

Hemoptysis (expectoration of blood from the respiratory tract) is a symptom of both pulmonary and cardiac disorders. The onset of hemoptysis is usually sudden, and it may be intermittent or continuous. Signs, which vary from blood-stained sputum to a large, sudden hemorrhage, always merit investigation. The most common causes are:

- Pulmonary infection
- Carcinoma of the lung
- Abnormalities of the heart or blood vessels
- Pulmonary artery or vein abnormalities
- Pulmonary embolus and infarction

Diagnostic evaluation to determine the cause includes chest x-ray, chest angiography, and bronchoscopy. A careful history and physical examination are necessary to identify the underlying disorder, irrespective of whether the bleeding involved a small amount of blood in the sputum or a massive hemorrhage. The amount of blood produced is not always proportional to the seriousness of the cause.

First, it is important to determine the source of the bleeding—the gums, nasopharynx, lungs, or stomach. The nurse may be the only witness to the episode. When documenting the bleeding episode, the nurse considers the following points:

- Bloody sputum from the nose or the nasopharynx is usually preceded by considerable sniffing, with blood possibly appearing in the nose.
- Blood from the lung is usually bright red, frothy, and mixed with sputum. Initial symptoms include a tickling sensation in the throat, a salty taste, a burning or bubbling sensation in the chest, and perhaps chest pain, in which case the patient tends to splint the bleeding side. The term hemoptysis is reserved for the coughing up of blood arising from a pulmonary hemorrhage. This blood has an alkaline pH (greater than 7.0).
- If the hemorrhage is in the stomach, the blood is vomited (hematemesis) rather than coughed up. Blood that has been in contact with gastric juice is sometimes so dark that it is referred to as “coffee ground emesis.” This blood has an acid pH (less than 7.0).

Past Health, Family, and Social History

After exploring the current problem, the nurse obtains a brief history of events and conditions that could affect current health status. Specific questions are asked about childhood illnesses, immunizations, chronic medical conditions, injuries, hospitalizations, surgeries, allergies, and current medications (including over-the-counter medications and herbal remedies). Since many lung disorders are related to or exacerbated by tobacco smoke, smoking history (including exposure to second-hand smoke) is also obtained. Smoking history is usually expressed in pack-years, which is number of packs of cigarettes smoked per day times the number of years the patient smoked. It is important to find out if (and when) the patient quit smoking or is still smoking. The nurse assesses for risk factors and genetic factors that may contribute to the patient’s lung condition (Charts 21-5 and 21-6).

In addition, psychosocial factors that may affect the patient are explored (Chart 21-7). These factors include anxiety, role changes, family relationships, financial problems, employment status, and the strategies the patient uses to cope with them. Many respiratory diseases are chronic and progressively debilitating and disabling. It is important that the patient with a respiratory disorder understand the condition and be familiar with necessary self-care interventions. The nurse evaluates these factors over time and provides education as needed.

Physical Assessment of the Respiratory System

General Appearance

The patient’s general appearance may give clues to respiratory status. In particular, the nurse inspects for clubbing of the fingers and notes skin color.

Clubbing of the Fingers

Clubbing of the fingers is a sign of lung disease that is found in patients with chronic hypoxic conditions, chronic lung infections, or malignancies of the lung (Bickley, 2007). This finding may be manifested initially as sponginess of the nail bed and loss of the nail bed angle (Fig. 21-6).

Cyanosis

Cyanosis, a bluish coloring of the skin, is a very late indicator of hypoxia. The presence or absence of cyanosis is determined by the amount of unoxygenated hemoglobin in the blood. Cyanosis appears when there is at least 5 g/dL of unoxygenated hemoglobin. A patient with a hemoglobin

GENETICS IN NURSING PRACTICE

Genetic Influences

Various conditions that affect gas exchange and respiratory function are influenced by genetics factors, including:

- Asthma
- Chronic obstructive pulmonary disease
- Cystic fibrosis
- Alpha-1 antitrypsin deficiency

Nursing Assessments**Family History Assessment**

- Assess family history for other family members with histories of respiratory impairment.
- Assess family history for individuals with early-onset chronic pulmonary disease, family history of hepatic disease in infants (clinical symptoms of alpha-1 antitrypsin deficiency).
- Inquire about family history of genetic cystic fibrosis.

Patient Assessment

- Assess for symptoms such as changes in respiratory status associated with asthma (eg, wheezing, hyperresponsiveness, mucosal edema, and mucus production).
- Assess for multisystem effects characteristic of cystic fibrosis (eg, productive cough, wheezing, obstructive airways disease, gastrointestinal problems including pancreatic insufficiency, clubbing of the fingers).

Management Issues Specific to Genetics

- Inquire whether DNA mutation or other genetic testing has been performed on affected family members.

- Refer for further genetics counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetics testing and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related respiratory disorders.
- Participate in management and coordination of care of patients with genetic conditions, individuals predisposed to develop or pass on a genetic condition.

level of 15 g/dL does not demonstrate cyanosis until 5 g/dL of that hemoglobin becomes unoxygenated, reducing the effective circulating hemoglobin to two thirds of the normal level.

A patient with anemia rarely manifests cyanosis, and a patient with polycythemia may appear cyanotic even if adequately oxygenated. Therefore, cyanosis is *not* a reliable sign of hypoxia.

Assessment of cyanosis is affected by room lighting, the patient's skin color, and the distance of the blood vessels from the surface of the skin. In the presence of a pulmonary condition, central cyanosis is assessed by observing the

color of the tongue and lips. This indicates a decrease in oxygen tension in the blood. Peripheral cyanosis results from decreased blood flow to the body's periphery (fingers, toes, or earlobes), as in vasoconstriction from exposure to cold, and does not necessarily indicate a central systemic problem.

Upper Respiratory Structures

For a routine examination of the upper airway, only a simple light source, such as a penlight, is necessary. A more thorough examination requires the use of a nasal speculum.

CHART
21-7**Assessing for Psychosocial Factors Related to Pulmonary Disease and Respiratory Function**

- What strategies does the patient use to cope with the signs and symptoms and challenges associated with pulmonary disease?
- What effect has the pulmonary disease had on the patient's quality of life, goals, role within the family, and occupation?
- What changes has the pulmonary disease had on the patient's family and relationships with family members?
- Does the patient exhibit depression, anxiety, anger, hostility, dependency, withdrawal, isolation, avoidance, noncompliance, acceptance, or denial?
- What support systems does the patient use to cope with the illness?
- Are resources (relatives, friends, or community groups) available? Do the patient and family use them effectively?

Figure 21-6 Clubbed finger. In clubbing, the distal phalanx of each finger is rounded and bulbous. The nail plate is more convex, and the angle between the plate and the proximal nail fold increases to 180 degrees or more. The proximal nail fold, when palpated, feels spongy or floating. Among the many causes are chronic hypoxia and lung cancer.

Nose and Sinuses

The nurse inspects the external nose for lesions, asymmetry, or inflammation and then asks the patient to tilt the head backward. Gently pushing the tip of the nose upward, the nurse examines the internal structures of the nose, inspecting the mucosa for color, swelling, exudate, or bleeding. The nasal mucosa is normally redder than the oral mucosa. It may appear swollen and hyperemic if the patient has a common cold, but in allergic rhinitis, the mucosa appears pale and swollen.

Next, the nurse inspects the septum for deviation, perforation, or bleeding. Most people have a slight degree of septal deviation, but actual displacement of the cartilage into either the right or left side of the nose may produce nasal obstruction. Such deviation usually causes no symptoms.

While the head is still tilted back, the nurse inspects the inferior and middle turbinates. In chronic rhinitis, nasal polyps may develop between the inferior and middle turbinates; they are distinguished by their gray appearance. Unlike the turbinates, they are gelatinous and freely movable.

Next, the nurse may palpate the frontal and maxillary sinuses for tenderness (Fig. 21-7). Using the thumbs, the

Figure 21-7 Technique for palpating the frontal sinuses at left and the maxillary sinuses at right.

Figure 21-8 At left, the nurse positions the light source for transillumination of the frontal sinus. At right, the nurse shields the patient's brow and shines the light. In normal conditions (a darkened room), the light should shine through the tissues and appear as a reddish glow (above the nurse's hand) over the sinus.

nurse applies gentle pressure in an upward fashion at the supraorbital ridges (frontal sinuses) and in the cheek area adjacent to the nose (maxillary sinuses). Tenderness in either area suggests inflammation. The frontal and maxillary sinuses can be inspected by transillumination (passing a strong light through a bony area, such as the sinuses, to inspect the cavity; Fig. 21-8). If the light fails to penetrate, the cavity likely contains fluid or pus.

Mouth and Pharynx

After the nasal inspection, the nurse assesses the mouth and pharynx, instructing the patient to open the mouth wide and take a deep breath. Usually this flattens the posterior tongue and briefly allows a full view of the anterior and posterior pillars, tonsils, uvula, and posterior pharynx (see Chapter 35, Fig. 35-2). The nurse inspects these structures for color, symmetry, and evidence of exudate, ulceration, or enlargement. If a tongue blade is needed to depress the tongue to visualize the pharynx, it is pressed firmly beyond the midpoint of the tongue to avoid a gagging response.

Trachea

Next, the position and mobility of the trachea are noted by direct palpation. This is performed by placing the thumb and index finger of one hand on either side of the trachea just above the sternal notch. The trachea is highly sensitive, and palpating too firmly may trigger a coughing or gagging response. The trachea is normally in the midline as it enters the thoracic inlet behind the sternum, but it may be deviated by masses in the neck or mediastinum. Pleural or pulmonary disorders, such as a pneumothorax, may also displace the trachea.

Lower Respiratory Structures and Breathing

Assessment of the lower respiratory structures includes inspection, palpation, percussion, and auscultation of the thorax.

Thoracic Inspection

Inspection of the thorax provides information about the musculoskeletal structure, the patient's nutritional status, and the respiratory system. The nurse observes the skin over the thorax for color and turgor and for evidence of loss of subcutaneous tissue. It is important to note asymmetry, if present. In recording or reporting the findings, anatomic landmarks are used as points of reference (Chart 21-8).

Chest Configuration. Normally, the ratio of the anteroposterior diameter to the lateral diameter is 1:2. However, there are four main deformities of the chest associated with respiratory disease that alter this relationship: barrel chest, funnel chest (pectus excavatum), pigeon chest (pectus carinatum), and kyphoscoliosis.

BARREL CHEST. Barrel chest occurs as a result of overinflation of the lungs. There is an increase in the anteroposterior diameter of the thorax. In a patient with emphysema, the ribs are more widely spaced and the intercostal spaces tend to bulge on expiration. The appearance of the patient with advanced emphysema is thus quite characteristic and often allows the observer to detect its presence easily, even from a distance.

FUNNEL CHEST (PECTUS EXCAVATUM). Funnel chest occurs when there is a depression in the lower portion of the sternum. This may compress the heart and great vessels, resulting in murmurs. Funnel chest may occur with rickets or Marfan's syndrome.

PIGEON CHEST (PECTUS CARINATUM). A pigeon chest occurs as a result of displacement of the sternum. There is an increase in the anteroposterior diameter. This may occur with rickets, Marfan's syndrome, or severe kyphoscoliosis.

KYPHOSCOLIOSIS. Kyphoscoliosis is characterized by elevation of the scapula and a corresponding S-shaped spine. This deformity limits lung expansion within the thorax. It may occur with osteoporosis and other skeletal disorders that affect the thorax.

Breathing Patterns and Respiratory Rates. Observing the rate and depth of respiration is a simple but important aspect of assessment. The normal adult who is resting comfortably takes 12 to 18 breaths per minute. Except for occasional sighs, respirations are regular in depth and rhythm. This normal pattern is described as eupnea. The rate and depth of various patterns of respiration are presented in Table 21-3.

Certain patterns of respiration are characteristic of specific disease states. Respiratory rhythms and their deviation from normal are important observations that the nurse reports and documents. Temporary pauses of breathing, or **apnea**, may be noted. When apneas occur repeatedly during sleep, secondary to transient upper airway blockage, the condition is called **obstructive sleep apnea**. In thin people, it is quite normal to note a slight retraction of the intercostal spaces during quiet breathing. Bulging of the intercostal spaces during expiration implies obstruction of expiratory airflow, as in emphysema. Marked retraction on inspiration, particularly if asymmetric, implies blockage of a branch of the respiratory tree. Asymmetric bulging of the intercostal spaces, on one side or the other, is created by an increase in pressure within the hemithorax. This may be a result of air trapped under pressure within the pleural cavity, where it is not normally present

(pneumothorax), or the pressure of fluid within the pleural space (pleural effusion).

Thoracic Palpation

The nurse palpates the thorax for tenderness, masses, lesions, respiratory excursion, and vocal fremitus. If the patient has reported an area of pain or if lesions are apparent, the nurse performs direct palpation with the fingertips (for skin lesions and subcutaneous masses) or with the ball of the hand (for deeper masses or generalized flank or rib discomfort).

Respiratory Excursion. Respiratory excursion is an estimation of thoracic expansion and may disclose significant information about thoracic movement during breathing. The nurse assesses the patient for range and symmetry of excursion. For anterior assessment, the nurse places the thumbs along the costal margin of the chest wall and instructs the patient to inhale deeply. The nurse observes movement of the thumbs during inspiration and expiration. This movement is normally symmetric (Bickley, 2007).

Posterior assessment is performed by placing the thumbs adjacent to the spinal column at the level of the tenth rib (Fig. 21-9). The hands lightly grasp the lateral rib cage. Sliding the thumbs medially about 2.5 cm (1 inch) raises a small skin fold between the thumbs. The patient is instructed to take a full inspiration and to exhale fully. The nurse observes for normal flattening of the skin fold and feels the symmetric movement of the thorax.

Decreased chest excursion may be caused by chronic fibrotic disease. Asymmetric excursion may be due to splinting secondary to pleurisy, fractured ribs, trauma, or unilateral bronchial obstruction (Bickley, 2007).

Tactile Fremitus. Sound generated by the larynx travels distally along the bronchial tree to set the chest wall in resonant motion. This is especially true of consonant sounds. The detection of the resulting vibration on the chest wall by touch is called tactile **fremitus**.

Normal fremitus is widely varied. It is influenced by the thickness of the chest wall, especially if that thickness is muscular. However, the increase in subcutaneous tissue associated with obesity may also affect fremitus. Lower-pitched sounds travel better through the normal lung and produce greater vibration of the chest wall. Therefore, fremitus is more pronounced in men than in women because of the deeper male voice. Normally, fremitus is most pronounced where the large bronchi are closest to the chest wall and least palpable over the distant lung fields. Therefore, it is most palpable in the upper thorax, anteriorly and posteriorly.

The patient is asked to repeat "ninety-nine" or "one, two, three," or "eee, eee, eee" as the nurse's hands move down the patient's thorax. The vibrations are detected with the palmar surfaces of the fingers and hands, or the ulnar aspect of the extended hands, on the thorax. The hand or hands are moved in sequence down the thorax. Corresponding areas of the thorax are compared (Fig. 21-10). Bony areas are not tested.

Air does not conduct sound well, but a solid substance such as tissue does, provided that it has elasticity and is not compressed. Therefore, an increase in solid tissue per unit volume of lung enhances fremitus, and an increase in air per unit volume of lung impedes sound. Patients with emphysema, which results in the rupture of alveoli and trapping of air, exhibit almost no tactile fremitus. A patient with consolidation of a

Chart 21-8 • Locating Thoracic Landmarks

With respect to the thorax, location is defined both horizontally and vertically. With respect to the lungs, location is defined by lobe.

Horizontal Reference Points

Horizontally, thoracic locations are identified according to their proximity to the rib or the intercostal space under the examiner's fingers. On the anterior surface, identification of a specific rib is facilitated by first locating the angle of Louis. This is where the manubrium joins the body of the sternum in the midline. The second rib joins the sternum at this prominent landmark.

Other ribs may be identified by counting down from the second rib. The intercostal spaces are referred to in terms of the rib immediately above the intercostal space; for example, the fifth intercostal space is directly below the fifth rib.

Locating ribs on the posterior surface of the thorax is more difficult. The first step is to identify the spinous process. This is accomplished by finding the seventh cervical vertebra (*vertebra prominens*), which is the most prominent spinous process. When the neck is slightly flexed, the seventh cervical spinous process stands out. Other vertebrae are then identified by counting downward.

Vertical Reference Points

Several imaginary lines are used as vertical referents or landmarks to identify the location of thoracic findings. The *midsternal line* passes through the center of the sternum. The *midclavicular line* is an imaginary line that descends from the middle of the clavicle. The *point of*

maximal impulse of the heart normally lies along this line on the left thorax.

When the arm is abducted from the body at 90 degrees, imaginary vertical lines may be drawn from the anterior axillary fold, from the middle of the axilla, and from the posterior axillary fold. These lines are called, respectively, the *anterior axillary line*, the *midaxillary line*, and the *posterior axillary line*. A line drawn vertically through the superior and inferior poles of the scapula is called the *scapular line*, and a line drawn down the center of the vertebral column is called the *vertebral line*. Using these landmarks, for example, the examiner communicates findings by referring to an area of dullness extending from the vertebral to the scapular line between the seventh and tenth ribs on the right.

Lobes of the Lungs

The lobes of the lung may be mapped on the surface of the chest wall in the following manner. The line between the upper and lower lobes on the left begins at the fourth thoracic spinous process posteriorly, proceeds around to cross the fifth rib in the midaxillary line, and meets the sixth rib at the sternum. This line on the right divides the right middle lobe from the right lower lobe. The line dividing the right upper lobe from the middle lobe is an incomplete one that begins at the fifth rib in the midaxillary line, where it intersects the line between the upper and lower lobes and traverses horizontally to the sternum. Thus, the upper lobes are dominant on the anterior surface of the thorax and the lower lobes are dominant on the posterior surface. There is no presentation of the right middle lobe on the posterior surface of the chest.

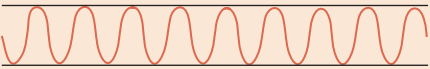

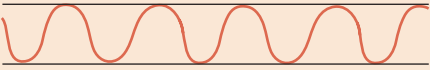

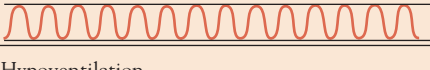

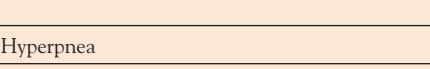

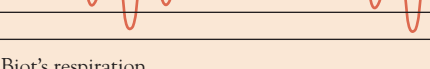

Table 21-3 RATES AND DEPTHS OF RESPIRATION	
Type	Description
Eupnea 	Normal, breathing at 12–18 breaths/min
Bradypnea 	Slower than normal rate (<10 breaths/min), with normal depth and regular rhythm Associated with increased intracranial pressure, brain injury, and drug overdose
Tachypnea 	Rapid, shallow breathing >24 breaths/min Associated with pneumonia, pulmonary edema, metabolic acidosis, septicemia, severe pain, or rib fracture
Hypoventilation 	Shallow, irregular breathing
Hyperpnea 	Increase depth of respirations
Hyperventilation 	Increased rate and depth of breathing that results in decreased PaCO ₂ level Inspiration and expiration are nearly equal in duration Called Kussmaul's respiration if associated with diabetic ketoacidosis or renal origin
Apnea 	Period of cessation of breathing; time duration varies; apnea may occur briefly during other breathing disorders, such as with sleep apnea; life-threatening if sustained
Cheyne-Stokes 	Regular cycle where the rate and depth of breathing increase, then decrease until apnea (usually about 20 seconds) occurs Duration of apnea may vary and progressively lengthen; therefore, it is timed and reported Associated with heart failure and damage to the respiratory center (drug-induced, tumor, trauma)
Biot's respiration 	Periods of normal breathing (3–4 breaths) followed by a varying period of apnea (usually 10–60 seconds) Also called cluster breathing Associated with some nervous system disorders

lobe of the lung from pneumonia has increased tactile fremitus over that lobe. Air in the pleural space does not conduct sound (Bickley, 2007).

Thoracic Percussion

Percussion sets the chest wall and underlying structures in motion, producing audible and tactile vibrations. The nurse uses percussion to determine whether underlying tissues are filled with air, fluid, or solid material. Percussion also is used to estimate the size and location of certain structures within the thorax (eg, diaphragm, heart, liver).

Percussion usually begins with the posterior thorax. Ideally, the patient is in a sitting position with the head flexed forward and the arms crossed on the lap. This position separates the scapulae widely and exposes more lung area for assessment. The nurse percusses across each shoulder top, locating the 5-cm width of resonance overlying the lung apices (Fig. 21-11). Then the nurse proceeds down the posterior thorax, percussing symmetric areas at intervals of 5 to 6 cm (2 to 2.5 inches). The middle finger is positioned parallel to the ribs in the intercostal space; the finger is placed firmly against the chest wall before it is struck with the middle finger of the opposite hand. Bony structures (scapulae or ribs) are not percussed.

Percussion over the anterior chest is performed with the patient in an upright position with shoulders arched backward and arms at the side. The nurse begins in the supraclavicular area and proceeds downward, from one intercostal space to the next. In the female patient, it may be necessary to displace the breasts for an adequate examination. Dullness noted to the left of the sternum between the third and fifth intercostal spaces is a normal finding, because that is the location of the heart. Similarly, there is a normal span of liver dullness in the right thorax, from the fifth intercostal space to the right costal margin at the midclavicular line (Bickley, 2007).

The anterior and lateral thorax is examined with the patient in a supine position. If the patient cannot sit up, percussion of the posterior thorax is performed with the patient positioned on the side.

Dullness over the lung occurs when air-filled lung tissue is replaced by fluid or solid tissue. Table 21-4 reviews percussion sounds and their characteristics.

Diaphragmatic Excursion. The normal resonance of the lung stops at the diaphragm. The position of the diaphragm is different during inspiration and expiration.

Figure 21-9 Method for assessing posterior respiratory excursion. Place both hands posteriorly at the level of T9 or T10. Slide hands medially to pinch a small amount of skin between your thumbs. Observe for symmetry as the patient exhales fully following a deep inspiration.

To assess the position and motion of the diaphragm, the nurse instructs the patient to take a deep breath and hold it while the maximal descent of the diaphragm is percussed. The point at which the percussion note at the midscapular line changes from resonance to dullness is marked with a pen. The patient is then instructed to exhale fully and hold it while the nurse again percusses downward to the dullness of the di-

aphragm. This point is also marked. The distance between the two markings indicates the range of motion of the diaphragm.

Maximal excursion of the diaphragm may be as much as 8 to 10 cm (3 to 4 inches) in healthy, tall young men, but for most people it is usually 5 to 7 cm (2 to 2.75 inches). Normally, the diaphragm is about 2 cm (0.75 inches) higher on the right because of the position of the heart and the liver above and below the left and right segments of the diaphragm, respectively. Decreased diaphragmatic excursion may occur with pleural effusion and emphysema. An increase in intra-abdominal pressure, as in pregnancy, obesity, or ascites, may account for a diaphragm that is positioned high in the thorax (Bickley, 2007).

Thoracic Auscultation

Assessment concludes with auscultation of the anterior, posterior, and lateral thorax. Auscultation is useful in assessing the flow of air through the bronchial tree and in evaluating the presence of fluid or solid obstruction in the lung. The nurse auscultates for normal breath sounds, adventitious sounds, and voice sounds.

The nurse places the diaphragm of the stethoscope firmly against the chest wall as the patient breathes slowly and deeply through the mouth. Corresponding areas of the chest are auscultated in a systematic fashion from the apices to the bases and along midaxillary lines. The sequence of auscultation and the positioning of the patient are similar to those used for percussion. It often is necessary to listen to two full inspirations and expirations at each anatomic location for valid interpretation of the sound heard. Repeated deep breaths may result in symptoms of hyperventilation (eg, lightheadedness); this is avoided by having the patient rest and breathe normally periodically during the examination.

Breath Sounds. Normal breath sounds are distinguished by their location over a specific area of the lung and

Figure 21-10 Palpation sequence for tactile fremitus: posterior thorax (left) and anterior thorax (right).

Figure 21-11 Percussion of the posterior thorax. With the patient in a sitting position, symmetric areas of the lungs are percussed at 5-cm intervals. This progression starts at the apex of each lung and concludes with percussion of each lateral chest wall.

are identified as vesicular, bronchovesicular, and bronchial (tubular) breath sounds (Table 21-5).

The location, quality, and intensity of breath sounds are determined during auscultation. When airflow is decreased by bronchial obstruction (atelectasis) or when fluid (pleural effusion) or tissue (obesity) separates the air passages from the stethoscope, breath sounds are diminished or absent. For example, the breath sounds of the patient with emphysema are faint or often completely inaudible. When they are heard, the expiratory phase is prolonged. In the obese or morbidly obese patient, breath sounds may be inaudible. Bronchial and bronchovesicular sounds that are audible anywhere except over the main bronchus in the lungs signify pathology, usually indicating consolidation in the lung (eg, pneumonia, heart failure). This finding requires further evaluation.

Adventitious Sounds. An abnormal condition that affects the bronchial tree and alveoli may produce adventitious (ad-

ditional) sounds. Adventitious sounds are divided into two categories: discrete, noncontinuous sounds (**crackles**) and continuous musical sounds (**wheezes**) (Table 21-6). The duration of the sound is the important distinction to make in identifying the sound as noncontinuous or continuous.

Voice Sounds. The sound heard through the stethoscope as the patient speaks is known as vocal resonance. The vibrations produced in the larynx are transmitted to the chest wall as they pass through the bronchi and alveolar tissue. During the process, the sounds are diminished in intensity and altered so that syllables are not distinguishable. Voice sounds are usually assessed by having the patient repeat “ninety-nine” or “eee” while the nurse listens with the stethoscope in corresponding areas of the chest from the apices to the bases.

Bronchophony describes vocal resonance that is more intense and clearer than normal. **Egophony** describes voice sounds that are distorted. It is best appreciated by having the patient repeat the letter E. The distortion produced by consolidation transforms the sound into a clearly heard A rather than E. Bronchophony and egophony are indicative of consolidation, such as occurs in pneumonia, or pleural effusion. When an abnormality is detected, it should be evident using more than one assessment method. A change in tactile fremitus is more subtle and can be missed, but bronchophony can be noted loudly and clearly.

Whispered pectoriloquy, distinctly hearing words that seem to come from the spot being auscultated, is a very subtle finding, which is heard in the presence of rather dense consolidation of the lungs. This transmission of high-frequency components of whispered sound is not noted in normal physiology. The significance is the same as that of bronchophony (Bickley, 2007).

Interpreting Findings

The physical findings for the most common respiratory diseases are summarized in Table 21-7.

Assessment of Respiratory Function in the Acutely or Critically Ill Patient

Assessment of respiratory status is essential for the well-being of the patient who is acutely or critically ill. Often, such a patient is intubated and receiving mechanical ventilation. This requires that the nurse have expertise in physical assessment, be skilled in monitoring techniques, and be

Table 21-4 CHARACTERISTICS OF PERCUSSION SOUNDS

Sound	Relative Intensity	Relative Pitch	Relative Duration	Location Example	Examples
Flatness	Soft	High	Short	Thigh	Large pleural effusion
Dullness	Medium	Medium	Medium	Liver	Lobar pneumonia
Resonance	Loud	Low	Long	Normal lung	Simple chronic bronchitis
Hyperresonance	Very loud	Lower	Longer	None normally	Emphysema, pneumothorax
Tympany	Loud	High*	—*	Gastric air bubble or puffed-out cheek	Large pneumothorax

*Distinguished mainly by its musical timbre.

Table 21-5 BREATH SOUNDS

	Duration of Sounds	Intensity of Expiratory Sound	Pitch of Expiratory Sound	Locations Where Heard Normally
Vesicular* 	Inspiratory sounds last longer than expiratory ones	Soft	Relatively low	Entire lung field except over the upper sternum and between the scapulae
Bronchovesicular 	Inspiratory and expiratory sounds are about equal	Intermediate	Intermediate	Often in the 1st and 2nd interspaces anteriorly and between the scapulae (over the main bronchus)
Bronchial 	Expiratory sounds last longer than inspiratory ones	Loud	Relatively high	Over the manubrium, if heard at all
Tracheal 	Inspiratory and expiratory sounds are about equal	Very loud	Relatively high	Over the trachea in the neck

*The thickness of the bars indicates intensity of breath sounds; the steeper their incline, the higher the pitch of the sounds.

knowledgeable about possible ventilator-induced lung injury. The nurse reviews the patient’s health history, including the history of disorders affecting lung function, signs and symptoms, and exposure to medications and other agents that can affect respiratory status. The nurse also observes the patient’s respiratory status to analyze and interpret a variety of clinical findings and laboratory test results. After checking the ventilator settings to make sure that

they are set as prescribed and that alarms are always in the “on” position, the nurse must assess for patient–ventilator synchrony and for agitation, restlessness, and other signs of respiratory distress (nasal flaring, excessive use of intercostals and accessory muscles, uncoordinated movement of the chest and abdomen, and a report by the patient of shortness of breath). The nurse must note changes in the patient’s vital signs and evidence of hemodynamic instability

Table 21-6 ABNORMAL (ADVENTITIOUS) BREATH SOUNDS

Breath Sound	Description	Etiology
Crackles		
Crackles in general	Soft, high-pitched, discontinuous popping sounds that occur during inspiration (while usually heard on inspiration, they may also be heard on expiration); may or may not be cleared by coughing	Secondary to fluid in the airways or alveoli or to delayed opening of collapsed alveoli Associated with heart failure and pulmonary fibrosis
Coarse crackles	Discontinuous popping sounds heard in early inspiration; harsh, moist sound originating in the large bronchi	Associated with obstructive pulmonary disease
Fine crackles	Discontinuous popping sounds heard in late inspiration; sounds like hair rubbing together; originates in the alveoli	Associated with interstitial pneumonia, restrictive pulmonary disease (eg, fibrosis); fine crackles in early inspiration are associated with bronchitis or pneumonia
Wheezes		
Wheezes in general	Usually heard on expiration, but may be heard on inspiration depending on the cause	Associated with bronchial wall oscillation and changes in airway diameter Associated with chronic bronchitis or bronchiectasis
Sonorous wheezes (rhonchi)	Deep, low-pitched rumbling sounds heard primarily during expiration; caused by air moving through narrowed tracheobronchial passages	Associated with secretions or tumor
Sibilant wheezes	Continuous, musical, high-pitched, whistle-like sounds heard during inspiration and expiration caused by air passing through narrowed or partially obstructed airways; may clear with coughing	Associated with bronchospasm, asthma, and buildup of secretions
Friction Rubs		
Pleural friction rub	Harsh, crackling sound, like two pieces of leather being rubbed together (sound imitated by rubbing thumb and finger together near the ear) Heard during inspiration alone or during both inspiration and expiration. May subside when patient holds breath; coughing will not clear sound Best heard over the lower lateral anterior surface of the thorax Sound can be enhanced by applying pressure to the chest wall with the diaphragm of the stethoscope	Secondary to inflammation and loss of lubricating pleural fluid

Table 21-7 ASSESSMENT FINDINGS IN COMMON RESPIRATORY DISORDERS

Disorder	Tactile Fremitus	Percussion	Auscultation
Consolidation (eg, pneumonia)	Increased	Dull	Bronchial breath sounds, crackles, bronchophony, egophony, whispered pectoriloquy
Bronchitis	Normal	Resonant	Normal to decreased breath sounds, wheezes
Emphysema	Decreased	Hyperresonant	Decreased intensity of breath sounds, usually with prolonged expiration
Asthma (severe attack)	Normal to decreased	Resonant to hyperresonant	Wheezes
Pulmonary edema	Normal	Resonant	Crackles at lung bases, possibly wheezes
Pleural effusion	Absent	Dull to flat	Decreased to absent breath sounds, bronchial breath sounds and bronchophony, egophony, and whispered pectoriloquy above the effusion over the area of compressed lung
Pneumothorax	Decreased	Hyperresonant	Absent breath sounds
Atelectasis	Absent	Flat	Decreased to absent breath sounds

and report them to the physician, because they may indicate that the mechanical ventilation is ineffective or that the patient's status has deteriorated. It is necessary to assess the position of the patient to be certain that the head of the bed is elevated to prevent aspiration, especially if the patient is receiving enteral feedings. In addition, the patient's mental status should be assessed and compared to previous status. Lethargy and somnolence may be signs of increasing carbon dioxide levels and should not be considered insignificant, even if the patient is receiving sedation or analgesic agents.

Chest auscultation, percussion, and palpation are essential parts of the evaluation of the critically ill patient with or without mechanical ventilation. Assessment of the anterior and posterior lung fields is part of the nurse's routine evaluation. If the patient is recumbent, it is essential to turn the patient to assess all lung fields. Dependent areas must be assessed for normal breath sounds and adventitious sounds. Failure to examine the dependent areas of the lungs can result in missing the findings associated with disorders such as atelectasis or pleural effusion. Percussion is performed to assess for pleural effusion; if pleural effusion is present, the affected lung fields are dull to percussion and breath sounds are absent. A pleural friction rub may also be present.

Tests of the patient's respiratory status are easily performed at the bedside by measuring the respiratory rate (see earlier discussion), tidal volume, minute ventilation, vital capacity, inspiratory force, and compliance. These tests are particularly important for patients who are at risk for pulmonary complications, including those who have undergone chest or abdominal surgery, have had prolonged anesthesia, have preexisting pulmonary disease, and those who are elderly or obese. These tests are also used routinely for mechanically ventilated patients.

The patient whose chest expansion is limited by external restrictions such as obesity or abdominal distention and who cannot breathe deeply because of postoperative pain or sedation will inhale and exhale a low volume of air (referred to as low tidal volumes). Prolonged hypoventilation at low tidal volumes can produce alveolar collapse (atelectasis). The amount of air remaining in the lungs after a normal expiration (functional residual capacity, FRC) decreases, the ability of the lungs to expand (compliance) is reduced, and the patient must breathe faster to maintain the same degree of tissue oxygenation. These events can be exaggerated in

patients who have preexisting pulmonary diseases, in elderly patients whose airways are less compliant because the small airways may collapse during expiration, or in patients who are obese, who have relatively low tidal volumes even when healthy. More details of the assessment of the patient with lung disease, including arterial blood gas (ABG) analysis, are described in subsequent chapters in this unit and in Chapter 14.

NURSING ALERT

The nurse should not rely only on visual inspection of the rate and depth of a patient's respiratory excursions to determine the adequacy of ventilation. Respiratory excursions may appear normal or exaggerated due to an increased work of breathing, but the patient may actually be moving only enough air to ventilate the dead space. If there is any question regarding adequacy of ventilation, auscultation or pulse oximetry (or both) should be used for additional assessment of respiratory status.

Tidal Volume

The volume of each breath is referred to as the **tidal volume** (see Table 21-1 to review lung capacities and volumes). A spirometer is an instrument that can be used at the bedside to measure volumes. If the patient is breathing through an endotracheal tube or tracheostomy, the spirometer is directly attached to it and the exhaled volume is obtained from the reading on the gauge. In other patients, the spirometer is attached to a face mask or a mouthpiece positioned so that it is airtight, and the exhaled volume is measured.

The tidal volume may vary from breath to breath. To ensure that the measurement is reliable, it is important to measure the volumes of several breaths and to note the range of tidal volumes, together with the average tidal volume.

Minute Ventilation

Respiratory rates and tidal volume alone are unreliable indicators of adequate ventilation, because both can vary widely from breath to breath. However, together the tidal volume and respiratory rate are important because the

CHART
21-9

Risk Factors for Hypoventilation

- Limited neurologic impulses transmitted from the brain to the respiratory muscles, as in spinal cord trauma, cerebrovascular accidents, tumors, myasthenia gravis, Guillain-Barré syndrome, polio, and drug overdose
- Depressed respiratory centers in the medulla, as with anesthesia, sedation, and drug overdose
- Limited thoracic movement (kyphoscoliosis), limited lung movement (pleural effusion, pneumothorax), or reduced functional lung tissue (chronic pulmonary diseases, severe pulmonary edema)

minute ventilation, which is useful in detecting respiratory failure, can be determined from them. Minute ventilation is the volume of air expired per minute. It is equal to the product of the tidal volume in liters multiplied by the respiratory rate or frequency. In practice, the minute ventilation is not calculated but is measured directly using a spirometer. In a patient receiving mechanical ventilation, minute volume is often monitored by the ventilator and can be viewed on the monitoring screen.

Minute ventilation may be decreased by a variety of conditions that result in hypoventilation. When the minute ventilation falls, alveolar ventilation in the lungs also decreases, and the PaCO₂ increases. Risk factors for hypoventilation are listed in Chart 21-9.

Vital Capacity

Vital capacity is measured by having the patient take in a maximal breath and exhale fully through a spirometer. The normal value depends on the patient's age, gender, body build, and weight.

NURSING ALERT

Most patients can generate a vital capacity twice the volume they normally breathe in and out (tidal volume). If the vital capacity is less than 10 mL/kg, the patient will be unable to sustain spontaneous ventilation and will require respiratory assistance.

When the vital capacity is exhaled at a maximal flow rate, the forced vital capacity (FVC) is measured. Most patients can exhale at least 80% of their vital capacity in 1 second (forced expiratory volume in 1 second, or FEV₁) and almost all of it in 3 seconds (FEV₃). A reduction in FEV₁ suggests abnormal pulmonary air flow. If the patient's FEV₁ and forced vital capacity are proportionately reduced, maximal lung expansion is restricted in some way. If the reduction in FEV₁ greatly exceeds the reduction in forced vital capacity (FEV₁/FVC less than 85%), the patient may have some degree of airway obstruction.

Inspiratory Force

Inspiratory force evaluates the effort the patient is making during inspiration. It does not require patient cooperation and therefore is a useful measurement in the unconscious patient. The equipment needed for this measurement in-

cludes a manometer that measures negative pressure and adapters that are connected to an anesthesia mask or a cuffed endotracheal tube. The manometer is attached and the airway is completely occluded for 10 to 20 seconds while the inspiratory efforts of the patient are registered on the manometer. The normal inspiratory pressure is about 100 cm H₂O. If the negative pressure registered after 15 seconds of occluding the airway is less than about 25 cm H₂O, mechanical ventilation is usually required because the patient lacks sufficient muscle strength for deep breathing or effective coughing.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with respiratory conditions.

Pulmonary Function Tests

Pulmonary function tests (PFTs) are routinely used in patients with chronic respiratory disorders. They are performed to assess respiratory function and to determine the extent of dysfunction. Such tests include measurements of lung volumes, ventilatory function, and the mechanics of breathing, diffusion, and gas exchange.

PFTs are useful in monitoring the course of a patient with an established respiratory disease and assessing the response to therapy. They are useful as screening tests in potentially hazardous industries, such as coal mining and those that involve exposure to asbestos and other noxious fumes, dusts, or gases. Prior to surgery, they are used to screen patients who are scheduled for thoracic and upper abdominal surgical procedures, patients who are obese, and symptomatic patients with a history suggesting high risk. In addition, PFTs may be used for evaluation of respiratory symptoms and disability for insurance or legal purposes (Porth & Matfin, 2009) and to diagnose occupational respiratory disease.

PFTs generally are performed by a technician using a spirometer that has a volume-collecting device attached to a recorder that demonstrates volume and time simultaneously. A number of tests are carried out because no single measurement provides a complete picture of pulmonary function. The most frequently used PFTs are described in Table 21-8. Technology is available that allows for more complex assessment of pulmonary function. Methods include exercise tidal flow-volume loops, negative expiratory pressure, nitric oxide, forced oscillation, and diffusing capacity for helium or carbon monoxide. These assessment methods allow for detailed evaluation of expiratory flow limitations and airway inflammation.

PFT results are interpreted on the basis of the degree of deviation from normal, taking into consideration the patient's height, weight, age, and gender. Because there is a wide range of normal values, PFTs may not detect early localized changes. The patient with respiratory symptoms (dyspnea, wheezing, cough, sputum production) usually undergoes a complete diagnostic evaluation, even if the results of PFTs are "normal." Trends of results provide information about disease progression as well as the patient's response to therapy.

Table 21-8 PULMONARY FUNCTION TESTS

Term Used	Symbol	Description	Remarks
Forced vital capacity	FVC	Vital capacity performed with a maximally forced expiratory effort	Forced vital capacity is often reduced in COPD because of air trapping.
Forced expiratory volume (qualified by subscript indicating the time interval in seconds)	FEV _t (usually FEV ₁)	Volume of air exhaled in the specified time during the performance of forced vital capacity; FEV ₁ is volume exhaled in 1 second	A valuable clue to the severity of the expiratory airway obstruction
Ratio of timed forced expiratory volume to forced vital capacity	FEV _t /FVC%, usually FEV ₁ /FVC%	FEV _t expressed as a percentage of the forced vital capacity	Another way of expressing the presence or absence of airway obstruction
Forced expiratory flow	FEF ₂₀₀₋₁₂₀₀	Mean forced expiratory flow between 200 and 1200 mL of the FVC	An indicator of large airway obstruction
Forced midexpiratory flow	FEF _{25-75%}	Mean forced expiratory flow during the middle half of the FVC	Slowed in small airway obstruction
Forced end expiratory flow	FEF _{75-85%}	Mean forced expiratory flow during the terminal portion of the FVC	Slowed in obstruction of smallest airways
Maximal voluntary ventilation	MVV	Volume of air expired in a specified period (12 seconds) during repetitive maximal effort	An important factor in exercise tolerance

COPD, chronic obstructive pulmonary disease.

Patients with respiratory disorders may be taught how to measure their peak flow rate (which reflects maximal expiratory flow) at home using a spirometer. This allows them to monitor the progress of therapy, to alter medications and other interventions as needed based on caregiver guidelines, and to notify the health care provider if there is inadequate response to their own interventions. Home care teaching instructions are described in Chapter 24, which discusses asthma.

Arterial Blood Gas Studies

Measurements of blood pH and of arterial oxygen and carbon dioxide tensions are obtained when managing patients with respiratory problems and adjusting oxygen therapy as needed. The arterial oxygen tension (partial pressure or PaO₂) indicates the degree of oxygenation of the blood, and the arterial carbon dioxide tension (partial pressure or PaCO₂) indicates the adequacy of alveolar ventilation. ABG studies aid in assessing the ability of the lungs to provide adequate oxygen and remove carbon dioxide and the ability of the kidneys to reabsorb or excrete bicarbonate ions to maintain normal body pH. Serial ABG analysis also is a sensitive indicator of whether the lung has been damaged after chest trauma. ABG levels are obtained through an arterial puncture at the radial, brachial, or femoral artery or through an indwelling arterial catheter. ABG levels are discussed in detail in Chapter 14.

Patients whose ABG levels are monitored repeatedly with blood obtained from arterial punctures should receive an explanation of the purpose of the procedure. Because of the nerves in arterial walls, patients often experience pain with repeated ABG level checks but are often unaware of the purpose of the puncture and the fact that the ABG results could make a major difference in their treatment (Crawford, 2004).

Pulse Oximetry

Pulse oximetry is a noninvasive method of continuously monitoring the **oxygen saturation** of hemoglobin (SaO₂). When oxygen saturation is measured with pulse oximetry, it is referred to as SpO₂ (Clark, Giuliano & Chen, 2006).

Although pulse oximetry does not replace ABG measurement, it is an effective tool to monitor for subtle or sudden changes in oxygen saturation. It is used in all settings where oxygen saturation monitoring is needed, such as the home, clinics, ambulatory surgical settings, and hospitals.

A probe or sensor is attached to the fingertip (Fig. 21-12), forehead, earlobe, or bridge of the nose. The sensor detects changes in oxygen saturation levels by monitoring light signals generated by the oximeter and reflected by blood pulsing through the tissue at the probe. Normal SpO₂ values are 95% to 100%. Values less than 85% indicate that the tissues are not receiving enough oxygen, and further evaluation is needed. SpO₂ values obtained by pulse oximetry are unreliable in cardiac arrest, shock, and other states of low perfusion (eg, sepsis, peripheral vascular disease, hypothermia) and when vasoconstrictor medications have been used. Additional causes of inaccurate pulse oximetry results include anemia, abnormal hemoglobin, high carbon monoxide level, use of dyes (eg, methylene blue), or if the patient has dark skin or is wearing nail polish. Bright light, particularly sunlight, fluorescent and xenon lights, and patient movement (including shivering) also affect accuracy. Furthermore, pulse oximetry values are not reliable detectors of hypoventilation if the patient is receiving supplemental oxygen (Clark, et al., 2006).

Cultures

Throat cultures (see Chapter 22) may be performed to identify organisms responsible for pharyngitis. Throat culture may also assist in identifying organisms responsible for infection of the lower respiratory tract. Nasal swabs may be performed for the same purpose.

Sputum Studies

Sputum is obtained for analysis to identify pathogenic organisms and to determine whether malignant cells are present. A sputum specimen also may be obtained to assess for hypersensitivity states (in which there is an increase in eosinophils). Periodic sputum examinations may be necessary for patients receiving antibiotics, corticosteroids, and immunosuppressive medications for prolonged periods

A

B

Figure 21-12 Measuring blood oxygenation with pulse oximetry reduces the need for invasive procedures, such as drawing blood for analysis of oxygen levels. **A**, Self-contained digital fingertip pulse oximeter, which incorporates the sensor and the display into one unit. **B**, Table top model with sensor attached. Memory permits tracking heart rate and oxygen saturation over time.

because these agents are associated with opportunistic infections.

Expectoration is the usual method for collecting a sputum specimen. The patient is instructed to clear the nose and throat and rinse the mouth to decrease contamination of the sputum. After taking a few deep breaths, the patient coughs (rather than spits), using the diaphragm, and expectorates into a sterile container.

If the sputum cannot be raised spontaneously, the patient often can be induced to cough deeply by breathing an

irritating aerosol of supersaturated saline, propylene glycol, or some other agent delivered with an ultrasonic nebulizer. Other methods of collecting sputum specimens include endotracheal aspiration, bronchoscopic removal, bronchial brushing, transtracheal aspiration, and gastric aspiration (the last is usually done for tuberculosis organisms; see Chapter 23). Generally, the deepest specimens (those from the base of the lungs) are obtained in the early morning after they have accumulated overnight.

The specimen is delivered to the laboratory within 2 hours by the patient or nurse. Allowing the specimen to stand for several hours in a warm room results in the overgrowth of contaminant organisms and may make it difficult to identify the pathogenic organisms (especially *Mycobacterium tuberculosis*). The home care nurse may assist patients who need help obtaining the sample or who cannot deliver the specimen to the laboratory in a timely fashion.

Imaging Studies

Imaging studies, including x-rays, computed tomography (CT), magnetic resonance imaging (MRI), contrast studies, and radioisotope diagnostic scans may be part of any diagnostic workup, ranging from a determination of the extent of infection in sinusitis to tumor growth in cancer.

Chest X-Ray

Normal pulmonary tissue is radiolucent; therefore, densities produced by fluid, tumors, foreign bodies, and other pathologic conditions can be detected by x-ray examination. A chest x-ray may reveal an extensive pathologic process in the lungs in the absence of symptoms. The routine chest x-ray consists of two views: the posteroanterior projection and the lateral projection. Chest x-rays are usually taken after full inspiration (a deep breath) because the lungs are best visualized when they are well aerated. Also, the diaphragm is at its lowest level and the largest expanse of lung is visible. If taken on expiration, x-ray films may accentuate an otherwise unnoticed pneumothorax or obstruction of a major artery.

Computed Tomography

CT is an imaging method in which the lungs are scanned in successive layers by a narrow-beam x-ray. The images produced provide a cross-sectional view of the chest. Whereas a chest x-ray shows major contrasts between body densities such as bone, soft tissue, and air, CT can distinguish fine tissue density. CT may be used to define pulmonary nodules and small tumors adjacent to pleural surfaces that are not visible on routine chest x-rays and to demonstrate mediastinal abnormalities and hilar adenopathy, which are difficult to visualize with other techniques. Contrast agents are useful when evaluating the mediastinum and its contents.

Magnetic Resonance Imaging

MRI is similar to CT except that magnetic fields and radiofrequency signals are used instead of a narrow-beam x-ray. MRI yields a much more detailed diagnostic image than CT because it visualizes soft tissues. MRI is used to characterize pulmonary nodules, to help stage bronchogenic carcinoma (assessment of chest wall invasion), and to evaluate inflammatory activity in interstitial lung disease, acute

pulmonary embolism, and chronic thrombotic pulmonary hypertension.

Fluoroscopic Studies

Fluoroscopy is used to assist with invasive procedures, such as a chest needle biopsy or transbronchial biopsy, that are performed to identify lesions. It also may be used to study the movement of the chest wall, mediastinum, heart, and diaphragm; to detect diaphragm paralysis; and to locate lung masses.

Pulmonary Angiography

Pulmonary angiography is most commonly used to investigate thromboembolic disease of the lungs, such as pulmonary emboli, and congenital abnormalities of the pulmonary vascular tree. It involves the rapid injection of a radiopaque agent into the vasculature of the lungs for radiographic study of the pulmonary vessels. It can be performed by injecting the radiopaque agent into a vein in one or both arms (simultaneously) or into the femoral vein, with a needle or catheter. The agent also can be injected into a catheter that has been inserted in the main pulmonary artery or its branches or into the great veins proximal to the pulmonary artery.

Radioisotope Diagnostic Procedures (Lung Scans)

Several types of lung scans—(\dot{V}/\dot{Q}) scan, gallium scan, and positron emission tomography (PET)—are used to assess normal lung functioning, pulmonary vascular supply, and gas exchange.

A (\dot{V}/\dot{Q}) lung scan is performed by injecting a radioactive agent into a peripheral vein and then obtaining a scan of the chest to detect radiation. The isotope particles pass through the right side of the heart and are distributed into the lungs in proportion to the regional blood flow, making it possible to trace and measure blood perfusion through the lung. This procedure is used clinically to measure the integrity of the pulmonary vessels relative to blood flow and to evaluate blood flow abnormalities, as seen in pulmonary emboli. The imaging time is 20 to 40 minutes, during which the patient lies under the camera with a mask fitted over the nose and mouth. This is followed by the ventilation component of the scan. The patient takes a deep breath of a mixture of oxygen and radioactive gas, which diffuses throughout the lungs. A scan is performed to detect ventilation abnormalities in patients who have regional differences in ventilation. It may be helpful in the diagnosis of bronchitis, asthma, inflammatory fibrosis, pneumonia, emphysema, and lung cancer. Ventilation without perfusion is seen with pulmonary emboli.

A gallium scan is a radioisotope lung scan used to detect inflammatory conditions, abscesses, adhesions, and the presence, location, and size of tumors. It is used to stage bronchogenic cancer and document tumor regression after chemotherapy or radiation. Gallium is injected intravenously, and scans are taken at intervals (eg, 6, 24, and 48 hours) to evaluate gallium uptake by the pulmonary tissues.

PET is a radioisotope study with advanced diagnostic capabilities that is used to evaluate lung nodules for malignancy. PET can detect and display metabolic changes in tissue, distinguish normal tissue from diseased tissue (such as

in cancer), differentiate viable from dead or dying tissue, show regional blood flow, and determine the distribution and fate of medications in the body. PET is more accurate in detecting malignancies than CT and has equivalent accuracy in detecting malignant nodules when compared with invasive procedures such as thoracoscopy.

Endoscopic Procedures

Endoscopic procedures include bronchoscopy, thoracoscopy, and thoracentesis.

Bronchoscopy

Bronchoscopy is the direct inspection and examination of the larynx, trachea, and bronchi through either a flexible fiberoptic bronchoscope or a rigid bronchoscope (Fig. 21-13). The fiberoptic scope is used more frequently in current practice.

Procedure

The purposes of diagnostic bronchoscopy are: (1) to examine tissues or collect secretions, (2) to determine the location and extent of the pathologic process and to obtain a tissue sample for diagnosis (by biting or cutting forceps, curettage, or brush biopsy), (3) to determine whether a tumor can be resected surgically, and (4) to diagnose bleeding sites (source of hemoptysis).

Therapeutic bronchoscopy is used to (1) remove foreign bodies from the tracheobronchial tree, (2) remove secretions obstructing the tracheobronchial tree when the patient cannot clear them, (3) treat postoperative atelectasis, and (4) destroy and excise lesions. It has also been used to insert stents to relieve airway obstruction that is caused by tumors or miscellaneous benign conditions or that occurs as a complication of lung transplantation.

Fiberoptic bronchoscopy

Rigid bronchoscopy

Figure 21-13 Endoscopic bronchoscopy permits visualization of bronchial structures. The bronchoscope is advanced into bronchial structures orally. Bronchoscopy permits the clinician not only to diagnose but also to treat various lung problems.

The fiberoptic bronchoscope is a thin, flexible bronchoscope that can be directed into the segmental bronchi. Because of its small size, its flexibility, and its excellent optical system, it allows increased visualization of the peripheral airways and is ideal for diagnosing pulmonary lesions. Fiberoptic bronchoscopy allows biopsy of previously inaccessible tumors and can be performed at the bedside. It also can be performed through endotracheal or tracheostomy tubes of patients on ventilators. Cytologic examinations can be performed without surgical intervention.

The rigid bronchoscope is a hollow metal tube with a light at its end. It is used mainly for removing foreign substances, investigating the source of massive hemoptysis, or performing endobronchial surgical procedures. Rigid bronchoscopy is performed in the operating room, not at the bedside.

Possible complications of bronchoscopy include a reaction to the local anesthetic, infection, aspiration, bronchospasm, **hypoxemia** (low blood oxygen level), pneumothorax, bleeding, and perforation.

Nursing Interventions

Before the procedure, a signed consent form is obtained from the patient. Food and fluids are withheld for 6 hours before the test to reduce the risk of aspiration when the cough reflex is blocked by anesthesia. The nurse explains the procedure to the patient to reduce fear and decrease anxiety and administers preoperative medications (usually atropine and a sedative or opioid) as prescribed to inhibit vagal stimulation (thereby guarding against bradycardia, dysrhythmias, and hypotension), suppress the cough reflex, sedate the patient, and relieve anxiety.

NURSING ALERT

Sedation given to patients with respiratory insufficiency may precipitate respiratory arrest.

The patient must remove dentures and other oral prostheses. The examination is usually performed under local anesthesia or moderate sedation, but general anesthesia may be used for rigid bronchoscopy. A topical anesthetic such as lidocaine (Xylocaine) may be sprayed on the pharynx or dropped on the epiglottis and vocal cords and into the trachea to suppress the cough reflex and minimize discomfort. Sedatives or opioids are administered intravenously as prescribed to provide moderate sedation.

After the procedure, it is important that the patient takes nothing by mouth until the cough reflex returns, because the preoperative sedation and local anesthesia impair the protective laryngeal reflex and swallowing for several hours. Once the patient demonstrates a cough reflex, the nurse may offer ice chips and eventually fluids. In the elderly patient, the nurse assesses for confusion and lethargy, which may be due to the large doses of lidocaine administered during the procedure. The nurse also monitors the patient's respiratory status and observes for hypoxia, hypotension, tachycardia, dysrhythmias, hemoptysis, and dyspnea. Any abnormality is reported promptly. The patient is not discharged from the recovery area until adequate cough reflex and respiratory status are present. The nurse instructs

the patient and family caregivers to report any shortness of breath or bleeding immediately.

Thoracoscopy

Thoracoscopy is a diagnostic procedure in which the pleural cavity is examined with an endoscope (Fig. 21-14).

Procedure

Small incisions are made into the pleural cavity in an intercostal space; the location of the incision depends on the clinical and diagnostic findings. After any fluid present in the pleural cavity is aspirated, the fiberoptic mediastinoscope is inserted into the pleural cavity, and its surface is inspected through the instrument. After the procedure, a chest tube may be inserted, and the pleural cavity is drained by negative-pressure water-seal drainage.

Thoracoscopy is primarily indicated in the diagnostic evaluation of pleural effusions, pleural disease, and tumor staging. Biopsies of the lesions can be performed under visualization for diagnosis.

Thoracoscopic procedures have expanded with the availability of video monitoring, which permits improved visualization of the lung. Video-assisted thoracoscopy (VATS) may be used in the diagnosis and treatment of empyema, pleural effusion, and other respiratory disorders

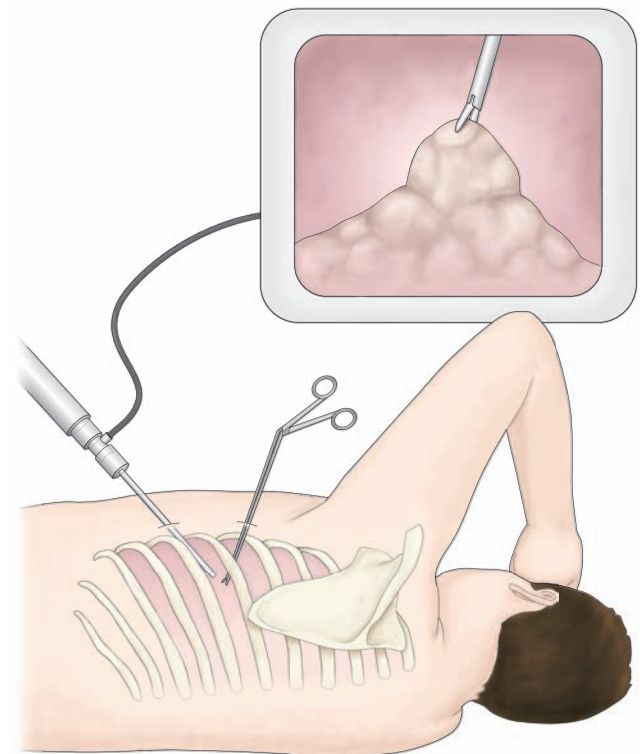

Figure 21-14 Endoscopic thoracoscopy. Like bronchoscopy, thoracoscopy uses fiberoptic instruments and video cameras for visualizing thoracic structures. Unlike bronchoscopy, thoracoscopy usually requires the surgeon to make a small incision before inserting the endoscope. A combined diagnostic-treatment procedure, thoracoscopy includes excising tissue for biopsy.

(Luh, Chou, Wang, et al., 2005). Such procedures also have been used with the carbon dioxide laser in the removal of pulmonary blebs and bullae and in the treatment of spontaneous pneumothorax. Lasers have also been used in the excision of peripheral pulmonary nodules. Although the laser does not replace the need for thoracotomy in the treatment of some lung cancers, its use continues to expand, because it is less invasive than open surgical procedures and hospitalization and recovery are shorter.

Nursing Interventions

Follow-up care in the health care facility and at home involves monitoring the patient for shortness of breath (which might indicate a pneumothorax) and minor activity restrictions, which vary depending on the intensity of the procedure. If a chest tube was inserted during the procedure, monitoring of the chest drainage system and chest tube insertion site is essential (see Chapter 25).

Thoracentesis

A thin layer of pleural fluid normally remains in the pleural space. An accumulation of pleural fluid may occur with some disorders. Thoracentesis (aspiration of fluid or air from the pleural space) is performed for diagnostic or therapeutic reasons (Chart 21-10). Purposes of the procedure include removal of fluid and air from the pleural cavity, aspiration of pleural fluid for analysis, pleural biopsy, and instillation of medication into the pleural space. When performed for biopsy, studies of pleural fluid include Gram stain culture and sensitivity, acid-fast staining and culture, differential cell count, cytology, pH, specific gravity, total protein, and lactic dehydrogenase. When thoracentesis is performed under ultrasound guidance, it has a lower rate of complications than when it is performed without ultrasound guidance.

Biopsy

Biopsy, the excision of a small amount of tissue, may be performed to permit examination of cells from the pharynx, larynx, and nasal passages. Local, topical, moderate sedation, or general anesthesia may be administered, depending on the site and the procedure.

Pleural Biopsy

Pleural biopsy is accomplished by needle biopsy of the pleura or by pleuroscopy, a visual exploration through a fiberoptic bronchoscope inserted into the pleural space. Pleural biopsy is performed when there is pleural exudate of undetermined origin or when there is a need to culture or stain the tissue to identify tuberculosis or fungi.

Lung Biopsy Procedures

If the chest x-ray findings are inconclusive or show pulmonary density (indicating an infiltrate or lesion), biopsy may be performed to obtain lung tissue for examination to identify the nature of the lesion. Several nonsurgical lung biopsy techniques are used because they yield accurate information with low morbidity: transcatheter bronchial brushing, transbronchial lung biopsy, and percutaneous (through-the-skin) needle biopsy.

Procedure

In transcatheter bronchial brushing, a fiberoptic bronchoscope is introduced into the bronchus under fluoroscopy. A small brush attached to the end of a flexible wire is inserted through the bronchoscope. Under direct visualization, the area under suspicion is brushed back and forth, causing cells to slough off and adhere to the brush. The catheter port of the bronchoscope may be used to irrigate the lung tissue with saline solution to secure material for additional studies. The brush is removed from the bronchoscope and a slide is made for examination under the microscope. The brush may be cut off and sent to the pathology laboratory for analysis.

This procedure is useful for cytologic evaluations of lung lesions and for the identification of pathogenic organisms (eg, *Nocardia*, *Aspergillus*, *Pneumocystis jiroveci*). It is especially useful in the immunologically compromised patient.

Another method of bronchial brushing involves the introduction of the catheter through the cricothyroid membrane by needle puncture. After this procedure, the patient is instructed to hold a finger or thumb over the puncture site while coughing to prevent air from leaking into the surrounding tissues.

In transbronchial lung biopsy, biting or cutting forceps are introduced by a fiberoptic bronchoscope. A biopsy is indicated when a lung lesion is suspected and the results of routine sputum samples and bronchoscopic washings are negative.

In percutaneous needle biopsy, a cutting needle or a spinal-type needle is used to obtain a tissue specimen for histologic study. Analgesia may be administered before the procedure. The skin over the biopsy site is cleansed and anesthetized, and a small incision is made. The biopsy needle is inserted through the incision into the pleura with the patient holding his or her breath in midexpiration. Using fluoroscopic monitoring, the surgeon guides the needle into the periphery of the lesion and obtains a tissue sample from the mass. Possible complications include pneumothorax, pulmonary hemorrhage, and empyema.

Nursing Interventions

After the procedure, recovery and home care are similar to those for bronchoscopy and thoracoscopy. Nursing care involves monitoring the patient for shortness of breath, bleeding, and infection. In preparation for discharge, the patient and family are instructed to report pain, shortness of breath, visible bleeding, redness of the biopsy site, or purulent drainage (pus) to the health care provider immediately. Patients who have undergone biopsy are often anxious because of the need for the biopsy and the potential findings; the nurse must consider this in providing postbiopsy care and teaching.

Lymph Node Biopsy

The scalene lymph nodes are enmeshed in the deep cervical pad of fat overlying the scalenus anterior muscle. They drain the lungs and mediastinum and may show histologic changes from intrathoracic disease. If these nodes are palpable on physical examination, a scalene node biopsy may

CHART
21-10

Guidelines for Assisting the Patient Undergoing Thoracentesis

Equipment

- Thoracentesis tray
- Sterile gloves
- Germicide solution
- Local anesthetic
- Sterile collection bottles

Implementation

Action

1. Ascertain in advance that a chest x-ray has been ordered and completed and the consent form for thoracentesis has been signed.
2. Assess the patient for allergy to the local anesthetic to be used.
3. Administer sedation if prescribed.
4. Inform the patient about the nature of the procedure and
 - a. The importance of remaining immobile
 - b. Pressure sensations to be experienced
 - c. That minimal discomfort is anticipated after the procedure.
5. Position the patient comfortably with adequate supports. If possible, place the patient upright or in one of the following positions:
 - a. Sitting on the edge of the bed with the feet supported and arms on a padded over-the-bed table
 - b. Straddling a chair with arms and head resting on the back of the chair
 - c. Lying on the unaffected side with the head of the bed elevated 30 to 45 degrees if unable to assume a sitting position.

Rationale

1. Posteroanterior and lateral chest x-ray films are used to localize fluid and air in the pleural cavity and to aid in determining the puncture site. When fluid is loculated (isolated in a pocket of pleural fluid), ultrasound scans are performed to help select the best site for needle aspiration.
2. If the patient is allergic to the initially prescribed anesthetic, assessment findings provide an opportunity to use a safer anesthetic.
3. Sedation enables the patient to cooperate with the procedure and promotes relaxation.
4. An explanation helps to orient the patient to the procedure, assists the patient to mobilize resources, and provides an opportunity to ask questions and verbalize anxiety.
5. The upright position facilitates the removal of fluid that usually localizes at the base of the thorax. A position of comfort helps the patient to relax.

Continued on following page

 CHART
21-10

Guidelines for Assisting the Patient Undergoing Thoracentesis (Continued)

Action

6. Support and reassure the patient during the procedure.
 - a. Prepare the patient for the cold sensation of skin germicide solution and for a pressure sensation from infiltration of local anesthetic agent.
 - b. Encourage the patient to refrain from coughing.
7. Expose the entire chest. The site for aspiration is visualized by chest x-ray and percussion. If fluid is in the pleural cavity, the thoracentesis site is determined by the chest x-ray, ultrasound scanning, and physical findings, with attention to the site of maximal dullness on percussion.
8. The procedure is performed under aseptic conditions. After the skin is cleansed, the physician uses a small-caliber needle to inject a local anesthetic slowly into the intercostal space.
9. The physician advances the thoracentesis needle with the syringe attached. When the pleural space is reached, suction may be applied with the syringe.
 - a. A 20-mL syringe with a three-way stopcock is attached to the needle (one end of the adapter is attached to the needle and the other to the tubing leading to a receptacle that receives the fluid being aspirated).
 - b. If a considerable quantity of fluid is removed, the needle is held in place on the chest wall with a small hemostat.
10. After the needle is withdrawn, pressure is applied over the puncture site and a small, airtight, sterile dressing is fixed in place.
11. Advise the patient that he or she will be on bed rest and a chest x-ray will be obtained after thoracentesis.
12. Record the total amount of fluid withdrawn from the procedure and document the nature of the fluid, its color, and its viscosity. If indicated, prepare samples of fluid for laboratory evaluation. A specimen container with formalin may be needed for a pleural biopsy.
13. Monitor the patient at intervals for increasing respiratory rate; asymmetry in respiratory movement; faintness; vertigo; tightness in chest; uncontrollable cough; blood-tinged, frothy mucus; a rapid pulse; and signs of hypoxemia.

Rationale

6. Sudden and unexpected movement, such as coughing, by the patient can traumatize the visceral pleura and lung.
7. If air is in the pleural cavity, the thoracentesis site is usually in the second or third intercostal space in the midclavicular line because air rises in the thorax.
8. An intradermal wheal is raised slowly; rapid injection causes pain. The parietal pleura is very sensitive and should be well infiltrated with anesthetic before the physician passes the thoracentesis needle through it.
9. Use of thoracentesis needle allows proper insertion.
 - a. When a large quantity of fluid is withdrawn, a three-way stopcock serves to keep air from entering the pleural cavity.
 - b. The hemostat steadies the needle on the chest wall. Sudden pleuritic chest pain or shoulder pain may indicate that the needle point is irritating the visceral or the diaphragmatic pleura.
10. Pressure helps to stop bleeding, and the airtight dressing protects the site and prevents air from entering the pleural cavity.
11. A chest x-ray verifies that there is no pneumothorax.
12. The fluid may be clear, serous, bloody, purulent, etc.
13. Pneumothorax, tension pneumothorax, subcutaneous emphysema, and pyogenic infection are complications of a thoracentesis. Pulmonary edema or cardiac distress can occur after a sudden shift in mediastinal contents when large amounts of fluid are aspirated.

be performed. A biopsy of these nodes may be performed to detect spread of pulmonary disease to the lymph nodes and to establish a diagnosis or prognosis in such diseases as Hodgkin lymphoma, sarcoidosis, fungal disease, tuberculosis, and carcinoma.

Procedure

Mediastinoscopy is the endoscopic examination of the mediastinum for exploration and biopsy of mediastinal lymph nodes that drain the lungs; this examination does not require a thoracotomy. Biopsy is usually performed through a suprasternal incision. Mediastinoscopy is carried out to detect mediastinal involvement of pulmonary malignancy and to obtain tissue for diagnostic studies of other conditions (eg, sarcoidosis).

An anterior mediastinotomy is thought to provide better exposure and diagnostic possibilities than a mediastinoscopy.

An incision is made in the area of the second or third costal cartilage. The mediastinum is explored, and biopsies are performed on any lymph nodes found. Chest tube drainage is required after the procedure. Mediastinotomy is particularly valuable to determine whether a pulmonary lesion is resectable.

Nursing Interventions

Postprocedure care focuses on providing adequate oxygenation, monitoring for bleeding, and providing pain relief. The patient may be discharged a few hours after the chest drainage system is removed. The nurse should instruct the patient and family about monitoring for changes in respiratory status, taking into consideration the impact of anxiety about the potential findings of the biopsy on their ability to remember those instructions.

CRITICAL THINKING EXERCISES

1 A 48-year-old woman with a long history of smoking (40 pack-years) is scheduled for surgery under general anesthesia to remove a lump from her breast. In preparation for surgery, she is scheduled for PFTs, which she refuses to have because she says her breathing is fine and has nothing to do with her breasts. How would you respond to her statement? What impact does her 40 pack-year history of cigarette smoking have on your preoperative, intraoperative, and postoperative assessment?

2 You are obtaining a health history from a 62-year-old patient who is seeking health care because of a persistent cough and extreme fatigue. She mentions that she cannot keep up with her grandchildren and even gets out of breath when reading to them or talking to them on the phone. What specific information about signs and symptoms would you obtain during the health history? How would you modify your physical examination based on your observations? What initial laboratory tests would you anticipate will be ordered for this patient?

3 An 88-year-old man has been recently relocated because his family does not want him to live by himself. He has never been seen at this pulmonary clinic and is here to get acquainted with his new health care providers. He says his lungs are “no good” because he has smoked since he was 18 years old and was exposed to asbestos during the 15 years he worked in shipyards. He brought a folder from his previous health care provider with results of tests that were done during a hospitalization for pneumonia 2 years earlier: PFTs, ABGs, sputum cultures, chest x-ray, and CT scan of the chest. What questions will you ask him about his health history? What tests do you anticipate being repeated at this time and why?

EBP 4 A 70-year-old patient who has cancer of the lung has undergone a thoracentesis with removal of 750 mL of pleural fluid to relieve his shortness of breath. Soon after the procedure is completed, the patient reports that his shortness of breath has increased rather than decreased. Based on your knowledge of risks associated with thoracentesis, what assessment data would you obtain from this patient and report to the physician? What additional nursing measures are warranted for the patient at this time? What is the evidence on which your nursing interventions are based? How would you determine the strength of that evidence? How would you respond if the patient had been discharged an hour after the thoracentesis and provided this information to you by telephone from home?

chapter 22

Management of Patients With Upper Respiratory Tract Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe nursing management of patients with upper airway disorders.
- 2 Compare and contrast the upper respiratory tract infections with regard to cause, incidence, clinical manifestations, management, and the significance of preventive health care.
- 3 Use the nursing process as a framework for care of patients with upper airway infection.
- 4 Describe nursing management of the patient with epistaxis.
- 5 Use the nursing process as a framework for care of patients undergoing laryngectomy.

GLOSSARY

- alaryngeal communication:** alternative modes of speaking that do not involve the normal larynx; used by patients whose larynx has been surgically removed
- aphonia:** impaired ability to use one's voice due to disease or injury to the larynx
- apnea:** cessation of breathing
- carcinogen:** agent that can cause cancer; carcinogens can be chemicals, viruses, hormones, ionizing radiation, or solid materials
- dysphagia:** difficulties in swallowing
- epistaxis:** hemorrhage from the nose due to rupture of tiny, distended vessels in the mucous membrane of any area of the nose
- herpes simplex:** cold sore (cutaneous viral infection with painful vesicles and erosions on the tongue, palate, gingiva, buccal membranes, or lips)
- laryngectomy:** surgical removal of all or part of the larynx and surrounding structures
- laryngitis:** inflammation of the larynx; may be caused by voice abuse, exposure to irritants, or infectious organisms
- medicamentosa:** rebound nasal congestion commonly associated with overuse of over-the-counter nasal decongestants
- nuchal rigidity:** stiffness of the neck or inability to bend the neck
- pharyngitis:** inflammation of the throat; usually viral or bacterial in origin
- rhinitis:** inflammation of the mucous membranes of the nose; may be infectious, allergic, or inflammatory in origin
- rhinorrhea:** drainage of a large amount of fluid from the nose
- rhinosinusitis:** inflammation of the nares and paranasal sinuses, including frontal, ethmoid, maxillary, and sphenoid sinuses; replaces the term "sinusitis"
- tonsillitis:** inflammation of the tonsils, usually due to an acute infection
- xerostomia:** dryness of the mouth from a variety of causes

Upper respiratory tract disorders are those that involve the nose, paranasal sinuses, pharynx, larynx, trachea, or bronchi. Many of these conditions are relatively minor, and their effects are limited to mild and temporary discomfort and inconvenience for the patient. However, others are acute, severe, and life-threatening and may require permanent alterations in breathing and speaking. Therefore, the nurse must have expert assessment skills, an understanding of the wide variety of disorders that may affect the upper airway, and an awareness of the impact of these alterations on patients. Because many of these disorders are treated outside the hospital or at home by patients themselves, patient teaching is an important aspect of nursing care. When caring for patients with acute, life-threatening disorders, the nurse needs highly developed assessment and clinical management skills, along with a focus on rehabilitation needs.

UPPER AIRWAY INFECTIONS

Upper airway infections are the most common cause of illness and affect most people on occasion. Some infections are acute, with symptoms that last several days; others are chronic, with symptoms that last a long time or recur. Patients with these conditions seldom require hospitalization. However, nurses working in community settings or long-term care facilities may encounter patients who have these infections. Therefore, it is important for the nurse to recognize the signs and symptoms and to provide appropriate care.

Infections of the upper airway are also known as upper respiratory tract infections (URIs); the common cold is the most frequently occurring example. URIs occur when micro-organisms such as viruses and bacteria are inhaled. There are many causative organisms, and people are susceptible throughout life. URIs are the most common reason for seeking health care and for absences from school and work.

URIs affect the nasal cavity; ethmoidal air cells; and frontal, maxillary, and sphenoid sinuses; as well as the pharynx, larynx, and trachea. About 90% of upper respiratory disorders stem from a viral infection of the upper respiratory passages and subsequent mucous membrane inflammation. On average, adults typically develop two to four URIs per year because of the wide variety of respiratory viruses that circulate in the community. Although patients are rarely hospitalized for treatment of URIs, the nurse can influence patient outcomes in community settings and in long-term facilities through patient teaching. Special considerations with regard to URIs in the elderly are summarized in Chart 22-1.

Rhinitis

Rhinitis is a group of disorders characterized by inflammation and irritation of the mucous membranes of the nose. These conditions can have a significant impact on quality of life and contribute to sinus, ear, and sleep problems and learning disorders. Rhinitis often coexists with other respiratory disorders, such as asthma (Nihlén, Greiff, Montnémy, et al., 2006). It affects more than 50 million people in the United States annually.

CHART 22-1

Upper Respiratory Tract Disorders in the Elderly

- Upper respiratory infections in the elderly may have more serious consequences if patients have concurrent medical problems that compromise their respiratory or immune status.
- Influenza causes exacerbations of chronic obstructive pulmonary disease (COPD) and reduced pulmonary function.
- Antihistamines to treat upper respiratory disorders must be used cautiously in the elderly because of their side effects and potential interactions with other medications.
- Rhinosinusitis in the elderly is often preceded by nasal packing for treatment of epistaxis.
- As the population ages, it is likely that the number of patients with chronic rhinosinusitis (CRS) and the need for endoscopic sinus surgery will increase. Older patients with CRS present with symptoms similar to those of younger adults and experience a similar degree of improvement and quality of life after endoscopic sinus surgery (Reh, Mace, Robinson, et al., 2007).
- Laryngitis in the elderly is common and most frequently occurs secondary to gastroesophageal reflux disease (GERD). The elderly are more likely to have impaired esophageal peristalsis and a weaker esophageal sphincter. Treatment measures include sleeping with the head of the bed elevated and the use of medications such as H₂-receptor blockers (eg, famotidine [Pepcid], ranitidine [Zantac]) or proton pump inhibitors (omeprazole [Prilosec]).

Rhinitis may be acute or chronic, nonallergic or allergic. Allergic rhinitis is further classified as seasonal or perennial rhinitis and is commonly associated with exposure to airborne particles such as dust, dander, or plant pollens in people who are allergic to these substances. Seasonal rhinitis occurs during pollen seasons, and perennial rhinitis occurs throughout the year. Allergic disorders, including allergic rhinitis, are described in detail in Chapter 53.

Pathophysiology

Rhinitis may be caused by a variety of factors, including changes in temperature or humidity; odors; infection; age; systemic disease; use of over-the-counter (OTC) and prescribed nasal decongestants; and the presence of a foreign body. Allergic rhinitis may occur with exposure to allergens such as foods (eg, peanuts, walnuts, brazil nuts, wheat, shellfish, soy, cow's milk, and eggs), medications (eg, penicillin, sulfa medications, aspirin, and others with the potential to produce an allergic reaction), and particles in the indoor and outdoor environment (Chart 22-2). The most common cause of nonallergic rhinitis is the common cold. Drug-induced rhinitis may occur with antihypertensive agents, such as angiotensin-converting enzyme (ACE) inhibitors and beta-blockers; "statins," such as atorvastatin (Lipitor) and simvastatin (Zocor); antidepressants; aspirin; and some antianxiety medications. Other causes of rhinitis are identified in Table 22-1. Figure 22-1 shows the pathologic processes involved in rhinitis and rhinosinusitis.

Clinical Manifestations

The signs and symptoms of rhinitis include **rhinorrhea** (excessive nasal drainage, runny nose); nasal congestion; nasal discharge (purulent with bacterial rhinitis); sneezing; and

Chart 22-2 • Examples of Common Indoor and Outdoor Allergens

Common Indoor Allergens

- Dust mite feces
- Dog dander
- Cat dander
- Cockroach droppings
- Molds

Common Outdoor Allergens

- Trees (eg, oak, elm, western red cedar, ash, birch, sycamore, maple, walnut, cypress)
- Weeds (eg, ragweed, tumbleweed, sagebrush, pigweed, cockleweed, Russian thistle)
- Grasses (eg, timothy, orchard, sweet vernal, bermuda, sour dock, redbud, bluegrass)
- Molds (*Alternaria*, *Cladosporium*, *Aspergillus*)

pruritus of the nose, roof of the mouth, throat, eyes, and ears. Headache may occur, particularly if rhinosinusitis is also present. Nonallergic rhinitis can occur throughout the year.

Medical Management

The management of rhinitis depends on the cause, which may be identified through the history and physical examination. The nurse asks the patient about recent symptoms as well as possible exposure to allergens in the home, environment, or workplace. If viral rhinitis is the cause, medications may be prescribed to relieve the symptoms. In allergic rhinitis, allergy tests may be performed to identify possible allergens. Depending on the severity of the allergy, desensitizing immunizations and corticosteroids may be

A. Rhinitis

B. Rhinosinusitis

Figure 22-1 Pathophysiologic processes in rhinitis and rhinosinusitis. Although pathophysiologic processes are similar in rhinitis and rhinosinusitis, they affect different structures. **A**, In rhinitis, the mucous membranes lining the nasal passages become inflamed, congested, and edematous. The swollen nasal conchae block the sinus openings, and mucus is discharged from the nostrils. **B**, Rhinosinusitis is also marked by inflammation and congestion, with thickened mucous secretions filling the sinus cavities and occluding the openings.

required (see Chapter 53 for more details). If symptoms suggest a bacterial infection, an antimicrobial agent is used (see later discussion of rhinosinusitis). Patients with nasal septal deformities or nasal polyps may be referred to an ear, nose, and throat specialist.

Pharmacologic Therapy

Medication therapy for allergic and nonallergic rhinitis focuses on symptom relief. Antihistamines and corticosteroid nasal sprays may be useful. Antihistamines remain the most common treatment and are administered for sneezing, pruritus, and rhinorrhea. Examples of commonly prescribed antihistamines are discussed in more detail in Chapter 53. Brompheniramine/pseudoephedrine (Dimetapp) is an

Table 22-1 CAUSES OF RHINOSINUSITIS

Category	Causes
Vasomotor	Idiopathic
	Abuse of nasal decongestants (rhinitis medicamentosa)
	Psychological stimulation (anger, sexual arousal)
	Irritants (smoke, air pollution, exhaust fumes, cocaine)
Mechanical	Tumor
	Deviated septum
	Crusting
	Hypertrophied turbinates
	Foreign body
Chronic inflammatory	Cerebrospinal fluid leak
	Polyps (in cystic fibrosis)
	Sarcoidosis
	Wegener's granulomatosis
Infectious	Midline granuloma
	Acute viral infection
	Acute or chronic rhinosinusitis
	Rare nasal infections (syphilis, tuberculosis)
Hormonal	Pregnancy
	Use of oral contraceptives
	Hypothyroidism

Adapted from Carr, M. M. Differential diagnosis of rhinitis. Available at: <http://icar.us.med.utoronto.ca/carr/manual/ddxrhinitis.html>

example of combination antihistamine/decongestant medications. Cromolyn (NasalCrom), a mast cell stabilizer that inhibits the release of histamine and other chemicals, is also used in the treatment of rhinitis. Oral decongestant agents may be used for nasal obstruction. Use of saline nasal spray can act as a mild decongestant and can liquefy mucus to prevent crusting. Two inhalations of intranasal ipratropium (Atrovent) can be administered in each nostril two to three times per day for symptomatic relief of rhinorrhea. In addition, intranasal corticosteroids may be used for severe congestion, and ophthalmic agents (cromolyn ophthalmic solution 4%) may be used to relieve irritation, itching, and redness of the eyes. Newer allergy treatments include leukotriene modifiers (eg, montelukast [Singulair], zafirlukast [Accolate], zileuton [Zyflo]), immunoglobulin E modifiers (Xolair), and immunomodulatory medications, which are all part of the revised asthma treatment guidelines and are discussed further in Chapter 24. The choice of medications depends on the symptoms, adverse reactions, adherence factors, risk of drug interactions, and cost to the patient.

Nursing Management

Teaching Patients Self-Care

The nurse instructs the patient with allergic rhinitis to avoid or reduce exposure to allergens and irritants, such as dusts, molds, animals, fumes, odors, powders, sprays, and tobacco smoke. Patient education is essential when assisting the patient in the use of all medications. To prevent possible drug interactions, the patient is cautioned to read drug labels before taking any OTC medication.

The nurse instructs the patient about the importance of controlling the environment at home and at work. Saline nasal sprays or aerosols may be helpful in soothing mucous membranes, softening crusted secretions, and removing irritants. The nurse instructs the patient in correct administration of nasal medications. To achieve maximal relief, the patient is instructed to blow the nose before applying any medication into the nasal cavity. In addition, the patient is taught to keep the head upright; spray quickly and firmly into each nostril away from the nasal septum; and wait at least 1 minute before administering the second spray. The container should be cleaned after each use and should never be shared with other people to avoid cross-contamination.

In the case of infectious rhinitis, the nurse reviews hand hygiene technique with the patient as a measure to prevent transmission of organisms. This is especially important for those in contact with vulnerable populations such as the very young, the elderly, or people who are immunosuppressed (eg, patients with human immunodeficiency virus [HIV] infection, those taking immunosuppressive medications). In the elderly and other high-risk populations, the nurse reviews the value of receiving an influenza vaccination each year to achieve immunity before the beginning of the flu season.

Viral Rhinitis (Common Cold)

Viral rhinitis is the most frequent viral infection in the general population. The term common cold often is used when referring to a URI that is self-limited and caused by a virus.

The term cold refers to an infectious, acute inflammation of the mucous membranes of the nasal cavity characterized by nasal congestion, rhinorrhea, sneezing, sore throat, and general malaise. More broadly, the term refers to an acute URI, whereas terms such as rhinitis, pharyngitis, and laryngitis distinguish the sites of the symptoms. The term is also used when the causative virus is influenza (the flu). Colds are highly contagious because virus is shed for about 2 days before the symptoms appear and during the first part of the symptomatic phase.

In the United States, colds are more frequent during the late fall and winter seasons. The incidence of viral rhinitis follows a specific pattern during the year, depending on the causative agent. Although viral rhinitis can occur at any time, three periods account for the epidemics in the United States: in September, just after the opening of school; in late January; and toward the end of April.

Seasonal changes in relative humidity may affect the prevalence of colds. The most common cold-causing viruses survive better when humidity is low, in the colder months of the year.

Colds are believed to be caused by as many as 200 different viruses (National Institute of Allergy and Infectious Disease, 2007). Rhinoviruses are the most likely causative organisms. Other viruses implicated in the common cold include coronavirus, adenovirus, respiratory syncytial virus, influenza virus, and parainfluenza virus. Each virus may have multiple strains; as a result, people are susceptible to colds throughout life (Tierney, McPhee & Papadakis, 2007). Development of a vaccine against the multiple strains of virus is almost impossible. Immunity after recovery is variable and depends on many factors, including a person's natural host resistance and the specific virus that caused the cold. Despite popular belief, cold temperatures and exposure to cold rainy weather do not increase the incidence or severity of the common cold.

Clinical Manifestations

Signs and symptoms of viral rhinitis are low-grade fever, nasal congestion, rhinorrhea and nasal discharge, halitosis, sneezing, tearing watery eyes, "scratchy" or sore throat, general malaise, chills, and often headache and muscle aches. As the illness progresses, cough usually appears. In some people, the virus exacerbates **herpes simplex**, commonly called a cold sore (Chart 22-3).

The symptoms of viral rhinitis may last from 1 to 2 weeks. If severe systemic respiratory symptoms occur, it is no longer considered viral rhinitis but one of the other acute URIs. Allergic conditions can affect the nose, mimicking the symptoms of a cold.

Medical Management

Management consists of symptomatic therapy that includes an adequate fluid intake, rest, prevention of chilling, and use of expectorants as needed. Warm salt-water gargles soothe the sore throat, and nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen, relieve aches and pains. Antihistamines are used to relieve sneezing, rhinorrhea, and nasal congestion.

Chart 22-3 • Colds and Cold Sores (Herpes Simplex Virus HSV-1)

Herpes labialis is an infection that is caused by the herpes simplex virus. It is characterized by an eruption of small, painful blisters on the skin of the lips, mouth, gums, tongue, or the skin around the mouth. The blisters are commonly referred to as “cold sores” or “fever blisters.” Once the person is infected with this virus, it can lie latent in the cells for a period of time. The incubation period is about 2 to 12 days. It is activated by overexposure to sunlight or wind, colds, influenza and similar infections, heavy alcohol use, and physical or emotional stress.

Herpes labialis is extremely common and is caused by the herpes simplex virus type 1. HSV-1 is also an important cause of genital herpes, which is increasing in college students and selected populations in the United States (Xu, Sternberg, Kottiri, et al., 2006). (In contrast, HSV-2 typically causes painful vesicular and ulcerative lesions in the genital and anal areas.) Most Americans are infected with the type 1 virus by the age of 20 years, because HSV-1 is typically transmitted during childhood through nonsexual contact. Herpes labialis is extremely contagious and can be spread through contaminated razors, towels, and dishes. Oral/genital contact can spread oral herpes to the genitals (and vice versa). People with active herpetic lesions should avoid oral sex. It is extremely important for patients to understand that the virus can be transmitted by asymptomatic people.

Early symptoms of herpes labialis include burning, itching, and increased sensitivity or tingling sensation. These symptoms may occur several days before the appearance of lesions. The lesions appear as macules or papules, progressing to small blisters (vesicles) filled with clear, yellowish fluid. They are raised, red, and painful and can break and ooze. The lesions typically extend through the epidermis and penetrate into the underlying dermis, consistent with a partial-thickness wound (Patel, Romanelli, Roberts, et al., 2007). Eventually yellow crusts slough to reveal pink, healing skin. Typically, the virus is no longer detectable in the lesion or wound 5 days after the vesicle has developed.

Medications used in the management of herpes labialis include acyclovir (Zovirax) and valacyclovir (Valtrex), which help to minimize the symptoms and the duration or length of flare-up. Other medications used for analgesia include acetaminophen with codeine and other milder forms of opioids. Topical anesthetics such as xylocaine can help in the control of discomfort. Occlusive dressings have been shown to speed the healing process. Not only do such dressings prevent desiccation and scab formation, they also maintain an aqueous wound environment rich in growth factors and matrix materials; however, occlusive dressings are not practical for lip and mucosa lesions (Patel, et al., 2007). In this case, alternatives include occlusive ointments such as Herpecin-L or docosanol (Abreva).

Guaifenesin (Mucinex), an expectorant, is available without a prescription and is used to promote removal of secretions. Several antiviral medications are available by prescription, including amantadine (Symmetrel) and rimantadine (Flumadine). These medications can reduce the severity of symptoms and may reduce the duration of the common cold. Antimicrobial agents (antibiotics) should not be used, because they do not affect the virus or reduce the incidence of bacterial complications. In addition, their inappropriate use has been implicated in development of organisms resistant to therapy.

Topical nasal decongestants (eg, phenylephrine nasal [Neo-Synephrine], oxymetazoline nasal [Afrin]) should be used with caution. Topical therapy delivers medication directly to the nasal mucosa, and its overuse can produce rhinitis **medicamentosa**, or rebound rhinitis. Most patients treat the common cold with OTC medications that produce moderate clinical benefits, such as relief of symptoms.

In addition, herbal medicines (eg, echinacea, zinc lozenges, zinc nasal spray) are frequently used to treat the common cold; however, evidence regarding their effectiveness in shortening the symptomatic phase is questionable (Linde, Barrett, Wolkart, et al., 2006; Wu, Zhang, Qiu, et al., 2007). The inhalation of steam or heated, humidified air has been a mainstay of home remedies for common cold sufferers, but the value of this therapy has not been demonstrated.

Nursing Management

Teaching Patients Self-Care

Most viruses can be transmitted in several ways: direct contact with infected secretions; inhalation of large particles from others' coughing or sneezing; or inhalation of small particles (aerosol) that may be suspended in the air for up to an hour. Handwashing (or use of alcohol-based antibacterial cleaning agents) remains the most effective measure to prevent transmission of organisms. The nurse teaches the patient how to break the chain of infection with appropriate handwashing or hand hygiene and the use of tissues to avoid the spread of the virus with coughing and sneezing. The nurse teaches methods to treat symptoms of the common cold and provides both verbal and written information to assist the patient in the prevention and management of URIs.

Rhinosinusitis

Rhinosinusitis, formerly called sinusitis, is an inflammation of the paranasal sinuses and nasal cavity. The clinical practice guideline for adult sinusitis released by the American Academy of Otolaryngology-Head and Neck Surgery Foundation (Rosenfeld, Andes, Bhattacharyya, et al., 2007) recommends use of the term rhinosinusitis since sinusitis is almost always accompanied by inflammation of the nasal mucosa. Rhinosinusitis affects one in seven Americans. About 31 million people in the United States are diagnosed with this condition each year, resulting in direct annual health care costs of \$5.8 billion in ambulatory and emergency services alone (Rosenfeld, et al., 2007).

Uncomplicated rhinosinusitis is rhinosinusitis without extension of inflammation outside of the paranasal sinuses and

nasal cavity. Rhinosinusitis is classified by duration of symptom as acute (less than 4 weeks), subacute (4 to 12 weeks), and chronic (more than 12 weeks). Rhinosinusitis can be a bacterial or viral infection.

ACUTE RHINOSINUSITIS

Acute rhinosinusitis is classified as acute bacterial rhinosinusitis (ABRS) or viral rhinosinusitis (AVRS). Recurrent acute rhinosinusitis is characterized by four or more acute episodes of ABRS per year (Rosenfeld, et al., 2007) and is discussed with chronic rhinosinusitis.

Pathophysiology

Acute rhinosinusitis usually follows a viral URI or cold, such as an unresolved viral or bacterial infection, or an exacerbation of allergic rhinitis. Normally, the sinus openings into the nasal passages are clear and infections resolve promptly. However, if their drainage is obstructed by a deviated septum or by hypertrophied turbinates, spurs, or nasal polyps or tumors, sinus infection may persist as a smoldering (persistent) secondary infection or progress to an acute suppurative process (causing purulent discharge).

Nasal congestion, caused by inflammation, edema, and transudation of fluid secondary to URI, leads to obstruction of the sinus cavities (see Fig. 22-1). This provides an excellent medium for bacterial growth. Other conditions that can block the normal flow of sinus secretions include abnormal structures of the nose, enlarged adenoids, diving and swimming, tooth infection, trauma to the nose, tumors, and the pressure of foreign objects. Some people are more prone to rhinosinusitis because exposure to environmental hazards such as paint, sawdust, and chemicals may result in chronic inflammation of the nasal passages.

Bacterial organisms account for more than 60% of the cases of acute sinusitis. Typical pathogens include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and less commonly *Staphylococcus aureus* and *Moraxella catarrhalis* (Tierney, et al., 2007). Biofilms, which consist of organized, heterogeneous communities of bacteria, have been found to be 10 to 1000 times more resistant to antibiotic treatment and more likely to contribute to host resistance when compared with other bacteria. They serve as bacterial reservoirs that can cause systemic illness when released into the circulation. Although antibiotics kill bacteria in the biofilm margin, cells deep in the biofilm are not affected, allowing for regrowth once antibiotic therapy has been discontinued. Pathogens in the upper respiratory tract that form biofilms include those species listed above as well as *Pseudomonas aeruginosa* (Post, Hiller, Nistico, et al., 2007).

Other organisms that are occasionally isolated include *Chlamydia pneumoniae*, *Streptococcus pyogenes*, viruses, and fungi (*Aspergillus fumigatus*). Fungal infections occur most often in immunosuppressed patients.

Clinical Manifestations

Symptoms of ABRS include purulent nasal drainage (anterior, posterior, or both) accompanied by nasal obstruction or a combination of facial pain, pressure, or a sense of fullness (referred to collectively as facial pain–pressure–fullness), or both (Rosenfeld, et al., 2007). The facial pain–pressure–fullness

may involve the anterior face or the periorbital region. The patient may also report cloudy or colored nasal discharge congestion, blockage, or stuffiness as well as a localized or diffuse headache. The occurrence of symptoms for 10 days or more days after the initial onset of upper respiratory symptoms indicates ABRS. A red streak visible in the lateral recess of the oropharynx suggests ABRS, but its presence requires further study (Thomas & Aizin, 2006).

The symptoms of AVRS are similar to those of ABRS with the exception of the duration of symptoms. Symptoms of AVRS occur for less than 10 days after the onset of upper respiratory symptoms and do not worsen (Rosenfeld, et al., 2007).

Assessment and Diagnostic Findings

A careful history and physical examination are performed. The head and neck, particularly the nose, ears, teeth, sinuses, pharynx, and chest, are examined. There may be tenderness to palpation over the infected sinus area. The sinuses are percussed using the index finger, tapping lightly to determine whether the patient experiences pain. Although less frequently performed, transillumination of the affected area may reveal a decrease in the transmission of light with rhinosinusitis (see Chapter 21). Diagnostic imaging (x-ray, computed tomography [CT], magnetic resonance imaging [MRI]) is not recommended and generally not needed for the diagnosis of acute rhinosinusitis if the patient meets clinical diagnostic criteria (Rosenfeld, et al., 2007). When a complication or alternative diagnosis is suspected, CT scans may be indicated because these scans are sensitive to inflammatory changes and bone destruction and identify anatomical variations that can guide sinus surgery if indicated.

To confirm the diagnosis of maxillary and frontal rhinosinusitis and identify the pathogen, sinus aspirates may be obtained. Flexible endoscopic culture techniques and swabbing of the sinuses have been used for this purpose.

Complications

If untreated, acute rhinosinusitis may lead to severe complications. Local complications include osteomyelitis and mucocoele (cyst of the paranasal sinuses). Osteomyelitis requires prolonged antibiotic therapy and at times removal of necrotic bone. Intracranial complications, although rare, include cavernous sinus thrombosis, meningitis, brain abscess, ischemic brain infarction, and severe orbital cellulitis (Tierney, et al., 2007). Mucocoeles may require surgical treatment to establish intranasal drainage or complete excision with ablation of the sinus cavity. Brain abscesses occur by direct spread and can be life-threatening. Frontal epidural abscesses are usually quiescent but can be detected by CT scan.

Medical Management

Treatment of acute rhinosinusitis depends on the cause; oral therapies can include antibiotics for bacterial cases and oral corticosteroids for acute inflammation. The goals of treatment of acute rhinosinusitis are to shrink the nasal mucosa, relieve pain, and treat infection. Because of inappropriate use of antibiotics for nonbacterial illness, including viral rhinosinusitis, and the resulting resistance that has occurred, caution must be used if oral antibiotics are prescribed. Saline lavage is an alternative to oral antibiotics and has been effective in relieving symptoms, reducing inflammation,

Table 22-2 NASAL CORTICOSTEROIDS AND COMMON SIDE EFFECTS

Nasal Corticosteroids	Side Effects	Contraindications (for all nasal corticosteroids)
Beclomethasone (Beconase)	Nasal irritation, headache, nausea, lightheadedness, epistaxis, rhinorrhea, watering eyes, sneezing, dry nose and throat	Avoid in patients with recurrent epistaxis, glaucoma, and cataracts. Patients who have been exposed to measles/varicella or who have adrenal insufficiency should avoid these medications.
Budesonide (Rhinocort)	Epistaxis, pharyngitis, cough, nasal irritation, bronchospasm	
Mometasone (Nasonex)	Headache, viral infection, pharyngitis, epistaxis, cough, dysmenorrhea, musculoskeletal pain, arthralgia	
Triamcinolone (Nasacort AQ)	Pharyngitis, epistaxis, cough, headache	

clearing the passages of stagnant mucus, and reducing the likelihood of development of opportunistic infections (Sharp, Denman, Puumala, et al., 2007).

Observation without the use of antibiotics is an option for some patients with uncomplicated ABRS (mild pain, temperature of less than 38.3°C [101°F]). In this case, follow-up is essential. When ABRS is confirmed, antibiotic therapy is prescribed. Amoxicillin (Amoxil) is the antibiotic of choice. For patients who are allergic to penicillin, trimethoprim-sulfamethoxazole (Bactrim, Septra) (Rosenfeld, et al., 2007), macrolides (clarithromycin [Biaxin], azithromycin [Zithromax]), and quinolones (ciprofloxacin [Cipro], levofloxacin [Levaquin]) can be used. Other antibiotics used to treat ABRS include cephalosporins such as cephalexin (Keflex), cefuroxime (Ceftin), cefaclor (Ceclor), and cefixime (Suprax). Most patients improve spontaneously, and antibiotics should be reserved for patients with prolonged symptoms (Sharp, et al., 2007). However, deep-seated bacterial rhinosinusitis can be a serious infection that requires antibiotic treatment for 2 to 3 weeks.

Treatment of acute rhinosinusitis typically involves nasal saline lavage and decongestants (guaifenesin/pseudoephedrine [Entex PSE]). Decongestants or nasal saline sprays can increase patency of the ostiomeatal unit and improve drainage of the sinuses. Topical decongestants should not be used for longer than 3 or 4 days. Oral decongestants must be used cautiously in patients with hypertension. OTC antihistamines, such as diphenhydramine (Benadryl) and cetirizine (Zyrtec), and prescription antihistamines such as fexofenadine (Allegra) are used if an allergic component is suspected.

Intranasal corticosteroids have been shown to produce complete or marked improvement in acute symptoms of rhinosinusitis; however, they are not recommended as routine treatment (Rosenfeld, et al., 2007). Examples of intranasal corticosteroids, side effects, and precautions are presented in Table 22-2.

If the patient continues to have symptoms after 7 to 10 days, the sinuses may need to be irrigated.

Nursing Management

Teaching Patients Self-Care

Patient teaching is an important aspect of nursing care for the patient with acute rhinosinusitis. The nurse instructs the

patient about symptoms of complications that require immediate follow-up. Referral to a physician is indicated if periorbital edema and severe pain on palpation occur. The nurse instructs the patient about methods to promote drainage of the sinuses, including humidification of the air in the home and use of warm compresses to relieve pressure. The patient is advised to avoid swimming, diving, and air travel during the acute infection. Patients using tobacco are instructed to immediately stop smoking or using any form of tobacco. Most patients use nasal sprays incorrectly, which can lead to several side effects that include nasal irritation, nasal burning, bad taste, and drainage in the throat or even epistaxis. Therefore, if an intranasal corticosteroid is prescribed, it is important to teach the patient the correct use of prescribed nasal sprays through demonstration, explanation, and return demonstration to evaluate the patient's understanding of the correct method of administration. The nurse also teaches the patient about the side effects of prescribed and OTC nasal sprays and about rebound congestion, medicamentosa. Once the decongestant is discontinued, the nasal passages close and congestion results. Appropriate medications to use for pain relief include acetaminophen (Tylenol) and NSAIDs such as ibuprofen (Advil), naproxen sodium (Aleve), and aspirin for adults older than 20 years of age.

The nurse tells patients with recurrent sinusitis to begin decongestants at the first sign of rhinosinusitis. This promotes drainage and decreases the risk of bacterial infection. Patients should also check with their health care provider or pharmacist before using OTC medications because many cold medications can worsen symptoms or other health problems, specifically hypertension.

The nurse stresses the importance of following the recommended antibiotic regimen because a consistent blood level of the medication is critical to treat the infection. The nurse teaches the patient the early signs of a sinus infection and recommends preventive measures such as following healthy practices and avoiding contact with people with URIs.

The nurse explains to the patient that fever, severe headache, and **nuchal rigidity** (stiffness of the neck or inability to bend the neck) are signs of potential complications. Patients with chronic symptoms of rhinosinusitis who do not have marked improvement in 4 weeks with continuous medical treatment may be candidates for aspiration of the sinus or for sinus surgery.

NURSING ALERT

Patients with nasotracheal and nasogastric tubes in place are at risk for development of sinus infections. Thus, accurate assessment of patients with these tubes is critical. Removal of the nasotracheal or nasogastric tube as soon as the patient's condition permits allows the sinuses to drain, possibly avoiding septic complications.

CHRONIC RHINOSINUSITIS AND RECURRENT ACUTE RHINOSINUSITIS

Chronic rhinosinusitis (CRS) affects 14% to 16% of the U.S. population. It occurs more often in women than men. CRS accounts for almost 20 million office visits annually, and people with CRS have five times more prescriptions filled than people without CRS. It is diagnosed when the patient has experienced 12 weeks or longer of two or more of the following symptoms: mucopurulent drainage, nasal obstruction, facial pain–pressure–fullness, or decreased sense of smell. In about 29% to 36% of patients, CRS is accompanied by nasal polyps. Recurrent acute rhinosinusitis is diagnosed when four or more episodes of ABRS occur per year with no signs or symptoms of rhinosinusitis between the episodes. The use of antibiotics in people with recurrent acute rhinosinusitis is even higher than in CRS. Both CRS and recurrent acute rhinosinusitis affect quality of life as well as physical and social function (Rosenfeld, et al., 2007).

Pathophysiology

Mechanical obstruction in the ostia of the frontal, maxillary, and anterior ethmoid sinuses (known collectively as the ostiomeatal complex) is the usual cause of CRS and recurrent acute rhinosinusitis. Obstruction prevents adequate drainage of the nasal passages, resulting in accumulation of secretions and an ideal medium for bacterial growth. Persistent blockage in an adult may occur because of infection, allergy, or structural abnormalities. Other associated conditions and factors may include cystic fibrosis, ciliary dyskinesia, neoplastic disorders, gastroesophageal reflux disease, tobacco use, and environmental pollution (Rosenfeld, et al., 2007).

Both aerobic and anaerobic bacteria have been implicated in chronic rhinosinusitis and recurrent rhinosinusitis. Common aerobic bacteria include alpha-hemolytic streptococci, microaerophilic streptococci, and *S. aureus*. Common anaerobic bacteria include gram-negative bacilli, *Peptostreptococcus*, and *Fusobacterium*.

In addition, immunodeficiency should be considered in patients with CRS or acute recurrent rhinosinusitis. Acute fulminant/invasive sinusitis is a life-threatening illness and is commonly attributed to *Aspergillus* in immunocompromised patients. Chronic fungal sinusitis also poses a risk. Chronic invasive fungal sinusitis occurs in immunocompromised patients along with fungus ball/mycetoma and allergic fungal sinusitis, the more common forms of chronic fungal sinusitis, which are considered noninvasive conditions in immunocompromised patients. The fungus ball is usually a brown or greenish-black material with the consistency of peanut butter or cottage cheese. Symptoms include nasal stuffiness, nasal discharge, and facial pain (Taxy, 2006).

Clinical Manifestations

Clinical manifestations of CRS include impaired mucociliary clearance and ventilation, cough (because the thick discharge constantly drips backward into the nasopharynx), chronic hoarseness, chronic headaches in the periorbital area, and facial pain. As a result of chronic nasal congestion, the patient is usually required to breathe through the mouth. Snoring, sore throat, and, in some situations, adenoidal hypertrophy may also occur. Periorbital edema and facial pain are common. These symptoms are generally most pronounced on awakening in the morning. Fatigue and nasal congestion are also common. Many patients experience a decrease in smell and taste and a sense of fullness in the ears.

Assessment and Diagnostic Findings

The health assessment focuses on onset and duration of symptoms. It addresses the quantity and quality of nasal discharge and cough, the presence of pain, factors that relieve or aggravate the pain, and allergies. It is essential to obtain any history of comorbid conditions, including asthma, and history of tobacco use. A history of fever, fatigue, previous episodes and treatments, and previous response to therapies is also obtained.

In the physical assessment, the external nose is evaluated for any evidence of anatomical abnormality. A crooked-appearing external nose may imply septal deviation internally. The nasal mucous membranes are assessed for erythema, pallor, atrophy, edema, crusting, discharge, polyps, erosions, and septal perforations or deviations. Appropriate lighting improves visualization of the nasal cavity and should be used in every examination. Pain on examination of the teeth and with tapping with a tongue blade suggests tooth infection.

Assessment of the posterior oropharynx may reveal purulent or mucoid discharge, which is indicative of an infection caused by CRS. The patients' eyes are examined for conjunctival erythema, tearing, photophobia, and edema of the lids. Additional assessment techniques include transillumination of the sinuses and palpation of the sinuses. The frontal and maxillary sinuses are palpated, and the patient is asked whether this produces tenderness. The pharynx is inspected for erythema and discharge and palpated for cervical node adenopathy (Rosenfeld, et al., 2007).

Imaging studies such as x-ray, sinuscopy, ultrasound, CT, and MRI may be used in the diagnosis of chronic rhinosinusitis. X-ray is an inexpensive and readily available tool to assess disorders of the paranasal sinuses. CT of the paranasal sinuses can identify mucosal abnormalities, sinus ostial obstruction, anatomical variants, sinonasal polyposis, and neoplastic disease. In addition, nasal endoscopy allows for visualization of the posterior nasal cavity, nasopharynx, and sinus drainage pathways and can identify posterior septal deviation and polyps. Osseous destruction, extrasinus extension of the disease process, and local invasion suggest malignancy (Rosenfeld, et al., 2007).

Complications

Complications of chronic rhinosinusitis, although uncommon, include severe orbital cellulitis, subperiosteal abscess, cavernous sinus thrombosis, meningitis, encephalitis, and ischemic infarction. Chronic rhinosinusitis can lead to

intracranial infection either by direct spread through bone or via venous channels, resulting in epidural abscess, subdural empyema, meningitis, and brain abscess. Clinical sequelae can include personality changes with frontal lobe abscesses, headache, symptoms of elevated intracranial pressure to include alterations of consciousness, visual changes, focal neurologic deficits, seizures, and, ultimately, coma and death.

Frontal rhinosinusitis can lead to osteomyelitis of the frontal bones. Patients typically present with headache, fever, and a characteristic doughy edema over the involved bone. Ethmoid rhinosinusitis may result in orbital cellulitis, which usually begins with edema of the eyelids and rapidly progresses to ptosis (droopy eyelid), proptosis (bulging eye), chemosis (edema of the bulbar conjunctiva), and diminished extraocular movements. Patients are usually febrile and acutely ill and require immediate attention because pressure on the optic nerve can lead to loss of vision and spread of infection can lead to intracranial infection. Cavernous sinus thrombophlebitis can be a result of extension of infection along venous channels from the orbit, ethmoid, frontal sinuses, or nose. Symptoms may include altered consciousness, lid edema, and proptosis, as well as third, fourth, and sixth cranial nerve palsies.

Medical Management

Medical management of chronic rhinosinusitis and recurrent acute rhinosinusitis is similar to that of acute rhinosinusitis. Early identification of risk factors guides the selection of treatment and leads to early intervention and ultimately better patient outcomes. General measures include adequate hydration, steam inhalation 20 to 30 minutes three times per day whenever possible, saline irrigation (Harvey, Hannan, Badia, et al., 2007), and saline nose drops. Patients are instructed to sleep with the head of the bed elevated and to avoid exposure to cigarette smoke and fumes. Patients are cautioned to avoid caffeine and alcohol, which can cause dehydration.

Prescribed medications may be necessary. Antibiotics include amoxicillin, trimethoprim-sulfamethoxazole, doxycycline (Vibramycin), amoxicillin-clavulanic acid (Augmentin), cefpodoxime (Vantin), cefuroxime axetil, telithromycin (Ketek), azithromycin, clarithromycin, and levofloxacin. The course of antibiotic treatment for chronic rhinosinusitis and recurrent acute bacterial rhinosinusitis may be as long as 3 to 4 weeks to effectively eradicate the offending organism. Medications commonly used for relief of symptoms include loratadine (Claritin), fexofenadine, cetirizine, chlorpheniramine (Chlor-Trimeton), and diphenhydramine. For patients with concomitant asthma, leukotriene inhibitors such as montelukast, and zafirlukast may be used. Commonly used nasal steroids include mometasone furoate (Nasonex) and fluticasone propionate (Flonase). If allergies are a possible cause of chronic rhinosinusitis, oral antihistamines or nasal corticosteroids may also be prescribed. The use of intranasal inhalations has been associated with a significant improvement of symptoms of chronic rhinosinusitis and a reduction in nasal bacteria (Harvey, et al., 2007).

Surgical Management

If standard medical therapy fails and symptoms persist, surgery, usually endoscopic, may be indicated to correct structural deformities that obstruct the ostia (openings) of the

sinuses. Minimally invasive surgical procedures are used, reducing postoperative discomfort and producing significant improvement in the patient's quality of life. Some of the specific procedures performed include excising and cauterizing nasal polyps, correcting a deviated septum, incising and draining the sinuses, aerating the sinuses, and removing tumors. Antimicrobial agents are administered before and after surgery. Computer-assisted or computer-guided surgery is used to increase the precision of the surgical procedure and to minimize complications (Stelter, Andrasschke, Leunig, et al., 2006). Some patients with severe chronic rhinosinusitis obtain relief only by moving to a dry climate.

If rhinosinusitis is caused by a fungal infection, surgery is required to excise the fungus ball and necrotic tissue and drain the sinuses. Patients require aggressive surgical débridement and drainage as well as systemic antifungal medications. Although chronic invasive fungal rhinosinusitis tends to respond well to conservative medical management, surgical intervention may be required in acute invasive fungal rhinosinusitis.

Nursing Management

Because the patient usually performs care measures for sinusitis at home, nursing management consists mainly of patient teaching.

Teaching Patients Self-Care

Many people with sinus infections tend to blow their nose frequently and with force to clear their nasal passages. However, doing so often increases the symptoms. Therefore, the patient is instructed to blow the nose gently and to use tissue to remove the nasal drainage. Increasing fluid intake, applying local heat (hot wet packs), and elevating the head of the bed promote drainage of the sinuses. The nurse also instructs the patient about the importance of following the prescribed medication regimen. Instructions on the early signs of a sinus infection are provided, and preventive measures are reviewed. The nurse instructs the patient about signs and symptoms that require follow-up and provides these instructions verbally and in writing. Instructions in alternate formats (eg, large font, patient's language) may be needed to increase the patient's understanding and adherence to the treatment plan. The nurse encourages the patient to follow-up with his or her primary health care provider if symptoms persist.

NURSING ALERT

URIs, specifically chronic rhinosinusitis and recurrent acute rhinosinusitis, may be linked to primary or secondary immune deficiency or treatment with immunosuppressive therapy (ie, for cancer or organ transplantation). Typical symptoms may be blunted or absent due to immunosuppression. Immunocompromised patients are at increased risk for acute or chronic fungal infections; these infections can progress rapidly and become life-threatening. Thus, assessment, early reporting of symptoms to the physician, and immediate initiation of treatment are essential.

Pharyngitis

ACUTE PHARYNGITIS

Acute **pharyngitis** is a sudden painful inflammation of the pharynx, the back portion of the throat that includes the posterior third of the tongue, soft palate, and tonsils. It is commonly referred to as a sore throat. In the United States, it is estimated that approximately 11 million people experience pharyngitis each year. Because of environmental exposure to viral agents and poorly ventilated rooms, the incidence of viral pharyngitis peaks during winter and early spring in regions that have warm summers and cold winters. Viral pharyngitis spreads easily in the droplets of coughs and sneezes and unclean hands that have been exposed to the contaminated fluids.

Pathophysiology

Viral infection causes most cases of acute pharyngitis. Responsible viruses include the adenovirus, influenza virus, Epstein-Barr virus, and herpes simplex virus. Bacterial infection accounts for the remainder of cases. Ten percent of adults with pharyngitis have group A beta-hemolytic streptococcus (GABHS), which is commonly referred to as group A streptococcus (GAS) or streptococcal pharyngitis. Streptococcal pharyngitis warrants use of antibiotic treatment. When GAS causes acute pharyngitis, the condition is known as strep throat. The body responds by triggering an inflammatory response in the pharynx. This results in pain, fever, vasodilation, edema, and tissue damage, manifested by redness and swelling in the tonsillar pillars, uvula, and soft palate. A creamy exudate may be present in the tonsillar pillars (Fig. 22-2). Other bacterial organisms implicated in acute pharyngitis include *Mycoplasma pneumoniae*, *Neisseria gonorrhoeae*, and *H. influenzae* type B (Braun, Wagner, Huttner, et al., 2006). *M. pneumoniae* is one of the most common known bacterial pathogens of the respiratory tract and is encountered frequently in people with upper respiratory symptoms.

Uncomplicated viral infections usually subside promptly, within 3 to 10 days after the onset. However, pharyngitis caused by more virulent bacteria, such as GAS, is a more severe illness. If left untreated, the complications can be severe and life-threatening. Complications include sinusitis, otitis media, peritonsillar abscess, mastoiditis, and cervical adenitis. In rare cases, the infection may lead to bacteremia, pneumonia, meningitis, rheumatic fever, and nephritis.

Clinical Manifestations

The signs and symptoms of acute pharyngitis include a fiery-red pharyngeal membrane and tonsils, lymphoid follicles that are swollen and flecked with white-purple exudate, enlarged and tender cervical lymph nodes, and no cough. Fever (higher than 38.3°C [101°F]), malaise, and sore throat also may be present. Occasionally, patients with GAS pharyngitis exhibit vomiting, anorexia, and a scarlatina-form rash with urticaria known as scarlet fever.

People who have streptococcal pharyngitis suddenly develop a painful sore throat 1 to 5 days after being exposed to the streptococcus bacteria. They usually report malaise, fever (with or without chills), headache, myalgia, painful cervical adenopathy, and nausea. The tonsils appear swollen and erythematous, and they may or may not have an exudate. The roof of the mouth is often erythematous and may demonstrate petechiae. Bad breath is common.

Assessment and Diagnostic Findings

Accurate diagnosis of pharyngitis is essential to determine the cause (viral or bacterial) and to initiate treatment early. Once a definitive diagnosis of GAS is made, administration of appropriate antibiotics hastens symptom resolution and reduces the transmission of the illness. The most dependable method of testing relies on swab specimens obtained from posterior pharynx and tonsils as recommended by the Infectious Diseases Society of America (Fox, Marcon & Bonsu, 2006). Both the tonsillar pillars and the posterior pharyngeal wall should be touched by the swabs; the tongue should not be included. In most communities, preliminary culture reports are available in 24 hours.

Newer and more rapid diagnostic tests (eg, the rapid streptococcal antigen test [RSAT]) are available. However, the accuracy of rapid antigen tests for detecting GAS in throat specimens varies widely, depending on the person performing the test. When RSAT is performed correctly and used together with professional clinical evaluation, it is considered a valid test for the diagnosis of GAS (Humair, Revaz, Bovier, et al., 2006).

RSAT is also available for self-testing; however, back-up culture of negative rapid antigen tests should be performed in all settings to reliably diagnose GAS pharyngitis. Therefore, self-testing is not recommended (Fox, Cohen, Marcon, et al., 2006).

Figure 22-2 Pharyngitis—inflammation without exudate. **A**, Redness and vascularity of the pillars and uvula are mild to moderate. **B**, Redness is diffuse and intense. Each patient would probably complain of a sore throat. From Bickley, L. S. (2007). *Bates' guide to physical examination and history taking* (9th ed.). Philadelphia: Lippincott Williams & Wilkins.

Medical Management

Viral pharyngitis is treated with supportive measures because antibiotics have no effect on the causal organism. Bacterial pharyngitis is treated with a variety of antimicrobial agents.

Pharmacologic Therapy

If the cause of pharyngitis is bacterial, penicillin is usually the treatment of choice. Penicillin V potassium given for 5 days is the regimen of choice. Traditionally, penicillin was administered as a single injection; however, oral forms are used more often and are as effective and less painful than injections. Penicillin injections are recommended only if there is a concern that the patient will not comply with therapy (Tierney, et al., 2007).

For patients who are allergic to penicillin or have organisms that are resistant to erythromycin (one fifth of GAS and most *S. aureus* organisms are resistant to penicillin and erythromycin), cephalosporins, and macrolides (clarithromycin and azithromycin) may be used. Once-daily azithromycin may be given for only 3 days due to its long half-life (Tierney, et al., 2007). A 5- or 10-day course of cephalosporin may be prescribed. Five-day administration of cefpodoxime and cefuroxime has also been successful in producing bacteriologic cures.

Severe sore throats can also be relieved by analgesic medications, as prescribed. For example, aspirin or acetaminophen can be taken at 4- to 6-hour intervals; if required, acetaminophen with codeine can be taken three or four times daily. Some patients find salt-water gargling to be soothing. In severe cases, gargles with benzocaine may relieve symptoms.

Nutritional Therapy

A liquid or soft diet is provided during the acute stage of the disease, depending on the patient's appetite and the degree of discomfort that occurs with swallowing. Cool beverages, warm liquids, and flavored frozen desserts such as Popsicles are often soothing. Occasionally, the throat is so sore that liquids cannot be taken in adequate amounts by mouth. In severe situations, intravenous (IV) fluids may be needed. Otherwise, the patient is encouraged to drink as much fluid as possible (at least 2 to 3 L per day).

Nursing Management

Nursing care for patients with viral pharyngitis focuses on symptomatic management. For patients who demonstrate signs of strep throat and have a history of rheumatic fever, who appear toxic, who have clinical scarlet fever, or who have symptoms suggesting peritonsillar abscess, nursing care focuses on prompt initiation and correct administration of prescribed antibiotic therapy. The nurse instructs the patient about signs and symptoms that warrant prompt contact with the physician. These include dyspnea, drooling, inability to swallow, and inability to fully open the mouth.

The nurse instructs the patient to stay in bed during the febrile stage of illness and to rest frequently once up and about. Used tissues should be disposed of properly to prevent the spread of infection. The nurse (or the patient or family member, if the patient is not hospitalized) should examine the skin once or twice daily for possible rash, because

acute pharyngitis may precede some other communicable diseases (eg, rubella).

Depending on the severity of the pharyngitis and the degree of pain, warm saline gargles or throat irrigations are used. The benefits of this treatment depend on the degree of heat that is applied. The nurse teaches the patient about these procedures and about the recommended temperature of the solution: high enough to be effective and as warm as the patient can tolerate, usually 40.6°C to 43.3°C (105°F to 110°F). Irrigating the throat may reduce spasm in the pharyngeal muscles and relieve soreness of the throat.

An ice collar also can relieve severe sore throats. Mouth care may promote the patient's comfort and prevent the development of fissures (cracking) of the lips and oral inflammation when bacterial infection is present. The nurse instructs the patient to resume activity gradually and to delay returning to work or school until after 24 hours of antibiotic therapy. A full course of antibiotic therapy is indicated in patients with strep infection because of the potential complications such as nephritis and rheumatic fever, which may have their onset 2 or 3 weeks after the pharyngitis has subsided. The nurse instructs the patient and family about the importance of taking the full course of therapy and informs them about the symptoms to watch for that may indicate complications.

In addition, the nurse instructs the patient about preventive measures that include not sharing eating utensils, glasses, napkins, food, or towels; cleaning telephones after use; using a tissue to cough or sneeze; disposing of used tissues appropriately; and avoiding exposure to tobacco and secondhand smoke. The nurse also teaches the patient with pharyngitis, especially streptococcal pharyngitis, to replace his or her toothbrush with a new one.

CHRONIC PHARYNGITIS

Chronic pharyngitis is a persistent inflammation of the pharynx. It is common in adults who work in dusty surroundings, use their voice to excess, suffer from chronic cough, or habitually use alcohol and tobacco.

There are three types of chronic pharyngitis:

- Hypertrophic: characterized by general thickening and congestion of the pharyngeal mucous membrane
- Atrophic: probably a late stage of the first type (the membrane is thin, whitish, glistening, and at times wrinkled)
- Chronic granular ("clergyman's sore throat"), characterized by numerous swollen lymph follicles on the pharyngeal wall

Clinical Manifestations

Patients with chronic pharyngitis complain of a constant sense of irritation or fullness in the throat, mucus that collects in the throat and can be expelled by coughing, and difficulty swallowing. This is often associated with intermittent postnasal drip that causes minor irritation and inflammation of the pharynx. A sore throat that is worse with swallowing in the absence of pharyngitis suggests the possibility of thyroiditis, and patients with this symptom are referred for evaluation for possible thyroiditis.

Medical Management

Treatment of chronic pharyngitis is based on relieving symptoms, avoiding exposure to irritants, and correcting any upper respiratory, pulmonary, gastrointestinal, or cardiac condition that might be responsible for a chronic cough.

Nasal congestion may be relieved by short-term use of nasal sprays or medications containing ephedrine sulfate (Kondon's Nasal) or phenylephrine hydrochloride (Neo-Synephrine). For a patient with a history of allergy, one of the antihistamine decongestant medications, such as Pseudoephedrine (Sudafed) or brompheniramine/pseudoephedrine, is prescribed orally every 4 to 6 hours. Aspirin (for patients older than 20 years of age) or acetaminophen is recommended for its anti-inflammatory and analgesic properties.

For adults with chronic pharyngitis, tonsillectomy is an effective option, if consideration is given to morbidity and complications relating to the surgery. For further information, see the section Tonsillitis and Adenoiditis, below.

Nursing Management

Teaching Patients Self-Care

To prevent the infection from spreading, the nurse instructs the patient to avoid contact with others until the fever subsides. The nurse recommends avoidance of alcohol, tobacco, secondhand smoke, and exposure to cold or to environmental or occupational pollutants. The patient may minimize exposure to pollutants by wearing a disposable facemask. The nurse encourages the patient to drink plenty of fluids. Gargling with warm saline solution may relieve throat discomfort. Lozenges keep the throat moistened.

Tonsillitis and Adenoiditis

The tonsils are composed of lymphatic tissue and are situated on each side of the oropharynx. The faucial or palatine tonsils and lingual tonsils are located behind the pillars of fauces and tongue, respectively. They frequently serve as the site of acute infection (**tonsillitis**). Acute tonsillitis can be confused with pharyngitis. Chronic tonsillitis is less common and may be mistaken for other disorders such as allergy, asthma, and sinusitis.

The adenoids or pharyngeal tonsils consist of lymphatic tissue near the center of the posterior wall of the nasopharynx. Infection of the adenoids frequently accompanies acute tonsillitis. Frequently occurring bacterial pathogens include GABHS, the most common organism. The most common viral pathogen is Epstein-Barr virus, present in 90% of affected adults. Cytomegalovirus may also cause tonsillitis and adenoiditis. Often thought of as a childhood disorder, tonsillitis can occur in adults.

Clinical Manifestations

The symptoms of tonsillitis include sore throat, fever, snoring, and difficulty swallowing. Enlarged adenoids may cause mouth-breathing, earache, draining ears, frequent head colds, bronchitis, foul-smelling breath, voice impairment, and noisy respiration. Unusually enlarged adenoids fill the space behind the posterior nares, making it difficult for the

air to travel from the nose to the throat and resulting in nasal obstruction. Infection can extend to the middle ears by way of the auditory (eustachian) tubes and may result in acute otitis media, which can lead to spontaneous rupture of the tympanic membranes (eardrums) and further extension of the infection into the mastoid cells, causing acute mastoiditis. The infection also may reside in the middle ear as a chronic, low-grade, smoldering process that eventually may cause permanent deafness.

Assessment and Diagnostic Findings

The diagnosis of acute tonsillitis is primarily clinical, with attention given to whether the illness is viral or bacterial in nature. As in acute pharyngitis, RSAT is quick and convenient; however, it is less sensitive than the throat swab culture.

A thorough physical examination is performed, and a careful history is obtained to rule out related or systemic conditions. The tonsillar site is cultured to determine the presence of bacterial infection. When cytomegalovirus infection is present, the differential diagnosis should include HIV, hepatitis A, and rubella (McKerrow, 2007). In adenoiditis, if recurrent episodes of suppurative otitis media result in hearing loss, comprehensive audiometric assessment is warranted (see Chapter 59).

Medical Management

Tonsillitis is treated through the use of supportive measures that include increased fluid intake, analgesics, salt-water gargles, and rest. Bacterial infections are treated with penicillin (first-line therapy) or cephalosporins. Viral tonsillitis is not effectively treated with antibiotic therapy.

Tonsillectomy and adenoidectomy continue to be commonly performed surgical procedures, with evolving surgical techniques aimed at reducing complications and improving postoperative recovery. Patients who experience no adverse events for 6 hours have a low overall risk of later bleeding and other complications (Tierney, et al., 2007). Adults who have undergone a tonsillectomy to treat recurrent streptococcal infections experience a decrease in the number of episodes of streptococcal or other throat infections or days with throat pain (Alho, Koivunen, Penna, et al., 2007).

Tonsillectomy or adenoidectomy is indicated if the patient has had repeated episodes of tonsillitis despite antibiotic therapy; hypertrophy of the tonsils and adenoids that could cause obstruction and obstructive sleep apnea; repeated attacks of purulent otitis media; suspected hearing loss due to serous otitis media that has occurred in association with enlarged tonsils and adenoids; and in some other conditions, such as an exacerbation of asthma or rheumatic fever. Indications for adenoidectomy include chronic nasal airway obstruction, chronic rhinorrhea, obstruction of the eustachian tube with related ear infections, and abnormal speech. Surgery is also indicated if the patient has developed a peritonsillar abscess that occludes the pharynx, making swallowing difficult and endangering the patency of the airway (particularly during sleep). The presence of persistent tonsillar asymmetry should prompt an excisional biopsy to rule out lymphoma (Tierney, et al., 2007). Antibiotic therapy may be initiated for patients undergoing tonsillectomy or adenoidectomy. Therapy may include oral penicillin, and

cephalosporin (eg, cefdinir [Omnicef]), or moxifloxacin (Avelox).

Nursing Management

Providing Postoperative Care

Continuous nursing observation is required in the immediate postoperative and recovery periods because of the significant risk of hemorrhage. In the immediate postoperative period, the most comfortable position is prone, with the patient's head turned to the side to allow drainage from the mouth and pharynx. The nurse must not remove the oral airway until the patient's gag and swallowing reflexes have returned. The nurse applies an ice collar to the neck, and a basin and tissues are provided for the expectoration of blood and mucus.

Symptoms of postoperative complications include fever, throat pain, ear pain, and bleeding. Pain can be effectively controlled with analgesic medications. Postoperative bleeding, which occurs in only 2% to 4% of tonsillectomy cases, may be classified as primary (occurring within the first 24 hours), or secondary (occurring between 24 hours and 8 days). The blood may be bright red if the patient expectorates it before swallowing it. If the patient swallows the blood, it becomes brown because of the action of the acidic gastric juice. If the patient vomits large amounts of dark blood or bright-red blood at frequent intervals, or if the pulse rate and temperature rise and the patient is restless, the nurse notifies the surgeon immediately. The nurse should have the following items ready for examination of the surgical site for bleeding: a light, a mirror, gauze, curved hemostats, and a waste basin.

Occasionally, suture or ligation of a bleeding vessel is required. In such cases, the patient is taken to the operating room and given general anesthesia. After ligation, continuous nursing observation and postoperative care are required, as in the initial postoperative period. If there is no bleeding, water and ice chips may be given to the patient as soon as desired. The patient is instructed to refrain from too much talking and coughing because these activities can produce throat pain.

Postoperative antibiotics are often prescribed to prevent complications. The possible benefits of antibiotic use should be weighed against the risks.

Teaching Patients Self-Care

Tonsillectomy and adenoidectomy are usually performed as outpatient surgery and the patient is sent home from the recovery room once awake, oriented, and able to drink liquids and void. The patient and family must understand the signs and symptoms of hemorrhage. As previously stated, bleeding may occur up to 8 days after surgery. The nurse instructs the patient about use of liquid acetaminophen with or without codeine for pain control and explains that the pain will subside during the first 3 to 5 days. The nurse informs the patient about the need to take the full course of any prescribed antibiotic.

Alkaline mouthwashes and warm saline solutions are useful in coping with the thick mucus and halitosis that may be present after surgery. The nurse should explain to the patient that a sore throat, stiff neck, minor ear pain, and vomiting may occur in the first 24 hours. The patient

should eat an adequate diet with soft foods, which are more easily swallowed than hard foods. The patient should avoid spicy, hot, acidic, or rough foods. Milk and milk products (ice cream and yogurt) may be restricted because they make removal of mucus more difficult for some patients. The nurse instructs the patient about the need to maintain good hydration. It is important to tell the patient to avoid vigorous tooth brushing or gargling because these activities can cause bleeding. The nurse encourages the use of a cool-mist vaporizer or humidifier in the home postoperatively. The patient should avoid smoking and heavy lifting or exertion for 10 days.

Peritonsillar Abscess

Peritonsillar abscess (also called quinsy) is the most common major suppurative complication of sore throat. This collection of purulent exudate between the tonsillar capsule and the surrounding tissues, including the soft palate, may develop after an acute tonsillar infection that progresses to a local cellulitis and abscess. However, many patients do not experience symptoms or report a respiratory tract infection prior to diagnosis (Dunn, Lane, Everitt, et al., 2007). The most common causative organism is GABHS (Kaminski, 2007). In more severe cases, the infection can spread over the palate and to the neck and chest. Edema can cause airway obstruction, which can be life-threatening and is a medical emergency. Peritonsillar abscess can be life-threatening with mediastinitis, intracranial abscess, and empyema resulting from spread of infection. Early detection and aggressive management are essential (Collin & Beasley, 2006). Although peritonsillar abscess is most common between 20 and 40 years, it can occur at any age. In older adults, it can progress to mediastinitis (Kinzer, Maier & Ridder, 2007).

Clinical Manifestations

The person with a peritonsillar abscess appears acutely ill. The patient often has a severe sore throat, fever, trismus (inability to open the mouth), and drooling. Inflammation of the medial pterygoid muscle that lies lateral to the tonsil results in spasm, severe pain, and difficulty in opening the mouth fully. The pain may be so intense that the patient has difficulty swallowing saliva. The patient's breath often smells rancid. Other symptoms include a raspy voice, odynophagia (a severe sensation of burning, squeezing pain while swallowing), **dysphagia** (difficulty swallowing), and otalgia (pain in the ear). Odynophagia is caused by the inflammation of the superior constrictor muscle of the pharynx that forms the lateral wall of the tonsil. This causes pain on lateral movement of the head. The patient may also have tender and enlarged cervical lymph nodes. Examination of the oropharynx reveals erythema of the anterior pillar and soft palate as well as a purulent tonsil on the side of the peritonsillar abscess. The tonsil is pushed inferomedially and the uvula is shifted contralaterally. The patient may also have erythema of the skin of the chest.

If the clinical presentation reveals bilateral swollen tonsils with a midline uvula, bilateral peritonsillar abscess should be a consideration.

Assessment and Diagnostic Findings

Emergency department physicians are often required to make the diagnosis of peritonsillar abscess and to decide whether aspiration, an invasive procedure, should be carried out based on the patient's clinical picture. Intraoral ultrasound and transcutaneous cervical ultrasound are used in the diagnosis of peritonsillar cellulitis and abscesses.

Medical Management

Antimicrobial agents and corticosteroid therapy are used for treatment of peritonsillar abscess. Antibiotics (usually penicillin) are extremely effective in controlling the infection and, if they are prescribed early in the course of the disease, the abscess may resolve without needing to be incised. However, if the abscess does not resolve, treatment choices include needle aspiration, incision and drainage under local or general anesthesia, and drainage of the abscess with simultaneous tonsillectomy. Following needle aspiration (discussed below) intramuscular administration of clindamycin (Cleocin) can be used in the outpatient setting, thus reducing both antibiotic and hospital costs. Use of topical anesthetic agents and throat irrigations may be prescribed to promote comfort along with administration of prescribed analgesic agents.

Patients with signs of toxicity or complications require hospitalization for IV antibiotics, imaging studies, observation, and proper airway management. Rarely, the patient with a peritonsillar abscess presents with acute airway obstruction and requires immediate airway management. Procedures may include intubation, cricothyroidotomy, or tracheotomy.

Surgical Management

Needle aspiration may be preferred over a more extensive procedure due to its high efficacy, low cost, and patient tolerance. The mucous membrane over the swelling is first sprayed with a topical anesthetic and then injected with a local anesthetic. Single or repeated needle aspirations are performed to decompress the abscess. Alternatively, the abscess may be incised and drained. These procedures are performed best with the patient in the sitting position to make it easier to expectorate the pus and blood that accumulate in the pharynx. The patient experiences almost immediate relief. Incision and drainage is also an effective option but is more painful than needle aspiration. On occasion, patients may require a second aspiration for successful treatment of peritonsillar abscess. If 3 mL or more of purulent material is aspirated, the patient will likely need to be seen the next day for further aspiration (Viljoen & Looek, 2007).

Tonsillectomy is considered for patients who are poor candidates for needle aspiration or incision and drainage. The risk of hemorrhage following tonsillectomy to treat peritonsillar abscess is higher than that of elective tonsillectomy and may be due to the patient's previous use of aspirin for pain relief.

Nursing Management

If the patient requires intubation, cricothyroidotomy, or tracheotomy to treat airway obstruction, the nurse assists with the procedure and provides support to the patient before, during, and after the procedure. The nurse also assists with the needle aspiration when indicated.

The nurse encourages the patient to use prescribed topical anesthetic agents and assists with throat irrigations or the frequent use of mouthwashes or gargles, using saline or alkaline solutions at a temperature of 40.6°C to 43.3°C (105°F to 110°F). Gentle gargling after the procedure with a cool normal saline gargle may relieve discomfort. The patient must be upright and clearly expectorate forward. The nurse instructs the patient to gargle *gently* at intervals of 1 or 2 hours for 24 to 36 hours. Liquids that are cool or at room temperature are usually well tolerated. Adequate fluids must be provided to treat dehydration and prevent its recurrence.

The nurse also observes the patient for complications and instructs the patient about signs and symptoms of complications that require prompt attention by the physician. At discharge, the nurse provides verbal and written instructions regarding foods to avoid, when to return to work, and the need to refrain from or cease smoking; it is also important to reinforce the need for continuation of good oral hygiene.

Laryngitis

Laryngitis, an inflammation of the larynx, often occurs as a result of voice abuse or exposure to dust, chemicals, smoke, and other pollutants or as part of a URI. It also may be caused by isolated infection involving only the vocal cords. Laryngitis is also associated with gastroesophageal reflux (referred to as reflux laryngitis).

Laryngitis is very often caused by the pathogens that cause the common cold and pharyngitis; the most common cause is a virus, and laryngitis is often associated with allergic rhinitis or pharyngitis. Bacterial invasion may be secondary. The onset of infection may be associated with exposure to sudden temperature changes, dietary deficiencies, malnutrition, or an immunosuppressed state. Viral laryngitis is common in the winter and is easily transmitted to others.

Clinical Manifestations

Signs of acute laryngitis include hoarseness or **aphonia** (complete loss of voice) and severe cough. Chronic laryngitis is marked by persistent hoarseness. Other signs of acute laryngitis include sudden onset made worse by cold dry wind. The throat feels worse in the morning and improves when the patient is indoors in a warmer climate. At times, the patient presents with a dry cough and a dry, sore throat that worsens in the evening hours. If allergies are present, the uvula will be visibly edematous. Many patients also complain of a "tickle" in the throat that is made worse by cold air or cold liquids.

Medical Management

Management of acute laryngitis includes resting the voice, avoiding irritants (including smoking), resting, and inhaling cool steam or an aerosol. If the laryngitis is part of a more extensive respiratory infection caused by a bacterial organism or if it is severe, appropriate antibacterial therapy is instituted. The majority of patients recover with conservative treatment; however, laryngitis tends to be more severe in elderly patients and may be complicated by pneumonia.

For chronic laryngitis, the treatment includes resting the voice, eliminating any primary respiratory tract infection, eliminating smoking, and avoiding secondhand smoke. Topical corticosteroids, such as beclomethasone dipropionate (Vanceril), may be given by inhalation. These preparations have few systemic or long-lasting effects and may reduce local inflammatory reactions. Treatment for reflux laryngitis typically involves use of proton pump inhibitors such as omeprazole (Prilosec OTC) given once daily.

Nursing Management

The nurse instructs the patient to rest the voice and to maintain a well-humidified environment. If laryngeal secretions are present during acute episodes, expectorant agents are suggested, along with a daily fluid intake of 2 to 3 L to thin secretions. The nurse instructs the patient about the importance of taking prescribed medications, including proton pump inhibitors, and using continuous positive airway therapy at bedtime, if prescribed for obstructive sleep apnea. In cases involving infection, the nurse informs the patient that the symptoms of laryngitis often extend a week to 10 days after completion of antibiotic therapy. The nurse instructs the patient about signs and symptoms that require contacting the health care provider. These signs and symptoms include loss of voice with sore throat that makes swallowing saliva difficult, hemoptysis, and noisy respirations. It is important to report continued hoarseness after voice rest or laryngitis that persists for longer than 5 days because of the possibility of malignancy.

NURSING PROCESS

THE PATIENT WITH UPPER AIRWAY INFECTION

Assessment

A health history may reveal signs and symptoms of headache, sore throat, pain around the eyes and on either side of the nose, difficulty in swallowing, cough, hoarseness, fever, stuffiness, and generalized discomfort and fatigue. Determining when the symptoms began, what precipitated them, what if anything relieves them, and what aggravates them is part of the assessment. The nurse should also determine any history of allergy or the existence of a concomitant illness. Inspection may reveal swelling, lesions, or asymmetry of the nose as well as bleeding or discharge. The nurse inspects the nasal mucosa for abnormal findings such as increased redness, swelling, exudate, and nasal polyps, which may develop in chronic rhinitis. The mucosa of the nasal turbinates may also be swollen (boggy) and pale, bluish-gray. The nurse palpates the frontal and maxillary sinuses for tenderness, which suggests inflammation, and then inspects the throat by having the patient open the mouth wide and take a deep breath. Redness, asymmetry, or evidence of drainage, ulceration, or enlargement of the tonsils and pharynx are abnormal. Palpation of the neck lymph nodes for enlargement and tenderness is necessary.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective airway clearance related to excessive mucus production secondary to retained secretions and inflammation
- Acute pain related to upper airway irritation secondary to an infection
- Impaired verbal communication related to physiologic changes and upper airway irritation secondary to infection or swelling
- Deficient fluid volume related to decreased fluid intake and increased fluid loss secondary to diaphoresis associated with a fever
- Deficient knowledge regarding prevention of URIs, treatment regimen, surgical procedure, or postoperative care

Collaborative Problems/Potential Complications

Based on assessment data, potential complications include:

- Sepsis
- Meningitis or brain abscess
- Peritonsillar abscess, otitis media, or sinusitis

Planning and Goals

The major goals for the patient may include maintenance of a patent airway, relief of pain, maintenance of effective means of communication, normal hydration, knowledge of how to prevent upper airway infections, and absence of complications.

Nursing Interventions

Maintaining a Patent Airway

An accumulation of secretions can block the airway in patients with an upper airway infection. As a result, changes in the respiratory pattern occur, and the work of breathing increases to compensate for the blockage. The nurse can implement several measures to loosen thick secretions or to keep the secretions moist so that they can be easily expectorated. Increasing fluid intake helps thin the mucus. Use of room vaporizers or steam inhalation also loosens secretions and reduces inflammation of the mucous membranes. To enhance drainage from the sinuses, the nurse instructs the patient about positioning; this depends on the location of the infection or inflammation. For example, drainage for sinusitis or rhinitis is achieved in the upright position. In some conditions, topical or systemic medications, when prescribed, help relieve nasal or throat congestion.

Promoting Comfort

URIs usually produce localized discomfort. In sinusitis, pain may occur in the area of the sinuses, or a general headache may be produced. In pharyngitis, laryngitis, or tonsillitis, a sore throat occurs. The nurse encourages the patient to take analgesics, such as acetaminophen with codeine, as prescribed, to relieve this discomfort. A pain intensity rating scale (see Chapter 13) may be used to assess effectiveness of pain relief measures. Other helpful measures include topical

anesthetic agents for symptomatic relief of herpes simplex blisters (see Chart 22-3) and sore throats, hot packs to relieve the congestion of sinusitis and promote drainage, and warm-water gargles or irrigations to relieve the pain of a sore throat. The nurse encourages rest to relieve the generalized discomfort and fever that accompany many upper airway conditions (especially rhinitis, pharyngitis, and laryngitis). The nurse instructs the patient in general hygiene techniques to prevent the spread of infection. For postoperative care after tonsillectomy and adenoidectomy, an ice collar may reduce swelling and decrease bleeding.

Promoting Communication

Upper airway infections may result in hoarseness or loss of speech. The nurse instructs the patient to refrain from speaking as much as possible and, if possible, to communicate in writing instead. Additional strain on the vocal cords may delay full return of the voice. The nurse encourages the patient and family to use alternative forms of communication, such as a memo pad or a bell to signal for assistance.

Encouraging Fluid Intake

Upper airway infections lead to fluid loss. Sore throat, malaise, and fever may interfere with a patient's willingness to eat and drink. The nurse provides a list of easily ingested foods to increase caloric intake during the acute phase of illness. These include soups, pudding, yogurt, cottage cheese, high protein drinks, and Popsicles. The nurse encourages the patient to drink 2 to 3 L of fluid per day during the acute stage of airway infection, unless contraindicated, to thin the secretions and promote drainage. Liquids (hot or cold) may be soothing, depending on the disorder.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Prevention of most upper airway infections is difficult because of the many potential causes. But because most URIs are transmitted by hand-to-hand contact, the nurse teaches the patient and family techniques to minimize the spread of infection to others, including frequent handwashing. The nurse advises the patient to avoid exposure to people who are at risk for serious illness if respiratory infection is transmitted (elderly adults, immunosuppressed people, and those with chronic health problems).

The nurse teaches patients and their families strategies to relieve symptoms of URIs. It is important to reinforce the need to complete the treatment regimen, particularly when antibiotics are prescribed.

CONTINUING CARE. Referral for home care is rare. However, it may be indicated for people whose health status was compromised before the onset of the respiratory infection and for those who cannot manage self-care without assistance. In such circumstances, the home care nurse assesses the patient's respiratory status and progress in recovery. The nurse may advise elderly patients and those at increased risk from a respiratory infection to consider annual influenza and pneumococcal vaccination as recommended by the physician. A follow-up appointment with the primary care provider may be indicated for patients with

compromised health status to ensure that the respiratory infection has resolved.

Monitoring and Managing Potential Complications

Although major complications of URIs are rare, the nurse must be aware of them and assess the patient for them. Because most patients with URIs are managed at home, patients and their families must be instructed to monitor for signs and symptoms and to seek immediate medical care if the patient's condition does not improve or if the patient's physical status appears to be worsening.

Sepsis or meningitis may occur in patients with compromised immune status or in those with an overwhelming bacterial infection. The patient with a URI and family members are instructed to seek medical care if the patient's condition fails to improve within several days after the onset of symptoms, if unusual symptoms develop, or if the patient's condition deteriorates. They are instructed about signs and symptoms that require further attention: persistent or high fever, increasing shortness of breath, confusion, and increasing weakness and malaise. The patient with sepsis requires expert care to treat the infection, stabilize vital signs, and prevent or treat septicemia and shock. Deterioration of the patient's condition necessitates intensive care measures (eg, hemodynamic monitoring and administration of vasoactive medications, IV fluids, nutritional support, corticosteroids) to monitor the patient's status and to support the patient's vital signs. High doses of antibiotics may be administered to treat the causative organism. The nurse's role is to monitor the patient's vital signs, hemodynamic status, and laboratory values, administer needed treatment, alleviate the patient's physical discomfort, and provide explanations, teaching, and emotional support to the patient and family.

Peritonsillar abscess may develop after an acute infection of the tonsils. The patient requires treatment to drain the abscess and receives antibiotics for infection and topical anesthetic agents and throat irrigations to relieve pain and sore throat. Follow-up is necessary to ensure that the abscess resolves; tonsillectomy may be required. The nurse assists the patient in administering throat irrigations and instructs the patient and family about the importance of adhering to the prescribed treatment regimen and recommended follow-up appointments.

In some severe situations, peritonsillar abscess may progress to meningitis or brain abscess. The nurse assesses for changes in mental status ranging from subtle personality changes through drowsiness to coma, nuchal rigidity, and focal neurologic signs that signal increasing cerebral edema around the abscess. Seizures, typically grand mal, occur in this setting. Intensive care measures are necessary. High doses of antibiotics may be used to treat the causative organism. The nurse's role is similar to caring for the patient with sepsis in an intensive care setting. The nurse monitors the patient's neurologic status and reports changes immediately to the physician.

Otitis media and rhinosinusitis may develop with URI. The patient and family are instructed about the signs and symptoms of otitis media and rhinosinusitis and about the importance of follow-up with the primary health care practitioner to ensure adequate evaluation and treatment of these conditions.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Maintains a patent airway by managing secretions
 - a. Reports decreased congestion
 - b. Assumes best position to facilitate drainage of secretions
 - c. Uses self-care measures appropriately and consistently to manage secretions during the acute phase of illness
2. Reports relief of pain and discomfort using pain intensity scale
 - a. Uses comfort measures: analgesics, hot packs, gargles, rest
 - b. Demonstrates adequate oral hygiene
3. Demonstrates ability to communicate needs, wants, level of comfort
4. Maintains adequate fluid and nutrition intake
5. Utilizes strategies to prevent upper airway infections and allergic reactions
 - a. Demonstrates hand hygiene technique
 - b. Identifies the value of the influenza vaccine
6. Demonstrates an adequate level of knowledge and performs self-care adequately
7. Becomes free of signs and symptoms of infection
 - a. Exhibits normal vital signs (temperature, pulse, respiratory rate)
 - b. Absence of purulent drainage
 - c. Free of pain in ears, sinuses, and throat
 - d. Absence of signs of inflammation
8. Absence of complications
 - a. No signs of sepsis: fever, hypotension, deterioration of cognitive status
 - b. Vital signs and hemodynamic status normal
 - c. No evidence of neurologic involvement
 - d. No signs of development of peritonsillar abscess
 - e. Resolution of URI without development of otitis media or sinusitis
 - f. No signs and symptoms of brain abscess

OBSTRUCTION AND TRAUMA OF THE UPPER RESPIRATORY AIRWAY

Obstruction During Sleep

Obstructive sleep apnea (OSA) is a disorder characterized by recurrent episodes of upper airway obstruction and a reduction in ventilation. It is defined as cessation of breathing (**apnea**) during sleep usually caused by repetitive upper airway obstruction. As many as 18 million Americans suffer from sleep apnea (Pagel, 2007). OSA interferes with people's ability to obtain adequate rest, thus affecting memory, learning, and decision making.

Risk factors for OAS include obesity, male gender, postmenopausal status, and advanced age. The major risk factor is obesity; a larger neck circumference and increased amounts of peripharyngeal fat narrow and compress the

upper airway. OSA affects 4% of males and 2% of females. Women are not often referred for evaluation of OSA, possibly because they are less likely to report classic symptoms (Patil, Schneider, Schwartz, et al., 2007). Other associated factors include alterations in the upper airway, such as structural changes (eg, tonsillar hypertrophy, abnormal posterior positioning of one or both jaws, and variations in craniofacial structures) that contribute to the collapsibility of the upper airway.

Pathophysiology

The pharynx is a collapsible tube that can be compressed by the soft tissues and structures surrounding it. The tone of the muscles of the upper airway is reduced during sleep. Mechanical factors such as reduced diameter of the upper airway or dynamic changes in the upper airway during sleep may result in obstruction. These sleep-related changes may predispose to upper airway collapse when small amounts of negative pressure are generated during inspiration.

Repetitive apneic events result in hypoxia (decreased oxygen saturation) and hypercapnia (increased concentration of carbon dioxide), which triggers a sympathetic response. As a consequence, patients with OSA have a high prevalence of hypertension and an increased risk of myocardial infarction and stroke. In patients with preexisting cardiovascular disease, the nocturnal hypoxemia may predispose to dysrhythmias. Patients who have a diagnosis of heart failure and who have untreated OSA are at increased risk of death (Wang, Parker, Newton, et al., 2007). OSA in the absence of identifiable cardiovascular disease can increase insulin resistance and other metabolic changes that can increase the risk of vascular disease (McArdle, Hillman, Beilin, et al., 2007). OSA is more prevalent in people with coronary artery disease, congestive heart failure, metabolic syndrome, and type 2 diabetes (Patil, et al., 2007).

Clinical Manifestations

OSA is characterized by frequent and loud snoring with breathing cessation for 10 seconds or longer, for at least five episodes per hour, followed by awakening abruptly with a loud snort as the blood oxygen level drops. Patients with sleep apnea may have anywhere from five apneic episodes per hour to several hundred per night.

Classic signs and symptoms of obstructive sleep apnea include snoring, snorting, gasping, choking, and witnessed apneic episodes commonly reported by the bed partner. Common signs and symptoms of OSA are presented in Chart 22-4. Symptoms typically progress with increases in weight, aging, and during the transition to menopause (Patil, et al., 2007). Patients are typically unaware of nocturnal upper airway obstruction during sleep. They frequently complain of insomnia including difficulty in going to sleep, nighttime awakenings, and early morning awakenings with an inability to go back to sleep, as well as chronic fatigue and hypersomnolence (daytime sleepiness). When obtaining the health history, the nurse asks the patient about sleeping during normal activities such as eating or talking. Patients with this symptom are considered to have pathologic hypersomnolence (Patil, et al., 2007).

CHART
22-4

Assessing for Obstructive Sleep Apnea (OSA)

Be alert for the following signs and symptoms:

- Excessive daytime sleepiness
- Frequent nocturnal awakening
- Insomnia
- Loud snoring
- Morning headaches
- Intellectual deterioration
- Personality changes, irritability
- Impotence
- Systemic hypertension
- Dysrhythmias
- Pulmonary hypertension, cor pulmonale
- Polycythemia
- Enuresis

Assessment and Diagnostic Evaluation

The diagnosis of sleep apnea is based on clinical features plus a polysomnographic finding (sleep study), which is the definitive test for OSA. The test is an overnight study that measures multiple physiologic signals to include those related to sleep (electroencephalogram [EEG], electro-oculogram, segmental electrocardiogram [ECG]), respiration (airflow, thoracoabdominal effort, and oximetry), and cardiac dysrhythmia (electrocardiogram) (Patil, et al., 2007).

Medical Management

Patients usually seek medical treatment because their sleeping partners express concern or because they experience excessive sleepiness at inappropriate times or settings (eg, while driving a car). A variety of treatments are used. Weight loss and avoidance of alcohol and hypnotic medications are the first steps (Tierney, et al., 2007). In more severe cases involving hypoxemia and severe hypercapnia, the treatment includes continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) therapy with supplemental oxygen via nasal cannula. (The use of CPAP is discussed in more detail in Chapter 25.) CPAP is used to prevent airway collapse, whereas BiPAP makes breathing easier and results in a lower average airway pressure (Basner, 2007). Although these treatments are effective in management of OSA, compliance with treatment continues to be a major concern (Lin, Prasad, Pan, et al., 2007).

Surgical procedures also may be performed to correct OSA. Simple tonsillectomy may be effective for patients with larger tonsils and low body mass index (Nakata, Noda, Yanagi, et al., 2006). Uvulopalatopharyngoplasty is the resection of pharyngeal soft tissue and removal of approximately 15 mm of the free edge of the soft palate and uvula. Effective in about 50% of patients, it is more effective in eliminating snoring than apnea. Nasal septoplasty may be performed for gross anatomic nasal septal deformities. Tracheostomy relieves upper airway obstruction but has numerous adverse effects, including speech difficulties and increased risk of infections. These procedures, as well as other maxillofacial surgeries, are reserved for patients with life-threatening dysrhythmias or severe disability who have not responded to conventional therapy (Tierney, et al., 2007).

Pharmacologic Therapy

Although medications are not generally recommended for OSA, modafinil (Provigil) has been shown to reduce daytime sleepiness (Valentino & Foldvary-Schaefer, 2007). Protriptyline (Triptil) given at bedtime may increase the respiratory drive and improve upper airway muscle tone. Medroxyprogesterone acetate (Provera) and acetazolamide (Diamox) have been used for sleep apnea associated with chronic alveolar hypoventilation, but their benefits have not been well established. The patient must understand that these medications are not a substitute for CPAP or BiPAP. Administration of low-flow nasal oxygen at night can help relieve hypoxemia in some patients but has little effect on the frequency or severity of apnea. Further studies on the effectiveness of pharmacologic therapy are needed.

Nursing Management

The patient with OSA may not recognize the potential consequences of the disorder. Therefore, the nurse explains the disorder in terms that are understandable to the patient and relates symptoms (daytime sleepiness) to the underlying disorder. The nurse also instructs the patient and family about treatments, including the correct and safe use of CPAP, BiPAP, and oxygen therapy, if prescribed. The nurse teaches the patient about the risk of untreated OSA and the benefits of treatment approaches.

Epistaxis (Nosebleed)

Epistaxis, a hemorrhage from the nose, is caused by the rupture of tiny, distended vessels in the mucous membrane of any area of the nose. Rarely does epistaxis originate in the densely vascular tissue over the turbinates. Most commonly, the site is the anterior septum, where three major blood vessels enter the nasal cavity: (1) the anterior ethmoidal artery on the forward part of the roof (Kiesselbach's plexus), (2) the sphenopalatine artery in the posterosuperior region, and (3) the internal maxillary branches (the plexus of veins located at the back of the lateral wall under the inferior turbinate).

Several risk factors are associated with epistaxis (Chart 22-5).

CHART
22-5

Risk Factors for Epistaxis

- Local infections (vestibulitis, rhinitis, sinusitis)
- Systemic infections (scarlet fever, malaria)
- Drying of nasal mucous membranes
- Nasal inhalation of illicit drugs (eg, cocaine)
- Trauma (digital trauma as in picking the nose; blunt trauma; fracture; forceful nose blowing)
- Arteriosclerosis
- Hypertension
- Tumor (sinus or nasopharynx)
- Thrombocytopenia
- Use of aspirin
- Liver disease
- Redu-Osler-Weber syndrome (hereditary hemorrhagic telangiectasia)

Medical Management

Management of epistaxis depends on its cause and the location of the bleeding site. A nasal speculum, penlight, or headlight may be used to identify the site of bleeding in the nasal cavity. Most nosebleeds originate from the anterior portion of the nose. Initial treatment may include applying direct pressure. The patient sits upright with the head tilted forward to prevent swallowing and aspiration of blood and is directed to pinch the soft outer portion of the nose against the midline septum for 5 or 10 minutes continuously. Application of nasal decongestants (phenylephrine, one or two sprays) to act as vasoconstrictors may be necessary. If these measures are unsuccessful in stopping the bleeding, the nose must be examined using good illumination and suction to determine the site of bleeding. Topical cocaine (4%) may be applied using an applicator or spray. It serves as both an anesthetic and a vasoconstrictor. If cocaine is not available, oxymetazoline (topical decongestant) and tetracaine (Pontocaine; topical anesthetic) can be substituted with equal results. Visible bleeding sites may be cauterized with silver nitrate or electrocautery (high-frequency electrical current). A supplemental patch of Surgicel or Gelfoam may be used (Tierney, et al., 2007).

Alternatively, a cotton tampon may be used to try to stop the bleeding. Suction may be used to remove excess blood and clots from the field of inspection. The search for the bleeding site should shift from the anteroinferior quadrant to the anterosuperior, then to the posterosuperior, and finally to the posteroinferior area. The field is kept clear by using suction and by shifting the cotton tampon.

If the origin of the bleeding cannot be identified, the nose may be packed with gauze impregnated with petrolatum jelly or antibiotic ointment; a topical anesthetic spray and decongestant agent may be used before the gauze packing is inserted, or a balloon-inflated catheter may be used (Fig. 22-3). Alternatively, a compressed nasal sponge may be used. Once the sponge becomes saturated with blood or is moistened with a small amount of saline, it will expand and produce tamponade to halt the bleeding. The packing may remain in place for 48 hours or up to 5 or 6 days if necessary to control bleeding. Antibiotics may be prescribed because of the risk of iatrogenic sinusitis and toxic shock syndrome.

Nursing Management

The nurse monitors the patient's vital signs, assists in the control of bleeding, and provides tissues and an emesis basin to allow the patient to expectorate any excess blood. It is common for patients to be anxious in response to a nosebleed. Blood loss on clothing and handkerchiefs can be frightening, and the nasal examination and treatment are uncomfortable. Assuring the patient in a calm, efficient manner that bleeding can be controlled can help reduce anxiety. The nurse continuously assesses the patient's airway and breathing as well as vital signs. On rare occasions, a patient with significant hemorrhage requires IV infusions of crystalloid solutions (normal saline) as well as cardiac and pulse oximetry monitoring.

Teaching Patients Self-Care

Once the bleeding is controlled, the nurse instructs the patient to avoid vigorous exercise for several days and to avoid hot or spicy foods and tobacco because this may cause va-

Figure 22-3 Packing to control bleeding from the posterior nose. **A**, Catheter is inserted and packing is attached. **B**, Packing is drawn into position as the catheter is removed. **C**, Strip is tied over a bolster to hold the packing in place with an anterior pack installed “accordion pleat” style. **D**, Alternative method, using a balloon catheter instead of gauze packing.

sodilation and increase the risk of rebleeding. Discharge teaching includes reviewing ways to prevent epistaxis: avoiding forceful nose blowing, straining, high altitudes, and nasal trauma (including nose picking). Adequate humidification may prevent drying of the nasal passages. The nurse explains how to apply direct pressure to the nose with the thumb and the index finger for 15 minutes in the case of a recurrent nosebleed. If recurrent bleeding cannot be stopped, the patient is instructed to seek additional medical attention.

Nasal Obstruction

The passage of air through the nostrils is frequently obstructed by a deviation of the nasal septum, hypertrophy of the turbinate bones, or the pressure of nasal polyps. Chronic nasal congestion forces the patient to breathe through the mouth, thus producing dryness of the oral mucosa and associated problems including persistent dry, cracked lips. Patients with chronic nasal congestion often suffer from sleep deprivation due to difficulty maintaining an adequate airway while lying flat and during sleep.

Persistent nasal obstruction also may lead to chronic infection of the nose and result in frequent episodes of nasopharyngitis. Frequently, the infection extends to the nasal sinuses. When rhinosinusitis develops and the drainage from these cavities is obstructed by deformity or swelling within the nose, pain is experienced in the region of the affected sinus.

Medical Management

The treatment of nasal obstruction requires the removal of the obstruction, followed by measures to treat whatever chronic infection exists. In many patients, an underlying

allergy also requires treatment. Measures to reduce or alleviate nasal obstruction include nonsurgical as well as surgical techniques. Commonly used medications include nasal corticosteroids (see Table 22-2) as well as oral leukotriene inhibitors, such as montelukast. Treatment with nasal corticosteroids for 1 to 3 months is usually successful for treatment of small polyps and may even reduce the need for surgical intervention. A short course of oral corticosteroids (6-day course of prednisone) may be beneficial in the treatment of nasal obstruction due to polyps (Tierney, et al., 2007). Additional medications may include antibiotics for the treatment of underlying infection or antihistamines for management of allergies. Hypertrophied turbinates may be treated by applying an astringent agent to shrink them.

A more aggressive approach in treating nasal obstruction caused by turbinate hypertrophy involves surgical reduction of the hypertrophy. Surgical procedures used to treat obstructive nasal conditions are collectively known as functional rhinoplasty. Technical advances with newer techniques provide a number of options for reconstruction and reshaping of the nose (Swartout & Toriumi, 2007).

Nursing Management

Most of the surgical procedures are performed on an outpatient basis. The nurse explains the procedure after the physician provides the initial description. Postoperatively, the nurse elevates the head of the bed to promote drainage and to alleviate discomfort from edema. Frequent oral hygiene is encouraged to overcome dryness caused by breathing through the mouth. Before discharge from the outpatient or same-day surgical unit, the patient is instructed to avoid blowing the nose with force during the postoperative recovery period. The patient is also instructed about the signs and symptoms of bleeding and infection and when to contact the physician. The patient is provided with written postoperative instructions, including emergency phone numbers.

Fractures of the Nose

The location of the nose makes it susceptible to injury. Nasal fracture is the most common facial fracture and the most common fracture in the body. Fractures of the nose usually result from a direct assault. Nasal fractures may affect the ascending process of the maxilla and the septum. The torn mucous membrane results in a nosebleed. Complications include hematoma, infection, abscess, and avascular or septic necrosis. However, as a rule, serious consequences usually do not occur.

Clinical Manifestations

The signs and symptoms of a nasal fracture are pain, bleeding from the nose externally and internally into the pharynx, swelling of the soft tissues adjacent to the nose, periorbital ecchymosis, nasal obstruction, and deformity. The patient's nose may have an asymmetric appearance that may not be obvious until the edema subsides.

Assessment and Diagnostic Findings

The nose is examined internally to rule out the possibility that the injury may be complicated by a fracture of the nasal septum and a submucosal septal hematoma. Intranasal examination is performed in all cases to rule out septal hematoma (Tierney, et al., 2007). Because of the swelling and bleeding that occur with a nasal fracture, an accurate diagnosis can be made only after the swelling subsides.

Clear fluid draining from either nostril suggests a fracture of the cribriform plate with leakage of cerebrospinal fluid. Because cerebrospinal fluid contains glucose, it can readily be differentiated from nasal mucus by means of a dipstick (Dextrostix). Usually, careful inspection or palpation discloses any deviations of the bone or disruptions of the nasal cartilages. An x-ray may reveal displacement of the fractured bones and may help rule out extension of the fracture into the skull.

Medical Management

A nasal fracture very often produces bleeding from the nasal passage. As a rule, bleeding is controlled with the use of packing. Cold compresses are used to prevent or reduce edema. For the patient who has sustained enough trauma to break the nose or any facial bone, the emergency medical team must consider the possibility of a cervical spine fracture. Therefore, it is essential to ensure a patent airway and to rule out a cervical spine fracture. Uncomplicated nasal fractures may be treated initially with antibiotics, analgesic agents, and a decongestant nasal spray.

Treatment of nasal fractures is aimed at restoring nasal function and returning the appearance of the nose to baseline. The patient is referred to a specialist to evaluate the need to realign the bones. Although improved outcomes are obtained when reduction of the fracture is performed during the first 3 hours after the injury, this is often not possible because of the edema. If immediate reduction of the fracture is not possible, it is performed within 3 to 7 days. Timing is important when treating nasal fractures because further delay in treatment may result in significant bone healing, which ultimately may require surgical intervention that includes rhinoplasty to reshape the external appearance of the nose. A septorhinoplasty is performed when the nasal septum needs to be repaired. In patients who develop a septal hematoma, the physician drains the hematoma through a small incision. A septal hematoma that is not drained can lead to permanent deformity of the nose.

Nursing Management

Immediately after the fracture, the nurse applies ice and encourages the patient to keep the head elevated. The nurse instructs the patient to apply ice packs to the nose for 20 minutes four times a day to decrease swelling. The patient who experiences bleeding from the nose (epistaxis) is usually frightened and anxious and needs reassurance. The packing inserted to stop the bleeding may be uncomfortable and unpleasant, and obstruction of the nasal passages by the packing forces the patient to breathe through the mouth. This in turn causes the oral mucous membranes to become dry. Mouth rinses help to moisten the mucous membranes and to reduce the odor and taste of dried blood in the

oropharynx and nasopharynx. Use of analgesic agents such as acetaminophen or NSAIDs such as ibuprofen or naproxen is encouraged. When removing the cotton pledgets, the nurse carefully inspects the mucosa for lacerations or a septal hematoma. The nurse instructs the patient to avoid sports activities for 6 weeks.

Laryngeal Obstruction

Obstruction of the larynx because of edema is a serious, often fatal, condition. The larynx is a stiff box that will not stretch. It contains a narrow space between the vocal cords (glottis), through which air must pass. Swelling of the laryngeal mucous membranes may close off the opening tightly, leading to life-threatening hypoxia or suffocation. Edema of the glottis occurs rarely in patients with acute laryngitis, occasionally in patients with urticaria, and more frequently in patients with severe inflammation of the throat, as in scarlet fever. It is an occasional but usually preventable cause of death in severe anaphylaxis (angioedema).

Hereditary angioedema (HAE) is also characterized by episodes of life-threatening laryngeal edema. Laryngeal edema in people with HAE can occur at any age, although young adults are at greatest risk. Risk factors for laryngeal obstruction are given in Table 22-3.

Foreign bodies frequently are aspirated into the pharynx, the larynx, or the trachea and cause a twofold problem. First, they obstruct the air passages and cause difficulty in breathing, which may lead to asphyxia; later, they may be drawn farther down, entering the bronchi or a bronchial branch and causing symptoms of irritation, such as a croupy cough, expectoration of blood or mucus, or labored breathing. The physical signs and x-ray findings confirm the diagnosis.

Clinical Manifestations

The patient's clinical presentation and x-ray findings confirm the diagnosis of laryngeal obstruction. The patient may demonstrate lowered oxygen saturation; however, normal oxygen saturation should not be interpreted as a sign that the obstruction is not significant. Use of accessory muscles to maximize airflow may occur and is often manifested by retractions in the neck or abdomen during inspirations. Patients who demonstrate these symptoms are at an immediate

risk of collapse, and respiratory support (ie, mechanical ventilation or positive-pressure ventilation) is considered.

Assessment and Diagnostic Findings

A thorough history can be very useful in diagnosing and treating the patient with a laryngeal obstruction. However, emergency measures to secure the patient's airway should not be delayed to obtain a history or perform tests. If possible, the nurse obtains a history from the patient or family about heavy alcohol or tobacco consumption, current medications, history of airway problems, recent infections, pain or fever, dental pain or poor dentition, and any previous surgeries, radiation therapy, or trauma.

Rarely, patients with nasogastric tubes in place develop a postcricoid ulceration (referred to as "nasogastric tube syndrome"). This ulceration affects the posterior cricoarytenoid muscles, causing vocal cord abduction paralysis and ultimately upper airway obstruction (Marcus, Caine, Hamdan, et al., 2006).

Medical Management

Medical management is based on the initial evaluation of the patient and the need to ensure a patent airway. If the airway is obstructed by a foreign body and signs of asphyxia are apparent, immediate treatment is necessary. Frequently, if the foreign body has lodged in the pharynx and can be visualized, the finger can dislodge it. If the obstruction is in the larynx or the trachea, the clinician or other rescuer tries the subdiaphragmatic abdominal thrust maneuver (Chart 22-6). If all efforts are unsuccessful, an immediate tracheotomy is necessary (see Chapter 25 for further discussion). If the obstruction is caused by edema resulting from an allergic reaction, treatment may include immediate administration of subcutaneous epinephrine and a corticosteroid (see Chapter 53). Ice may be applied to the neck in an effort to reduce edema. Continuous pulse oximetry is essential in the patient who has experienced acute upper airway obstruction.

Cancer of the Larynx

Cancer of the larynx accounts for approximately half of all head and neck cancers. The American Cancer Society (ACS, 2007b) estimates that about 11,300 new cases and

Table 22-3 RISK FACTORS FOR LARYNGEAL OBSTRUCTION

Precipitating Event	Mechanism of Obstruction
History of allergies; exposure to medications, latex, foods (peanuts, tree nuts [eg, walnuts, pecans]), bee stings Foreign body	Anaphylaxis
Heavy alcohol consumption; heavy tobacco use Family history of airway problems	Inhalation/ingestion of meat or other food items, coin, chewing gum, balloon fragments, drug packets (ingested to avoid criminal arrest) Obstruction from tumor Suggests angioedema (type I hypersensitivity reaction)
Use of angiotensin-converting enzyme (ACE) inhibitor Recent throat pain or recent fever History of surgery or previous tracheostomy History of nasogastric tube placement	Increased risk of angioedema of the mucous membranes Infectious process Possible subglottic stenosis Nasogastric tube syndrome

Chart 22-6 • Performing the Abdominal Thrust Maneuver

To assist a patient or other person who is choking on a foreign object, the nurse performs the abdominal thrust maneuver (sometimes called the Heimlich maneuver) according to guidelines set forth by the American Heart Association. (Note: Hands crossed at the neck is the universal sign for choking.)

1. Stand behind the person who is choking.
2. Place both arms around the person's waist.
3. Make a fist with one hand with the thumb outside the fist.
4. Place thumb side of fist against the person's abdomen above the navel and below the xiphoid process.
5. Grasp fist with other hand.
6. Quickly and forcefully exert pressure against the person's diaphragm, pressing upward with quick, firm thrusts.
7. Apply thrusts 6 to 10 times until the obstruction is cleared.
8. The pressure from the thrusts should lift the diaphragm, force air into the lungs, and create an artificial cough powerful enough to expel the aspirated object.

3,660 deaths occur annually, with an overall survival rate of 65%. Cancer of the larynx is most common in people between the ages of 60 and 70 years (Schiech, 2007), and it occurs four to five times more frequently in men than in women.

Carcinogens that have been associated with laryngeal cancer include tobacco (smoke, smokeless) and alcohol and their combined effects (Chart 22-7). Use of chewing tobacco from other countries has increased the risk of laryngeal cancer because of its stronger potency, and the risk of laryngeal cancer may be greater than that associated with cigarette smoking (Sapkota, Gajalakshmi, Jetly, et al.,

2007). Occupational exposure to coal dust, steel dust, iron compounds and fumes, formaldehyde, and dust from hard alloys (eg., still or iron compounds) is associated with hypopharyngeal or laryngeal cancer (Shangina, Brennan, Szeszenia-Dabrowska, et al., 2006). Dietary patterns of Western cultures are associated with an increased risk of supraglottic cancer of the larynx. Other risk factors include straining the voice, chronic laryngitis, nutritional deficiencies (riboflavin), and family predisposition.

Almost all malignant tumors of the larynx arise from the surface epithelium and are classified as squamous cell carcinoma. Approximately 55% of patients with laryngeal cancer present with involved lymph nodes at the time of diagnosis, with bilateral lesions present in 16% of patients (De Vita, Hellman & Rosenberg, 2005). The lifetime survival rate for patients who have small laryngeal cancers without evidence of spread to the lymph nodes is about 75% to 95%. Recurrence occurs usually within the first 2 to 3 years after diagnosis. The presence of disease after 5 years is often secondary to a new primary malignancy. The incidence of distant metastasis with squamous cell carcinoma of the head and neck (including larynx cancer) is relatively low.

Clinical Manifestations

Hoarseness of more than 2 weeks' duration occurs in the patient with cancer in the glottic area because the tumor impedes the action of the vocal cords during speech. The voice may sound harsh, raspy, and lower in pitch. Affected voice sounds are not early signs of subglottic or supraglottic cancer. The patient may complain of a persistent cough or sore throat and pain and burning in the throat, especially when consuming hot liquids or citrus juices. A lump may be felt in the neck. Later symptoms include dysphagia, dyspnea (difficulty breathing), unilateral nasal obstruction or discharge, persistent hoarseness, persistent ulceration, and foul breath. Cervical lymph adenopathy, unintentional weight loss, a general debilitated state, and pain radiating to the ear may occur with metastasis.

CHART 22-7 Risk Factors for Laryngeal Cancer

Carcinogens

- Tobacco (smoke, smokeless)
- Combined effects of alcohol and tobacco
- Asbestos
- Secondhand smoke
- Paint fumes
- Wood dust
- Cement dust
- Chemicals
- Tar products
- Mustard gas
- Leather and metals

Other Factors

- Straining the voice
- Chronic laryngitis
- Nutritional deficiencies (riboflavin)
- History of alcohol abuse
- Familial predisposition
- Age (higher incidence after 60 years of age)
- Gender (more common in men)
- Race (more prevalent in African Americans)
- Weakened immune system

Assessment and Diagnostic Findings

An initial assessment includes a complete history and physical examination of the head and neck. This includes identification of risk factors, family history, and any underlying medical conditions. An indirect laryngoscopy, using a flexible endoscope, is initially performed in the otolaryngologist's office to visually evaluate the pharynx, larynx, and possible tumor. Mobility of the vocal cords is assessed; if normal movement is limited, the growth may affect muscle, other tissue, and even the airway. The neck and the thyroid gland are palpated for enlarged lymph nodes and enlarged thyroid gland.

Diagnostic procedures that may be used include endoscopy, including virtual endoscopy, optical imaging, and CT. If a tumor of the larynx is suspected on an initial examination, a direct laryngoscopic examination is performed under local or general anesthesia to evaluate all areas of the larynx. In some cases, intraoperative examination obtained by direct microscopic visualization and palpation of the vocal folds may yield a more accurate diagnosis. Samples of the suspicious tissue are obtained for analysis.

The classification, including stage of the tumor (ie, size and histology of the tumor, presence and extent of cervical lymph node involvement) and location of the tumor serve as a basis for treatment. CT and MRI are used to assess regional adenopathy and soft tissues and to stage and determine the extent of a tumor. MRI is also helpful in posttreatment follow-up to detect a recurrence. Positron emission tomography (PET) scanning may also be used to detect recurrence of a laryngeal tumor after treatment.

Medical Management

The goals of treatment of laryngeal cancer include cure, preservation of safe, effective swallowing, preservation of useful voice, and avoidance of permanent tracheostoma (Tierney, et al., 2007). Treatment options include surgery, radiation therapy, and chemotherapy. The prognosis depends on the tumor stage, the patient's gender and age, and pathologic features of the tumor, including the grade and depth of infiltration. The treatment plan also depends on whether the cancer is an initial diagnosis or a recurrence. In addition, before treatment begins, a complete dental examination is performed to rule out any oral disease. Any dental problems are resolved, if possible, before surgery and radiotherapy.

For patients with early stage tumors and lesions without lymph node involvement, radiation therapy or surgery may be effective. Surgical procedures may include transoral endoscopic laser resection, classic open vertical hemilaryngectomy for glottic tumors, or classic horizontal supraglottic laryngectomy. Five-year survival rates exceed 80% to 90% with excellent patient-reported satisfaction. In supraglottic tumors, selective neck dissection or irradiation is necessary because of the high risk of neck node involvement (Tierney, et al., 2007). Chemotherapy followed by radiation therapy allows conservation of the larynx without any effect on survival. Concurrent chemoradiotherapy provides high rates of laryngeal preservation (Lefebvre, 2006). Patients with complete response to chemotherapy have a higher probability of cure after hyperfractionation (radiation treatments given in smaller doses but more often than

standard radiation therapy). Some tumors may be treated with hyperfractionated radiation therapy; however, this form of radiation therapy may have more severe short-term side effects (varying degrees of mucositis or inflammation of the mucous membranes) but fewer long-term side effects (Majem, Mesia, Mañós, et al., 2006).

For patients with more advanced disease, cisplatin-based chemotherapy plus radiation protocols have been used effectively. 5-Fluorouracil (5-FU) is also commonly used in the treatment of laryngeal squamous cell cancer. Patients and their physicians must carefully consider the various side effects and complications associated with the different treatment modalities (Tierney, et al., 2007).

The presence of lymph node involvement in the neck can affect the outcome. Supraglottic tumors metastasize early and bilaterally even when there appears to be no lymph node involvement at the time of diagnosis. When the neck is involved, the treatment includes surgery or chemoradiation or both (Tierney, et al., 2007).

Surgical Management

The overall goals for the patient undergoing surgical treatment include minimizing the effects of surgery on speech, swallowing, and breathing while maximizing the cure of the cancer. Several different curative procedures are available that can offer voice-sparing results while achieving a positive cure rate for the patient who has an early laryngeal carcinoma. Surgical options include (1) vocal cord stripping, (2) cordectomy, (3) laser surgery, (4) partial laryngectomy, or (5) total laryngectomy.

Vocal Cord Stripping

Stripping of the cord is used to treat dysplasia, hyperkeratosis, and leukoplakia and is often curative for these lesions. The procedure involves removal of the mucosa of the edge of the vocal cord, using an operating microscope. Early vocal cord lesions are initially treated with radiation therapy.

Cordectomy

Cordectomy, which is an excision of the vocal cord, is usually performed via transoral laser. This procedure is used for lesions limited to the middle third of the vocal cord. The resulting voice quality is related to the extent of tissue removed.

Laser Surgery

Laser microsurgery is well known to have several advantages for treatment of early glottic cancers. Treatment and recovery are shorter, with fewer side effects, and treatment may be less costly than for other forms of therapy (De Vita, et al., 2005). Microelectrodes are useful for surgical resection of smaller laryngeal carcinomas. The carbon dioxide (CO₂) laser can be used for the treatment of many laryngeal tumors, with the exception of large vascular tumors. When compared with the results of other treatments for early laryngeal cancer, laser microsurgery is considered to be the method of choice based on patient outcomes (Ambrosch, 2007).

Partial Laryngectomy

A partial laryngectomy (laryngofissure–thyrotomy) is often used for smaller cancers of the larynx. It is recommended in

the early stages of cancer in the glottic area when only one vocal cord is involved. The surgery is associated with a very high cure rate. It may also be performed for recurrence when high-dose radiation has failed. A portion of the larynx is removed, along with one vocal cord and the tumor; all other structures remain. The airway remains intact, and the patient is expected to have no difficulty swallowing. The voice quality may change, or the patient may sound hoarse.

Total Laryngectomy

Complete removal of the larynx (total **laryngectomy**) can provide the desired cure in most advanced laryngeal cancers, when the tumor extends beyond the vocal cords, or for cancer that recurs or persists after radiation therapy. In a total laryngectomy, the laryngeal structures are removed, including the hyoid bone, epiglottis, cricoid cartilage, and two or three rings of the trachea. The tongue, pharyngeal walls, and trachea are preserved. A total laryngectomy results in permanent loss of the voice and a change in the airway, requiring a permanent tracheostomy (Fig. 22-4). Occasionally, patients continue to have a laryngectomy tube in the stoma. Laryngectomy tubes are similar in appearance to tracheostomy tubes; however, a laryngectomy tube can be distinguished from a tracheostomy tube because the patient is unable to speak or breathe when the laryngectomy tube is occluded. Patients who have a total laryngectomy require alternatives to normal speech; these may include a prosthetic device, such as the Blom-Singer valve, to speak without aspirating.

Surgery is more difficult when the lesion involves the midline structures or both vocal cords. With or without neck dissection, a total laryngectomy requires a permanent tracheal stoma because the larynx that provides the protective sphincter is no longer present. The tracheal stoma prevents the aspiration of food and fluid into the lower respiratory tract. The patient has no voice but has normal swallowing. A total laryngectomy changes the manner in which airflow is used for breathing and speaking, as depicted in Figure 22-4. The patient has significant loss of the natural voice and the need to breathe through an opening (stoma) created in the lower neck. Complications that may occur include a salivary leak, wound infection from the development of a pharyngocutaneous fistula, stomal stenosis, and dysphagia secondary to esophageal stricture. Despite these changes and potential complications, many patients who have undergone a total laryngectomy maintain a good quality of life overall (Woodard, Oplatek & Petruzzelli, 2007). In some cases, the patient may be a candidate for a near-total laryngectomy. In this situation, the patient would be a candidate for chemotherapy and radiotherapy regimens postoperatively. Voice preservation can be achieved in most cases.

Advances in surgical techniques for treating laryngeal cancer may minimize the cosmetic and functional deficits previously seen with total laryngectomy. Some microlaryngeal surgery can be performed endoscopically.

Radiation Therapy

The goal of radiation therapy is to eradicate the cancer and preserve the function of the larynx. The decision to use radiation therapy is based on several factors, including the

Figure 22-4 Total laryngectomy produces a change in airflow for breathing and speaking. **A**, Normal airflow. **B**, Airflow after total laryngectomy.

staging of the tumor and the patient's overall health status, lifestyle (including occupation), and personal preference. Excellent results have been achieved with radiation therapy in patients with early stage glottic tumors when only one vocal cord is involved and there is normal mobility of the cord (ie, with phonation), as well as in small supraglottic lesions. One of the benefits of radiation therapy is that patients retain a near-normal voice. A few may develop chondritis (inflammation of the cartilage) or stenosis; a small number may later require laryngectomy.

Radiation therapy may also be used preoperatively to reduce the tumor size. Radiation therapy is combined with surgery in advanced laryngeal cancer as adjunctive therapy to surgery or chemotherapy and as a palliative measure. A variety of clinical trials have combined chemotherapy and radiation therapy in the treatment of advanced laryngeal tumors.

NURSING RESEARCH PROFILE

Speech Impairment After Surgery for Head and Neck Cancer

Rodriguez, C. S. & VanCott, M. L. (2005). Speech impairment in the postoperative head and neck cancer patient: Nurses' and patients' perceptions, *Qualitative Health Research*, 15(7), 897–911.

Purpose

Patients who undergo surgery for treatment of head and neck cancer are often unable to verbally communicate their needs in the immediate postoperative period. Furthermore, these patients have postoperative pain, and nurses caring for these patients need strategies to assess and manage the patients' pain. The purposes of this study were (1) to explore the experience of postoperative pain for the patient with head and neck cancer and speech impairment and (2) to explore strategies used by nurses to assess and manage pain related to head and neck cancer treatment in the immediate postoperative period.

Design

This qualitative study, which was part of a larger study that included quantitative and qualitative methods, used individual written interviews for nine patients following surgical treatment of head and neck cancer and individual interviews as well as a focus group of six nurses. Patients were asked about their pain and how they tried to describe the pain without the use of speech. Nurses were asked what strategies they used to measure pain in patients with pain and communication impairment and how they made decisions about pain management when the patient with head and neck cancer is unable to communicate. Interviews from both patients and nurses were analyzed to uncover patterns.

Findings

Two issues identified from the nurses' responses related to measuring pain and decision making about pain management. Nurses identified use of a systematic approach in measuring postoperative pain in patients with head and neck cancer,

including use of questions and observation of vital signs and patient behaviors to assess the presence and severity of pain. They reported asking patients directly about the presence of pain and described the importance of giving patients time to express their needs. Decision making for nurses was based on the need to relieve the patient's pain level to promote healing and recovery.

Patients described the challenge of trying to communicate their pain with a speech impairment and the strategies that they found useful in trying to convey information about their pain to others. They used nonverbal methods (gestures, pointing to painful area, grimacing) and a pain intensity scale to indicate the presence and severity of the pain. They reported the need to be persistent in communicating pain, especially when moved from the critical care area to a general medical-surgical unit.

Both nurses and patients expressed frustration about the pain experience. Patients were more likely to report an inability to express themselves, and nurses were more likely to report problems in adequately assessing pain.

Nursing Implications

Strategies for assessment and management of pain following head and neck surgery for treatment of cancer should be established prior to surgery. These approaches should be developed both by nurses and patients, and strategies should address not only the immediate postoperative period spent in critical care units, but also medical-surgical units, where there are fewer nurses caring for patients than in specialized units. Methods of communication must be established for patients out of the immediate view of nurses because patients are unable to summon assistance through an intercom system. Advanced planning that targets effective assessment and management of postoperative pain is more likely to reduce the frustrations experienced by patients and nurses and result in more effective pain management.

Advances in research and treatment of these tumors with surgery, chemotherapy, and radiation therapy have improved outcomes and decreased the incidence of posttreatment morbidities (De Vita, et al., 2005). Radiation therapy combined with chemotherapy may be an alternative to a total laryngectomy.

Complications from radiation therapy are a result of external radiation to the head and neck area, which may also include the parotid gland, which is responsible for mucus production. Symptoms may include acute mucositis, ulceration of the mucous membranes, pain, **xerostomia** (dry mouth), loss of taste, dysphasia, fatigue, and skin reactions. Later complications may include laryngeal necrosis, edema, and fibrosis.

Speech Therapy

The patient who undergoes a laryngectomy and the patient's family face potentially complex challenges, including significant changes in the ability to communicate. To minimize anxiety and frustration on the part of the patient and family, it is necessary to discuss the loss or alteration of

speech with them. To plan postoperative communication strategies and speech therapy, the speech therapist or pathologist conducts a preoperative evaluation. During this time, the nurse discusses with the patient and family methods of communication that will be available in the immediate postoperative period. These include writing, lip speaking and reading, and communication or word boards (Chart 22-8). A system of communication is established with the patient, family, nurse, and physician and is implemented consistently after surgery.

In addition, a long-term postoperative communication plan for **alaryngeal communication** is developed. The three most common techniques of alaryngeal communication are esophageal speech, artificial larynx (electrolarynx), and tracheoesophageal puncture. Training in these techniques begins once medical clearance is obtained from the physician.

Esophageal Speech

Esophageal speech was the primary method of alaryngeal speech taught to patients until the 1980s. The patient needs the ability to compress air into the esophagus and expel it,

setting off a vibration of the pharyngeal esophageal segment. The technique can be taught once the patient begins oral feedings, approximately 1 week after surgery. First, the patient learns to belch and is reminded to do so an hour after eating. Then the technique is practiced repeatedly. Later, this conscious belching action is transformed into simple explosions of air from the esophagus for speech purposes. The speech therapist continues to work with the patient to make speech intelligible and as close to normal as possible. Because it takes a long time to become proficient, the success rate is low.

Electric Larynx

If esophageal speech is not successful, or until the patient masters the technique, an electric larynx may be used for communication. This battery-powered apparatus projects sound into the oral cavity. When the mouth forms words (articulation), the sounds from the electric larynx become audible words. The voice that is produced sounds mechanical, and some words may be difficult to understand. The advantage is that the patient is able to communicate with relative ease while working to become proficient at either esophageal or tracheoesophageal puncture speech.

Tracheoesophageal Puncture

The third technique of alaryngeal speech is tracheoesophageal puncture (Fig. 22-5). This technique for voice restoration is simple and has few complications. It is associated with high phonation success, good phonation quality, and steady long-term results. This technique is widely used because the speech associated with it most resembles normal speech (the sound produced is a combination of esophageal speech and voice), and it is easily learned. A valve is placed in the tracheal stoma to divert air into the esophagus and out the mouth. Once the puncture is surgically created and has healed, a voice prosthesis (Blom-Singer) is fitted over the puncture site. A speech therapist

Figure 22-5 Schematic representation of tracheoesophageal puncture speech. Air travels from the lung through a puncture in the posterior wall of the trachea into the esophagus and out the mouth. A voice prosthesis is fitted over the puncture site.

teaches the patient how to produce sounds. Moving the tongue and lips to form the sound into words produces speech as before. To prevent airway obstruction, the prosthesis is removed and cleaned when mucus builds up.

The success of these various approaches to preserve or restore speech varies. Tracheoesophageal puncture is recommended in patients without previous radiation therapy since success rates decline for patients who have had previous radiation therapy (Kummer, Chahoud, Schuster, et al., 2006).

NURSING PROCESS

THE PATIENT UNDERGOING LARYNGECTOMY

Assessment

The nurse obtains a health history and assesses the patient's physical, psychosocial, and spiritual domains. The health history addresses the following symptoms: hoarseness, sore throat, dyspnea, dysphagia, and pain or burning in the throat. The physical assessment includes a thorough head and neck examination with an emphasis on the patient's airway. In addition, the neck and thyroid are palpated for swelling, nodularity, or adenopathy.

The nurse also assesses the patient's general state of nutrition, including height and weight and body mass index and reviews laboratory values that assist in determining the patient's nutritional status (albumin, protein, glucose, and electrolyte levels). If treatment includes surgery, the nurse must know the nature of the surgery to plan appropriate care. If the patient is expected to have no voice as a result of the surgical procedure, a preoperative evaluation by the speech therapist is essential. The patient's ability to hear, see, read, and write is assessed. Visual impairment and functional illiteracy may create additional problems with communication and may require creative approaches to ensure that the patient is able to communicate any needs. Because alcohol abuse is a risk factor for cancer of the larynx, it is essential to assess the patient's pattern of alcohol intake. Patients who are accustomed to daily consumption of alcohol are at risk for alcohol withdrawal syndrome (delirium tremens) when alcohol intake is stopped suddenly.

In addition, the nurse assesses the psychological readiness of the patient and family (Chart 22-9). The thought of having cancer is frightening to most people. Fear is compounded by the possibility of permanent voice loss and, in some cases, some degree of disfigurement. The nurse evaluates the patient's and family's knowledge of the planned surgical procedure and expected postoperative course and assesses the patient's and family's coping methods and support systems. The nurse assesses the patient's spirituality needs based on the patient's individual preferences, beliefs, and culture.

Diagnosis

Nursing Diagnoses

Based on all the assessment data, major nursing diagnoses may include the following:

- Deficient knowledge about the surgical procedure and postoperative course

Ethics and Related Issues

Situation

You are the nurse working the morning shift on a medical-surgical unit at your local hospital. You are caring for an elderly 82-year-old man with a new diagnosis of advanced stage IV cancer of the larynx. The surgeon has determined that this patient needs to undergo a total laryngectomy for better control of the disease. Although the patient continues to live at home, he has early signs of senile dementia along with significant weight loss; he is quite debilitated and frail. He has a history of tobacco abuse and continues to smoke one pack of cigarettes per day. He is a widow with two living children: one daughter and one son. Because of his dementia, the patient is not able to sign consent for his total laryngectomy. The patient's daughter has informed the surgeon that she will not agree to sign surgical consent for a total laryngectomy. She is very concerned about the possible outcome of the surgery and has informed you that she knows for certain that her father would not want this surgery and would want to live at home and not in a nursing home facility. The daughter has asked to speak with you regarding her concerns. The patient's son is in agreement with the recommendation for a total laryngectomy and would be willing to sign surgical consent, but he lives out of state and cannot travel at this time. He is estranged from his sister. The patient does not have a designated health care surrogate or power of attorney.

Dilemma

This patient has been diagnosed with a life-threatening illness and needs surgical intervention for control of the disease. He is unable to make medical decisions due to his dementia, and therefore it is now the responsibility of his children in the absence of a spouse to function as his health care surrogate. Based on his physical appearance and condition, he appears to be unable to care for himself. His children are not in agreement regarding the recommended treatment plan. This poses an ethical dilemma that must be resolved so that the patient can receive adequate and timely treatment for his illness and appropriate physical, psychological, and home care should he undergo this procedure.

Discussion

1. Based on the above scenario, what further assessment of the patient's physical and psychosocial condition is needed prior to his surgery and why?
2. What is the relevance for evaluation of the patient's home environment in relation to his need for total laryngectomy?
3. You need to reinforce the education given by the surgeon to the patient's daughter and son regarding the possible complications of a total laryngectomy. Briefly discuss each complication as you would with the patient's daughter and son.
4. What other health care resources should be consulted given the above scenario?
5. Given the patient's dementia, would it be reasonable to communicate to him the plan of care and education about the recommended treatment and possible side effects?

- Anxiety and depression related to the diagnosis of cancer and impending surgery
- Ineffective airway clearance related to excess mucus production secondary to surgical alterations in the airway
- Impaired verbal communication related to anatomic deficit secondary to removal of the larynx and to edema
- Imbalanced nutrition: less than body requirements, related to inability to ingest food secondary to swallowing difficulties
- Disturbed body image and low self-esteem secondary to major neck surgery, change in appearance, and altered structure and function
- Self-care deficit related to pain, weakness, fatigue, musculoskeletal impairment related to surgical procedure and postoperative course

Collaborative Problems/Potential Complications

Based on assessment data, potential complications that may develop include the following:

- Respiratory distress (hypoxia, airway obstruction, tracheal edema)
- Hemorrhage, infection, and wound breakdown
- Aspiration
- Tracheostomal stenosis

Planning and Goals

The major goals for the patient may include attainment of an adequate level of knowledge, reduction in anxiety, maintenance of a patent airway (patient is able to handle own secretions), effective use of alternative means of communication, attainment of optimal levels of nutrition and hydration, improvement in body image and self-esteem, improved self-care management, and absence of complications.

Nursing Interventions

Teaching the Patient Preoperatively

The diagnosis of laryngeal cancer often produces misconceptions and fears. Many people assume that loss of speech and disfigurement are inevitable with this condition. Once the physician explains the diagnosis and discusses treatment options with the patient and family, the nurse clarifies any misconceptions by identifying the location of the larynx, its function, the nature of the planned surgical procedure, and its effect on speech. Further, the patient's ability to sing, laugh, and whistle will be lost. Informational materials (written and audiovisual) about the surgery are given to the patient and family for review and reinforcement. If a complete laryngectomy is planned, the patient must understand that the natural voice will be lost, but that special training can provide a means for communicating. The patient needs to know that until training is started, communication will be possible by using the call light, by writing, or by using a special communication board. The interdisciplinary team conducts an initial assessment of the patient and family. In addition to the nurse in charge of the patient's care and the physician, the team might include an advanced practice nurse or nurse practitioner, speech therapist, respiratory therapist, social worker, dietitian, and home care nurse. The

services of a spiritual advisor are made available to the patient and family, as appropriate.

The nurse also reviews equipment and treatments for postoperative care with the patient and family, teaches important coughing and deep-breathing exercises, and helps the patient perform return demonstrations. The nurse clarifies the patient's role in the postoperative and rehabilitation periods. The family's needs must also be addressed because family members are often responsible for complex care of the patient in the home.

Reducing Anxiety and Depression

Because surgery of the larynx is performed most often for a malignant tumor, the patient may have many questions: Will the surgeon be able to remove all of the tumor? Is it cancer? Will I die? Will I choke? Will I suffocate? Will I ever speak again? What will I look like? Because of these and other questions, the psychological preparation of the patient is as important as the physical preparation.

Any patient undergoing surgery may have many fears. In laryngeal surgery, these fears may relate to the diagnosis of cancer and the possibility of permanent loss of the voice and disfigurement. The nurse provides the patient and family with opportunities to ask questions, verbalize feelings, and discuss perceptions. The nurse should address any questions and misconceptions the patient and family have. During the preoperative or postoperative period, a visit from someone who has had a laryngectomy may reassure the patient that people are available to assist and that rehabilitation is possible.

In the immediate postoperative period, the nurse attempts to spend uninterrupted time with the patient that is focused on building trust and reducing the patient's anxiety. Active listening provides an environment that promotes open communication and allows the patient to verbalize feelings. Clear instructions and explanations are given to the patient and family in a calm, reassuring manner. The nurse listens attentively, encourages the patient, and identifies and reduces environmental stressors. The nurse seeks to learn from the patient what activities promote feelings of comfort and assists the patient in such activities (eg, listening to music, reading). Relaxation techniques such as guided imagery and meditation are often helpful. The nurse remains with the patient during episodes of severe anxiety and includes the patient in decision making. To support the family, it may be necessary to allow extra visiting periods.

Maintaining a Patent Airway

The nurse promotes a patent airway by positioning the patient in the semi-Fowler's or Fowler's position after recovery from anesthesia. This position decreases surgical edema and promotes lung expansion. Observing the patient for restlessness, labored breathing, apprehension, and increased pulse rate helps identify possible respiratory or circulatory problems. The nurse assesses the patient's lung sounds and reports changes that may indicate impending complications. Medications that depress respiration, particularly opioids, should be used cautiously. However, adequate use of analgesic medications is essential for pain relief because postoperative pain can result in shallow breathing and an ineffective cough. The nurse encourages the patient to turn, cough, and take deep breaths. If necessary, suctioning may

be performed to remove secretions, but disruption of suture lines must be avoided. The nurse also encourages and assists the patient with early ambulation to prevent atelectasis, pneumonia, and deep vein thrombosis. Pulse oximetry is used to monitor the patient's oxygen saturation level.

If a total laryngectomy was performed, a laryngectomy tube will most likely be in place. In some instances a laryngectomy tube is not used; in others it is used temporarily; and in many it is used permanently. The laryngectomy tube, which is shorter than a tracheostomy tube but has a larger diameter, is the patient's only airway. The care of this tube is similar to that for a tracheostomy tube (see Chapter 25). The nurse changes the inner cannula (if present) every 8 hours if it is disposable. Although nondisposable tubes are used infrequently, if one is used, the nurse cleans the inner cannula every 4 to 6 hours or more often as needed. It should be replaced within 30 to 60 minutes after removal (Schiech, 2007). If a tracheostomy tube without an inner cannula is used, humidification and suctioning of this tube are essential to prevent formation of mucous plugs. If a T-shaped laryngectomy tube is used, both sides of the T-tube should be suctioned to prevent obstruction due to copious secretions. The nurse should also use secure tracheostomy ties to prevent tube dislodgement. The nurse cleans the stoma daily with soap and water or another prescribed solution and a soft cloth or gauze, taking care to prevent water and soap or solution from entering the stoma (Schiech, 2007). If a non-oil-based antibiotic ointment is prescribed, it is applied around the stoma and suture line. If crusting appears around the stoma, the crusts are removed with sterile tweezers and additional ointment is applied.

Wound drains, inserted during surgery, may be in place to assist in removal of fluid and air from the surgical site. Suction also may be used, but cautiously, to avoid trauma to the surgical site and incision. The nurse observes, measures, and records drainage. When drainage is less than 30 mL/day for 2 consecutive days, the physician usually removes the drains.

Frequently, the patient coughs up large amounts of mucus through this opening. Because air passes directly into the trachea without being warmed and moistened by the upper respiratory mucosa, the tracheobronchial tree compensates by secreting excessive amounts of mucus. Therefore, the patient has frequent coughing episodes and may develop a brassy-sounding, mucus-producing cough. The nurse reassures the patient that these problems will diminish in time, as the tracheobronchial mucosa adapts to the altered physiology.

After the patient coughs, the tracheostomy opening must be wiped clean and clear of mucus. A simple gauze dressing, washcloth, or even paper towel (because of its size and absorbency) worn below the tracheostomy may serve as a barrier to protect the clothing from the copious mucus that the patient may initially expel.

One of the most important factors in decreasing cough, mucus production, and crusting around the stoma is adequate humidification of the environment. Mechanical humidifiers and aerosol generators (nebulizers) increase the humidity and are important for the patient's comfort. The laryngectomy tube may be removed when the stoma is well healed, within 3 to 6 weeks after surgery. The nurse teaches the patient how to clean and change the tube (see Chapter 25) and remove secretions.

Promoting Alternative Communication Methods

Establishing an effective means of communication is usually the ultimate goal in the rehabilitation of the laryngectomy patient. To understand and anticipate the patient's postoperative needs, the nurse works with the patient, speech therapist, and family to encourage use of alternative communication methods. These means of communication are established preoperatively and must be used consistently by all personnel who come in contact with the patient postoperatively. The patient is now unable to use an intercom system. A call bell or hand bell must be placed within easy reach of the patient. A Magic Slate is often used for communication, and the nurse documents which hand the patient uses for writing so that the opposite arm can be used for IV infusions. (To ensure the patient's privacy, the nurse discards notes used for communication.) If the patient cannot write, a picture-word-phrase board or hand signals can be used.

Writing everything or communicating through gestures can be very time-consuming and frustrating. The patient must be given adequate time to communicate his or her needs. The patient may become impatient and angry when not understood.

Promoting Adequate Nutrition and Hydration

Postoperatively, the patient may not be permitted to eat or drink for several days. Alternative sources of nutrition and hydration include IV fluids, enteral feedings through a nasogastric or gastrostomy tube, and parenteral nutrition.

When the patient is ready to start oral feedings, a speech therapist or radiologist may conduct a swallow study (a video fluoroscopy radiology procedure) to evaluate the patient's risk of aspiration. Once the patient is cleared for oral feedings, the nurse explains that thick liquids will be used first because they are easy to swallow. Different swallowing maneuvers are attempted with various food consistencies. Once the patient is cleared for food intake, the nurse stays with the patient during initial oral feedings and keeps a suction setup at the bedside for needed suctioning. The nurse instructs the patient to avoid sweet foods, which increase salivation and suppress the appetite. Solid foods are introduced as tolerated. The patient is instructed to rinse the mouth with warm water or mouthwash after oral feedings and to brush the teeth frequently.

Because taste and smell are so closely related, taste sensations are altered for a while after surgery because inhaled air passes directly into the trachea, bypassing the nose and the olfactory end organs. In time, however, the patient usually accommodates to this change and olfactory sensation adapts, often with return of interest in eating. The nurse observes the patient for any difficulty in swallowing, particularly when eating resumes, and reports its occurrence to the physician.

The patient's weight and laboratory data are monitored to ensure that nutritional and fluid intake are adequate. In addition, skin turgor and vital signs are assessed for signs of decreased fluid volume.

Promoting Positive Body Image and Self-Esteem

Disfiguring surgery and an altered communication pattern are threats to a patient's body image and self-esteem. The

reaction of family members and friends is a major concern for the patient. The nurse encourages the patient to express feelings about the changes brought about by surgery, particularly feelings related to fear, anger, depression, and isolation. Encouraging use of previous effective coping strategies may be helpful. Referral to a support group, such as International Association of Laryngectomees (IAL), WebWhispers, and I Can Cope (through the American Cancer Society) may help the patient and family deal with the changes in their lives. Contact information for these support groups can be found at the end of the chapter.

Promoting Self-Care Management

A positive approach along with promotion of self-care activities are important when caring for the patient. The patient should begin participating in self-care activities as soon as possible. The nurse assesses the patient's readiness for decision making and encourages the patient to participate actively in performing care. The nurse provides positive reinforcement when the patient makes an effort in self-care. The nurse needs to be a good listener and a support to the family, especially when explaining the tubes, dressings, and drains that are in place postoperatively.

In addition to its work through support groups, the IAL encourages an exchange of ideas and methods for learning and teaching alaryngeal methods of communication. It also works to promote employers' understanding about cancer of the larynx and to enable patients to retain or obtain employment after surgery.

Monitoring and Managing Potential Complications

The potential complications after laryngectomy include respiratory distress and hypoxia, hemorrhage, infection, wound breakdown, aspiration, and tracheostomal stenosis.

RESPIRATORY DISTRESS AND HYPOXIA. The nurse monitors the patient for signs and symptoms of respiratory distress and hypoxia, particularly restlessness, irritation, agitation, confusion, tachypnea, use of accessory muscles, and decreased oxygen saturation on pulse oximetry (SpO₂). Any change in respiratory status requires immediate intervention. Hypoxia may cause restlessness and an initial rise in blood pressure; this is followed by hypotension and somnolence. Cyanosis is a late sign of hypoxia. Obstruction needs to be ruled out immediately by suctioning and by having the patient cough and breathe deeply. Hypoxia and airway obstruction, if not immediately treated, are life-threatening.

Other nursing measures include repositioning of the patient to ensure an open airway and administering oxygen as prescribed and used with caution in patients with chronic obstructive pulmonary disease. The nurse should always be prepared for possible intubation and mechanical ventilation. The nurse must be knowledgeable about the hospital's emergency code protocols and skilled in use of emergency equipment. The nurse must remain with the patient at all times during respiratory distress. The emergency call bell and telephone should be used to initiate a code, call for further assistance, and summon the physician immediately if nursing measures do not improve the patient's respiratory status.

HEMORRHAGE. Bleeding from the drains at the surgical site or with tracheal suctioning may signal the occurrence of

hemorrhage. The nurse promptly notifies the surgeon of any active bleeding, which can occur at a variety of sites, including the surgical site, drains, and trachea. Rupture of the carotid artery is especially dangerous. Should this occur, the nurse must apply direct pressure over the artery, summon assistance, and provide emotional support to the patient until the vessel is ligated. The nurse monitors vital signs for changes, particularly increased pulse rate, decreased blood pressure, and rapid deep respirations. Cold, clammy, pale skin may indicate active bleeding. IV fluids and blood components may be administered and other measures implemented to prevent or treat hemorrhagic shock. Management of the patient with shock is discussed in detail in Chapter 15.

INFECTION. The nurse monitors the patient for signs of postoperative infection. These include an increase in temperature and pulse, a change in the type of wound drainage, and increased areas of redness or tenderness at the surgical site. Other signs include purulent drainage, odor, and increased wound drainage. The nurse monitors the patient's white blood cell (WBC) count; a rise in WBCs may indicate the body's effort to combat infection. In elderly patients, infection can be present without an increase in the patient's WBC count; therefore, the nurse must monitor the patient for more subtle signs. WBCs are suppressed in the patient with decreased immune function (eg, patients with HIV infection, or those receiving chemotherapy or radiation therapy); this predisposes the patient to a severe infection and sepsis. Antimicrobial (antibiotic) medications must be administered as scheduled. All suspicious drainage is cultured, and the patient may be placed in isolation as indicated. Strategies are implemented to minimize the exposure of the patient to micro-organisms and their spread to others. The nurse reports any significant change in the patient's status to the surgeon.

WOUND BREAKDOWN. Wound breakdown caused by infection, poor wound healing, development of a fistula, radiation therapy, or tumor growth can create a life-threatening emergency. The carotid artery, which is close to the stoma, may rupture from erosion if the wound does not heal properly. The nurse observes the stoma area for wound breakdown, hematoma, and bleeding and reports their occurrence to the surgeon. If wound breakdown occurs, the patient must be monitored carefully and identified as at high risk for carotid hemorrhage.

ASPIRATION. The patient who has undergone a laryngectomy is at risk for aspiration and aspiration pneumonia due to depressed cough, the sedating effects of anesthetic and analgesic medications, alteration in the airway, impaired swallowing, and the administration of tube feedings. The nurse assesses for the presence of nausea and administers antiemetic medications, as prescribed. The nurse keeps a suction setup available in the hospital and instructs the family to do so at home for use if needed. Patients receiving tube feedings are positioned with the head of the bed at 30 degrees or higher during feedings and for 30 to 45 minutes after tube feedings. Patients receiving oral feedings are positioned with the head of the bed in an upright position for 30 to 45 minutes after feedings. For patients with a naso-

gastric or gastrostomy tube, the placement of the tube and residual gastric volume must be checked before each feeding. High amounts of residual volume (greater than 50% of previous intake) indicate delayed gastric emptying; this can lead to reflux and aspiration. Signs or symptoms of aspiration are reported to the physician immediately.

TRACHEOSTOMAL STENOSIS. Tracheostomal stenosis is an abnormal narrowing of the trachea or the tracheostomy stoma. Infection at the stoma site, excessive traction on the tracheostomy tube by the connecting tubing, and persistent high tracheostomy cuff pressure are risk factors for tracheostomal stenosis. The incidence of this condition varies widely, and it is often preventable. The nurse assesses the patient's stoma for signs and symptoms of infection and reports any evidence of this to the physician immediately. Tracheostomy care is performed routinely. The nurse assesses the connecting tubing (eg, ventilation tubing) and secures the tubing to avoid excessive traction on the patient's tracheostomy. The nurse ensures that the tracheostomy cuff is deflated (for a patient with a cuffed tube) except for short periods, such as when the patient is eating or taking medications.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The nurse has an important role in the recovery and rehabilitation of the patient who has had a laryngectomy. In an effort to facilitate the patient's ability to manage self-care, discharge instruction begins as soon as the patient is able to participate. Nursing care and patient teaching in the hospital, outpatient setting, and rehabilitation or long-term care facility must take into consideration the many emotions, physical changes, and lifestyle changes experienced by the patient. In preparing the patient to go home, the nurse assesses the patient's readiness to learn and the level of knowledge about self-care management. The nurse also reassures the patient and family that most self-care management strategies can be mastered. The patient needs to learn a variety of self-care behaviors, including tracheostomy and stoma care, wound care, and oral hygiene. The nurse also instructs the patient about the need for adequate dietary intake, safe hygiene, and recreational activities.

Tracheostomy and Stoma Care. The nurse provides specific instructions to the patient and family about what to expect with a tracheostomy and its management. The nurse teaches the patient and caregiver to perform suctioning and emergency measures and tracheostomy and stoma care. The nurse stresses the importance of humidification at home and instructs the family to obtain and set up a humidification system before the patient returns home. In addition, the nurse cautions the patient and family that air-conditioned air may be too cool or too dry, and therefore irritating for the patient with a new laryngectomy. (See Chapter 25 for details about tracheostomy care.)

Hygiene and Safety Measures. The nurse instructs the patient and family about safety precautions that are needed because of the changes in structure and function resulting from the surgery. Special precautions are needed in the

CHART
22-10  HOME CARE CHECKLIST
The Patient With a Laryngectomy

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate methods to clear the airway and handle secretions	✓	✓
• Explain the rationale for maintaining adequate humidification with a humidifier or nebulizer	✓	✓
• Demonstrate how to clean the skin around the stoma and how to use ointments and tweezers to remove encrustations	✓	✓
• State the rationale for wearing a loose-fitting protective cloth at the stoma	✓	✓
• Discuss the need to avoid cold air from air conditioning and the environment to prevent irritation of the airway	✓	✓
• Demonstrate safe technique in changing the laryngectomy/tracheostomy tube	✓	✓
• Identify the signs and symptoms of wound infection and state what to do about them	✓	✓
• Describe safety or emergency measures to implement in case of breathing difficulty or bleeding	✓	✓
• State the rationale for wearing or carrying special medical identification and ways to obtain help in an emergency	✓	✓
• Explain the importance of covering the stoma when showering or bathing	✓	✓
• Identify fluid and caloric needs	✓	✓
• Describe mouth care and discuss its importance	✓	✓
• Demonstrate alternative communication methods	✓	
• Identify support groups and agency resources	✓	✓
• State the need for regular checkups and reporting of any problems immediately	✓	✓

shower to prevent water from entering the stoma. Wearing a loose-fitting plastic bib over the tracheostomy or simply holding a hand over the opening is effective. Swimming is not recommended because a person with a laryngectomy can drown without submerging his or her face. Barbers and beauticians need to be alerted so that hair sprays, loose hair, and powder do not get near the stoma, because they can block or irritate the trachea and possibly cause infection. These self-care points are summarized in Chart 22-10.

The nurse teaches the patient and caregiver the signs and symptoms of infection and identifies indications that require contacting the physician after discharge. A discussion regarding cleanliness and infection control behaviors is essential in the education of the patient. The nurse teaches the patient and family to wash their hands before and after caring for the tracheostomy, to use tissue to remove mucus, and to dispose of soiled dressings and equipment properly. If the patient's surgery included cervical lymph node dissection, the nurse teaches the patient exercises for strengthening the shoulder and neck muscles.

Recreation and exercise are important for the patient's well-being and quality of life, and all but very strenuous exercise can be enjoyed safely. Avoidance of strenuous exercise and fatigue is important because the patient will have more difficulty speaking when tired, which can be discouraging. Additional safety points to address include the need for the patient to wear or carry medical identification, such as a bracelet or card, to alert medical personnel to the special requirements for resuscitation should this need arise. If

resuscitation is needed, direct mouth-to-stoma ventilation should be performed. For home emergency situations, pre-recorded emergency messages for police, the fire department, or other rescue services can be kept near the phone to be used quickly.

The nurse instructs and encourages the patient to perform oral care on a regular basis to prevent halitosis and infection. If the patient is receiving radiation therapy, synthetic saliva may be required because of decreased saliva production. The nurse instructs the patient to drink water or sugar-free liquids throughout the day and to use a humidifier at home. Brushing the teeth or dentures and rinsing the mouth several times a day will assist in maintaining proper oral hygiene.

CONTINUING CARE. Referral for home care is an important aspect of postoperative care for the patient who has had a laryngectomy and will assist the patient and family in the transition to the home. The home care nurse assesses the patient's general health status and the ability of the patient and family to care for the stoma and tracheostomy. The nurse assesses the surgical incisions, nutritional and respiratory status, and adequacy of pain management. The nurse assesses for signs and symptoms of complications and the patient's and family's knowledge of signs and symptoms to be reported to the physician. During the home visit, the nurse identifies and addresses other learning needs and concerns of the patient and family, such as adaptation to physical, lifestyle, and functional changes, as well as the patient's progress with learning and using new communication strategies. The nurse

assesses the patient's psychological status as well. The home care nurse reinforces previous teaching and provides reassurance and support to the patient and family caregivers as needed.

It is important that the person who has had a laryngectomy have regular physical examinations and seek advice concerning any problems related to recovery and rehabilitation. The nurse also reminds the patient to participate in health promotion activities and health screening and about the importance of keeping scheduled appointments with the physician, speech therapist, and other health care providers.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Demonstrates an adequate level of knowledge, verbalizing an understanding of the surgical procedure and performing self-care adequately
2. Demonstrates less anxiety and depression
 - a. Expresses a sense of hope
 - b. Is aware of available community organizations and agencies that provide patient education and support groups
 - c. Participates in support group for people with a laryngectomy
3. Maintains a clear airway and handles own secretions; also demonstrates practical, safe, and correct technique for cleaning and changing the tracheostomy or laryngectomy tube
4. Acquires effective communication techniques
 - a. Uses assistive devices and strategies for communication (Magic Slate, call bell, picture board, sign language, speech reading, computer aids)
 - b. Follows the recommendations of the speech therapist
 - c. Demonstrates ability to communicate with new communication strategy
 - d. Reports availability of prerecorded messages to summon emergency assistance by telephone
5. Maintains adequate nutrition and adequate fluid intake
6. Exhibits improved body image, self-esteem, and self-concept
 - a. Expresses feelings and concerns
 - b. Participates in self-care and decision making
 - c. Accepts information about support group
7. Adheres to rehabilitation and home care program
 - a. Practices recommended speech therapy
 - b. Demonstrates proper methods for caring for stoma and laryngectomy or tracheostomy tube (if present)
 - c. Verbalizes understanding of symptoms that require medical attention
 - d. States safety measures to take in emergencies
 - e. Performs oral hygiene as prescribed
8. Absence of complications
 - a. Demonstrates a patent airway
 - b. No bleeding from surgical site and minimal bleeding from drains; vital signs (blood pressure, temperature, pulse, respiratory rate) are normal

- c. No redness, tenderness, or purulent drainage at surgical site
- d. No wound breakdown
- e. Clear breath sounds; oxygen saturation level within acceptable range; chest x-ray clear
- f. No indications of infection, stenosis, or obstruction of tracheal stoma

CRITICAL THINKING EXERCISES

1 A 20-year-old male college student comes to the student health clinic with complaints of a sore throat and a fever lasting more than 12 days. Your physical assessment reveals a fiery-red pharyngeal membrane and tonsils with white-purple exudates and a scarlatina-form rash on the chest, abdomen, and axilla. What diagnostic tests and treatment would you anticipate for this patient? What teaching is needed to ensure that he complies with the treatment plan? What additional nursing measures would be indicated for this patient if he indicates that he is opposed to use of all medications because of his cultural and religious beliefs?

2 You are working in a sleep apnea clinic. A man has been referred to the clinic for testing. What risk factors for obstructive sleep apnea (OSA) will your health history focus on? What are the common signs and symptoms of OSA? What diagnostic tool is used to diagnose sleep apnea and how would you explain the diagnostic procedure to the patient? Once the diagnosis of OSA is confirmed, continuous positive airway pressure (CPAP) is prescribed. What instructions would you provide about CPAP? How would you modify your teaching if the patient does not speak English? If he is blind?

EBP 3 You are with your family at a company picnic and you see that a coworker is grasping her throat and is unable to speak or cough. You suspect that she is choking. You know that the abdominal thrust is used to remove a foreign object from a conscious adult who is choking. Briefly describe what you would do in this situation. What is the evidence base for your actions? How would you determine the strength of the evidence on which your actions are based?

EBP 4 You are the home health nurse for a female patient who has undergone a total laryngectomy for the treatment of cancer of the larynx. You are responsible to provide patient education regarding tracheostomy care and gastric tube feedings. The overall plan is for the patient to begin to assume responsibility for her own care and to consider speech therapy, but the patient and her husband believe she is not yet ready to do so. What are your priorities in terms of assessment of this patient? What is your plan to address the patient's fear, anxiety, communication, and nutrition needs? What is the evidence base for your actions in response to the patient's fear, anxiety, communication, and nutritional needs? How would you assess the strength of the evidence on which your actions are based?

Management of Patients With Chest and Lower Respiratory Tract Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify patients at risk for atelectasis and nursing interventions related to its prevention and management.
- 2 Compare the various pulmonary infections with regard to causes, clinical manifestations, nursing management, complications, and prevention.
- 3 Use the nursing process as a framework for care of the patient with pneumonia.
- 4 Describe nursing measures to prevent aspiration.
- 5 Relate pleurisy, pleural effusion, and empyema to pulmonary infection.
- 6 Describe smoking and air pollution as causes of pulmonary disease.
- 7 Relate the therapeutic management techniques of acute respiratory distress syndrome to the underlying pathophysiology of the syndrome.
- 8 Describe risk factors and measures appropriate for prevention and management of pulmonary embolism.
- 9 Describe preventive measures appropriate for controlling and eliminating occupational lung disease.
- 10 Discuss the modes of therapy and related nursing management for patients with lung cancer.
- 11 Describe the complications of chest trauma and their clinical manifestations and nursing management.

GLOSSARY

- acute lung injury:** an umbrella term for hypoxemic, respiratory failure; acute respiratory distress syndrome is a severe form of acute lung injury
- acute respiratory distress syndrome:** nonspecific pulmonary response to a variety of pulmonary and nonpulmonary insults to the lung; characterized by interstitial infiltrates, alveolar hemorrhage, atelectasis, decreased compliance, and refractory hypoxemia
- asbestosis:** diffuse lung fibrosis resulting from exposure to asbestos fibers
- atelectasis:** collapse or airless condition of the alveoli caused by hypoventilation, obstruction to the airways, or compression

GLOSSARY (Continued)

- central cyanosis:** bluish discoloration of the skin or mucous membranes due to hemoglobin carrying reduced amounts of oxygen
- consolidation:** lung tissue that has become more solid in nature due to collapse of alveoli or infectious process (pneumonia)
- cor pulmonale:** “heart of the lungs”; enlargement of the right ventricle from hypertrophy or dilation or as a secondary response to disorders that affect the lungs
- empyema:** accumulation of purulent material in the pleural space
- fine-needle aspiration:** insertion of a needle through the chest wall to obtain cells of a mass or tumor; usually performed under fluoroscopy or chest computed tomography guidance
- hemoptysis:** the coughing up of blood from the lower respiratory tract
- hemothorax:** partial or complete collapse of the lung due to blood accumulating in the pleural space; may occur after surgery or trauma
- induration:** an abnormally hard lesion or reaction, as in a positive tuberculin skin test
- nosocomial:** pertaining to or originating from a hospitalization; not present at the time of hospital admission
- open lung biopsy:** biopsy of lung tissue performed through a limited thoracotomy incision
- orthopnea:** shortness of breath when reclining or in the supine position
- pleural effusion:** abnormal accumulation of fluid in the pleural space
- pleural friction rub:** localized grating or creaking sound caused by the rubbing together of inflamed parietal and visceral pleurae
- pleural space:** the area between the parietal and visceral pleurae; a potential space
- pneumothorax:** partial or complete collapse of the lung due to positive pressure in the pleural space
- pulmonary edema:** increase in the amount of extravascular fluid in the lung
- pulmonary embolism:** obstruction of the pulmonary vasculature with an embolus; embolus may be due to blood clot, air bubbles, or fat droplets
- purulent:** consisting of, containing, or discharging pus
- restrictive lung disease:** disease of the lung that causes a decrease in lung volumes
- tension pneumothorax:** pneumothorax characterized by increasing positive pressure in the pleural space with each breath; this is an emergency situation and the positive pressure needs to be decompressed or released immediately
- thoracentesis:** insertion of a needle into the pleural space to remove fluid that has accumulated and decrease pressure on the lung tissue; may also be used diagnostically to identify potential causes of a pleural effusion
- transbronchial:** through the bronchial wall, as in a transbronchial lung biopsy
- ventilation-perfusion ratio:** the ratio between ventilation and perfusion in the lung; matching of ventilation to perfusion optimizes gas exchange

Conditions affecting the lower respiratory tract range from acute problems to chronic disorders. Many of these disorders are serious and often life-threatening. Patients with lower respiratory tract disorders require care from nurses with astute assessment and clinical management skills who understand the impact of the particular disorder on the patient's quality of life and ability to carry out usual activities of daily living. Patient and family teaching is an important nursing intervention in the management of all lower respiratory tract disorders.

ATELECTASIS

Atelectasis refers to closure or collapse of alveoli and often is described in relation to x-ray findings and clinical signs and symptoms. Atelectasis may be acute or chronic and may cover a broad range of pathophysiologic changes, from microatelectasis (which is not detectable on chest x-ray) to macroatelectasis with loss of segmental, lobar, or overall lung volume. The most commonly described atelectasis is acute atelectasis, which occurs most often in the postoperative setting or in people who are immobilized and have a shallow, monotonous breathing pattern. Excess secretions or mucous plugs may also cause obstruction of airflow and result in atelectasis in an area of the lung. Atelectasis also is observed in patients with a chronic airway obstruction that impedes or blocks air flow to an area of the lung (eg, obstructive atelectasis in the patient with lung cancer that is invading or compressing the airways). This type of atelectasis is more insidious and slower in onset.

Pathophysiology

Atelectasis may occur in adults as a result of reduced ventilation or any blockage that obstructs passage of air to and from the alveoli, thus reducing alveolar ventilation. After the trapped alveolar air is absorbed into the bloodstream, no additional air can enter into the alveoli because of the blockage. As a result, the affected portion of the lung becomes airless and the alveoli collapse. Possible causes are altered breathing patterns, retained secretions, pain, alterations in small airway function, prolonged supine positioning, increased abdominal pressure, reduced lung volumes due to musculoskeletal or neurologic disorders, restrictive defects, and specific surgical procedures (eg, upper abdominal, thoracic, or open heart surgery).

Patients are at high risk for atelectasis postoperatively because of several factors. A monotonous, low tidal breathing pattern may cause small airway closure and alveolar collapse. This can result from the effects of anesthesia or analgesic agents, supine positioning, splinting of the chest wall because of pain, or abdominal distention. Secretion retention, airway obstruction, and an impaired cough reflex may also occur, or patients may be reluctant to cough because of pain. Figure 23-1 shows the mechanisms and consequences of acute atelectasis in postoperative patients.

Atelectasis resulting from bronchial obstruction by secretions may also occur in patients with impaired cough mechanisms (eg, musculoskeletal or neurologic disorders) as well as in those who are debilitated and bedridden. In addition, atelectasis may develop because of excessive pressure on the lung tissue, which restricts normal lung expansion on in-

spiration. Such pressure can be produced by fluid accumulating within the pleural space (**pleural effusion**), air in the pleural space (**pneumothorax**), or blood in the pleural space (**hemothorax**). The **pleural space** is the area between the parietal and the visceral pleurae. Pressure may also be produced by a pericardium distended with fluid (pericardial effusion), tumor growth within the thorax, or an elevated diaphragm.

Clinical Manifestations

The development of atelectasis usually is insidious. Signs and symptoms include increasing dyspnea, cough, and sputum production.

In acute atelectasis involving a large amount of lung tissue (lobar atelectasis), marked respiratory distress may be observed. In addition to the previously mentioned signs and symptoms, tachycardia, tachypnea, pleural pain, and **central cyanosis** (a bluish skin hue that is a late sign of hypoxemia) may be anticipated. Patients characteristically have difficulty breathing in the supine position and are anxious.

In chronic atelectasis, signs and symptoms are similar to those of acute atelectasis. The chronic nature of the alveolar collapse predisposes patients to infection distal to the obstruction. Therefore, the signs and symptoms of a pulmonary infection also may be present.

Assessment and Diagnostic Findings

When clinically significant atelectasis develops, it is generally characterized by increased work of breathing and hypoxemia. Decreased breath sounds and crackles are heard over the affected area. A chest x-ray may suggest a diagnosis of atelectasis before clinical symptoms appear; the x-ray may reveal patchy infiltrates or consolidated areas. Depending on the degree of hypoxemia, pulse oximetry (SpO_2) may demonstrate a low saturation of hemoglobin with oxygen (less than 90%) or a lower-than-normal partial pressure of arterial oxygen (PaO_2).

NURSING ALERT

Tachypnea, dyspnea, and mild to moderate hypoxemia are hallmarks of the severity of atelectasis.

Prevention

Nursing measures to prevent atelectasis include frequent turning, early mobilization, and strategies to expand the lungs and to manage secretions. Voluntary deep-breathing maneuvers (at least every 2 hours) assist in preventing and treating atelectasis. The performance of these maneuvers requires the patient to be alert and cooperative. Patient education and reinforcement are key to the success of these interventions. The use of incentive spirometry or voluntary deep breathing enhances lung expansion, decreases the potential for airway closure, and may generate a cough. Secretion management techniques include directed cough, suctioning, aerosol nebulizer treatments followed by chest physical therapy (postural drainage and chest percussion), and bronchoscopy. In some settings, a metered-dose inhaler is used to dispense a bronchodilator rather than an aerosol nebulizer. Chart 23-1 summarizes measures used to prevent atelectasis.

Physiology ■■■ Pathophysiology

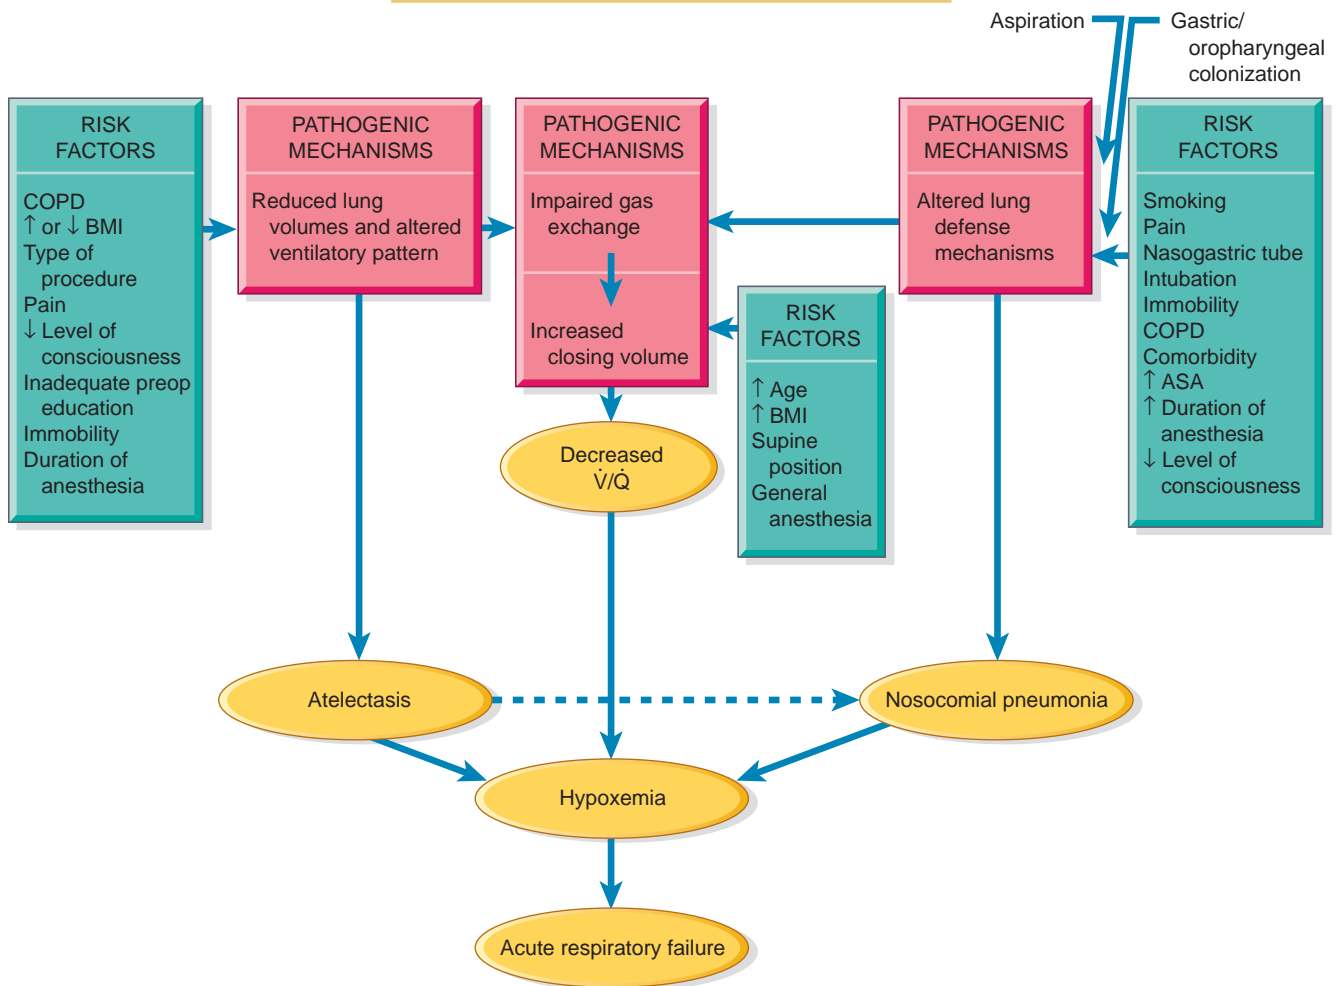

Figure 23-1 Relationship of risk factors, pathogenic mechanisms, and consequences of acute atelectasis in the postoperative patient. ASA, acetylsalicylic acid; COPD, chronic obstructive pulmonary disease; BMI, body mass index; (\dot{V}/\dot{Q}), ventilation-perfusion ratio. From the work of Jo Ann Brooks-Brunn, DNS, RN, FAAN, FCCP, Indiana University Medical Center, Indianapolis.

Management

The goal of treatment is to improve ventilation and remove secretions. Strategies to prevent atelectasis, which include frequent turning, early ambulation, lung volume expansion maneuvers (eg, deep-breathing exercises, incentive spirometry), and coughing, also serve as the first-line measures to minimize or treat atelectasis by improving ventilation. In patients who do not respond to first-line measures or who cannot perform deep-breathing exercises, other treatments such as positive end-expiratory pressure (PEEP; a simple mask and one-way valve system that provides varying amounts of expiratory resistance, usually 10 to 15 cm H₂O), continuous positive pressure breathing (CPPB), or bronchoscopy may be used. Before initiating more complex, costly, and labor-intensive therapies, the nurse should ask several questions:

- Has the patient been given an adequate trial of deep-breathing exercises?
- Has the patient received adequate education, supervision, and coaching to carry out the deep-breathing exercises?

- Have other factors been evaluated that may impair ventilation or prevent a good patient effort (eg, lack of turning, mobilization; excessive pain; excessive sedation)?

Chart 23-1 • Preventing Atelectasis

- Change patient's position frequently, especially from supine to upright position, to promote ventilation and prevent secretions from accumulating.
- Encourage early mobilization from bed to chair followed by early ambulation.
- Encourage appropriate deep breathing and coughing to mobilize secretions and prevent them from accumulating.
- Teach/reinforce appropriate technique for incentive spirometry.
- Administer prescribed opioids and sedatives judiciously to prevent respiratory depression.
- Perform postural drainage and chest percussion, if indicated.
- Institute suctioning to remove tracheobronchial secretions, if indicated.

If the cause of atelectasis is bronchial obstruction from secretions, the secretions must be removed by coughing or suctioning to allow air to reenter that portion of the lung. Chest physical therapy (chest percussion and postural drainage) may also be used to mobilize secretions. Nebulizer treatments with a bronchodilator or sodium bicarbonate may be used to assist patients in the expectoration of secretions. If respiratory care measures fail to remove the obstruction, a bronchoscopy is performed. Although bronchoscopy is an excellent measure to acutely remove secretions and increase ventilation, it is imperative for the nurse to assist the patient with maintaining the patency of the airways after bronchoscopy, using the traditional techniques of deep breathing, coughing, and suctioning. Severe or massive atelectasis may lead to acute respiratory failure, especially in patients with underlying lung disease. Endotracheal intubation and mechanical ventilation may be necessary.

If the cause of atelectasis is compression of lung tissue, the goal is to decrease the compression. With a large pleural effusion that is compressing lung tissue and causing alveolar collapse, treatment may include **thoracentesis** (removal of the fluid by needle aspiration) or insertion of a chest tube. The measures to increase lung expansion described previously also are used.

Management of chronic atelectasis focuses on removing the cause of the obstruction of the airways or the compression of the lung tissue. For example, bronchoscopy may be used to open an airway obstructed by lung cancer or a nonmalignant lesion, and the procedure may involve cryotherapy or laser therapy. If the atelectasis is a result of obstruction caused by lung cancer, an airway stent or radiation therapy to shrink a tumor may be used to open the airways and provide ventilation to the collapsed area. However, in patients who have experienced chronic, long-term collapse, it may not be possible to reopen the airways and re-aerate the area of the lung. In some cases, surgical management may be indicated.

RESPIRATORY INFECTIONS

Acute Tracheobronchitis

Acute tracheobronchitis, an acute inflammation of the mucous membranes of the trachea and the bronchial tree, often follows infection of the upper respiratory tract (see Chapter 22). Patients with viral infections have decreased resistance and can readily develop a secondary bacterial infection. Adequate treatment of upper respiratory tract infection is one of the major factors in the prevention of acute bronchitis.

Pathophysiology

In acute tracheobronchitis, the inflamed mucosa of the bronchi produces mucopurulent sputum, often in response to infection by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Mycoplasma pneumoniae*. In addition, a fungal infection (eg, *Aspergillus*) may also cause tracheobronchitis. A sputum culture is essential to identify the specific causative organism. In addition to infection, inhalation of physical and chemical irritants, gases, or other air contaminants can also cause acute bronchial irritation.

Clinical Manifestations

Initially, the patient has a dry, irritating cough and expectorates a scanty amount of mucoid sputum. The patient may report sternal soreness from coughing and have fever or chills, night sweats, headache, and general malaise. As the infection progresses, the patient may be short of breath, have noisy inspiration and expiration (inspiratory stridor and expiratory wheeze), and produce **purulent** (pus-filled) sputum. In severe tracheobronchitis, blood-streaked secretions may be expectorated as a result of the irritation of the mucosa of the airways.

Medical Management

Antibiotic treatment may be indicated depending on the symptoms, sputum purulence, and results of the sputum culture. Antihistamines usually are not prescribed, because they can cause excessive drying and make secretions more difficult to expectorate. Expectorants may be prescribed, although their efficacy is questionable. Fluid intake is increased to thin the viscous and tenacious secretions. Copious, purulent secretions that cannot be cleared by coughing place patients at risk for increasing airway obstruction and the development of more severe lower respiratory tract infections, such as pneumonia. Suctioning and bronchoscopy may be needed to remove secretions. Rarely, endotracheal intubation may be necessary in cases of acute tracheobronchitis leading to acute respiratory failure, such as in patients who are severely debilitated or who have coexisting diseases that also impair the respiratory system.

In most cases, treatment of tracheobronchitis is largely symptomatic. Increasing the vapor pressure (moisture content) in the air reduces airway irritation. Cool vapor therapy or steam inhalations may help relieve laryngeal and tracheal irritation. Moist heat to the chest may relieve the soreness and pain. Mild analgesic or antipyretic agents may be indicated.

Nursing Management

Acute tracheobronchitis is usually treated in the home setting. A primary nursing function is to encourage bronchial hygiene, such as increased fluid intake and directed coughing to remove secretions. The nurse encourages and assists the patient to sit up frequently to cough effectively and to prevent retention of mucopurulent sputum. If the patient is taking antibiotics for an underlying infection, it is important to emphasize the need to complete the full course of antibiotics prescribed. Fatigue is a consequence of tracheobronchitis; therefore, the nurse cautions the patient against overexertion, which can induce a relapse or exacerbation of the infection. The patient is advised to rest.

Pneumonia

Pneumonia is an inflammation of the lung parenchyma caused by various microorganisms, including bacteria, mycobacteria, fungi, and viruses. *Pneumonitis* is a more general term that describes an inflammatory process in the lung tissue that may predispose or place the patient at risk for microbial invasion. Pneumonia and influenza are the most

common causes of death from infectious diseases in the United States. Together they account for nearly 60,000 deaths annually and rank as the eighth leading cause of death in the United States (Minino, Heron, Murphy, et al., 2007).

Classification

Pneumonias are classified as community-acquired pneumonia (CAP), hospital-acquired (nosocomial) pneumonia (HAP), pneumonia in the immunocompromised host, and aspiration pneumonia (Table 23-1). There is overlap in how specific pneumonias are classified, because they may occur in differing settings.

Community-Acquired Pneumonia

CAP occurs either in the community setting or within the first 48 hours after hospitalization or institutionalization. The need for hospitalization for CAP depends on the severity of the pneumonia. The causative agents for CAP that requires hospitalization are most frequently *S. pneumoniae*, *H. influenzae*, *Legionella*, *Pseudomonas aeruginosa*, and other gram-negative rods. The specific etiologic agent is identified in about 50% of cases. It is estimated that more than 915,000 episodes of CAP occur in adults 65 years of age and older each year in the United States (Mandell, Wunderink, Anzueto, et al., 2007).

S. pneumoniae (pneumococcus) is the most common cause of CAP in people younger than 60 years of age without comorbidity and in those 60 years and older with comorbidity. *S. pneumoniae*, a gram-positive organism that resides naturally in the upper respiratory tract, colonizes the upper respiratory tract and can cause disseminated invasive infections, pneumonia and other lower respiratory tract infections, and upper respiratory tract infections, such as otitis media and rhinosinusitis. It may occur as a lobar or bronchopneumonic form in patients of any age and may follow a recent respiratory illness.

H. influenzae causes a type of CAP that frequently affects elderly people and those with comorbid illnesses (eg, chronic obstructive pulmonary disease [COPD], alcoholism, diabetes mellitus). The presentation is indistinguishable from that of other forms of bacterial CAP and may be subacute, with cough or low-grade fever for weeks before diagnosis.

Mycoplasma pneumonia is caused by *M. pneumoniae*. Mycoplasma pneumonia is spread by infected respiratory droplets through person-to-person contact. Patients can be tested for mycoplasma antibodies. The inflammatory infiltrate is primarily interstitial rather than alveolar. It spreads throughout the entire respiratory tract, including the bronchioles, and has the characteristics of a bronchopneumonia. Earache and bullous myringitis are common. Impaired ventilation and diffusion may occur.

Viruses are the most common cause of pneumonia in infants and children but are relatively uncommon causes of CAP in adults. In immunocompromised adults, cytomegalovirus is the most common viral pathogen, followed by herpes simplex virus, adenovirus, and respiratory syncytial virus. The acute stage of a viral respiratory infection occurs within the ciliated cells of the airways, followed by infiltration of the tracheobronchial tree. With pneumonia, the inflammatory process extends into the alveolar area, resulting

in edema and exudation. The clinical signs and symptoms of a viral pneumonia are often difficult to distinguish from those of a bacterial pneumonia.

Hospital-Acquired Pneumonia

HAP, also known as **nosocomial** pneumonia, is defined as the onset of pneumonia symptoms more than 48 hours after admission in patients with no evidence of infection at the time of admission. The most lethal nosocomial infection, HAP accounts for approximately 15% of hospital-acquired infections and is the leading cause of death in patients with such infections (File, 2007). The estimated incidence of HAP is 4 to 7 episodes per 1000 hospitalizations (File, 2007). Ventilator-associated pneumonia is considered a type of nosocomial pneumonia that is associated with endotracheal intubation and mechanical ventilation. This type of pneumonia is defined as bacterial pneumonia that develops in patients with acute respiratory failure who have been receiving mechanical ventilation for at least 48 hours.

Certain factors may predispose patients to HAP because of impaired host defenses (eg, severe acute or chronic illness), a variety of comorbid conditions, supine positioning and aspiration, coma, malnutrition, prolonged hospitalization, hypotension, and metabolic disorders. Hospitalized patients are also exposed to potential bacteria from other sources (eg, respiratory therapy devices and equipment, transmission of pathogens by the hands of health care personnel). Numerous intervention-related factors also may play a role in the development of HAP (eg, therapeutic agents leading to central nervous system depression with decreased ventilation, impaired removal of secretions, or potential aspiration; prolonged or complicated thoracoabdominal procedures, which may impair mucociliary function and cellular host defenses; endotracheal intubation; prolonged or inappropriate use of antibiotics; use of nasogastric tubes). In addition, immunocompromised patients are at particular risk. HAP is associated with a high mortality rate, in part because of the virulence of the organisms, their resistance to antibiotics, and the patient's underlying disorder.

The common organisms responsible for HAP include the pathogens *Enterobacter* species, *Escherichia coli*, *H. influenzae*, *Klebsiella* species, *Proteus*, *Serratia marcescens*, *P. aeruginosa*, methicillin-sensitive or methicillin-resistant *Staphylococcus aureus* (MRSA), and *S. pneumoniae*. Most patients with HAP are colonized by multiple organisms. Pseudomonal pneumonia occurs in patients who are debilitated, those with altered mental status, and those with prolonged intubation or with tracheostomy. Staphylococcal pneumonia can occur through inhalation of the organism or spread through the hematogenous route. It is often accompanied by bacteremia and positive blood cultures. Its mortality rate is high. Specific strains of staphylococci are resistant to all available antimicrobial agents except vancomycin. Overuse and misuse of antimicrobial agents are major risk factors for the emergence of these resistant pathogens. Because MRSA is highly virulent, steps must be taken to prevent its spread. Patients with MRSA are isolated in a private room, and contact precautions (gown, mask, glove, and antibacterial soap) are used. The number of people in contact with affected patients is minimized, and appropriate precautions must be

Table 23-1 COMMONLY ENCOUNTERED PNEUMONIAS

Type (Causal Organism)	Epidemiology	Clinical Features	Treatment	Complications/Comments
Community-Acquired Pneumonia				
Streptococcal pneumonia (<i>Streptococcus pneumoniae</i>)	<p>Most prevalent in winter months</p> <p>More frequent occurrence in African Americans</p> <p>Incidence greatest in the elderly and in patients with COPD, heart failure, alcoholism, asplenia, diabetes, and after influenza</p> <p>Leading infectious cause of illness worldwide among young children, people with underlying chronic health conditions, and the elderly</p> <p>Mortality in hospitalized adults with invasive disease: 14%</p>	<p>Abrupt onset, toxic appearance, pleuritic chest pain. Usually involves one or more lobes</p> <p>Lobar infiltrate common on chest x-ray or bronchopneumonia pattern</p>	<p>Penicillin nonresistant—penicillin G, amoxicillin</p> <p>Penicillin resistant—cefotaxime, ceftriaxone, fluoroquinolone</p>	Shock, pleural effusion, superinfections, pericarditis, and otitis media
<i>Haemophilus influenzae</i> (<i>Haemophilus influenzae</i>)	<p>Incidence greatest in alcoholics, the elderly, patients in long-term care facilities and nursing homes, patients with diabetes or COPD, and children <5 yr of age</p> <p>Accounts for 5–20% of community-acquired pneumonias</p> <p>Mortality rate: 30%</p>	<p>Frequently insidious onset associated with upper respiratory tract infection 2–6 wk before onset of illness. Fever, chills, productive cough. Usually involves one or more lobes. Bacteremia is common. Infiltrate, occasional bronchopneumonia pattern on chest x-ray</p>	<p>Non-β-lactamase producing—amoxicillin; β-lactamase producing—second- or third-generation cephalosporin, amoxicillin-clavulanate</p>	Lung abscess, pleural effusion, meningitis, arthritis, pericarditis, epiglottitis
Legionnaires' disease (<i>Legionella pneumophila</i>)	<p>Highest occurrence in summer and fall</p> <p>May cause disease sporadically or as part of an epidemic</p> <p>Incidence greatest in middle-aged and older men, smokers, patients with chronic diseases, those receiving immunosuppressive therapy, and those in close proximity to excavation sites</p> <p>Accounts for 15% of community-acquired pneumonias</p> <p>Mortality rate: 15–50%.</p>	<p>Flulike symptoms. High fevers, mental confusion, headache, pleuritic pain, myalgias, dyspnea, productive cough, hemoptysis, leukocytosis</p> <p>Bronchopneumonia, unilateral or bilateral disease, lobar consolidation</p>	Fluoroquinolone, azithromycin	Hypotension, shock, and acute renal failure
<i>Mycoplasma pneumoniae</i> (<i>Mycoplasma pneumoniae</i>)	<p>Increase in fall and winter</p> <p>Responsible for epidemics of respiratory illness</p> <p>Most common type of atypical pneumonia</p> <p>Accounts for 20% of community-acquired pneumonias. More common in children and young adults</p> <p>Mortality rate: <0.1%</p>	<p>Onset is usually insidious. Patients not usually as ill as in other pneumonias. Sore throat, nasal congestion, ear pain, headache, low-grade fever, pleuritic pain, myalgias, diarrhea, erythematous rash, pharyngitis. Interstitial infiltrates on chest x-ray</p>	Macrolide, a tetracycline	Aseptic meningitis, meningoencephalitis, transverse myelitis, cranial nerve palsies, pericarditis, myocarditis
Viral pneumonia (influenza viruses types A, B adenovirus, parainfluenza, cytomegalovirus, coronavirus, varicella-zoster)	<p>Incidence greatest in winter months</p> <p>Epidemics occur every 2–3 yr.</p> <p>Most common causative organisms in adults. Other organisms in children (eg, cytomegalovirus, respiratory syncytial virus)</p> <p>Accounts for 20% of community-acquired pneumonias</p>	<p>Patchy infiltrate, small pleural effusion on chest x-ray</p> <p>In most patients, influenza begins as an acute upper respiratory infection; others have bronchitis, pleurisy, and so on, and still others develop gastrointestinal symptoms.</p>	<p>Oseltamivir or zanamivir</p> <p>Treated symptomatically</p> <p>Does not respond to treatment with currently available antimicrobials</p>	Superimposed bacterial infection, bronchopneumonia

Table 23-1 COMMONLY ENCOUNTERED PNEUMONIAS (Continued)

Type (Causal Organism)	Epidemiology	Clinical Features	Treatment	Complications/Comments
Chlamydial pneumonia (<i>Chlamydia pneumoniae</i>)	Reported mainly in college students, military recruits, and the elderly May be a common cause of community-acquired pneumonia or observed in combination with other pathogens Mortality rate is low because the majority of cases are relatively mild. The elderly with coexistent infections, comorbidities, and reinfections may require hospitalization.	Hoarseness, fever, chills, pharyngitis, rhinitis, nonproductive cough, myalgias, arthralgias Single infiltrate on chest x-ray; pleural effusion possible	Fluoroquinolone	Reinfection and acute respiratory failure
Hospital-Acquired Pneumonia				
<i>Pseudomonas pneumoniae</i> (<i>Pseudomonas aeruginosa</i>)	Incidence greatest in those with preexisting lung disease, cancer (particularly leukemia); those with homograft transplants, burns; debilitated people; and patients receiving antimicrobial therapy and treatments such as tracheostomy, suctioning, and in postoperative settings. Almost always of nosocomial origin. Accounts for 15% of hospital-acquired pneumonias Mortality rate: 40–60%	Diffuse consolidation on chest x-ray. Toxic appearance: fever, chills, productive cough, relative bradycardia, leukocytosis	Antipseudomonal beta-lactam plus ciprofloxacin, levofloxacin or aminoglycoside	Lung cavitation. Has capacity to invade blood vessels, causing hemorrhage and lung infarction. Usually requires hospitalization
Staphylococcal pneumonia (<i>Staphylococcus aureus</i>)	Incidence greatest in immunocompromised patients, IV drug users, and as a complication of epidemic influenza Commonly nosocomial in origin Accounts for 10–30% of hospital-acquired pneumonias Mortality rate: 25–60% Methicillin-resistant <i>S. aureus</i> (MRSA) may also cause community-based infection.	Severe hypoxemia, cyanosis, necrotizing infection. Bacteremia is common.	Methicillin susceptible—antistaphylococcal penicillin Methicillin resistant—vancomycin or linezolid	Pleural effusion/pneumothorax, lung abscess, empyema, meningitis, endocarditis. Frequently requires hospitalization. Treatment must be vigorous and prolonged because disease tends to destroy lung tissue.
<i>Klebsiella pneumoniae</i> (<i>Klebsiella pneumoniae</i> [Friedländer's bacillus-encapsulated gram-negative aerobic bacillus])	Incidence greatest in the elderly; alcoholics; patients with chronic disease, such as diabetes, heart failure, COPD; patients in chronic care facilities and nursing homes Accounts for 2–5% of community-acquired and 10–30% of hospital-acquired pneumonias Mortality rate: 40–50%	Tissue necrosis occurs rapidly. Toxic appearance: fever, cough, sputum production, bronchopneumonia, lung abscess. Lobar consolidation, bronchopneumonia pattern on chest x-ray	Meropenem or levofloxacin or piperacillin/tazobactam plus amikacin	Multiple lung abscesses with cyst formation, empyema, pericarditis, pleural effusion. May be fulminating, progressing to fatal outcome

Continued on following page

Table 23-1 COMMONLY ENCOUNTERED PNEUMONIAS (Continued)

Type (Causal Organism)	Epidemiology	Clinical Features	Treatment	Complications/Comments
Pneumonia in the Immunocompromised Host				
<i>Pneumocystis pneumonia</i> (PCP) (<i>Pneumocystis jiroveci</i>)	Incidence greatest in patients with AIDS and patients receiving immunosuppressive therapy for cancer, organ transplantation, and other disorders. Frequently seen with cytomegalovirus infection. Mortality rate 15–20% in hospitalized patients and fatal if not treated.	Pulmonary infiltrates on chest x-ray. Nonproductive cough, fever, dyspnea.	Trimethoprim/sulfamethoxazole (TMP-SMZ)	Respiratory failure.
Fungal pneumonia (<i>Aspergillus fumigatus</i>)	Incidence greatest in immunocompromised and neutropenic patients. Mortality rate: 15–20%.	Cough, hemoptysis, infiltrates, fungus ball on chest x-ray.	Voriconazole or anidulafungin or caspofungin. Lobectomy for fungus ball.	Dissemination to brain, myocardium, and thyroid gland.
Tuberculosis (<i>Mycobacterium tuberculosis</i>)	Incidence increased in indigent, immigrant, and prison populations, people with AIDS, and the homeless. Mortality rate <1% (depending on comorbidity).	Weight loss, fever, night sweats, cough, sputum production, hemoptysis, nonspecific infiltrate (lower lobe), hilar node enlargement, pleural effusion on chest x-ray.	Isoniazid plus rifampin plus ethambutol plus pyrazinamide (see section on TB).	Reinfection and acute respiratory infection.
Pneumonia from Aspiration				
Anaerobic bacteria (<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>S. aureus</i>)	Risk: reduced consciousness, dysphagia, disorders of upper GI tract; mechanical disruption of glottic closure (endotracheal tube, tracheostomy, nasogastric feeding).	Abrupt onset of dyspnea, low-grade fever, cough, predisposing condition for aspiration.	Clindamycin or beta-lactam antibiotics.	Identification of potential aspirate is important for treatment.

AIDS, acquired immunodeficiency syndrome; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; TB, tuberculosis.

taken when transporting these patients within or between facilities.

The usual presentation of HAP is a new pulmonary infiltrate on chest x-ray combined with evidence of infection such as fever, respiratory symptoms, purulent sputum, or leukocytosis. Pneumonias from *Klebsiella* or other gram-negative organisms (*E. coli*, *Proteus*, *Serratia*) are characterized by destruction of lung structure and alveolar walls, **consolidation** (tissue that solidifies as a result of collapsed alveoli or infectious process such as pneumonia), and bacteremia. Elderly patients and those with alcoholism, chronic lung disease, or diabetes are at particular risk. Development of a cough or increased cough and sputum production are common presentations, along with low-grade fever and general malaise. In debilitated or dehydrated patients, sputum production may be minimal or absent. Pleural effusion, high fever, and tachycardia are common.

Pneumonia in the Immunocompromised Host

Pneumonia in immunocompromised hosts includes *Pneumocystis pneumonia* (PCP), fungal pneumonias, and *Mycobacterium tuberculosis*. The organism that causes PCP is now known as *Pneumocystis jiroveci* instead of *Pneumocystis carinii*. The acronym PCP still applies because it can be read “*Pneumocystis pneumonia*.”

Pneumonia in the immunocompromised host occurs with use of corticosteroids or other immunosuppressive agents, chemotherapy, nutritional depletion, use of broad-spectrum antimicrobial agents, acquired immunodeficiency syndrome (AIDS), genetic immune disorders, and long-term advanced life-support technology (mechanical ventilation). It is seen with increasing frequency because affected patients constitute a growing portion of the population; however, pneumonias that typically occur in immunocompromised people may also occur in immunocompetent people. Patients with compromised immune systems commonly develop pneumonia from organisms of low virulence. In addition, increasing numbers of patients with impaired defenses develop HAP from gram-negative bacilli (*Klebsiella*, *Pseudomonas*, *E. coli*, Enterobacteriaceae, *Proteus*, *Serratia*).

Pneumonia in immunocompromised hosts may be caused by the organisms also observed in CAP or HAP (*S. pneumoniae*, *S. aureus*, *H. influenzae*, *P. aeruginosa*, *M. tuberculosis*). PCP is rarely observed in immunocompetent hosts and is often an initial AIDS-defining complication. Whether patients are immunocompromised or immunocompetent, the clinical presentation of pneumonia is similar. PCP has a subtle onset, with progressive dyspnea, fever, and a nonproductive cough.

Aspiration Pneumonia

Aspiration pneumonia refers to the pulmonary consequences resulting from entry of endogenous or exogenous substances into the lower airway. The most common form of aspiration pneumonia is bacterial infection from aspiration of bacteria that normally reside in the upper airways. Aspiration pneumonia may occur in the community or hospital setting. Common pathogens are *S. pneumoniae*, *H. influenzae*, and *S. aureus*. Substances other than bacteria may be aspirated into the lung, such as gastric contents, exogenous chemical contents, or irritating gases. This type of aspiration or ingestion may impair the lung defenses, cause inflammatory changes, and lead to bacterial growth and a resulting pneumonia. (See later discussion of aspiration.)

Pathophysiology

Normally, the upper airway prevents potentially infectious particles from reaching the sterile lower respiratory tract. Pneumonia arises from normal flora present in patients whose resistance has been altered or from aspiration of flora present in the oropharynx; patients often have an acute or chronic underlying disease that impairs host defenses. Pneumonia may also result from bloodborne organisms that enter the pulmonary circulation and are trapped in the pulmonary capillary bed.

Pneumonia affects both ventilation and diffusion. An inflammatory reaction can occur in the alveoli, producing an exudate that interferes with the diffusion of oxygen and carbon dioxide. White blood cells, mostly neutrophils, also migrate into the alveoli and fill the normally air-filled spaces. Areas of the lung are not adequately ventilated because of secretions and mucosal edema that cause partial occlusion of the bronchi or alveoli, with a resultant decrease in alveolar oxygen tension. Bronchospasm may also occur in patients with reactive airway disease. Because of hypoventilation, a ventilation–perfusion mismatch occurs in the affected area of the lung. Venous blood entering the pulmonary circulation passes through the underventilated area and travels to the left side of the heart poorly oxygenated. The mixing of oxygenated and unoxygenated or poorly oxygenated blood eventually results in arterial hypoxemia.

If a substantial portion of one or more lobes is involved, the disease is referred to as *lobar pneumonia*. The term *bronchopneumonia* is used to describe pneumonia that is distributed in a patchy fashion, having originated in one or more localized areas within the bronchi and extending to the adjacent surrounding lung parenchyma. Bronchopneumonia is more common than lobar pneumonia (Fig. 23-2).

Risk Factors

Being knowledgeable about the factors and circumstances that commonly predispose people to pneumonia helps identify patients at high risk for the disease. Table 23-2 describes risk factors for pneumonia; additional risk factors are travel or exposure to certain environments and residence in a long-term care facility. Increasing numbers of patients who have compromised defenses against infections are susceptible to pneumonia. Some types of pneumonia, such as those caused by viral infections, occur in previously healthy people, often after a viral illness.

Figure 23-2 Distribution of lung involvement in bronchial and lobar pneumonia. In bronchopneumonia (*left*), patchy areas of consolidation occur. In lobar pneumonia (*right*), an entire lobe is consolidated.

Pneumonia occurs in patients with certain underlying disorders such as heart failure, diabetes, alcoholism, COPD, and AIDS. Certain diseases also have been associated with specific pathogens. For example, staphylococcal pneumonia has been noted after epidemics of influenza, and patients with COPD are at increased risk for development of pneumonia caused by pneumococci or *H. influenzae*. In addition, cystic fibrosis is associated with respiratory infection caused by pseudomonal and staphylococcal organisms, and PCP has been associated with AIDS. Pneumonias occurring in hospitalized patients often involve organisms not usually found in CAP, including enteric gram-negative bacilli and *S. aureus*.

Clinical Manifestations

Pneumonia varies in its signs and symptoms depending on the type, causal organism, and presence of underlying disease. However, it is not possible to diagnose a specific form of pneumonia (CAP, HAP, immunocompromised host, or aspiration) by clinical manifestations alone. The patient with streptococcal (pneumococcal) pneumonia usually has a sudden onset of chills, rapidly rising fever (38.5° to 40.5°C [101° to 105°F]), and pleuritic chest pain that is aggravated by deep breathing and coughing. The patient is severely ill, with marked tachypnea (25 to 45 breaths/min), accompanied by other signs of respiratory distress (eg, shortness of breath, use of accessory muscles in respiration). The pulse is rapid and bounding, and it usually increases about 10 bpm for every degree (Celsius) of temperature elevation. A relative bradycardia (a pulse–temperature deficit in which the pulse is slower than that expected for a given temperature) may suggest viral infection, mycoplasma infection, or infection with a *Legionella* organism.

Some patients exhibit an upper respiratory tract infection (nasal congestion, sore throat), and the onset of symptoms of pneumonia is gradual and nonspecific. The predominant symptoms may be headache, low-grade fever, pleuritic pain, myalgia, rash, and pharyngitis. After a few

Table 23-2 RISK FACTORS AND PREVENTIVE MEASURES FOR PNEUMONIA

Risk Factor	Preventive Measure
Conditions that produce mucus or bronchial obstruction and interfere with normal lung drainage (eg, cancer, cigarette smoking, chronic obstructive pulmonary disease)	Promote coughing and expectoration of secretions. Encourage smoking cessation.
Immunosuppressed patients and those with a low neutrophil count (neutropenic)	Initiate special precautions against infection.
Smoking; cigarette smoke disrupts both mucociliary and macrophage activity	Encourage smoking cessation.
Prolonged immobility and shallow breathing pattern	Reposition frequently and promote lung expansion exercises and coughing. Initiate suctioning and chest physical therapy if indicated.
Depressed cough reflex (due to medications, a debilitated state, or weak respiratory muscles); aspiration of foreign material into the lungs during a period of unconsciousness (head injury, anesthesia, depressed level of consciousness), or abnormal swallowing mechanism	Reposition frequently to prevent aspiration and administer medications judiciously, particularly those that increase risk for aspiration. Perform suctioning and chest physical therapy if indicated.
Nothing-by-mouth (NPO) status; placement of nasogastric, orogastric, or endotracheal tube	Promote frequent oral hygiene. Minimize risk for aspiration by checking placement of tube and proper positioning of patient.
Supine positioning in patients unable to protect their airway	Elevate head of bed at least 30 degrees.
Antibiotic therapy (in very ill people, the oropharynx is likely to be colonized by gram-negative bacteria)	Monitor patients receiving antibiotic therapy for signs and symptoms of pneumonia.
Alcohol intoxication (because alcohol suppresses the body's reflexes, may be associated with aspiration, and decreases white cell mobilization and tracheobronchial ciliary motion)	Encourage reduced or moderate alcohol intake (in case of alcohol stupor, position patient to prevent aspiration).
General anesthetic, sedative, or opioid preparations that promote respiratory depression, which causes a shallow breathing pattern and predisposes to the pooling of bronchial secretions and potential development of pneumonia	Observe the respiratory rate and depth during recovery from general anesthesia and before giving medications. If respiratory depression is apparent, withhold the medication and contact the physician.
Advanced age, because of possible depressed cough and glottic reflexes and nutritional depletion	Promote frequent turning, early ambulation and mobilization, effective coughing, breathing exercises, and nutritious diet.
Respiratory therapy with improperly cleaned equipment	Make sure that respiratory equipment is cleaned properly; participate in continuous quality improvement monitoring with the respiratory care department.
Transmission of organisms from health care providers	Use strict hand hygiene and gloves. Implement health care provider education.

days, mucoid or mucopurulent sputum is expectorated. In severe pneumonia, the cheeks are flushed and the lips and nail beds demonstrate central cyanosis (a late sign of poor oxygenation [hypoxemia]).

The patient may exhibit **orthopnea** (shortness of breath when reclining), preferring to be propped up or sitting in bed leaning forward (orthopneic position) in an effort to achieve adequate gas exchange without coughing or breathing deeply. Appetite is poor, and the patient is diaphoretic and tires easily. Sputum is often purulent; however, this is not a reliable indicator of the etiologic agent. Rusty, blood-tinged sputum may be expectorated with streptococcal (pneumococcal), staphylococcal, and *Klebsiella pneumoniae*.

Signs and symptoms of pneumonia may also depend on a patient's underlying condition. Different signs occur in patients with conditions such as cancer, and in those who are undergoing treatment with immunosuppressants, which decrease the resistance to infection. Such patients have fever, crackles, and physical findings that indicate consolidation of lung tissue, including increased tactile fremitus (vocal vibration detected on palpation), percussion dullness, bronchial breath sounds, egophony (when auscultated, the spoken "E" becomes a loud, nasal-sounding "A"), and whispered pectoriloquy (whispered sounds are easily auscultated through the chest wall). These changes occur because sound is transmitted better through solid or dense tissue (consolidation) than

through normal air-filled tissue; these sounds are described in Chapter 21.

Purulent sputum or slight changes in respiratory symptoms may be the only sign of pneumonia in patients with COPD. It may be difficult to determine whether an increase in symptoms is an exacerbation of the underlying disease process or an additional infectious process.

Assessment and Diagnostic Findings

The diagnosis of pneumonia is made by history (particularly of a recent respiratory tract infection), physical examination, chest x-ray, blood culture (bloodstream invasion [bacteremia] occurs frequently), and sputum examination. The sputum sample is obtained by having patients do the following: (1) rinse the mouth with water to minimize contamination by normal oral flora, (2) breathe deeply several times, (3) cough deeply, and (4) expectorate the raised sputum into a sterile container.

More invasive procedures may be used to collect specimens. Sputum may be obtained by nasotracheal or orotracheal suctioning with a sputum trap or by fiberoptic bronchoscopy (see Chapter 21). Bronchoscopy is often used in patients with acute severe infection, in patients with chronic or refractory infection, in immunocompromised patients when a diagnosis cannot be made from an expectorated or induced specimen, and in mechanically ventilated patients.

Prevention

A pneumococcal vaccine provides specific prevention against pneumococcal pneumonia and other infections caused by *S. pneumoniae* (otitis media, other upper respiratory tract infections). Such vaccination has been demonstrated to prevent pneumonia in otherwise healthy patients with an efficiency of 65% to 85%. To reduce or prevent serious complications of CAP in high-risk groups, vaccination against pneumococcal infection is advised for the following:

- People 65 years of age or older
- Immunocompetent people who are at increased risk for illness and death associated with pneumococcal disease because of chronic illness (eg, cardiovascular disease, pulmonary disease, diabetes mellitus, chronic liver disease) or disability
- People with functional or anatomic asplenia
- People living in environments or social settings in which the risk of disease is high
- Immunocompromised people at high risk for infection

The Centers for Disease Control and Prevention (CDC) recommends one-time revaccination after 5 years for people in high-risk categories, including those previously vaccinated up to 5 years ago and those who were older than 65 years of age at the time of primary vaccination (CDC, 2007b).

In addition, the CDC (2004) has identified four specific strategies for the prevention of HAP: (1) staff education and involvement in infection prevention, (2) infection and microbiologic surveillance, (3) prevention of transmission of microorganisms, and (4) modifying host risk for infection. Important nursing measures for prevention of HAP include providing anticipatory interventions and preventive care.

Medical Management

Pharmacologic Therapy

The treatment of pneumonia includes administration of the appropriate antibiotic as determined by the results of a Gram stain. However, the causative organism is not identified in half of CAP cases when therapy is started. Guidelines are used to guide antibiotic choice; however, the resistance patterns, prevalence of causative organisms, patient risk factors, treatment setting (inpatient versus outpatient), and costs and availability of newer antibiotic agents must all be considered. Examples of risk factors that may increase the risk of infection with certain types of pathogens appear in Chart 23-2. See Table 23-1 for treatment of patients with pneumonia due to specific pathogens.

Management of CAP includes blood cultures performed quickly for identification of the causal pathogen and prompt administration of antibiotics (within 4 hours) in patients in whom CAP is strongly suspected. In the outpatient setting, empirical treatment of CAP is often used, that is, treatment based on the clinician's estimation of likely causative organisms. In previously healthy people with no risk factors for drug-resistant *S. pneumoniae*, a macrolide antibiotic (azithromycin, clarithromycin, or erythromycin) is recommended. For outpatients with CAP who have cardiopulmonary disease or other modifying factors, treatment should

CHART
23-2

Risk Factors for Pathogenic Lung Infections

Risk Factors for Infection with Penicillin-Resistant and Drug-Resistant Pneumococci

- Age over 65 years
- Alcoholism
- Beta-lactam therapy (eg, cephalosporins) in past 3 months
- Immunosuppressive disorders
- Multiple medical comorbidities
- Exposure to a child in a day care facility

Risk Factors for Infection with Enteric Gram-Negative Bacteria

- Residency in a long-term care facility
- Underlying cardiopulmonary disease
- Multiple medical comorbidities
- Recent antibiotic therapy

Risk Factors for Infection with *Pseudomonas aeruginosa*

- Structural lung disease (eg, bronchiectasis)
- Corticosteroid therapy
- Broad-spectrum antibiotic therapy (more than 7 days in the past month)
- Malnutrition

include a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin) or a beta-lactam agent (cefepime or ceftazidime) plus a macrolide (Mandell, et al., 2007). These are guidelines only; treatment regimens may be modified for individual patients.

For patients with CAP, criteria for hospital admission include age, home environment/caregiver support, severity of illness (eg, pneumonia severity index), and presence of comorbid conditions. For those who are not receiving intensive care, a respiratory fluoroquinolone or a beta-lactam agent plus a macrolide are recommended. Criteria for intensive care unit (ICU) admission include need for mechanical ventilation; presence of septic shock and need for vasopressors; acute respiratory failure; and at least three minor criteria, including increased respiratory rate, multilobar infiltrates, confusion, uremia, leukopenia, and hypothermia (Mandell, et al., 2007). For acutely ill ICU patients, management includes a beta-lactam agent plus azithromycin or a fluoroquinolone. For *Pseudomonas* infection, an antipseudomonal beta-lactam is used plus either ciprofloxacin or levofloxacin. Lastly, for community-acquired MRSA, vancomycin or linezolid should be added to the regimen.

Inpatients should be switched from intravenous (IV) to oral therapy when they are hemodynamically stable, are improving clinically, are able to take medications/fluids by mouth, and have a normally functioning gastrointestinal tract. As soon as patients are clinically stable, have no medical problems, and have a safe environment for continued care, they should be discharged from the hospital (Mandell, et al., 2007). Clinical stability is defined as temperature less than or equal to 37.8°C (100°F), heart rate less than or

equal to 100 bpm, respiratory rate less than or equal to 24 breaths/min, systolic blood pressure greater than or equal to 90 mm Hg, and oxygen saturation greater than or equal to 90%, with ability to maintain oral intake and normal (baseline) mental status.

In suspected HAP or nosocomial pneumonia, treatment is usually initiated with a broad-spectrum IV antibiotic and may be monotherapy or combination therapy. For patients with no known multidrug resistance, monotherapy with ceftriaxone, ampicillin/sulbactam, levofloxacin, or erapenem is used. With known multidrug resistance, a three-drug combination therapy may be used; this drug regimen may include an antipseudomonal cephalosporin or ceftazidime or antipseudomonal carbapenem or piperacillin-tazobactam plus antipseudomonal fluoroquinolone or aminoglycoside plus linezolid or vancomycin. The patient's status must be assessed 72 hours after the initiation of therapy, and antibiotics should be discontinued or modified based on the culture results (File, 2007).

Of concern is the rampant rise in respiratory pathogens that are resistant to available antibiotics (Siegel, Rhinehart, Jackson, et al., 2006). Examples include vancomycin-resistant enterococcus (VRE), MRSA, and drug-resistant *S. pneumoniae*. There is a tendency for clinicians to use antibiotics aggressively and inappropriately; they may use broad-spectrum agents when narrow-spectrum agents are more appropriate. Mechanisms to monitor and minimize the inappropriate use of antibiotics are in place. Education of clinicians about the use of evidence-based guidelines in the treatment of respiratory infection is important, and some institutions have implemented algorithms to assist clinicians in choosing the appropriate antibiotics. Monitoring and surveillance of susceptibility patterns for pathogens are also important.

Other Therapeutic Regimens

Antibiotics are ineffective in viral upper respiratory tract infections and pneumonia, and their use may be associated with adverse effects. Treatment of viral infections with antibiotics is a major reason for the overuse of these medications in the United States. Antibiotics are indicated with a viral respiratory infection *only* if a secondary bacterial pneumonia, bronchitis, or rhinosinusitis is present. With the exception of the use of antimicrobial therapy, treatment of viral pneumonia is the same as that for bacterial pneumonia.

Treatment of viral pneumonia is primarily supportive. Hydration is a necessary part of therapy, because fever and tachypnea may result in insensible fluid losses. Antipyretics may be used to treat headache and fever; antitussive medications may be used for the associated cough. Warm, moist inhalations are helpful in relieving bronchial irritation. Antihistamines may provide benefit with reduced sneezing and rhinorrhea. Nasal decongestants may also be used to treat symptoms and improve sleep; however, excessive use can cause rebound nasal congestion. Bed rest is prescribed until the infection shows signs of clearing. If hospitalized, the patient is observed carefully until the clinical condition improves.

If hypoxemia develops, oxygen is administered. Pulse oximetry or arterial blood gas analysis is used to determine the need for oxygen and to evaluate the effectiveness of the

therapy. Arterial blood gases may be used to obtain a baseline measure of the patient's oxygenation and acid-base status; however, pulse oximetry is used to continuously monitor the patient's oxygen saturation and response to therapy. More aggressive respiratory support measures include administration of high concentrations of oxygen (fraction of inspired oxygen [FiO₂]), endotracheal intubation, and mechanical ventilation. Different modes of mechanical ventilation may be required; see Chapter 25.

Gerontologic Considerations

Pneumonia in elderly patients may occur as a primary diagnosis or as a complication of a chronic disease. Pulmonary infections in older people frequently are difficult to treat and result in a higher mortality rate than in younger people. General deterioration, weakness, abdominal symptoms, anorexia, confusion, tachycardia, and tachypnea may signal the onset of pneumonia. The diagnosis of pneumonia may be missed because the classic symptoms of cough, chest pain, sputum production, and fever may be absent or masked in elderly patients. Also, the presence of some signs may be misleading. Abnormal breath sounds, for example, may be caused by microatelectasis that occurs as a result of decreased mobility, decreased lung volumes, or other respiratory function changes. Chest x-rays may be needed to differentiate chronic heart failure, which is often seen in the elderly, from pneumonia as the cause of clinical signs and symptoms.

Supportive treatment includes hydration (with caution and with frequent assessment because of the risk of fluid overload in the elderly), supplemental oxygen therapy, and assistance with deep breathing, coughing, frequent position changes, and early ambulation. All of these are particularly important in the care of elderly patients with pneumonia. To reduce or prevent serious complications of pneumonia in the elderly, vaccination against pneumococcal and influenza infections is recommended (Fiore, Shay, Haber, et al., 2007).

Complications

Shock and Respiratory Failure

Severe complications of pneumonia include hypotension and shock and respiratory failure (especially with gram-negative bacterial disease in elderly patients). These complications are encountered chiefly in patients who have received no specific treatment or inadequate or delayed treatment. These complications are also encountered when the infecting organism is resistant to therapy, when a comorbid disease complicates the pneumonia, or when the patient is immunocompromised.

If the patient is seriously ill, aggressive therapy may include hemodynamic and ventilatory support to combat peripheral collapse, maintain arterial blood pressure, and provide adequate oxygenation. A vasopressor agent may be administered by continuous IV infusion and at a rate adjusted in accordance with the pressure response. Corticosteroids may be administered parenterally to combat shock and toxicity in patients who are extremely ill with pneumonia and at apparent risk for death from the infection. Patients may require endotracheal intubation and mechanical ventilation. Heart failure, cardiac dysrhythmias, pericarditis,

and myocarditis also are complications of pneumonia that may lead to shock.

Pleural Effusion

Parapneumonic pleural effusions occur in at least 40% of bacterial pneumonias. A parapneumonic effusion is any pleural effusion associated with bacterial pneumonia, lung abscess, or bronchiectasis. After the pleural effusion is detected on a chest x-ray, a thoracentesis may be performed to remove the fluid. The fluid is sent to the laboratory for analysis. There are three stages of parapneumonic pleural effusions based on pathogenesis: uncomplicated, complicated, and thoracic empyema. An **empyema** occurs when thick, purulent fluid accumulates within the pleural space, often with fibrin development and a loculated (walled-off) area where the infection is located (see later discussion). A chest tube may be inserted to treat pleural infection by establishing proper drainage of the empyema. Sterilization of the empyema cavity requires 4 to 6 weeks of antibiotics, which may include clindamycin, meropenem, or piperacillin/tazobactam (Bartlett, 2007). Sometimes surgical management is required.

NURSING PROCESS

THE PATIENT WITH PNEUMONIA

Assessment

Nursing assessment is critical in detecting pneumonia. Fever, chills, or night sweats in a patient who also has respiratory symptoms should alert the nurse to the possibility of bacterial pneumonia. Respiratory assessment further identifies the clinical manifestations of pneumonia: pleuritic-type pain, fatigue, tachypnea, use of accessory muscles for breathing, bradycardia or relative bradycardia, coughing, and purulent sputum. The nurse monitors the patient for the following: changes in temperature and pulse; amount, odor, and color of secretions; frequency and severity of cough; degree of tachypnea or shortness of breath; changes in physical assessment findings (primarily assessed by inspecting and auscultating the chest); and changes in the chest x-ray findings.

In addition, it is important to assess elderly patients for unusual behavior, altered mental status, dehydration, excessive fatigue, and concomitant heart failure.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses may include the following:

- Ineffective airway clearance related to copious tracheobronchial secretions
- Activity intolerance related to impaired respiratory function
- Risk for deficient fluid volume related to fever and a rapid respiratory rate
- Imbalanced nutrition: less than body requirements
- Deficient knowledge about the treatment regimen and preventive health measures

Collaborative Problems/Potential Complications

Based on the assessment data, collaborative problems or potential complications that may occur include the following:

- Continuing symptoms after initiation of therapy
- Shock
- Respiratory failure
- Atelectasis
- Pleural effusion
- Confusion

Planning and Goals

The major goals may include improved airway patency, rest to conserve energy, maintenance of proper fluid volume, maintenance of adequate nutrition, an understanding of the treatment protocol and preventive measures, and absence of complications.

Nursing Interventions

Improving Airway Patency

Removing secretions is important because retained secretions interfere with gas exchange and may slow recovery. The nurse encourages hydration (2 to 3 L/day), because adequate hydration thins and loosens pulmonary secretions. Humidification may be used to loosen secretions and improve ventilation. A high-humidity face mask (using either compressed air or oxygen) delivers warm, humidified air to the tracheobronchial tree, helps liquefy secretions, and relieves tracheobronchial irritation. Coughing can be initiated either voluntarily or by reflex. Lung expansion maneuvers, such as deep breathing with an incentive spirometer, may induce a cough. To improve airway patency, the nurse encourages the patient to perform an effective, directed cough, which includes correct positioning, a deep inspiratory maneuver, glottic closure, contraction of the expiratory muscles against the closed glottis, sudden glottic opening, and an explosive expiration. In some cases, the nurse may assist the patient by placing both hands on the lower rib cage (either anteriorly or posteriorly) to focus the patient on a slow deep breath, and then manually assisting the patient by applying constant, external pressure during the expiratory phase.

Chest physiotherapy (percussion and postural drainage) is important in loosening and mobilizing secretions (see Chapter 25). Indications for chest physiotherapy include sputum retention not responsive to spontaneous or directed cough, a history of pulmonary problems previously treated with chest physiotherapy, continued evidence of retained secretions (decreased or abnormal breath sounds, change in vital signs), abnormal chest x-ray findings consistent with atelectasis or infiltrates, and deterioration in oxygenation. The patient is placed in the proper position to drain the involved lung segments, and then the chest is percussed and vibrated either manually or with a mechanical percussor. Other devices, such as the Flutter device (Axcan Pharma), assist in secretion removal. The nurse may consult the respiratory therapist for volume-expansion protocols and secretion-management protocols that help direct the respiratory care of the patient and match the patient's needs with appropriate treatment schedules.

After each position change, the nurse encourages the patient to breathe deeply and cough. If the patient is too weak to cough effectively, the nurse may need to remove the mucus by nasotracheal suctioning (see Chapter 25). It may take time for secretions to mobilize and move into the central airways for expectoration. Therefore, it is important for the nurse to monitor the patient for cough and sputum production after the completion of chest physiotherapy.

The nurse also administers and titrates oxygen therapy as prescribed or via protocols. The effectiveness of oxygen therapy is monitored by improvement in clinical signs and symptoms, patient comfort, and adequate oxygenation values as measured by pulse oximetry or arterial blood gas analysis.

Promoting Rest and Conserving Energy

The nurse encourages the debilitated patient to rest and avoid overexertion and possible exacerbation of symptoms. The patient should assume a comfortable position to promote rest and breathing (eg, semi-Fowler's position) and should change positions frequently to enhance secretion clearance and pulmonary ventilation and perfusion. It is important to instruct outpatients not to overexert themselves and to engage in only moderate activity during the initial phases of treatment.

Promoting Fluid Intake

The respiratory rate of patients with pneumonia increases because of the increased workload imposed by labored breathing and fever. An increased respiratory rate leads to an increase in insensible fluid loss during exhalation and can lead to dehydration. Therefore, it is important to encourage increased fluid intake (at least 2 L/day), unless contraindicated. Note that hydration must be achieved more slowly and with careful monitoring in patients with preexisting conditions such as heart failure.

Maintaining Nutrition

Many patients with shortness of breath and fatigue have a decreased appetite and consume only fluids. Fluids with electrolytes (commercially available drinks, such as Gatorade) may help provide fluid, calories, and electrolytes. Other nutritionally enriched drinks or shakes may be helpful. In addition, IV fluids and nutrients may be administered if necessary.

Promoting Patients' Knowledge

The patient and family are instructed about the cause of pneumonia, management of symptoms, signs and symptoms that should be reported to the physician or nurse, and the need for follow-up. The patient also needs information about factors (both patient risk factors and external factors) that may have contributed to development of pneumonia and strategies to promote recovery and prevent recurrence. If the patient is hospitalized, he or she is instructed about the purpose and importance of management strategies that have been implemented and about the importance of adhering to them during and after the hospital stay. Explanations should be given simply and in language that the patient can understand. If possible, written instructions and information should be provided, and alternative formats

should be provided for patients with hearing or vision loss, if necessary. Because of the severity of symptoms, the patient may require that instructions and explanations be repeated several times.

Monitoring and Managing Potential Complications

CONTINUING SYMPTOMS AFTER INITIATION OF THERAPY. The patient is observed for response to antibiotic therapy; patients usually begin to respond to treatment within 24 to 48 hours after antibiotic therapy is initiated. If the patient started taking antibiotics before evaluation by culture and sensitivity of the causative organisms, antibiotics may need to be changed once the results are available. The patient is monitored for changes in physical status (deterioration of condition or resolution of symptoms) and for persistent recurrent fever, which may be a result of medication allergy (signaled possibly by a rash); medication resistance or slow response (greater than 48 hours) of the susceptible organism to therapy; pleural effusion; or pneumonia caused by an unusual organism, such as *P. jiroveci* or *Aspergillus fumigatus*. Failure of the pneumonia to resolve or persistence of symptoms despite changes on the chest x-ray raises the suspicion of other underlying disorders, such as lung cancer. As previously described, lung cancers may invade or compress airways, causing an obstructive atelectasis that may lead to pneumonia.

In addition to monitoring for continuing symptoms of pneumonia, the nurse also monitors for other complications, such as shock and multisystem failure and atelectasis, which may develop during the first few days of antibiotic treatment.

SHOCK AND RESPIRATORY FAILURE. The nurse assesses for signs and symptoms of shock and respiratory failure by evaluating the patient's vital signs, pulse oximetry values, and hemodynamic monitoring parameters. The nurse reports signs of deteriorating patient status and assists in administering IV fluids and medications prescribed to combat shock. Intubation and mechanical ventilation may be required if respiratory failure occurs. Shock is described in detail in Chapter 15, and care of the patient receiving mechanical ventilation is described in Chapter 25.

PLEURAL EFFUSION. If pleural effusion develops and thoracentesis is performed to remove fluid, the nurse assists in the procedure and explains it to the patient. After thoracentesis, the nurse monitors the patient for pneumothorax or recurrence of pleural effusion. If a chest tube needs to be inserted, the nurse monitors the patient's respiratory status (see Chapter 25 for more information on care of patients with chest tubes).

CONFUSION. A patient with pneumonia is assessed for confusion and other more subtle changes in cognitive status. Confusion and changes in cognitive status resulting from pneumonia are poor prognostic signs. Confusion may be related to hypoxemia, fever, dehydration, sleep deprivation, or developing sepsis. The patient's underlying comorbid conditions may also play a part in the development of confusion. Addressing the underlying factors and ensuring patient safety are important nursing interventions.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Depending on the severity of the pneumonia, treatment may occur in the hospital or in the outpatient setting. Patient education is crucial regardless of the setting, and the proper administration of antibiotics is important. In some instances, the patient may be initially treated with IV antibiotics as an inpatient and then discharged to continue the IV antibiotics at home. It is important that a seamless system of care be maintained for the patient from hospital to home; this includes communication between the nurses caring for the patient in both settings.

If oral antibiotics are prescribed, it is important to teach the patient about their proper administration and potential side effects. The patient should be instructed about symptoms that require contacting the health care provider: difficulty breathing, worsening cough, recurrent/increasing fever, and medication intolerance.

After the fever subsides, the patient may gradually increase activities. Fatigue and weakness may be prolonged after pneumonia, especially in the elderly. The nurse encourages breathing exercises to promote secretion clearance and volume expansion. A patient who is being treated as an outpatient should be contacted by the health care team or instructed to contact the health care provider 24 to 48 hours after starting therapy. The patient is also instructed to return to the clinic or physician's office for a follow-up chest x-ray and physical examination. Often improvement in chest x-ray findings lags behind improvement in clinical signs and symptoms.

The nurse encourages the patient to stop smoking. Smoking inhibits tracheobronchial ciliary action, which is the first line of defense of the lower respiratory tract. Smoking also irritates the mucous cells of the bronchi and inhibits the function of alveolar macrophage (scavenger) cells. The patient is instructed to avoid stress, fatigue, sudden changes in temperature, and excessive alcohol intake, all of which lower resistance to pneumonia. The nurse reviews with the patient the principles of adequate nutrition and rest, because one episode of pneumonia may make a patient susceptible to recurring respiratory tract infections.

CONTINUING CARE. A patient who is severely debilitated or who cannot care for himself or herself may require referral for home care. During home visits, the nurse assesses the patient's physical status, monitors for complications, assesses the home environment, and reinforces previous teaching. The nurse evaluates the patient's adherence to the therapeutic regimen (ie, taking medications as prescribed, performing breathing exercises, consuming adequate fluid and dietary intake, and avoiding smoking, alcohol, and excessive activity). The nurse stresses to the patient and family the importance of monitoring for complications or exacerbation of the pneumonia. The nurse encourages the patient to obtain an influenza vaccination at the prescribed times, because influenza increases susceptibility to secondary bacterial pneumonia, especially that caused by staphylococci, *H. influenzae*, and *S. pneumoniae*. The nurse also urges the patient to seek medical advice about receiving the vaccine (Pneumovax) against *S. pneumoniae*.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Demonstrates improved airway patency, as evidenced by adequate oxygenation by pulse oximetry or arterial blood gas analysis, normal temperature, normal breath sounds, and effective coughing
2. Rests and conserves energy by limiting activities and remaining in bed while symptomatic and then slowly increasing activities
3. Maintains adequate hydration, as evidenced by an adequate fluid intake and urine output and normal skin turgor
4. Consumes adequate dietary intake, as evidenced by maintenance or increase in body weight without excess fluid gain
5. States explanation for management strategies
6. Complies with management strategies
7. Exhibits no complications
 - a. Exhibits acceptable vital signs, pulse oximetry, and arterial blood gas measurements
 - b. Reports productive cough that diminishes over time
 - c. Has absence of signs or symptoms of shock, respiratory failure, or pleural effusion
 - d. Remains oriented and aware of surroundings
 - e. Maintains or increases weight
8. Complies with treatment protocol and prevention strategies

Aspiration

Aspiration of stomach contents into the lungs is a serious complication that can cause pneumonia and result in the following clinical picture: tachycardia, dyspnea, central cyanosis, hypertension, hypotension, and finally death. It can occur when the protective airway reflexes are decreased or absent due to a variety of factors (Chart 23-3).

CHART
23-3

Risk Factors for Aspiration

- Seizure activity
- Brain injury
- Decreased level of consciousness from trauma, drug or alcohol intoxication, excessive sedation, or general anesthesia
- Nausea and vomiting in the patient with a decreased level of consciousness
- Endotracheal intubation; tube malposition; high residual volumes
- Flat body positioning
- Stroke
- Swallowing disorders
- Cardiac arrest
- Silent aspiration

NURSING ALERT

When a nonfunctioning nasogastric tube allows the gastric contents to accumulate in the stomach, a condition known as silent aspiration may result. Silent aspiration often occurs unobserved and may be more common than suspected. If untreated, massive inhalation of gastric contents develops in a period of several hours.

Pathophysiology

The primary factors responsible for death and complications after aspiration of gastric contents are the volume and character of the aspirated gastric contents. For example, a small, localized aspiration from regurgitation can cause pneumonia and acute respiratory distress; a massive aspiration is usually fatal.

A full stomach contains solid particles of food. If these are aspirated, the problem then becomes one of mechanical blockage of the airways and secondary infection. During periods of fasting, the stomach contains acidic gastric juice, which, if aspirated, can be very destructive to the alveoli and capillaries. Fecal contamination (more likely seen in intestinal obstruction) increases the likelihood of death, because the endotoxins produced by intestinal organisms may be absorbed systemically, or the thick proteinaceous material found in the intestinal contents may obstruct the airway, leading to atelectasis and secondary bacterial invasion.

Aspiration pneumonitis may develop from aspiration of substances with a low pH. The aspiration of gastric contents causes a chemical burn of the tracheobronchial tree and pulmonary parenchyma, and an inflammatory response. This leads to the destruction of alveolar–capillary endothelial cells, with a consequent outpouring of protein-rich fluids into the interstitial and intra-alveolar spaces. As a result, surfactant is lost, which in turn causes the airways to close and the alveoli to collapse. Finally, the impaired exchange of oxygen and carbon dioxide causes respiratory failure.

Aspiration pneumonia develops after inhalation of colonized oropharyngeal material. The pathologic process involves an acute inflammatory response to bacteria and bacterial products. Most commonly, the bacteriologic findings include gram-positive cocci, gram-negative rods, and occasionally anaerobic bacteria (Bartlett, 2006).

Prevention

Prevention is the primary goal when caring for patients at risk for aspiration. Several preventive interventions, including positioning, dietary changes, drugs, oral hygiene, and tube feeding, have been proposed, especially for elderly patients. However, a systematic review of these measures is insufficient to confirm their effectiveness (Bartlett, 2006).

Compensating for Absent Reflexes

Aspiration may occur if the patient cannot adequately coordinate protective glottic, laryngeal, and cough reflexes. This hazard is increased if the patient has a distended abdomen, is supine, has the upper extremities immobilized by IV infusions or hand restraints, receives local anesthetic agents to the oropharyngeal or laryngeal area for

diagnostic procedures, has been sedated, or has had long-term intubation.

When vomiting, people can normally protect their airway by sitting up or turning on the side and coordinating breathing, coughing, gag, and glottic reflexes. If these reflexes are active, an oral airway should not be inserted. If an airway is in place, it should be pulled out the moment the patient gags so as not to stimulate the pharyngeal gag reflex and promote vomiting and aspiration. Suctioning of oral secretions with a catheter should be performed with minimal pharyngeal stimulation.

Assessing Feeding Tube Placement

When a patient is intubated, aspiration may occur even with a nasogastric tube in place and may result in nosocomial pneumonia. Assessment of nasogastric tube placement is key to prevention of aspiration. The best method for determining tube placement is via x-ray. Other methods have been studied; research results are inconsistent, although observation of the aspirate and testing of its pH are the most reliable (Bourgault, Ipe, Weaver, et al., 2007; Metheny, Meert & Clouse, 2007). Inadvertent tube placement in the respiratory tract is only one source of complications related to tube insertion. A tube with feeding ports in the esophagus significantly increases the risk of aspiration.

Patients who receive continuous or timed-interval tube feedings must be positioned properly. Patients receiving continuous infusions are given small volumes under low pressure in an upright position, which helps prevent aspiration. Patients receiving tube feedings at timed intervals are maintained in an upright or semirecumbent position (elevation of the head of the bed to a 30- to 45-degree angle) during the feeding (Bourgault, et al., 2007). Tube feedings must be given only when it is certain that the feeding tube is positioned correctly in the stomach. Many patients today receive enteral feeding directly into the duodenum through a small-bore flexible feeding tube or surgically implanted tube. Correct placement is confirmed by chest x-ray. Feedings are given slowly and are regulated by a feeding pump.

Identifying Delayed Stomach Emptying

A full stomach can cause aspiration because of increased intragastric or extragastric pressure. Situations that delay emptying of the stomach include intestinal obstruction; increased gastric secretions in gastroesophageal reflux disease; increased gastric secretions during anxiety, stress, or pain; and abdominal distention because of paralytic ileus, ascites, peritonitis, use of opioids or sedatives, severe illness, or vaginal delivery.

When a feeding tube is present, contents are aspirated, usually every 4 hours, to determine the amount of the last feeding left in the stomach (residual volume). Preliminary evidence suggests that gastric residuals are insensitive and sometimes unreliable markers of tolerance to tube feedings. Patients should be assessed for indications of intolerance to feedings if gastric residual volume is greater than 200 to 250 mL. Prokinetic agents and small bowel feeding should be considered if gastric residual volumes remain high. Stopping enteral nutrition because of a single elevated gastric residual volume should be avoided (Bourgault, et al., 2007).

Managing Effects of Prolonged Intubation

Prolonged endotracheal intubation or tracheostomy can depress the laryngeal and glottic reflexes because of disuse. Patients with prolonged tracheostomies are encouraged to phonate and exercise their laryngeal muscles. For patients who have had long-term intubation or tracheostomies, it may be helpful to have a speech therapist experienced in swallowing disorders work with the patient to address swallowing problems.

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a viral respiratory illness caused by a coronavirus, called SARS-associated coronavirus. It was first reported in Asia in 2003 and quickly spread to countries in North America, South America, Europe, and Asia. The World Health Organization (WHO) reported that 8422 people worldwide became sick with SARS during the 2003 outbreak, and 916 died (Hirsch, 2007).

SARS develops in people who either have close contact with a person who has been diagnosed with the disease or a history of travel or residence in an area with known cases. The SARS-associated coronavirus is transmitted via respiratory droplets when an infected person coughs or sneezes; the droplets may be deposited on the mucous membranes (mouth, nose, eyes) of a nearby person. The virus may also be spread when a person touches a surface or object contaminated by the droplets and then touches his or her mucous membranes. The virus may be transmitted in other ways, including sewage and water, but these methods of transmission are unclear at this time (Hirsch, 2007).

Characteristic symptoms of SARS are a fever (greater than 38.0°C [100.4°F]), coughing, and difficulty breathing. The incubation period is usually 2 to 7 days; however, longer periods have been reported. About 95% of patients develop symptoms within 10 days (Hirsch, 2007). Risk factors associated with poor outcomes include older age, comorbid conditions (eg, diabetes, chronic hepatitis B, COPD), atypical symptoms, elevated serum lactate dehydrogenase on admission, and acute renal failure. Currently, no treatment except supportive care is recommended (Hirsch, 2007). Antibiotics, antiviral agents, and corticosteroids have been given, but there are no data to support their efficacy.

Infection control measures designed to limit transmission of SARS are a priority. In health care settings, the general CDC guidelines for infection control in health care facilities should be followed; in addition, specific strategies for SARS should be in place including use of negative pressure isolation rooms, personal protective equipment, hand hygiene, environmental cleaning and disinfection techniques, and source control measures to contain patients' secretions (Hirsch, 2007). Additional and updated information is available on the CDC Web site (www.cdc.gov/ncidod/sars).

Pulmonary Tuberculosis

Tuberculosis (TB) is an infectious disease that primarily affects the lung parenchyma. It also may be transmitted to other parts of the body, including the meninges, kidneys,

bones, and lymph nodes. The primary infectious agent, *M. tuberculosis*, is an acid-fast aerobic rod that grows slowly and is sensitive to heat and ultraviolet light. *Mycobacterium bovis* and *Mycobacterium avium* have rarely been associated with the development of a TB infection.

TB is a worldwide public health problem that is closely associated with poverty, malnutrition, overcrowding, substandard housing, and inadequate health care. Mortality and morbidity rates continue to rise; *M. tuberculosis* infects an estimated one third of the world's population and remains the leading cause of death from infectious disease in the world. According to the WHO, an estimated 1.6 million deaths resulted from TB in 2005 (WHO, 2007).

In the United States, almost 15,000 cases of TB are reported annually to the CDC (2005a). Factors that prevent elimination of TB in the United States are the prevalence of TB among foreign-born residents, delays in detecting and reporting cases of TB, lack of protection of contacts of people with infections cases of TB, presence of substantial number of people with latent TB, and maintaining clinical and public health expertise in TB (CDC, 2005a).

Transmission and Risk Factors

TB spreads from person to person by airborne transmission. An infected person releases droplet nuclei (usually particles 1 to 5 µm in diameter) through talking, coughing, sneezing, laughing, or singing. Larger droplets settle; smaller droplets remain suspended in the air and are inhaled by a susceptible person. Chart 23-4 lists risk factors for TB. Chart 23-5 summarizes the CDC's recommendations for prevention of TB transmission in health care settings.

CHART
23-4

Risk Factors for Tuberculosis (TB)

- Close contact with someone who has active TB. Inhalation of airborne nuclei from an infected person is proportional to the amount of time spent in the same air space, the proximity of the person, and the degree of ventilation.
- Immunocompromised status (eg, those with HIV infection, cancer, transplanted organs, and prolonged high-dose corticosteroid therapy)
- Substance abuse (IV/injection drug users and alcoholics)
- Any person without adequate health care (the homeless; impoverished; minorities, particularly children under age 15 year and young adults between ages 15 and 44 year)
- Preexisting medical conditions or special treatment (eg, diabetes, chronic renal failure, malnourishment, selected malignancies, hemodialysis, transplanted organ, gastrectomy, jejunioileal bypass)
- Immigration from countries with a high prevalence of TB (southeastern Asia, Africa, Latin America, Caribbean)
- Institutionalization (eg, long-term care facilities, psychiatric institutions, prisons)
- Living in overcrowded, substandard housing
- Being a health care worker performing high-risk activities: administration of aerosolized pentamidine and other medications, sputum induction procedures, bronchoscopy, suctioning, coughing procedures, caring for the immunosuppressed patient, home care with the high-risk population, and administering anesthesia and related procedures (eg, intubation, suctioning)

Chart 23-5 • CDC Recommendations for Preventing Transmission of Tuberculosis (TB) in Health Care Settings

1. Early identification and treatment of persons with active TB
 - a. Maintain a high index of suspicion for TB to identify cases rapidly.
 - b. Promptly initiate effective multidrug anti-TB therapy based on clinical and drug-resistance surveillance data.
2. Prevention of spread of infectious droplet nuclei by source control methods and by reduction of microbial contamination of indoor air
 - a. Initiate acid-fast bacilli (AFB) isolation precautions immediately for all patients who are suspected or confirmed to have active TB and who may be infectious. AFB isolation precautions include use of a private room with negative pressure in relation to surrounding areas and a minimum of six air exchanges per hour. Air from the room should be exhausted directly to the outside. Use of ultraviolet lamps and/or high-efficiency particulate air filters to supplement ventilation may be considered.
 - b. Persons entering the AFB isolation room should use disposable particulate respirators that fit snugly around the face.
 - c. Continue AFB isolation precautions until there is clinical evidence of reduced infectiousness (ie, cough has substantially decreased, and the number of organisms on sequential sputum smears is decreasing). If drug resistance is suspected or confirmed, continue AFB precautions until the sputum smear is negative for AFB.
 - d. Use special precautions during cough-inducing procedures.
3. Surveillance for TB transmission
 - a. Maintain surveillance for TB infection among health care workers (HCWs) by routine, periodic tuberculin skin testing. Recommend appropriate preventive therapy for HCWs when indicated.
 - b. Maintain surveillance for TB cases among patients and HCWs.
 - c. Promptly initiate contact investigation procedures among HCWs, patients, and visitors exposed to an untreated, or ineffectively treated, patient with infectious TB for whom appropriate AFB procedures are not in place. Recommend appropriate therapy or preventive therapy for contacts with disease or TB infection without current disease. Therapeutic regimens should be chosen based on the clinical history and local drug-resistance surveillance data.

Pathophysiology

TB begins when a susceptible person inhales mycobacteria and becomes infected. The bacteria are transmitted through the airways to the alveoli, where they are deposited and begin to multiply. The bacilli also are transported via the lymph system and bloodstream to other parts of the body (kidneys, bones, cerebral cortex) and other areas of the lungs (upper lobes). The body's immune system responds by initiating an inflammatory reaction. Phagocytes (neutrophils and macrophages) engulf many of the bacteria, and TB-specific lymphocytes lyse (destroy) the bacilli and normal tissue. This tissue reaction results in the accumulation of exudate in the alveoli, causing bronchopneumonia. The initial infection usually occurs 2 to 10 weeks after exposure.

Granulomas, new tissue masses of live and dead bacilli, are surrounded by macrophages, which form a protective wall. They are then transformed to a fibrous tissue mass, the central portion of which is called a Ghon tubercle. The material (bacteria and macrophages) becomes necrotic, forming a cheesy mass. This mass may become calcified and form a collagenous scar. At this point, the bacteria become dormant, and there is no further progression of active disease.

After initial exposure and infection, active disease may develop because of a compromised or inadequate immune system response. Active disease also may occur with reinfection and activation of dormant bacteria. In this case, the Ghon tubercle ulcerates, releasing the cheesy material into the bronchi. The bacteria then become airborne, resulting in further spread of the disease. Then the ulcerated tubercle heals and forms scar tissue. This causes the infected lung to become more inflamed, resulting in further development of bronchopneumonia and tubercle formation.

Unless this process is arrested, it spreads slowly downward to the hilum of the lungs and later extends to adjacent

lobes. The process may be prolonged and is characterized by long remissions when the disease is arrested, followed by periods of renewed activity. Approximately 10% of people who are initially infected develop active disease. Some people develop reactivation TB (also called adult-type TB). This type of TB results from a breakdown of the host defenses. It most commonly occurs in the lungs, usually in the apical or posterior segments of the upper lobes or the superior segments of the lower lobes.

Clinical Manifestations

The signs and symptoms of pulmonary TB are insidious. Most patients have a low-grade fever, cough, night sweats, fatigue, and weight loss. The cough may be nonproductive, or mucopurulent sputum may be expectorated. Hemoptysis also may occur. Both the systemic and the pulmonary symptoms are chronic and may have been present for weeks to months. Elderly patients usually present with less pronounced symptoms than younger patients. Extrapulmonary disease occurs in up to 16% of cases in the United States. In patients with AIDS, extrapulmonary disease is more prevalent.

Assessment and Diagnostic Findings

A complete history, physical examination, tuberculin skin test, chest x-ray, acid-fast bacillus smear, and sputum culture are used to diagnose TB. If the patient is infected with TB, the chest x-ray usually reveals lesions in the upper lobes, and the acid-fast bacillus smear contains mycobacteria.

Clinical manifestations of fever, anorexia, weight loss, night sweats, fatigue, cough, and sputum production prompt a more thorough assessment of respiratory function, for example, assessing the lungs for consolidation by evaluating breath sounds (diminished, bronchial sounds; crackles), fremitus, and egophony.

Figure 23-3 The Mantoux test for tuberculosis. **A**, Correct technique for inserting the needle involves depositing the purified protein derivative (PPD) subcutaneously with the needle bevel facing upward. **B**, The reaction to the Mantoux test usually consists of a wheal, a hivelike, firm welt. **C**, To determine the extent of the reaction, the wheal is measured using a commercially prepared gauge. Interpretation of the Mantoux test is discussed in the text.

Tuberculin Skin Test

The Mantoux method is used to determine whether a person has been infected with the TB bacillus. The Mantoux method is a standardized, intracutaneous injection procedure and should be performed only by those trained in its administration and reading. Tubercle bacillus extract (tuberculin), purified protein derivative (PPD), is injected into the intradermal layer of the inner aspect of the forearm, approximately 4 inches below the elbow (Fig. 23-3). Intermediate-strength PPD, in a tuberculin syringe with a half-inch 26- or 27-gauge needle, is used. The needle, with the bevel facing up, is inserted beneath the skin. Then 0.1 mL of PPD is injected, creating an elevation in the skin, a well-demarcated wheal 6 to 10 mm in diameter. The site, antigen name, strength, lot number, date, and time of the test are recorded. The test result is read 48 to 72 hours after injection. Tests read after 72 hours tend to underestimate the true size of **induration** (hardening). A delayed localized reaction indicates that the person is sensitive to tuberculin.

A reaction occurs when both induration and erythema (redness) are present. After the area is inspected for induration, it is lightly palpated across the injection site, from the area of normal skin to the margins of the induration. The diameter of the induration (not erythema) is measured in millimeters at its widest part (see Fig. 23-3), and the size of the induration is documented. Erythema without induration is not considered significant.

The size of the induration determines the significance of the reaction. A reaction of 0 to 4 mm is considered not significant. A reaction of 5 mm or greater may be significant in people who are considered to be at risk. It is defined as positive in patients who are human immunodeficiency virus (HIV) positive or have HIV risk factors and are of unknown HIV status, in those who are close contacts of someone with active TB, and in those who have chest x-ray results consistent with TB. An induration of 10 mm or greater is usually considered significant in people who have normal or mildly impaired immunity. A significant reaction indicates past exposure to *M. tuberculosis* or vaccination with bacille Calmette-Guérin (BCG) vaccine. The BCG vaccine is given to produce a greater resistance to development of TB. It is effective in up to 76% of people who receive it. The BCG vaccine is used in Europe and Latin America but not routinely in the United States.

A significant (positive) reaction does not necessarily mean that active disease is present in the body. More than 90% of people who are tuberculin-significant reactors do not develop clinical TB. However, all significant reactors are

candidates for active TB. In general, the more intense the reaction, the greater the likelihood of an active infection.

A nonsignificant (negative) skin test does not exclude TB infection or disease, because patients who are immunosuppressed cannot develop an immune response that is adequate to produce a positive skin test. This is referred to as anergy.

QuantiferON-TB Gold Test

In 2005, the U.S. Food and Drug Administration approved a new test for the detection of TB. The QuantiFERON-TB Gold (QFT-G) test is an enzyme-linked immunosorbent assay (ELISA) that detects the release of interferon-gamma by white blood cells when the blood of a patient with TB is incubated with peptides similar to those in *M. tuberculosis*. The results of the QFT-G test are available in less than 24 hours and are not affected by prior vaccination with BCG. A positive tuberculin skin test or QFT-G only indicates that a person has been infected with TB. It does not indicate whether or not the person has active progression of the disease (CDC, 2005c).

Classification

Data from the history, physical examination, TB test, chest x-ray, and microbiologic studies are used to classify TB into one of five classes. A classification scheme provides public health officials with a systematic way to monitor epidemiology and treatment of the disease.

- Class 0: no exposure; no infection
- Class 1: exposure; no evidence of infection
- Class 2: latent infection; no disease (eg, positive PPD reaction but no clinical evidence of active TB)
- Class 3: disease; clinically active
- Class 4: disease; not clinically active
- Class 5: suspected disease; diagnosis pending

Gerontologic Considerations

TB may have atypical manifestations in elderly patients, whose symptoms may include unusual behavior and altered mental status, fever, anorexia, and weight loss. In many elderly patients, the tuberculin skin test produces no reaction (loss of immunologic memory) or delayed reactivity for up to 1 week (recall phenomenon). A second skin test is performed in 1 to 2 weeks.

Medical Management

Pulmonary TB is treated primarily with antituberculosis agents for 6 to 12 months. A prolonged treatment duration is necessary to ensure eradication of the organisms

and to prevent relapse. The continuing and increasing resistance of *M. tuberculosis* to TB medications is a worldwide concern and challenge in TB therapy. Several types of drug resistance must be considered when planning effective therapy:

- Primary drug resistance: resistance to one of the first-line antituberculosis agents in people who have not had previous treatment
- Secondary or acquired drug resistance: resistance to one or more antituberculosis agents in patients undergoing therapy
- Multidrug resistance: resistance to two agents, isoniazid (INH) and rifampin. The populations at greatest risk for multidrug resistance are those who are HIV positive, institutionalized, or homeless.

The increasing prevalence of drug resistance points out the need to begin TB treatment with four or more medications, to ensure completion of therapy, and to develop and evaluate new anti-TB medications.

Pharmacologic Therapy

In current TB therapy, four first-line medications are used (Table 23-3), INH, rifampin (Rifadin), pyrazinamide, and ethambutol (Myambutol). Combination medications, such as INH and rifampin (Rifamate) or INH, pyrazinamide (PZA), and rifampin (Rifater) and medications adminis-

tered twice a week (eg, rifapentine [Priftin]) are available to help improve patient adherence. Capreomycin (Capastat), ethionamide (Trecator), para-aminosalicylate sodium, and cycloserine (Seromycin) are second-line medications. Additional potentially effective medications include other aminoglycosides, quinolones, rifabutin, and clofazimine (Lamprene).

Recommended treatment guidelines for newly diagnosed cases of pulmonary TB (CDC, 2003) have two parts: an initial treatment phase and a continuation phase. The initial phase consists of a multiple-medication regimen of INH, rifampin, pyrazinamide, and ethambutol. This initial intensive-treatment regimen is administered daily for 8 weeks, after which options for the continuation phase of treatment include INH and rifampin or INH and rifapentine. The continuation regimen lasts for an additional 4 or 7 months. The 4-month period is used for the large majority of patients (CDC, 2003). The 7-month period is recommended for patients with cavitary pulmonary TB whose sputum culture after the initial 2 months of treatment is positive, for those whose initial phase of treatment did not include PZA, and for those being treated once weekly with INH and rifapentine whose sputum culture is positive at the end of the initial phase of treatment. People are considered noninfectious after 2 to 3 weeks of continuous medication therapy. Vitamin B (pyridoxine) is usually

Commonly Used Agents	Adult Daily Dosage*	Most Common Side Effects	Drug Interactions [†]	Remarks*
Isoniazid (INH)	5 mg/kg (300 mg maximum daily)	Peripheral neuritis, hepatic enzyme elevation, hepatitis, hypersensitivity	Phenytoin—synergistic Antabuse Alcohol	Bactericidal Pyridoxine is used as prophylaxis for neuritis. Monitor AST and ALT.
Rifampin (Rifadin)	10 mg/kg (600 mg maximum daily)	Hepatitis, febrile reaction, purpura (rare), nausea, vomiting	Rifampin increases metabolism of oral contraceptives, quinidine, corticosteroids, coumarin derivatives and methadone, digoxin, oral hypoglycemics; PAS may interfere with absorption of rifampin.	Bactericidal Orange urine and other body secretions Discoloring of contact lenses Monitor AST and ALT
Rifabutin (Mycobutin)	5 mg/kg (300 mg maximum daily)			
Rifapentine (Priftin)	10 mg/kg (600 mg twice weekly)	Hepatotoxicity, thrombocytopenia	Avoid protease inhibitors.	Orange-red coloration of body secretions, contact lenses, dentures Use with caution in elderly or in those with renal disease.
Pyrazinamide	15–30 mg/kg (2.0 g maximum daily)*	Hyperuricemia, hepatotoxicity, skin rash, arthralgias, GI distress		Bactericidal Monitor uric acid, AST, ALT
Ethambutol (Myambutol)	15–25 mg/kg (no maximum daily dose, but base on lean body wt)*	Optic neuritis (may lead to blindness; very rare at 15 mg/kg), skin rash		Bacteriostatic Use with caution with renal disease or when eye testing is not feasible. Monitor visual acuity, color discrimination. [‡]
Combinations: INH + rifampin (eg, Rifamate)	150-mg & 300-mg caps (2 caps daily)			

*Check product labeling for detailed information on dose, contraindications, drug interactions, adverse reactions, and monitoring.

[†]Refer to current literature, particularly on rifampin, because it increases hepatic microenzymes and therefore interacts with many drugs.

[‡]Initial examination should be performed at start of treatment.

administered with INH to prevent INH-associated peripheral neuropathy (see Table 23-3). The total number of doses taken, not simply the duration of treatment, more accurately determines whether a course of therapy has been completed.

INH also may be used as a prophylactic (preventive) measure for people who are at risk for significant disease, including:

- Household family members of patients with active disease
- Patients with HIV infection who have a PPD test reaction with 5 mm of induration or more
- Patients with fibrotic lesions suggestive of old TB detected on a chest x-ray and a PPD reaction with 5 mm of induration or more
- Patients whose current PPD test results show a change from former test results, suggesting recent exposure to TB and possible infection (skin test converters)
- Users of IV/injection drugs who have PPD test results with 10 mm of induration or more
- Patients with high-risk comorbid conditions and a PPD result with 10 mm of induration or more

Other candidates for preventive INH therapy are those 35 years or younger who have PPD test results with 10 mm of induration or more and one of the following criteria:

- Foreign-born individuals from countries with a high prevalence of TB
- High-risk, medically underserved populations
- Institutionalized patients

Prophylactic INH treatment involves taking daily doses for 6 to 12 months. Liver enzymes, blood urea nitrogen (BUN), and creatinine levels are monitored monthly. Sputum culture results are monitored for acid-fast bacillus to evaluate the effectiveness of treatment and the patient's adherence to the treatment regimen.

Nursing Management

Nursing management includes promoting airway clearance, advocating treatment regimen, promoting activity and nutrition, and preventing transmission.

Promoting Airway Clearance

Copious secretions obstruct the airways in many patients with TB and interfere with adequate gas exchange. Increasing the fluid intake promotes systemic hydration and serves as an effective expectorant. The nurse instructs the patient about correct positioning to facilitate airway drainage (postural drainage); this is described in Chapter 25.

Advocating Adherence to Treatment Regimen

The multiple-medication regimen that the patient must follow can be quite complex. Understanding of the medications, schedule, and side effects is important. The nurse teaches the patient that TB is a communicable disease and that taking medications is the most effective means of preventing transmission. The major reason treatment fails is that patients do not take their medications regularly and for the prescribed duration. This may be due to side effects or the complexity of the treatment regimen.

The nurse instructs the patient to take the medication either on an empty stomach or at least 1 hour before meals because food interferes with medication absorption (although

taking medications on an empty stomach frequently results in gastrointestinal upset). Patients taking INH should avoid foods that contain tyramine and histamine (tuna, aged cheese, red wine, soy sauce, yeast extracts), because eating them while taking INH may result in headache, flushing, hypotension, lightheadedness, palpitations, and diaphoresis.

In addition, rifampin can alter the metabolism of certain other medications, making them less effective. These medications include beta-blockers, oral anticoagulants such as warfarin (Coumadin), digoxin, quinidine, corticosteroids, oral hypoglycemic agents, oral contraceptives, theophylline, and verapamil (Calan, Isoptin). This issue should be discussed with the physician and pharmacist so that medication dosages can be adjusted accordingly. The nurse informs the patient that rifampin may discolor contact lenses and that the patient may want to wear eyeglasses during treatment. The nurse monitors for other side effects of anti-TB medications, including hepatitis, neurologic changes (hearing loss, neuritis), and rash. Liver enzymes, BUN, and serum creatinine levels are monitored to detect changes in liver and kidney function. Sputum culture results are monitored for acid-fast bacilli to evaluate the effectiveness of the treatment regimen and adherence to therapy.

The nurse instructs the patient about the risk of drug resistance if the medication regimen is not strictly and continuously followed. The nurse carefully monitors vital signs and observes for spikes in temperature or changes in the patient's clinical status. Caregivers of patients who are not hospitalized are taught to monitor the patient's temperature and respiratory status. Changes in the patient's respiratory status are reported to the primary health care provider.

Promoting Activity and Adequate Nutrition

Patients with TB are often debilitated from prolonged chronic illness and impaired nutritional status. The nurse plans a progressive activity schedule that focuses on increasing activity tolerance and muscle strength. Anorexia, weight loss, and malnutrition are common in patients with TB. The patient's willingness to eat may be altered by fatigue from excessive coughing; sputum production; chest pain; generalized debilitated state; or cost, if the patient has few resources. Identifying facilities (eg, shelters, soup kitchens, Meals on Wheels) that provide meals in the patient's neighborhood may increase the likelihood that the patient with limited resources and energy will have access to a more nutritious intake. A nutritional plan that allows for small, frequent meals may be required. Liquid nutritional supplements may assist in meeting basic caloric requirements.

Preventing Spreading of Tuberculosis Infection

In an effort to prevent transmission of TB to others, the nurse carefully instructs the patient about important hygiene measures, including mouth care, covering the mouth and nose when coughing and sneezing, proper disposal of tissues, and handwashing. TB is a disease that must be reported to the health department so that people who have been in contact with the affected patient during the infectious stage can undergo screening and possible treatment, if indicated.

In addition to the risk of transmission of TB infection to other people, it can also be spread to other parts of the body of affected patients. Spread or dissemination of TB infection to nonpulmonary sites of the body is known as miliary TB. It is the result of invasion of the bloodstream by the tubercle bacillus. Usually it results from late reactivation of a dormant infection in the lung or elsewhere. The origin of the bacilli that enter the bloodstream is either a chronic focus that has ulcerated into a blood vessel or multitudes of miliary tubercles lining the inner surface of the thoracic duct. The organisms migrate from these foci into the bloodstream, are carried throughout the body, and disseminate throughout all tissues, with tiny miliary tubercles developing in the lungs, spleen, liver, kidneys, meninges, and other organs.

The clinical course of miliary TB may vary from an acute, rapidly progressive infection with high fever to a slowly developing process with low-grade fever, anemia, and debilitation. At first, there may be no localizing signs except an enlarged spleen and a reduced number of leukocytes. However, within a few weeks, the chest x-ray reveals small densities scattered diffusely throughout both lung fields; these are the miliary tubercles, which gradually grow.

The possibility of spread to nonpulmonary sites in the body requires careful monitoring for this very serious form of TB. The nurse monitors vital signs and observes for spikes in temperature as well as changes in renal and cognitive function. Few physical signs may be elicited on physical examination of the chest, but at this stage, the patient has a severe cough and dyspnea. Treatment of miliary TB is the same as for pulmonary TB.

Lung Abscess

A lung abscess is necrosis of the pulmonary parenchyma caused by microbial infection (Bartlett, 2007). It is generally caused by aspiration of anaerobic bacteria. By definition, in a lung abscess, the chest x-ray demonstrates a cavity of at least 2 cm. Patients who are at risk for aspiration of foreign material and development of a lung abscess include those with impaired cough reflexes who cannot close the glottis and those with swallowing difficulties. Other at-risk patients include those with central nervous system disorders (eg, seizure, stroke), drug addiction, alcoholism, esophageal disease, or compromised immune function; patients without teeth and those receiving nasogastric tube feedings; and patients with an altered state of consciousness due to anesthesia.

Pathophysiology

Most lung abscesses are a complication of bacterial pneumonia or are caused by aspiration of oral anaerobes into the lung. Abscesses also may occur secondary to mechanical or functional obstruction of the bronchi by a tumor, foreign body, or bronchial stenosis, or from necrotizing pneumonias, TB, pulmonary embolism (PE), or chest trauma.

Most lung abscesses are found in areas of the lung that may be affected by aspiration. The site of the lung abscess is related to gravity and is determined by position. For patients who are confined to bed, the posterior segment of an

upper lobe and the superior segment of the lower lobe are the most common areas. However, atypical presentations may occur, depending on the position of the patient when the aspiration occurred.

Initially, the cavity in the lung may or may not extend directly into a bronchus. Eventually, the abscess becomes surrounded, or encapsulated, by a wall of fibrous tissue. The necrotic process may extend until it reaches the lumen of a bronchus or the pleural space and establishes communication with the respiratory tract, the pleural cavity, or both. If the bronchus is involved, the purulent contents are expectorated continuously in the form of sputum. If the pleura is involved, an empyema results. A communication or connection between the bronchus and pleura is known as a bronchopleural fistula.

The organisms frequently associated with lung abscesses are *S. aureus*, *Klebsiella*, and other gram-negative species (Bartlett, 2007). However, anaerobic organisms may also be present. The organisms vary depending on the underlying predisposing factors.

Clinical Manifestations

The clinical manifestations of a lung abscess may vary from a mild productive cough to acute illness. Most patients have a fever and a productive cough with moderate to copious amounts of foul-smelling, sometimes bloody, sputum. The fever and cough may develop insidiously and may have been present for several weeks before diagnosis. Leukocytosis may be present. Pleurisy or dull chest pain, dyspnea, weakness, anorexia, and weight loss are common.

Assessment and Diagnostic Findings

Physical examination of the chest may reveal dullness on percussion and decreased or absent breath sounds with an intermittent **pleural friction rub** (grating or rubbing sound) on auscultation. Crackles may be present. Confirmation of the diagnosis is made by chest x-ray, sputum culture, and, in some cases, fiberoptic bronchoscopy. The chest x-ray reveals an infiltrate with an air–fluid level. A computed tomography (CT) scan of the chest may be required to provide more detailed images of different cross-sectional areas of the lung.

Prevention

The following measures reduce the risk of lung abscess:

- Appropriate antibiotic therapy before any dental procedures in patients who must have teeth extracted while their gums and teeth are infected
- Adequate dental and oral hygiene, because anaerobic bacteria play a role in the pathogenesis of lung abscess
- Appropriate antimicrobial therapy for patients with pneumonia

Medical Management

The findings of the history, physical examination, chest x-ray, and sputum culture indicate the type of organism and the treatment required. Adequate drainage of the lung abscess may be achieved through postural drainage and chest physiotherapy. Patients should be assessed for an adequate cough. Some patients require insertion of a percutaneous chest catheter for long-term drainage of the abscess. Therapeutic use of bronchoscopy to drain an abscess is uncommon. A diet

high in protein and calories is necessary, because chronic infection is associated with a catabolic state, necessitating increased intake of calories and protein to facilitate healing. Surgical intervention is rare, but pulmonary resection (lobectomy) is performed if massive **hemoptysis** (coughing up of blood) occurs or if there is little or no response to medical management.

Pharmacologic Therapy

IV antimicrobial therapy depends on the results of the sputum culture and sensitivity and is administered for an extended period. Standard treatment for an anaerobic lung infection is clindamycin (Cleocin). Large IV doses are usually required, because the antibiotic must penetrate the necrotic tissue and the fluid in the abscess. The IV dose is continued until there is evidence of symptom improvement.

Long-term therapy with oral antibiotics replaces IV therapy after the patient shows signs of improvement (usually 3 to 5 days). Improvement is demonstrated by normal temperature, decreased white blood cell count, and improvement on chest x-ray (resolution of surrounding infiltrate, reduction in cavity size, absence of fluid). Oral administration of antibiotic therapy is continued for an additional 4 to 8 weeks and sometimes longer. If treatment is stopped too soon, a relapse may occur.

Nursing Management

The nurse administers antibiotics and IV treatments as prescribed and monitors for adverse effects. Chest physiotherapy is initiated as prescribed to facilitate drainage of the abscess. The nurse teaches the patient to perform deep-breathing and coughing exercises to help expand the lungs. To ensure proper nutritional intake, the nurse encourages a diet that is high in protein and calories. The nurse also offers emotional support, because the abscess may take a long time to resolve.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

A patient who has had surgery may return home before the wound closes entirely or with a drain or tube in place. In these cases, the nurse teaches the patient or caregivers about how to change the dressings to prevent skin excoriation and odor, how to monitor for signs and symptoms of infection, and how to care for and maintain the drain or tube. The nurse also reminds the patient to perform deep-breathing and coughing exercises every 2 hours during the day and shows caregivers how to perform chest percussion and postural drainage to facilitate expectoration of lung secretions.

Continuing Care

A patient whose condition requires therapy at home may need referral for home care. During home visits, the nurse assesses the patient's physical condition, nutritional status, and home environment, as well as the ability of the patient and family to carry out the therapeutic regimen. Patient teaching is reinforced, and nutritional counseling is provided with the goal of attaining and maintaining an optimal state of nutrition. To prevent relapses, the nurse emphasizes the importance of completing the antibiotic regimen and of

following suggestions for rest and appropriate activity. If IV antibiotic therapy is to continue at home, the services of home care nurses may be arranged to initiate IV therapy and to evaluate its administration by the patient or family.

Although most outpatient IV therapy is administered in the home setting, the patient may visit a nearby clinic or physician's office for this treatment. In some cases, patients with lung abscess may have ignored their health. Therefore, it is important to use this opportunity to address health promotion strategies and health screening with the patient.

PLEURAL CONDITIONS

Pleural conditions are disorders that involve the membranes covering the lungs (visceral pleura) and the surface of the chest wall (parietal pleura) or disorders affecting the pleural space.

Pleurisy

Pathophysiology

Pleurisy (pleuritis) refers to inflammation of both layers of the pleurae (parietal and visceral). Pleurisy may develop in conjunction with pneumonia or an upper respiratory tract infection, TB, or collagen disease; after trauma to the chest, pulmonary infarction, or PE; in patients with primary or metastatic cancer; and after thoracotomy. The parietal pleura has nerve endings, and the visceral pleura does not. When the inflamed pleural membranes rub together during respiration (intensified on inspiration), the result is severe, sharp, knifelike pain.

Clinical Manifestations

The key characteristic of pleuritic pain is its relationship to respiratory movement. Taking a deep breath, coughing, or sneezing worsens the pain. Pleuritic pain is limited in distribution rather than diffuse; it usually occurs only on one side. The pain may become minimal or absent when the breath is held. It may be localized or radiate to the shoulder or abdomen. Later, as pleural fluid develops, the pain decreases.

Assessment and Diagnostic Findings

In the early period, when little fluid has accumulated, a pleural friction rub can be heard with the stethoscope, only to disappear later as more fluid accumulates and separates the inflamed pleural surfaces. Diagnostic tests may include chest x-rays, sputum analysis, thoracentesis to obtain a specimen of pleural fluid for examination, and, less commonly, a pleural biopsy.

Medical Management

The objectives of treatment are to discover the underlying condition causing the pleurisy and to relieve the pain. As the underlying disease (pneumonia, infection) is treated, the pleuritic inflammation usually resolves. At the same time, it is necessary to monitor for signs and symptoms of pleural effusion, such as shortness of breath, pain, assumption of a position that decreases pain, and decreased chest wall excursion.

Prescribed analgesic agents and topical applications of heat or cold provide symptomatic relief. Indomethacin (Indocin), a nonsteroidal anti-inflammatory agent, may provide pain relief while allowing the patient to take deep breaths and cough more effectively. If the pain is severe, an intercostal nerve block may be required.

Nursing Management

Because the patient has considerable pain on inspiration, the nurse offers suggestions to enhance comfort, such as turning frequently onto the affected side to splint the chest wall and reduce the stretching of the pleurae. The nurse also teaches the patient to use the hands or a pillow to splint the rib cage while coughing.

Pleural Effusion

Pleural effusion, a collection of fluid in the pleural space, is rarely a primary disease process; it is usually secondary to other diseases. Normally, the pleural space contains a small amount of fluid (5 to 15 mL), which acts as a lubricant that allows the pleural surfaces to move without friction (Fig. 23-4). Pleural effusion may be a complication of heart failure, TB, pneumonia, pulmonary infections (particularly viral infections), nephrotic syndrome, connective tissue disease, pulmonary embolus, and neoplastic tumors. The most common malignancy associated with a pleural effusion is bronchogenic carcinoma.

Pathophysiology

In certain disorders, fluid may accumulate in the pleural space to a point at which it becomes clinically evident. This almost always has pathologic significance. The effusion can be a relatively clear fluid, or it can be bloody or purulent. An effusion of clear fluid may be a transudate or an exudate. A transudate (filtrate of plasma that moves across intact

capillary walls) occurs when factors influencing the formation and reabsorption of pleural fluid are altered, usually by imbalances in hydrostatic or oncotic pressures. The finding of a transudative effusion generally implies that the pleural membranes are not diseased. A transudative effusion most commonly results from heart failure. An exudate (extravasation of fluid into tissues or a cavity) usually results from inflammation by bacterial products or tumors involving the pleural surfaces.

Clinical Manifestations

Usually, the clinical manifestations are caused by the underlying disease. Pneumonia causes fever, chills, and pleuritic chest pain, whereas a malignant effusion may result in dyspnea, difficulty lying flat, and coughing. The severity of symptoms is determined by the size of the effusion, the speed of its formation, and the underlying lung disease. A large pleural effusion causes dyspnea (shortness of breath). A small to moderate pleural effusion causes minimal or no dyspnea.

Assessment and Diagnostic Findings

Assessment of the area of the pleural effusion reveals decreased or absent breath sounds, decreased fremitus, and a dull, flat sound on percussion. In the case of an extremely large pleural effusion, the assessment reveals a patient in acute respiratory distress. Tracheal deviation away from the affected side may also be apparent.

Physical examination, chest x-ray, chest CT, and thoracentesis confirm the presence of fluid. In some instances, a lateral decubitus x-ray is obtained. For this x-ray, the patient lies on the affected side in a side-lying position. A pleural effusion can be diagnosed because this position allows for the “layering out” of the fluid, and an air–fluid line is visible.

Pleural fluid is analyzed by bacterial culture, Gram stain, acid-fast bacillus stain (for TB), red and white blood cell counts, chemistry studies (glucose, amylase, lactate dehydrogenase, protein), cytologic analysis for malignant cells, and pH. A pleural biopsy also may be performed as a diagnostic tool.

Medical Management

The objectives of treatment are to discover the underlying cause of the pleural effusion; to prevent reaccumulation of fluid; and to relieve discomfort, dyspnea, and respiratory compromise. Specific treatment is directed at the underlying cause (eg, heart failure, pneumonia, cirrhosis). If the pleural fluid is an exudate, more extensive diagnostic procedures are performed to determine the cause. Treatment for the primary cause is then instituted.

Thoracentesis is performed to remove fluid, to obtain a specimen for analysis, and to relieve dyspnea and respiratory compromise (see Chapter 21). Thoracentesis may be performed under ultrasound guidance. Depending on the size of the pleural effusion, the patient may be treated by removing the fluid during the thoracentesis procedure or by inserting a chest tube connected to a water-seal drainage system or suction to evacuate the pleural space and re-expand the lung.

However, if the underlying cause is a malignancy, the effusion tends to recur within a few days or weeks. Repeated thoracenteses result in pain, depletion of protein and electrolytes, and sometimes pneumothorax. Once the

Figure 23-4 In pleural effusion, an abnormal volume of fluid collects in the pleural space, causing pain and shortness of breath. Pleural effusion is usually secondary to other disease processes.

pleural space is adequately drained, a chemical pleurodesis may be performed to obliterate the pleural space and prevent reaccumulation of fluid. Pleurodesis may be performed using either a thoracoscopic approach or a chest tube. A chemically irritating agent (eg, talc or another chemical irritant) is instilled or aerosolized into the pleural space. With the chest tube approach, after the agent is instilled, the chest tube is clamped for 60 to 90 minutes and the patient is assisted to assume various positions to promote uniform distribution of the agent and to maximize its contact with the pleural surfaces. The tube is unclamped as prescribed, and chest drainage may be continued several days longer to prevent reaccumulation of fluid and to promote the formation of adhesions between the visceral and parietal pleurae.

Other treatments for pleural effusions caused by malignancy include surgical pleurectomy, insertion of a small catheter attached to a drainage bottle for outpatient management (Pleurx catheter [Denver Biomedical]), or implantation of a pleuroperitoneal shunt. A pleuroperitoneal shunt consists of two catheters connected by a pump chamber containing two one-way valves. Fluid moves from the pleural space to the pump chamber and then to the peritoneal cavity. The patient manually pumps on the reservoir daily to move fluid from the pleural space to the peritoneal space.

Nursing Management

The nurse's role in the care of patients with a pleural effusion includes implementing the medical regimen. The nurse prepares and positions the patient for thoracentesis and offers support throughout the procedure. The nurse is responsible for making sure the thoracentesis fluid amount is recorded and sent for appropriate laboratory testing. If a chest tube drainage and water-seal system is used, the nurse is responsible for monitoring the system's function and recording the amount of drainage at prescribed intervals. Nursing care related to the underlying cause of the pleural effusion is specific to the underlying condition. Care of the patient with a chest tube is discussed in Chapter 25.

If a chest tube is inserted for talc instillation, pain management is a priority and the nurse helps the patient assume positions that are the least painful. However, frequent turning and movement are important to facilitate adequate spreading of the talc over the pleural surface. The nurse evaluates the patient's pain level and administers analgesic agents as prescribed and as needed.

If the patient is to be managed as an outpatient with a pleural catheter for drainage, the nurse educates the patient and family about management and care of the catheter and drainage system.

Empyema

An empyema is an accumulation of thick, purulent fluid within the pleural space, often with fibrin development and a loculated (walled-off) area where infection is located.

Pathophysiology

Most empyemas occur as complications of bacterial pneumonia or lung abscess. They also result from penetrating chest trauma, hematogenous infection of the pleural space,

nonbacterial infections, and iatrogenic causes (after thoracic surgery or thoracentesis). At first the pleural fluid is thin, with a low leukocyte count, but it frequently progresses to a fibropurulent stage and, finally, to a stage where it encloses the lung within a thick exudative membrane (loculated empyema).

Clinical Manifestations

The patient is acutely ill and has signs and symptoms similar to those of an acute respiratory infection or pneumonia (fever, night sweats, pleural pain, cough, dyspnea, anorexia, weight loss). If the patient is immunocompromised, the symptoms may be vague. If the patient has received antimicrobial therapy, the clinical manifestations may be less obvious.

Assessment and Diagnostic Findings

Chest auscultation demonstrates decreased or absent breath sounds over the affected area, and there is dullness on chest percussion as well as decreased fremitus. The diagnosis is established by chest CT. Usually a diagnostic thoracentesis is performed, often under ultrasound guidance.

Medical Management

The objectives of treatment are to drain the pleural cavity and to achieve complete expansion of the lung. The fluid is drained, and appropriate antibiotics, in large doses, are prescribed based on the causative organism. Sterilization of the empyema cavity requires 4 to 6 weeks of antibiotics. Drainage of the pleural fluid depends on the stage of the disease and is accomplished by one of the following methods:

- Needle aspiration (thoracentesis) with a thin percutaneous catheter, if the volume is small and the fluid is not too purulent or too thick
- Tube thoracostomy (chest drainage using a large-diameter intercostal tube attached to water-seal drainage [see Chapter 25]) with fibrinolytic agents instilled through the chest tube in patients with loculated or complicated pleural effusions
- Open chest drainage via thoracotomy, including potential rib resection, to remove the thickened pleura, pus, and debris and to remove the underlying diseased pulmonary tissue

With long-standing inflammation, an exudate can form over the lung, trapping it and interfering with its normal expansion. This exudate must be removed surgically (decortication). The drainage tube is left in place until the pus-filled space is obliterated completely. The complete obliteration of the pleural space is monitored by serial chest x-rays, and the patient should be informed that treatment may be long term. Patients are frequently discharged from the hospital with a chest tube in place, with instructions to monitor fluid drainage at home.

Nursing Management

Resolution of empyema is a prolonged process. The nurse helps the patient cope with the condition and instructs the patient in lung-expanding breathing exercises to restore normal respiratory function. The nurse also provides care specific to the method of drainage of the pleural fluid (eg, needle aspiration, closed chest drainage, rib resection and

drainage). When the patient is discharged home with a drainage tube or system in place, the nurse instructs the patient and family on care of the drainage system and drain site, measurement and observation of drainage, signs and symptoms of infection, and how and when to contact the health care provider. (See Nursing Process: The Patient Undergoing Thoracic Surgery in Chapter 25.)

Pulmonary Edema

Pulmonary edema is defined as abnormal accumulation of fluid in the lung tissue, the alveolar space, or both. It is a severe, life-threatening condition.

Pathophysiology

Pulmonary edema most commonly occurs as a result of increased microvascular pressure from abnormal cardiac function. The backup of blood into the pulmonary vasculature resulting from inadequate left ventricular function causes an increased microvascular pressure, and fluid begins to leak into the interstitial space and the alveoli. Other causes of pulmonary edema are hypervolemia or a sudden increase in the intravascular pressure in the lung. One example, which may occur in the patient who has undergone pneumonectomy, is sometimes termed “flash” pulmonary edema. When one lung has been removed, all the cardiac output goes to the remaining lung. If the patient’s fluid status is not monitored closely, pulmonary edema can quickly develop in the postoperative period as the patient’s pulmonary vasculature attempts to adapt. A second example is called re-expansion pulmonary edema. This may result from a rapid reinflation of the lung after removal of air from a pneumothorax or evacuation of fluid from a large pleural effusion.

Clinical Manifestations

Increasing respiratory distress, characterized by dyspnea, air hunger, and central cyanosis, is present. Patients are usually very anxious and often agitated. As the fluid leaks into the alveoli and mixes with air, a foam or froth is formed. The patient coughs up (or the nurse suctions out) these foamy, frothy, and often blood-tinged secretions. The patient experiences acute respiratory distress and may become confused.

Assessment and Diagnostic Findings

Auscultation reveals crackles in the lung bases (especially in the posterior bases) that rapidly progress toward the apices of the lungs. These crackles are caused by the movement of air through the alveolar fluid. The chest x-ray reveals increased interstitial markings. The patient may have tachycardia. Pulse oximetry values begin to fall, and arterial blood gas analysis demonstrates worsening hypoxemia.

Medical Management

Management focuses on correcting the underlying disorder. If the pulmonary edema is cardiac in origin, then improvement in left ventricular function is the goal. Vasodilators, inotropic medications, afterload or preload agents, or contractility medications may be administered. Additional cardiac measures (eg, intra-aortic balloon pump) may be indicated if there is no response. If the problem is fluid

overload, diuretics are administered and fluids are restricted. Oxygen is administered to correct the hypoxemia; in some circumstances, intubation and mechanical ventilation are necessary. The patient is extremely anxious, and morphine is prescribed to reduce anxiety and control pain.

Nursing Management

Nursing management includes assisting with administration of oxygen and intubation and mechanical ventilation if respiratory failure occurs. The nurse also administers medications (eg, morphine, vasodilators, inotropic medications, preload and afterload agents) as prescribed and monitors the patient’s responses. Nursing management in pulmonary edema is described in more detail in Chapter 30.

Acute Respiratory Failure

Respiratory failure is a sudden and life-threatening deterioration of the gas exchange function of the lung and indicates failure of the lungs to provide adequate oxygenation or ventilation for the blood. Acute respiratory failure is defined as a decrease in arterial oxygen tension (PaO_2) to less than 50 mm Hg (hypoxemia) and an increase in arterial carbon dioxide tension (PaCO_2) to greater than 50 mm Hg (hypercapnia), with an arterial pH of less than 7.35.

It is important to distinguish between acute and chronic respiratory failure. Chronic respiratory failure is defined as deterioration in the gas exchange function of the lung that has developed insidiously or has persisted for a long period after an episode of acute respiratory failure. The absence of acute symptoms and the presence of a chronic respiratory acidosis suggest the chronicity of the respiratory failure. Two causes of chronic respiratory failure are COPD (discussed in Chapter 24) and neuromuscular diseases (discussed in Chapter 65). Patients with these disorders develop a tolerance to the gradually worsening hypoxemia and hypercapnia. However, patients with chronic respiratory failure can develop acute failure. For example, a patient with COPD may develop an exacerbation or infection that causes additional deterioration of gas exchange. The principles of management of acute versus chronic respiratory failure are different; the following discussion is limited to acute respiratory failure.

Pathophysiology

In acute respiratory failure, the ventilation or perfusion mechanisms in the lung are impaired. Ventilatory failure mechanisms leading to acute respiratory failure include impaired function of the central nervous system (drug overdose, head trauma, infection, hemorrhage, sleep apnea), neuromuscular dysfunction (myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, spinal cord trauma), musculoskeletal dysfunction (chest trauma, kyphoscoliosis, malnutrition), and pulmonary dysfunction (COPD, asthma, cystic fibrosis).

Oxygenation failure mechanisms leading to acute respiratory failure include pneumonia, acute respiratory distress syndrome, heart failure, COPD, pulmonary embolism, and **restrictive lung diseases**.

In the postoperative period, especially after major thoracic or abdominal surgery, inadequate ventilation and res-

piratory failure may occur because of several factors. During this period, for example, acute respiratory failure may be caused by the effects of anesthetic, analgesic, and sedative agents, which may depress respiration (as described earlier) or enhance the effects of opioids and lead to hypoventilation. Pain may interfere with deep breathing and coughing. A ventilation–perfusion mismatch is the usual cause of respiratory failure after major abdominal, cardiac, or thoracic surgery.

Clinical Manifestations

Early signs are those associated with impaired oxygenation and may include restlessness, fatigue, headache, dyspnea, air hunger, tachycardia, and increased blood pressure. As the hypoxemia progresses, more obvious signs may be present, including confusion, lethargy, tachycardia, tachypnea, central cyanosis, diaphoresis, and finally respiratory arrest. Physical findings are those of acute respiratory distress, including use of accessory muscles, decreased breath sounds if the patient cannot adequately ventilate, and other findings related specifically to the underlying disease process and cause of acute respiratory failure.

Medical Management

The objectives of treatment are to correct the underlying cause and to restore adequate gas exchange in the lung. Intubation and mechanical ventilation may be required to maintain adequate ventilation and oxygenation while the underlying cause is corrected.

Nursing Management

Nursing management of patients with acute respiratory failure includes assisting with intubation and maintaining mechanical ventilation (described in Chapter 25). Patients are usually managed in the intensive care unit. The nurse assesses the patient's respiratory status by monitoring the level of responsiveness, arterial blood gases, pulse oximetry, and vital signs. In addition, the nurse assesses the entire respiratory system and implements strategies (eg, turning schedule, mouth care, skin care, range of motion of extremities) to prevent complications. The nurse also assesses the patient's understanding of the management strategies that are used and initiates some form of communication to enable the patient to express concerns and needs to the health care team.

Finally, the nurse addresses the problems that led to the acute respiratory failure. As the patient's status improves, the nurse assesses the patient's knowledge of the underlying disorder and provides teaching as appropriate to address the disorder.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a severe form of **acute lung injury**. This clinical syndrome is characterized by a sudden and progressive pulmonary edema, increasing bilateral infiltrates on chest x-ray, hypoxemia unresponsive to oxygen supplementation regardless of the amount of PEEP, and the absence of an elevated left atrial pressure. Patients often demonstrate reduced lung compliance. A wide

Chart 23-6 • Etiologic Factors Related to Acute Respiratory Distress Syndrome (ARDS)

- Aspiration (gastric secretions, drowning, hydrocarbons)
- Drug ingestion and overdose
- Hematologic disorders (disseminated intravascular coagulopathy [DIC], massive transfusions, cardiopulmonary bypass)
- Prolonged inhalation of high concentrations of oxygen, smoke, or corrosive substances
- Localized infection (bacterial, fungal, viral pneumonia)
- Metabolic disorders (pancreatitis, uremia)
- Shock (any cause)
- Trauma (pulmonary contusion, multiple fractures, head injury)
- Major surgery
- Fat or air embolism
- Systemic sepsis

range of factors are associated with the development of ARDS (Chart 23-6), including direct injury to the lungs (eg, smoke inhalation) or indirect insult to the lungs (eg, shock). ARDS has been associated with a mortality rate ranging from 25% to 58% (Hansen-Flaschen & Siegel, 2007). The major cause of death in ARDS is nonpulmonary multiple-system organ failure, often with sepsis.

Pathophysiology

ARDS occurs as a result of diffuse alveolar damage. Inflammatory triggers initiate the release of cellular and chemical mediators, causing injury to the alveolar capillary membrane in addition to other structural damage to the lungs. Severe ventilation–perfusion mismatching occurs. Alveoli collapse because of the inflammatory infiltrate, blood, fluid, and surfactant dysfunction. Small airways are narrowed because of interstitial fluid and bronchial obstruction. Lung compliance may markedly decrease, resulting in decreased functional residual capacity and severe hypoxemia. The blood returning to the lung for gas exchange is pumped through the nonventilated, nonfunctioning areas of the lung, causing shunting. This means that blood is interfacing with nonfunctioning alveoli and gas exchange is markedly impaired, resulting in severe, refractory hypoxemia. Figure 23-5 shows the sequence of pathophysiologic events leading to ARDS.

Clinical Manifestations

By definition, ARDS is an acute event that typically develops over 4 to 48 hours (Hansen-Flaschen & Siegel, 2007). Initially, ARDS closely resembles severe hemodynamic pulmonary edema. The acute phase of ARDS is marked by a rapid onset of severe dyspnea that usually occurs 12 to 48 hours after the initiating event. Arterial hypoxemia that does not respond to supplemental oxygen is characteristic. Findings on chest x-ray are similar to those seen with cardiogenic pulmonary edema and are visible as bilateral infiltrates that quickly worsen. The acute lung injury then progresses to fibrosing alveolitis with persistent, severe hypoxemia. The patient also has increased alveolar dead space (ventilation to alveoli, but poor perfusion) and decreased pulmonary compliance (“stiff lungs,” which are difficult to ventilate).

Physiology ■■■ Pathophysiology

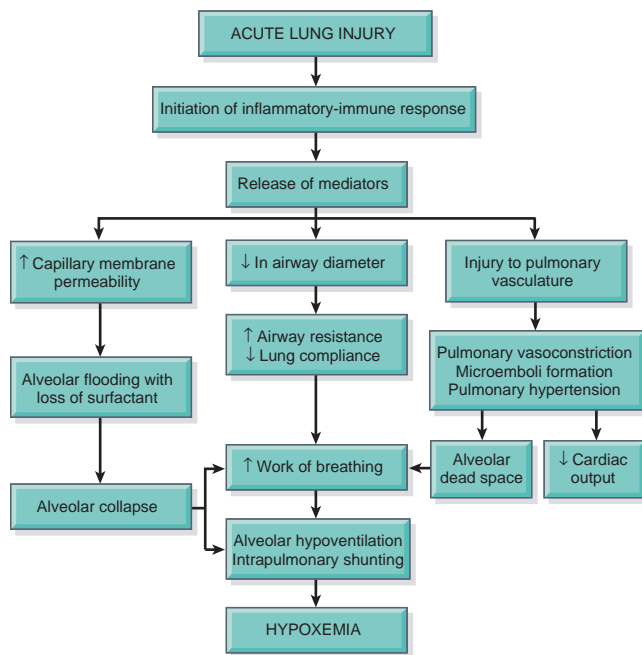

Figure 23-5 Pathogenesis and pathophysiology of acute respiratory distress syndrome.

Clinically, the patient is thought to be in the recovery phase if the hypoxemia gradually resolves, the chest x-ray improves, and the lungs become more compliant.

Assessment and Diagnostic Findings

On physical examination, intercostal retractions and crackles may be present as the fluid begins to leak into the alveolar interstitial space. Common diagnostic tests performed in patients with potential ARDS include plasma brain natriuretic peptide (BNP) levels, echocardiography, and pulmonary artery catheterization. The BNP level is helpful in distinguishing ARDS from hemodynamic pulmonary edema. Transthoracic echocardiography may be used if the BNP is not conclusive. Pulmonary artery catheterization is the definitive method to distinguish between hemodynamic (heart failure) and permeability pulmonary edema (ARDS) (Hansen-Flaschen & Siegel, 2007).

Medical Management

The primary focus in the management of ARDS includes identification and treatment of the underlying condition. Aggressive, supportive care must be provided to compensate for the severe respiratory dysfunction. This supportive therapy almost always includes intubation and mechanical ventilation. In addition, circulatory support, adequate fluid volume, and nutritional support are important. Supplemental oxygen is used as the patient begins the initial spiral of hypoxemia. As the hypoxemia progresses, intubation and mechanical ventilation are instituted. The concentration of oxygen and ventilator settings and modes are determined by the patient's status. This is monitored by arterial blood gas analysis, pulse oximetry, and bedside pulmonary function testing.

PEEP is a critical part of the treatment of ARDS. PEEP usually improves oxygenation, but it does not influence the natural history of the syndrome. Use of PEEP helps increase functional residual capacity and reverse alveolar collapse by keeping the alveoli open, resulting in improved arterial oxygenation and a reduction in the severity of the ventilation–perfusion imbalance. By using PEEP, a lower FiO_2 may be required. The goal is a PaO_2 greater than 60 mm Hg or an oxygen saturation level of greater than 90% at the lowest possible FiO_2 . PEEP and modes of mechanical ventilation are discussed in Chapter 25.

Systemic hypotension may occur in ARDS as a result of hypovolemia secondary to leakage of fluid into the interstitial spaces and depressed cardiac output from high levels of PEEP therapy. Hypovolemia must be carefully treated without causing further overload. Inotropic or vasopressor agents may be required. Pulmonary artery pressure catheters are used to monitor the patient's fluid status and the severe and progressive pulmonary hypertension sometimes observed in ARDS.

Pharmacologic Therapy

There is no specific pharmacologic treatment for ARDS except supportive care. Numerous pharmacologic treatments are under investigation to stop the cascade of events leading to ARDS. These include surfactant replacement therapy, pulmonary antihypertensive agents, and antisepsis agents.

Nutritional Therapy

Adequate nutritional support is vital in the treatment of ARDS. Patients with ARDS require 35 to 45 kcal/kg/day to meet caloric requirements. Enteral feeding is the first consideration; however, parenteral nutrition also may be required.

Nursing Management

General Measures

A patient with ARDS is critically ill and requires close monitoring in the intensive care unit, because the patient's condition could quickly become life-threatening. Most of the respiratory modalities discussed in Chapter 25 are used in this situation (oxygen administration, nebulizer therapy, chest physiotherapy, endotracheal intubation or tracheostomy, mechanical ventilation, suctioning, bronchoscopy). Frequent assessment of the patient's status is necessary to evaluate the effectiveness of treatment.

In addition to implementing the medical plan of care, the nurse considers other needs of the patient. Positioning is important. The nurse turns the patient frequently to improve ventilation and perfusion in the lungs and enhance secretion drainage. However, the nurse must closely monitor the patient for deterioration in oxygenation with changes in position. Oxygenation in patients with ARDS is sometimes improved in the prone position. This position may be evaluated for improvement in oxygenation and used in special circumstances. Devices and specialty beds are available to assist the nurse in placing the patient in a prone position.

The patient is extremely anxious and agitated because of the increasing hypoxemia and dyspnea. It is important to

reduce the patient's anxiety because anxiety increases oxygen expenditure by preventing rest. Rest is essential to limit oxygen consumption and reduce oxygen needs.

Ventilator Considerations

If the patient is intubated and receiving mechanical ventilation with PEEP, several considerations must be addressed. PEEP, which causes increased end-expiratory pressure, is an unnatural pattern of breathing and feels strange to patients. The patients may be anxious and “fight” the ventilator. Nursing assessment is important to identify problems with ventilation that may be causing the anxiety reaction: tube blockage by kinking or retained secretions; other acute respiratory problems (eg, pneumothorax, pain); a sudden decrease in the oxygen level; the level of dyspnea; or ventilator malfunction. In some cases, sedation may be required to decrease the patient's oxygen consumption, allow the ventilator to provide full support of ventilation, and decrease the patient's anxiety. Sedatives that may be used are lorazepam (Ativan), midazolam (Versed), dexmedetomidine (Precedex), propofol (Diprivan), and short-acting barbiturates.

If the PEEP level cannot be maintained despite the use of sedatives, neuromuscular blocking agents (paralytic agents) may be administered to paralyze the patient. Examples of these agents include pancuronium (Pavulon), vecuronium (Norcuron), atracurium (Tracrium), and rocuronium (Zemuron). The resulting paralysis allows the patient to be ventilated more easily. With paralysis, the patient appears to be unconscious; loses motor function; and cannot breathe, talk, or blink independently. However, the patient retains sensation and is awake and able to hear. The nurse must reassure the patient that the paralysis is a result of the medication and is temporary. Paralysis should be used for the shortest possible time and never without adequate sedation and pain management.

Use of paralytic agents has many dangers and side effects. The nurse must be sure the patient does not become disconnected from the ventilator, because respiratory muscles are paralyzed and the patient will be apneic. Consequently, the nurse ensures that the patient is closely monitored, and all ventilator and patient alarms must be on at all times. Eye care is important as well, because the patient cannot blink, increasing the risk of corneal abrasions. Neuromuscular blockers predispose the patient to deep venous thrombi, muscle atrophy, and skin breakdown. Nursing assessment is essential to minimize the complications related to neuromuscular blockade. The patient may have discomfort or pain but cannot communicate these sensations. Analgesia is usually administered concurrently with neuromuscular blocking agents. The nurse must anticipate the patient's needs regarding pain and comfort. The nurse checks the patient's position to ensure it is comfortable and in normal alignment and talks to, and not about, the patient while in the patient's presence.

In addition, it is important for the nurse to describe the purpose and effects of the paralytic agents to the patient's family. If family members are unaware that these agents have been administered, they may become distressed by the change in the patient's status.

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension exists when the mean pulmonary artery pressure exceeds 25 mm Hg with a pulmonary capillary wedge pressure of less than 15 mm Hg (Badesch, Abman, Simonneau, et al., 2007). Unlike systemic blood pressure, these pressures cannot be measured indirectly; instead, they must be measured directly during right-sided heart catheterization. In the absence of these measurements, clinical recognition becomes the only indicator of pulmonary hypertension. However, pulmonary arterial hypertension is a condition that is not clinically evident until late in its progression.

There are two types of pulmonary arterial hypertension: idiopathic (or primary) pulmonary arterial hypertension and pulmonary arterial hypertension due to a known cause (Badesch, et al., 2007). It occurs most often in women 20 to 40 years of age, either sporadically or in patients with a family history, and is usually fatal within 5 years of diagnosis. There are several possible causes, but the exact cause is unknown (Chart 23-7). The clinical presentation may occur with no evidence of pulmonary or cardiac disease.

In contrast, pulmonary arterial hypertension due to a known cause is more common and results from existing cardiac or pulmonary disease. The prognosis depends on the severity of the underlying disorder and the changes in the pulmonary vascular bed. A common cause of pulmonary arterial hypertension is pulmonary artery constriction due to hypoxemia from COPD (cor pulmonale), which is discussed below.

Pathophysiology

Conditions such as collagen vascular disease, congenital heart disease, anorexigens (specific appetite depressants), chronic use of stimulants, portal hypertension, and HIV infection increase the risk of pulmonary arterial hypertension in susceptible patients. Vascular injury occurs with endothelial dysfunction and vascular smooth muscle dysfunction, which leads to disease progression (vascular smooth

Chart 23-7 • Causes of Pulmonary Arterial Hypertension

Idiopathic (Primary) Arterial Hypertension and Pulmonary Arterial Hypertension Due to a Known Cause

- Collagen vascular diseases
- Congenital systemic-to-pulmonary shunts
- Portal hypertension
- Altered immune mechanisms (HIV infection)
- Diseases associated with significant venous or capillary involvement
- Chronic thrombotic or embolic disease
- Pulmonary venous hypertension
- Pulmonary vasoconstriction due to hypoxemia
- Chronic obstructive pulmonary disease (COPD), interstitial lung disease, sleep-disordered breathing
- Miscellaneous causes: sarcoidosis, histiocytosis, compression of pulmonary vessels

muscle hypertrophy, adventitial and intimal proliferation [thickening of the wall], and advanced vascular lesion formation). Normally, the pulmonary vascular bed can handle the blood volume delivered by the right ventricle. It has a low resistance to blood flow and compensates for increased blood volume by dilation of the vessels in the pulmonary circulation. However, if the pulmonary vascular bed is destroyed or obstructed, as in pulmonary hypertension, the ability to handle whatever flow or volume of blood it receives is impaired, and the increased blood flow then increases the pulmonary artery pressure. As the pulmonary arterial pressure increases, the pulmonary vascular resistance also increases. Both pulmonary artery constriction (as in hypoxemia or hypercapnia) and a reduction of the pulmonary vascular bed (which occurs with pulmonary emboli) result in increased pulmonary vascular resistance and pressure. This increased workload affects right ventricular function. The myocardium ultimately cannot meet the increasing demands imposed on it, leading to right ventricular hypertrophy (enlargement and dilation) and failure. Passive hepatic congestion may also develop.

Clinical Manifestations

Dyspnea, the main symptom of pulmonary hypertension, occurs at first with exertion and eventually at rest. Substernal chest pain also is common. Other signs and symptoms include weakness, fatigue, syncope, occasional hemoptysis, and signs of right-sided heart failure (peripheral edema, ascites, distended neck veins, liver engorgement, crackles, heart murmur). Anorexia and abdominal pain in the right upper quadrant may also occur.

Assessment and Diagnostic Findings

Several tests are used to determine if there is a known cause for the pulmonary hypertension. If the diagnostic tests and thorough evaluation of the patient reveal no known cause, a diagnosis of primary pulmonary hypertension is made. Complete diagnostic evaluation includes a history, physical examination, chest x-ray, pulmonary function studies, electrocardiogram (ECG), echocardiogram, ventilation–perfusion scan, sleep studies, autoantibody tests (to identify diseases of collagen vascular origin), HIV tests, liver function testing, and cardiac catheterization. Pulmonary function studies may be normal or show a slight decrease in vital capacity and lung compliance, with a mild decrease in the diffusing capacity. The PaO₂ also is decreased (hypoxemia). The ECG reveals right ventricular hypertrophy, right axis deviation, and tall peaked P waves in inferior leads; tall anterior R waves; and ST-segment depression, T-wave inversion, or both anteriorly. An echocardiogram can assess the progression of the disease and rule out other conditions with similar signs and symptoms. A ventilation–perfusion scan or pulmonary angiography detects defects in pulmonary vasculature, such as pulmonary emboli. Cardiac catheterization of the right side of the heart reveals elevated pulmonary arterial pressure and determines whether there is a vasoactive component to the pulmonary hypertension.

Medical Management

The goal of treatment is to manage the underlying condition related to pulmonary hypertension of known cause. Recommendations regarding therapy are tailored to the patient's

individual situation, functional New York Heart Association class, and specific needs (Badesch, et al., 2007). Anti-coagulation should be considered for patients with pulmonary hypertension and patients with an indwelling catheter for administration of medications. Most patients with pulmonary hypertension do not have hypoxemia at rest but require supplemental oxygen with exercise. Diuretics and oxygen should be added as needed. Appropriate oxygen therapy (see Chapter 25) reverses the vasoconstriction and reduces the pulmonary hypertension in a relatively short time.

Different classes of medications are used to treat pulmonary hypertension; these include calcium channel blockers, phosphodiesterase-5 inhibitors, endothelin antagonists, and prostanoids. The choice of therapeutic agents is based on the severity of the disease.

A small number of patients with pulmonary hypertension respond favorably to acute vasodilation and do well with a calcium channel blocking agent. However, because calcium channel blockers are effective in only a small percentage of patients, other treatment options, including prostacyclin, are often necessary (Badesch, et al., 2007).

The oral medication sildenafil (Revatio, Viagra) is a potent specific phosphodiesterase-5 inhibitor that degrades cyclic 3',5'-guanosine monophosphate (cGMP) and promotes pulmonary vasodilation.

Bosentan (Tracleer), an endothelin receptor antagonist, causes vasodilation and is prescribed for its antihypertensive effects in patients with pulmonary hypertension. It is administered orally twice a day. Liver function must be monitored in patients using bosentan. Other endothelin receptor antagonists are sitaxsentan (Thelin) and ambrisentan (Letairis).

Prostanoids mimic prostaglandin. Prostaglandin (prostacyclin) relaxes vascular smooth muscle by stimulating the production of cyclic 3',5'-adenosine monophosphate (AMP) and inhibiting the growth of smooth muscle cells. Epoprostenol (Flolan), treprostinil (Remodulin), and iloprost (Ventavis) are examples of prostanoids. Because of its short half-life in the circulation (ie, 3 minutes), epoprostenol can be administered only by continuous IV infusion and requires training of the patient and caregiver. Treprostinil has a longer half-life than epoprostenol and is subcutaneously infused. Iloprost is more stable than the other two prostanoids and is inhaled. The frequency of dosing is six to eight times per day.

Lung transplantation remains an option for all eligible patients who have severe disease and symptoms after 3 months of receiving epoprostenol. Atrial septostomy may be considered for selected patients with severe disease (Badesch, et al., 2007); this procedure results in shunting of blood from the right side of the heart to the left, decreasing the strain on the right side of the heart and maintaining left ventricular output.

Nursing Management

The major nursing goal is to identify patients at high risk for pulmonary arterial hypertension, such as those with COPD, pulmonary emboli, congenital heart disease, and mitral valve disease. The nurse must be alert for signs and symptoms, administer oxygen therapy appropriately,

and instruct the patient and family about the use of home oxygen therapy. In patients treated with prostanoids (ie, epoprostenol or treprostinil), education about the need for central venous access (epoprostenol), subcutaneous infusion (treprostinil), proper administration and dosing of the medication, pain at the injection site, and potential severe side effects is extremely important. Emotional and psychosocial aspects of this disease must be addressed. Formal and informal support groups for patients and families are extremely valuable.

Pulmonary Heart Disease (Cor Pulmonale)

Cor pulmonale is a condition in which the right ventricle of the heart enlarges (with or without right-sided heart failure) as a result of diseases that affect the structure or function of the lung or its vasculature. It is a type of pulmonary arterial hypertension due to a known cause. Any disease affecting the lungs and accompanied by hypoxemia may result in cor pulmonale. The most frequent cause is severe COPD (see Chapter 24), in which changes in the airway and retained secretions reduce alveolar ventilation. Other causes are conditions that restrict or compromise ventilatory function, leading to hypoxemia or acidosis (eg, deformities of the thoracic cage, massive obesity) and conditions that reduce the pulmonary vascular bed (eg, primary idiopathic pulmonary arterial hypertension, pulmonary embolus). Certain disorders of the nervous system, respiratory muscles, chest wall, and pulmonary arterial tree also may be responsible for cor pulmonale.

Pathophysiology

Pulmonary disease can produce physiologic changes that in time affect the heart and cause the right ventricle to enlarge and eventually fail. Any condition that deprives the lungs of oxygen can cause hypoxemia and hypercapnia, resulting in ventilatory insufficiency. Hypoxemia and hypercapnia cause pulmonary arterial vasoconstriction and possibly reduction of the pulmonary vascular bed, as in emphysema or pulmonary emboli. The result is increased resistance in the pulmonary circulatory system, with a subsequent rise in pulmonary blood pressure (pulmonary hypertension). A mean pulmonary arterial pressure of 45 mm Hg or more may occur in cor pulmonale. Right ventricular hypertrophy may result, followed by right ventricular failure. In short, cor pulmonale results from pulmonary hypertension, which causes the right side of the heart to enlarge because of the increased work required to pump blood against high resistance through the pulmonary vascular system.

Clinical Manifestations

Symptoms of cor pulmonale are usually related to the underlying lung disease, such as COPD. With right ventricular failure, the patient may develop increasing edema of the feet and legs, distended neck veins, an enlarged palpable liver, pleural effusion, ascites, and heart murmurs. Headache, confusion, and somnolence may occur as a result

of increased levels of carbon dioxide (hypercapnia). Patients often complain of increasing shortness of breath, wheezing, cough, and fatigue.

Medical Management

The objectives of treatment are to improve ventilation and to treat both the underlying lung disease and the manifestations of heart disease. Supplemental oxygen is administered to improve gas exchange and to reduce pulmonary arterial pressure and pulmonary vascular resistance. Improved oxygen transport relieves the pulmonary hypertension that is causing the cor pulmonale.

Continuous, 24-hour oxygen therapy in patients with severe hypoxemia reportedly leads to better survival rates and greater reduction in pulmonary vascular resistance. Substantial improvement may require 4 to 6 weeks of oxygen therapy, usually in the home. Periodic assessment of pulse oximetry and arterial blood gases is necessary to determine the adequacy of alveolar ventilation and to monitor the effectiveness of oxygen therapy.

Chest physical therapy and bronchial hygiene maneuvers as indicated to remove accumulated secretions and the administration of bronchodilators further improve ventilation. Additional measures depend on the patient's condition. If the patient is in respiratory failure, endotracheal intubation and mechanical ventilation may be necessary. If the patient is in heart failure, hypoxemia and hypercapnia must be relieved to improve cardiac function and output. Bed rest, sodium restriction, and diuretic therapy also are instituted judiciously to reduce peripheral edema (ie, to lower pulmonary arterial pressure through a decrease in total blood volume) and the circulatory load on the right side of the heart. Digitalis may be prescribed to relieve pulmonary hypertension if the patient also has left ventricular failure, a supraventricular dysrhythmia, or right ventricular failure that does not respond to other therapy.

ECG monitoring may be indicated because of the high incidence of dysrhythmias in patients with cor pulmonale. Any respiratory infection must be treated promptly to avoid further impaired gas exchange and exacerbations of hypoxemia and pulmonary heart disease. The prognosis depends on whether the pulmonary hypertension is reversible. (See earlier discussion of the management of acute respiratory failure.)

Nursing Management

Nursing care addresses the underlying disorder leading to cor pulmonale as well as the problems related to pulmonary hyperventilation and right-sided cardiac failure. If intubation and mechanical ventilation are required to manage acute respiratory failure, the nurse assists with the intubation procedure and maintains mechanical ventilation. The nurse assesses the patient's respiratory and cardiac status and administers medications as prescribed.

During the patient's hospital stay, the nurse instructs the patient about the importance of close self-monitoring (fluid retention, weight gain, edema) and adherence to the therapeutic regimen, especially the 24-hour use of oxygen. It is important to address factors that affect the patient's adherence to the treatment regimen.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Because cor pulmonale is a chronic disorder, most of the care and monitoring of patients with cor pulmonale is performed by patients and families in the home. If supplemental oxygen is administered, the nurse instructs the patient and family in its safe and correct use. Nutrition counseling is warranted if the patient is on a sodium-restricted diet or is taking diuretics. The nurse teaches the family to monitor for signs and symptoms of right ventricular failure and about emergency interventions and when to call for assistance. Most importantly, the nurse works with the patient to stop smoking.

Continuing Care

Referral for home care may be warranted for patients who cannot manage self-care and for those whose physical condition warrants close assessment. During home visits, the home care nurse evaluates the patient's status and the patient's and family members' understanding of the therapeutic regimen and their adherence to it. If oxygen is used in the home, the nurse determines whether it is being administered safely and as prescribed. It is important to assess the patient's progress in stopping smoking and to reinforce the importance of smoking cessation with the patient and family. The nurse identifies strategies to assist with smoking cessation and refers the patient and family to community support groups. In addition, the nurse reminds the patient about the importance of other health promotion and screening practices.

Pulmonary Embolism

Pulmonary embolism (PE) refers to the obstruction of the pulmonary artery or one of its branches by a thrombus (or thrombi) that originates somewhere in the venous system or in the right side of the heart. Deep venous thrombosis (DVT), a related condition, refers to thrombus formation in the deep veins, usually in the calf or thigh, but sometimes in the arm, especially in patients with peripherally inserted central catheters. DVT is discussed in detail in Chapter 31. Venous thromboembolism (VTE) is a term that includes both DVT and PE.

PE is a common disorder and often is associated with trauma, surgery (orthopedic, major abdominal, pelvic, gynecologic), pregnancy, heart failure, age older than 50 years, hypercoagulable states, and prolonged immobility. It also may occur in apparently healthy people. An estimated 237,000 nonfatal and 294,000 fatal cases of PE occur in the United States each year (AlMahmeed & Carman, 2007). Risk factors for PE are identified in Chart 23-8.

Pathophysiology

Most commonly, PE is due to a blood clot or thrombus. However, there are other types of emboli: air, fat, amniotic fluid, and septic (from bacterial invasion of the thrombus).

When a thrombus completely or partially obstructs a pulmonary artery or its branches, the alveolar dead space is increased. The area, although continuing to be ventilated, receives little or no blood flow. Therefore, gas exchange is impaired or absent in this area. In addition, various substances

CHART
23-8

Risk Factors for Pulmonary Embolus

Venous Stasis (slowing of blood flow in veins)

- Prolonged immobilization (especially postoperative)
- Prolonged periods of sitting/traveling
- Varicose veins
- Spinal cord injury

Hypercoagulability (due to release of tissue thromboplastin after injury/surgery)

- Injury
- Tumor (pancreatic, gastrointestinal, genitourinary, breast, lung)
- Increased platelet count (polycythemia, splenectomy)

Venous Endothelial Disease

- Thrombophlebitis
- Vascular disease
- Foreign bodies (IV/central venous catheters)

Certain Disease States (combination of stasis, coagulation alterations, and venous injury)

- Heart disease (especially heart failure)
- Trauma (especially fracture of hip, pelvis, vertebra, lower extremities)
- Postoperative state/postpartum period
- Diabetes mellitus
- Chronic obstructive pulmonary disease (COPD)

Other Predisposing Conditions

- Advanced age
- Obesity
- Pregnancy
- Oral contraceptive use
- History of previous thrombophlebitis, pulmonary embolism
- Constrictive clothing

are released from the clot and surrounding area that cause regional blood vessels and bronchioles to constrict. This results in an increase in pulmonary vascular resistance. This reaction compounds the ventilation–perfusion imbalance.

The hemodynamic consequences are increased pulmonary vascular resistance due to the regional vasoconstriction and reduced size of the pulmonary vascular bed. This results in an increase in pulmonary arterial pressure and, in turn, an increase in right ventricular work to maintain pulmonary blood flow. When the work requirements of the right ventricle exceed its capacity, right ventricular failure occurs, leading to a decrease in cardiac output followed by a decrease in systemic blood pressure and the development of shock. Atrial fibrillation also causes PE. An enlarged right atrium in fibrillation causes blood to stagnate and form clots in this area. These clots are prone to travel into the pulmonary circulation.

A massive PE is best defined by the degree of hemodynamic instability rather than the percentage of pulmonary vasculature occlusion. It is described as an occlusion of the outflow tract of the main pulmonary artery or of the bifurcation of the pulmonary arteries. Multiple small emboli

can lodge in the terminal pulmonary arterioles, producing multiple small infarctions of the lungs. A pulmonary infarction causes ischemic necrosis of part of the lung.

Clinical Manifestations

Symptoms of PE depend on the size of the thrombus and the area of the pulmonary artery occluded by the thrombus; they may be nonspecific. Dyspnea is the most frequent symptom; the duration and intensity of the dyspnea depend on the extent of embolization. Chest pain is common and is usually sudden and pleuritic in origin. It may be substernal and may mimic angina pectoris or a myocardial infarction. Other symptoms include anxiety, fever, tachycardia, apprehension, cough, diaphoresis, hemoptysis, and syncope. The most frequent sign is tachypnea (very rapid respiratory rate).

The clinical picture may mimic that of bronchopneumonia or heart failure. In atypical instances, PE causes few signs and symptoms, whereas in other instances it mimics various other cardiopulmonary disorders. Obstruction of the pulmonary artery results in pronounced dyspnea, sudden substernal pain, rapid and weak pulse, shock, syncope, and sudden death.

Assessment and Diagnostic Findings

Death from PE commonly occurs within 1 hour after the onset of symptoms; therefore, early recognition and diagnosis are priorities. Because the symptoms of PE can vary from few to severe, a diagnostic workup is performed to rule out other diseases. The initial diagnostic workup may include chest x-ray, ECG, arterial blood gas analysis, and ventilation-perfusion (\dot{V}/\dot{Q}) scan. The chest x-ray is usually normal but may show infiltrates, atelectasis, elevation of the diaphragm on the affected side, or a pleural effusion. The chest x-ray is most helpful in excluding other possible causes. The ECG usually shows sinus tachycardia, PR-interval depression, and nonspecific T-wave changes. Arterial blood gas analysis may show hypoxemia and hypocapnia (from tachypnea); however, arterial blood gas measurements may be normal even in the presence of PE.

Pulmonary angiography is considered the best method to diagnose PE; however, it may not be feasible, cost-effective, or easily performed, especially with critically ill patients. The pulmonary angiogram allows for direct visualization under fluoroscopy of the arterial obstruction and accurate assessment of the perfusion deficit. A specially trained team must be available to perform the procedure, in which a catheter is threaded through the vena cava to the right side of the heart to inject dye, similar to a cardiac catheterization.

The \dot{V}/\dot{Q} scan continues to be used to diagnose PE, especially in facilities that do not use pulmonary angiography or do not have access to a spiral CT scanner. The \dot{V}/\dot{Q} scan is minimally invasive, involving the IV administration of a contrast agent. This scan evaluates different regions of the lung (upper, middle, lower) and allows comparisons of the percentage of ventilation and perfusion in each area. This test has a high sensitivity but can be more cumbersome than a CT scan and is not as accurate as a pulmonary angiogram.

A high suspicion of PE may warrant a spiral computed CT scan of the lung, D-dimer assay (blood test for evidence of blood clots), and pulmonary arteriogram. Spiral CT of

the chest may also assist in the diagnosis. In spiral CT, the examination table advances at a constant rate through the scanner while the x-ray tube rotates continuously around the patient, following a spiral path, thus allowing the gathering of continuous data with no gaps between images. Unlike the traditional CT scan, the spiral CT scan evaluates slices as narrow as 1.0 mm, as compared with 5.0-mm slices obtained by traditional CT scan. This allows for a more accurate visualization of a PE. However, spiral CT has limitations. It cannot be performed at the bedside, so unstable patients must be transported to a CT scanner. In addition, IV infusion of contrast agent is necessary for visualization.

Prevention

For patients at risk for PE, the most effective approach for prevention is to prevent DVT. Active leg exercises to avoid venous stasis, early ambulation, and use of anti-embolism stockings are general preventive measures. Mechanical prophylaxis can be classified as either static or dynamic. Graduated compression stockings of either thigh or knee length are considered static devices; there is little evidence to support their use. Problematic issues include inappropriate application and inappropriate fit of the stockings. Sequential compression devices (SCDs), plastic sleeves that can be inflated with air, are dynamic and are used to prevent venous stasis through compression and relaxation of the calf muscles, as in muscle contraction. SCDs have been proven to successfully reduce the risk of DVT and have been shown to be an effective therapy when used in combination with pharmacologic prophylaxis (Limpus, Chaboyer, McDonald, et al., 2006). Several types of SCDs are used as sources of compression and use foot, calf, and thigh-high compression, as well as graduated, asymmetric, and circumferential compression. Little evidence supports any particular type of compression. Graduated compression involves the sequential movement of air in the sleeve up the leg, followed by relaxation of the sleeve. The advantage of this therapy is the extended duration of compression compared with standard inflation. Asymmetric compression involves inflating only the area on the back of the leg or foot. Circumferential compression involves even compression of the entire leg. Other interventions for preventing DVT and PE are shown in Chart 23-9.

Several organizations publish suggested regimens for the prevention of VTE in surgical patients. These recommendations include both nonpharmacologic (mechanical) and pharmacologic strategies. Patients are stratified by risk of DVT by type of surgical procedure and risk of VTE. The most widely used guidelines are those from the American College of Chest Physicians (2008). Surgical patients are the primary target for prevention of VTE, although all hospitalized patients are at risk. Anticoagulant therapy may be prescribed for patients whose hemostasis is adequate and who are undergoing major elective abdominal or thoracic surgery.

Medical Management

Because PE is often a medical emergency, emergency management is of primary concern. After emergency measures have been initiated and the patient is stabilized, the treatment goal is to dissolve (lyse) the existing emboli

CHART
23-9

HOME CARE CHECKLIST

Prevention of Recurrent Pulmonary Embolism

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe the underlying process leading to pulmonary embolism.	✓	✓
• Describe the need for continued anticoagulant therapy after the initial embolism.	✓	✓
• Name the anticoagulant prescribed and identify dosage and schedule of administration.	✓	✓
• Describe potential side effects of coagulation such as bruising and bleeding and identify ways to prevent bleeding: <ul style="list-style-type: none"> • Avoid the use of sharps (razors, knives, etc.) to prevent cuts; shave with an electric shaver. • Use a toothbrush with soft bristles to prevent gum injury. • Do not take aspirin or antihistamines while taking warfarin sodium (Coumadin). • Always check with health care provider before taking any medicine, including over-the-counter medications. • Avoid laxatives, because they may affect vitamin K absorption. • Report the occurrence of dark, tarry stools to the health care provider immediately. • Wear an identification bracelet or carry a medicine card stating that you are taking anticoagulants. 	✓	✓
• Describe strategies to prevent recurrent deep venous thrombosis and pulmonary emboli: <ul style="list-style-type: none"> • Continue to wear anti-embolism stockings (compression hose) as long as directed. • Avoid sitting with legs crossed or sitting for prolonged periods of time. • When traveling, change position regularly, walk occasionally, and do active exercises of moving the legs and ankles while sitting. • Drink fluids, especially while traveling and in warm weather, to avoid hemoconcentration due to fluid deficit. 	✓	✓
• Describe the signs and symptoms of lower extremity circulatory compromise and potential deep venous thrombosis: calf or leg pain, swelling, pedal edema.	✓	✓
• Describe the signs and symptoms of pulmonary compromise related to recurrent pulmonary embolism.	✓	✓
• Describe how and when to contact the health care provider if symptoms of circulatory compromise or pulmonary compromise are identified.	✓	✓

and prevent new ones from forming. Treatment may include a variety of modalities: general measures to improve respiratory and vascular status, anticoagulation therapy, thrombolytic therapy, and surgical intervention.

**Emergency Management**

Massive PE is a life-threatening emergency. The immediate objective is to stabilize the cardiopulmonary system. A sudden increase in pulmonary resistance increases the work of the right ventricle, which can cause acute right-sided heart failure with cardiogenic shock. Emergency management consists of the following actions:

- Nasal oxygen is administered immediately to relieve hypoxemia, respiratory distress, and central cyanosis.
- Intravenous infusion lines are inserted to establish routes for medications or fluids that will be needed.
- A perfusion scan, hemodynamic measurements, and arterial blood gas determinations are performed. Spiral (helical) CT or pulmonary angiography may be performed.
- Hypotension is treated by a slow infusion of dobutamine (Dobutrex), which has a dilating effect on the pulmonary vessels and bronchi, or dopamine (Intropin).

- The ECG is monitored continuously for dysrhythmias and right ventricular failure, which may occur suddenly.
- Digitalis glycosides, IV diuretics, and antiarrhythmic agents are administered when appropriate.
- Blood is drawn for serum electrolytes, complete blood count, and hematocrit.
- If clinical assessment and arterial blood gas analysis indicate the need, the patient is intubated and placed on a mechanical ventilator.
- If the patient has suffered massive embolism and is hypotensive, an indwelling urinary catheter is inserted to monitor urinary output.
- Small doses of IV morphine or sedatives are administered to relieve patient anxiety, to alleviate chest discomfort, to improve tolerance of the endotracheal tube, and to ease adaptation to the mechanical ventilator.

General Management

Measures are initiated to improve respiratory and vascular status. Oxygen therapy is administered to correct the hypoxemia, relieve the pulmonary vascular vasoconstriction, and reduce the pulmonary hypertension. Use of anti-embolism stockings or intermittent pneumatic leg compression devices reduces venous stasis. These measures compress the superficial veins and increase the velocity of blood

in the deep veins by redirecting the blood through the deep veins. Elevating the leg (above the level of the heart) also increases venous flow.

Pharmacologic Therapy

Anticoagulation Therapy

Anticoagulant therapy (heparin, warfarin sodium [Coumadin]) has traditionally been the primary method for managing acute DVT and PE. Unfractionated and low-molecular-weight heparins may be used to prevent recurrence of emboli, but they have no effect on emboli that are already present. Heparin is generally recommended for patients who have been diagnosed with PE; numerous specific options for treatment are available.

Unfractionated heparin administration is dosed by actual body weight and is associated with several concerns. Because the half-life of heparin is dose dependent, it is difficult and time-consuming to adjust and maintain the IV drip infusion at a therapeutic level; frequent laboratory testing is necessary. With long-term heparin use, there is also the risk of antibody formation and bleeding. Despite the risks, anticoagulation after initial clot formation and dislodgement is necessary because of the high risk for a recurrent thrombus. Therapy may be changed to an oral regimen, such as warfarin, as soon as the patient is able to take oral medications. Heparin must be continued until the international normalized ratio (INR) is within a therapeutic range, typically 2.0 to 2.5. Once the patient starts an oral regimen, it is important that he or she continue to take the same brand of warfarin, because the bioavailability may vary greatly among brands.

High doses of subcutaneous low-molecular-weight heparin (enoxaparin [Lovenox]) or heparinoids may also be used for PE. These include enoxaparin, fondaparinux (Arixtra), dalteparin (Fragmin), inzaparin (Innohep), lepirudin (Refludan), and argatroban (Novastan). These agents are direct thrombin inhibitors; therefore, they require less frequent monitoring and dose adjustment. All medications have contraindications and side effects that the nurse must be aware of before administration. Lepirudin and argatroban are both contraindicated in patients with overt major bleeding and in patients who are hypersensitive to these agents or at high risk for bleeding (eg, recent cerebrovascular accident [CVA, stroke], anomaly of vessels or organs, recent major surgery, recent puncture of large vessels or organ biopsy). Major side effects are bleeding anywhere in the body and anaphylactic reaction resulting in shock or death. Other side effects include fever, abnormal liver function, and allergic skin reaction. All patients must continue to take some form of anticoagulation for at least 3 to 6 months after the embolic event.

Thrombolytic Therapy

Thrombolytic therapy (urokinase, streptokinase, alteplase) is used in treating PE, particularly in patients who are severely compromised (eg, those who are hypotensive and have significant hypoxemia despite oxygen supplementation) (Carlbon & Davidson, 2007). Thrombolytic therapy resolves the thrombi or emboli quickly and restores more

normal hemodynamic functioning of the pulmonary circulation, thereby reducing pulmonary hypertension and improving perfusion, oxygenation, and cardiac output. However, bleeding is a significant side effect. Contraindications to thrombolytic therapy include a CVA within the past 2 months, other active intracranial processes, active bleeding, surgery within 10 days of the thrombotic event, recent labor and delivery, trauma, or severe hypertension. Consequently, thrombolytic agents are advocated only for PE affecting a significant area of blood flow to the lung and causing hemodynamic instability.

Before thrombolytic therapy is started, INR, partial thromboplastin time (PTT), hematocrit, and platelet counts are obtained. An anticoagulant is stopped prior to administration of a thrombolytic agent. During therapy, all but essential invasive procedures are avoided because of potential bleeding. If necessary, fresh whole blood, packed red cells, cryoprecipitate, or frozen plasma is administered to replace blood loss and reverse the bleeding tendency. After the thrombolytic infusion is completed (which varies in duration according to the agent used), anticoagulant therapy is initiated.

Surgical Management

A surgical embolectomy is rarely performed but may be indicated if the patient has a massive PE or hemodynamic instability or if there are contraindications to thrombolytic therapy. This invasive procedure involves removal of the actual clot and must be performed by a cardiovascular surgical team with the patient on cardiopulmonary bypass. It may be used for patients who fail to improve with thrombolytic therapy, have contraindications to thrombolytic therapy and have had a massive PE, or must have the clot removed to help reduce right-sided heart failure. Although surgical embolectomy ensures removal of the clot, it is not without risk. It has a mortality rate of 30% (Carlbon & Davidson, 2007).

Transvenous catheter embolectomy is a technique in which a vacuum-cupped catheter is introduced transvenously into the affected pulmonary artery. Suction is applied to the end of the embolus, and the embolus is aspirated into the cup. The surgeon maintains suction to hold the embolus within the cup, and the entire catheter is withdrawn through the right side of the heart and out the femoral vein. Catheters are available that pulverize the clot with high-velocity jets of normal saline solution. An inferior vena cava filter is usually inserted at the time of surgery to protect against a recurrence.

Interrupting the inferior vena cava is another surgical technique used when PE recurs or when the patient does not tolerate anticoagulant therapy. This approach prevents dislodged thrombi from being swept into the lungs while allowing adequate blood flow. The preferred approach is the application of Teflon clips to the inferior vena cava to divide the lumen into small channels without occluding caval blood flow. Also, the use of transvenous devices that occlude or filter the blood through the inferior vena cava is a fairly safe way to prevent recurrent PE. One such technique involves insertion of a filter (eg, Greenfield filter) through the internal jugular vein or common femoral vein (Fig. 23-6). This filter is advanced into the inferior vena

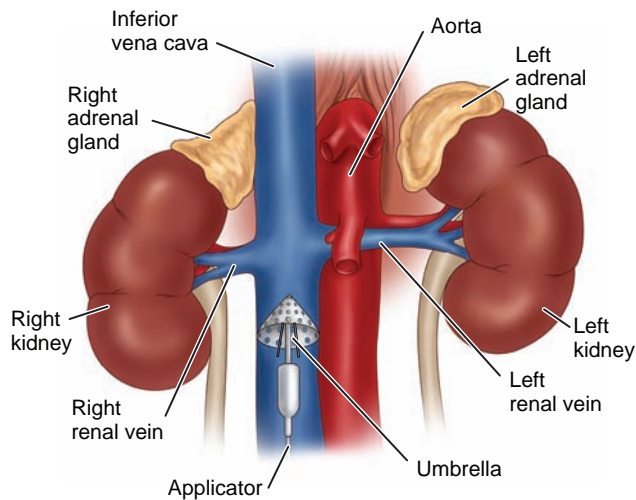

Figure 23-6 An umbrella filter is in place in the inferior vena cava to prevent pulmonary embolism. The filter (compressed within an applicator catheter) is inserted through an incision in the right internal jugular vein. The applicator is withdrawn when the filter fixes itself to the wall of the inferior vena cava after ejection from the applicator.

cava, where it is opened. The perforated umbrella permits the passage of blood but prevents the passage of large thrombi. It is recommended that anticoagulation be continued in patients with a vena cava filter if there are no contraindications to its use.

Nursing Management

Minimizing the Risk of Pulmonary Embolism

A key role of the nurse is to identify the patient at high risk for PE and to minimize the risk of PE in all patients. The nurse must have a high degree of suspicion for PE in all patients, but particularly in those with conditions predisposing to a slowing of venous return (see Chart 23-8).

Preventing Thrombus Formation

Preventing thrombus formation is a major nursing responsibility. The nurse encourages ambulation and active and passive leg exercises to prevent venous stasis in patients prescribed bed rest. The nurse instructs the patient to move the legs in a “pumping” exercise so that the leg muscles can help increase venous flow. The nurse also advises the patient not to sit or lie in bed for prolonged periods, not to cross the legs, and not to wear constrictive clothing. Legs should not be dangled or feet placed in a dependent position while the patient sits on the edge of the bed; instead, feet should rest on the floor or on a chair. In addition, IV catheters (for parenteral therapy or measurements of central venous pressure) should not be left in place for prolonged periods.

Assessing Potential for Pulmonary Embolism

All patients are evaluated for risk factors for thrombus formation and pulmonary embolus. The nurse conducts a careful assessment of the patient’s health history, family history, and medication record. On a daily basis, the patient is asked about pain or discomfort in the extremities.

In addition, the extremities are evaluated for warmth, redness, and inflammation.

Monitoring Thrombolytic Therapy

The nurse is responsible for monitoring thrombolytic and anticoagulant therapy. Thrombolytic therapy (streptokinase, urokinase, tissue plasminogen activator) causes lysis of deep vein thrombi and pulmonary emboli, which helps dissolve the clots. During thrombolytic infusion, while the patient remains on bed rest, vital signs are assessed every 2 hours and invasive procedures are avoided. Tests to determine INR or PTT are performed 3 to 4 hours after the thrombolytic infusion is started to confirm that the fibrinolytic systems have been activated. See Chapter 31 for nursing management for the patient receiving anticoagulant or thrombolytic therapy.

NURSING ALERT

Because of the prolonged clotting time, only essential arterial punctures or venipunctures are performed, and manual pressure is applied to any puncture site for at least 30 minutes. Pulse oximetry is used to monitor changes in oxygenation. The thrombolytic infusion is discontinued immediately if uncontrolled bleeding occurs.

Managing Pain

Chest pain, if present, is usually pleuritic rather than cardiac in origin. A semi-Fowler’s position provides a more comfortable position for breathing. However, it is important to continue to turn patients frequently and reposition them to improve the ventilation–perfusion ratio in the lung. The nurse administers opioid analgesic agents as prescribed for severe pain.

Managing Oxygen Therapy

Careful attention is given to the proper use of oxygen. It is important to ensure that the patient understands the need for continuous oxygen therapy. The nurse assesses the patient frequently for signs of hypoxemia and monitors the pulse oximetry values to evaluate the effectiveness of the oxygen therapy. Deep breathing and incentive spirometry are indicated for all patients to minimize or prevent atelectasis and improve ventilation. Nebulizer therapy or percussion and postural drainage may be used for management of secretions.

Relieving Anxiety

The nurse encourages the stabilized patient to talk about any fears or concerns related to this frightening episode, answers the patient’s and family’s questions concisely and accurately, explains the therapy, and describes how to recognize untoward effects early.

Monitoring for Complications

When caring for a patient who has had PE, the nurse must be alert for the potential complication of cardiogenic shock or right ventricular failure subsequent to the effect of PE on the cardiovascular system. Nursing activities for managing shock are found in Chapter 15.

Providing Postoperative Nursing Care

If the patient has undergone surgical embolectomy, the nurse measures the patient's pulmonary arterial pressure and urinary output. The nurse also assesses the insertion site of the arterial catheter for hematoma formation and infection. It is important to maintain the blood pressure at a level that supports perfusion of vital organs. To prevent peripheral venous stasis and edema of the lower extremities, the nurse elevates the foot of the bed and encourages isometric exercises, use of anti-embolism stockings, and walking when the patient is permitted out of bed. Sitting is discouraged, because hip flexion compresses the large veins in the legs.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Before hospital discharge and at follow-up visits to the clinic, the nurse instructs the patient about preventing recurrence and reporting signs and symptoms. Patient instructions, presented in Chart 23-9, are intended to help prevent recurrences and side effects of treatment.

Continuing Care

During follow-up or home care visits, the nurse monitors the patient's adherence to the prescribed management plan and reinforces previous instructions. The nurse also monitors the patient for residual effects of the PE and recovery. The patient is reminded about the importance of keeping follow-up appointments for coagulation tests and appointments with the primary care provider. The nurse also reminds the patient about the importance of participation in health promotion activities (eg, immunizations) and health screening.

Sarcoidosis

Sarcoidosis is a multisystem, granulomatous disease of unknown etiology. It may involve almost any organ or tissue but most commonly involves the lungs, lymph nodes, liver, spleen, central nervous system, skin, eyes, fingers, and parotid glands. The disease is not gender specific, but some manifestations are more common in women. In the United States, the disease is more common in African Americans (36 cases per 100,000) than in Caucasians (11 cases per 100,000), and the disease affects young and middle-aged adults (Weinberger, 2006).

Pathophysiology

Sarcoidosis is thought to be a hypersensitivity response to one or more exogenous agents (bacteria, fungi, virus, chemicals) in people with an inherited or acquired predisposition to the disorder. The hypersensitivity response results in noncaseating granuloma formation due to the release of cytokines and other substances that promote replication of fibroblasts. In the lung, granuloma infiltration and fibrosis may occur, resulting in low lung compliance, impaired diffusing capacity, and reduced lung volumes.

Clinical Manifestations

Hallmarks of sarcoidosis are its insidious onset and lack of prominent clinical signs or symptoms. The clinical picture depends on the systems affected. The lung is most commonly involved; signs and symptoms may include dyspnea, cough, hemoptysis, and congestion. Generalized symptoms include anorexia, fatigue, and weight loss. Other signs include uveitis, joint pain, fever, and granulomatous lesions of the skin, liver, spleen, kidney, and central nervous system. The granulomas may disappear or gradually convert to fibrous tissue. With multisystem involvement, patients may also have fatigue, fever, anorexia, and weight loss.

Assessment and Diagnostic Findings

Chest x-rays and CT are used to assess pulmonary adenopathy. These may show hilar adenopathy and disseminated miliary and nodular lesions in the lungs. A mediastinoscopy or **transbronchial** biopsy (in which a tissue specimen is obtained through the bronchial wall) may be used to confirm the diagnosis. In rare cases, an **open lung biopsy** is performed. Diagnosis is confirmed by a biopsy that shows noncaseating granulomas. Pulmonary function test results are abnormal if there is restriction of lung function (reduction in total lung capacity). Arterial blood gas measurements may be normal or may show reduced oxygen levels (hypoxemia) and increased carbon dioxide levels (hypercapnia).

Medical Management

Many patients undergo remission without specific treatment. Corticosteroids may be beneficial because of their anti-inflammatory effects, which relieve symptoms and improve organ function. They have shown to be useful in patients with ocular and myocardial involvement, skin involvement, extensive pulmonary disease that compromises pulmonary function, hepatic involvement, and hypercalcemia. However, it is not known if steroids alter the long-term course of the disease (Weinberger, 2006). Other cytotoxic and immunosuppressive agents have been used, but without the benefit of controlled clinical trials. There is no single test that monitors the progression or recurrence of sarcoidosis. Multiple tests are used to monitor involved systems.

OCCUPATIONAL LUNG DISEASES: PNEUMOCONIOSES

Pneumoconiosis refers to a nonneoplastic alteration of the lung resulting from inhalation of mineral or inorganic dust (eg, "dusty lung"). Pneumoconioses are caused by inhalation and deposition of mineral dusts in the lungs, resulting in pulmonary fibrosis and parenchymal changes. Usually, extended exposure to irritating or toxic substances accounts for these changes, although severe single exposures may also lead to chronic lung disease. Occupational lung disease is the number one work-related illness in the United States based on the frequency, severity, and preventability. Many people with early pneumoconiosis are asymptomatic, but advanced disease often is accompanied by disability and premature death.

Disease (Source)	Pathophysiology	Clinical Manifestations
Silicosis (glass manufacturing, foundry work, stone cutting)	Inhaled silica dust produces nodular lesions in the lungs. Nodules enlarge and coalesce. Dense masses form on upper portion of lungs, resulting in loss of pulmonary volume. Fibrotic destruction of pulmonary tissue can lead to restrictive lung disease, emphysema, pulmonary hypertension, and cor pulmonale.	<i>Acute silicosis:</i> Dyspnea, fever, cough, weight loss <i>Chronic silicosis:</i> Progressive symptoms indicative of hypoxemia, severe airflow obstruction, and right-sided heart failure
Asbestosis (shipbuilding, building demolition)	Inhaled asbestos fibers enter alveoli and are surrounded by fibrous tissue. Fibrous changes can also affect the pleura, which thicken and develop plaque. These changes lead to restrictive lung disease, with a decrease in lung volume, diminished exchange of oxygen and carbon dioxide, hypoxemia, cor pulmonale, and respiratory failure. It also increases risk for lung cancer, mesothelioma, and pleural effusion.	Progressive dyspnea; persistent, dry cough; mild to moderate chest pain; anorexia; weight loss; malaise; clubbing of the fingers
Coal worker's pneumoconiosis	Encompasses a variety of lung diseases; is also known as black lung disease. Inhaled dusts that are mixtures of coal, kaolin, mica, and silica are deposited in the alveoli and respiratory bronchioles. When macrophages that engulf the dust can no longer be cleared, they aggregate and fibroblasts appear. The bronchioles and alveoli become clogged with dust, dying macrophages, and fibroblasts, leading to formation of coal macules. Fibrotic lesions develop and subsequently localized emphysema develops, with cor pulmonale and respiratory failure.	Chronic cough, dyspnea, and expectoration of black or gray sputum, especially in miners who are smokers with cavitation in the lungs

Diseases of the lungs occur in numerous occupations as a result of exposure to several different types of agents, such as mineral dusts, metal dusts, biologic dusts, and toxic fumes. Smoking may compound the problem and may increase the risk of lung cancers in people exposed to the mineral asbestos and other potential carcinogens. The effects of inhaling these materials depend on the composition of the substance, its concentration, its ability to initiate an immune response, its irritating properties, the duration of exposure, and the individual's response or susceptibility to the irritant.

These diseases are not treatable once they develop, but they are preventable. Therefore, a major role for nurses, especially occupational health nurses, is that of advocate for employees. Nurses need to make every effort to promote measures to reduce the exposure of workers to industrial products. Strategies to control exposure should be identified and encouraged; these strategies include the use of protective devices (face masks, hoods, industrial respirators) to minimize exposure and screening/monitoring of individuals at risk.

Key aspects of any assessment of patients with a potential occupational respiratory history include job and job activities, exposure levels, general hygiene, time frame of exposure, effectiveness of respiratory protection used, and direct versus indirect exposures. Specific information that should be obtained includes the following:

- Exposure to an agent known to cause an occupational disorder
- Length of time from exposure of agent to onset of symptoms

- Congruence of symptoms with those of known exposure-related disorder
- Lack of other more likely explanations of the signs and symptoms

The most common pneumoconioses are silicosis, asbestosis, and coal worker's pneumoconiosis (Table 23-4). The nurse teaches preventive measures to patients and their families, assesses patients for a history of exposure to environmental agents, and makes referrals so that pulmonary function can be evaluated and the patient can be treated early in the course of the disease. There is no effective treatment for these diseases because damage is irreversible. Supportive therapy is aimed at preventing infections and managing complications.

CHEST TUMORS

Tumors of the lung may be benign or malignant. A malignant chest tumor can be primary, arising within the lung, chest wall, or mediastinum, or it can be a metastasis from a primary tumor site elsewhere in the body.

Lung Cancer (Bronchogenic Carcinoma)

Lung cancer is the leading cancer killer among men and women in the United States, with almost 162,000 deaths estimated in 2008. It is estimated that 31% of cancer deaths in men and 26% in women are related to lung or bronchus

cancers. Approximately 213,000 new cases of lung cancer are diagnosed annually; 15% of new cancers for men and women involve the lung or bronchus (American Cancer Society, 2008). In approximately 70% of patients with lung cancer, the disease has spread to regional lymphatics and other sites by the time of diagnosis. As a result, the long-term survival rate is low. Overall, the 5-year survival rate is 16%.

Pathophysiology

The most common cause of lung cancer is inhaled carcinogens, most often cigarette smoke (90%); other carcinogens include radon gas and occupational and environmental agents (American College of Chest Physicians [ACCP], 2007). Lung cancers arise from a single transformed epithelial cell in the tracheobronchial airways, in which the carcinogen binds to and damages the cell's DNA. This damage results in cellular changes, abnormal cell growth, and eventually a malignant cell. As the damaged DNA is passed on to daughter cells, the DNA undergoes further changes and becomes unstable. With the accumulation of genetic changes, the pulmonary epithelium undergoes malignant transformation from normal epithelium eventually to invasive carcinoma. Carcinoma tends to arise at sites of previous scarring (TB, fibrosis) in the lung.

Classification and Staging

For purposes of staging and treatment, most lung cancers are classified into one of two major categories: small cell lung cancer and non-small cell lung cancer. Small cell carcinoma represents 15% to 20% of tumors; non-small cell lung carcinoma (NSCLC) represents approximately 80% of tumors (ACCP, 2007). In NSCLC, the cell types include squamous cell carcinoma (20% to 30%), large cell carcinoma (15%), and adenocarcinoma (40%), including bronchoalveolar carcinoma. Most small cell cancers arise in the major bronchi and spread by infiltration along the bronchial wall (Yoder, 2006).

Non-small cell lung cancer is further classified by cell type. Squamous cell cancer is usually more centrally located and arises more commonly in the segmental and subsegmental bronchi. Adenocarcinoma is the most prevalent carcinoma of the lung in both men and women; it occurs peripherally as peripheral masses or nodules and often metastasizes. Large cell carcinoma (also called undifferentiated carcinoma) is a fast-growing tumor that tends to arise peripherally. Bronchoalveolar cell cancer is found in the terminal bronchi and alveoli and is usually slower growing compared with other bronchogenic carcinomas.

In addition to classification according to cell type, lung cancers are staged. The stage of the tumor refers to the size of the tumor, its location, whether lymph nodes are involved, and whether the cancer has spread (Collaborative Staging Task Force of the American Joint Committee on Cancer, 2007). NSCLC is staged as I to IV. Stage I is the earliest stage and has the highest cure rate, whereas stage IV designates metastatic spread. Estimated 5-year survival rates for the stages of NSCLC are as follows: stages IA and IB, 50% to 80%; stage IIA and IIB, 30% to 50%; stage IIIA, 10% to 40%; stage IIIB, 5% to 20%; and stage IV, less than 5% (ACCP, 2007). Small cell lung cancers are classified as limited or extensive. Diagnostic tools and further information on staging are described in Chapter 16.

Risk Factors

Various factors have been associated with the development of lung cancer, including tobacco smoke, secondhand (passive) smoke, environmental and occupational exposures, gender, genetics, and dietary deficits. Other factors that have been associated with lung cancer include genetic predisposition and underlying respiratory diseases, such as COPD and TB.

Tobacco Smoke

Tobacco use is responsible for more than one of every six deaths in the United States from pulmonary and cardiovascular diseases. Smoking is the most important single preventable cause of death and disease in this country. Lung cancer is 10 times more common in cigarette smokers than nonsmokers. Risk is determined by the pack-year history (number of packs of cigarettes used each day, multiplied by the number of years smoked), the age of initiation of smoking, the depth of inhalation, and the tar and nicotine levels in the cigarettes smoked. The younger a person is when he or she starts smoking, the greater the risk of developing lung cancer.

Secondhand Smoke

Passive smoking has been identified as a possible cause of lung cancer in nonsmokers (U.S. Department of Health and Human Services, 2006). It is estimated that secondhand smoke causes about 3000 deaths per year (ACCP, 2007). People who are involuntarily exposed to tobacco smoke in a closed environment (house, automobile, building) have an increased risk of lung cancer when compared with unexposed nonsmokers.

Environmental and Occupational Exposure

Various carcinogens have been identified in the atmosphere, including motor vehicle emissions and pollutants from refineries and manufacturing plants. Evidence suggests that the incidence of lung cancer is greater in urban areas as a result of the buildup of pollutants and motor vehicle emissions.

Radon is a colorless, odorless gas found in soil and rocks. For many years, it has been associated with uranium mines, but it is now known to seep into homes through ground rock. High levels of radon have been associated with the development of lung cancer, especially when combined with cigarette smoking. Homeowners are advised to have radon levels checked in their houses and to arrange for special venting if the levels are high.

Chronic exposure to industrial carcinogens, such as arsenic, asbestos, mustard gas, chromates, coke oven fumes, nickel, oil, and radiation, has been associated with the development of lung cancer. Laws have been passed to control exposure to these carcinogens in the workplace.

Genetics

Some familial predisposition to lung cancer seems apparent, because the incidence of lung cancer in close relatives of patients with lung cancer appears to be two to three times that in the general population regardless of smoking status.

Clinical Manifestations

Often, lung cancer develops insidiously and is asymptomatic until late in its course. The signs and symptoms depend on the location and size of the tumor, the degree of obstruction, and the existence of metastases to regional or distant sites.

The most frequent symptom of lung cancer is cough or change in a chronic cough. People frequently ignore this symptom and attribute it to smoking or a respiratory infection. The cough may start as a dry, persistent cough, without sputum production. When obstruction of airways occurs, the cough may become productive due to infection. Cough is present in 65% to 75% of patients with lung cancer, and more than 25% have a productive cough (Yoder, 2006).

NURSING ALERT

A cough that changes in character should arouse suspicion of lung cancer.

Dyspnea occurs in up to 60% of patients early in their disease (Yoder, 2006). Causes of dyspnea may include tumor occlusion of the airway or lung parenchyma, pleural effusion, pneumonia, or complications of treatment. Hemoptysis or blood-tinged sputum may be expectorated. Chest or shoulder pain may indicate chest wall or pleural involvement by a tumor. Pain also is a late manifestation and may be related to metastasis to the bone.

In some patients, a recurring fever is an early symptom in response to a persistent infection in an area of pneumonitis distal to the tumor. In fact, cancer of the lung should be suspected in people with repeated unresolved upper respiratory tract infections. If the tumor spreads to adjacent structures and regional lymph nodes, the patient may present with chest pain and tightness, hoarseness (involving the recurrent laryngeal nerve), dysphagia, head and neck edema, and symptoms of pleural or pericardial effusion. The most common sites of metastases are lymph nodes, bone, brain, contralateral lung, adrenal glands, and liver (Fig. 23-7). Non-specific symptoms of weakness, anorexia, and weight loss also may be present.

Assessment and Diagnostic Findings

If pulmonary symptoms occur in heavy smokers, cancer of the lung should always be considered. A chest x-ray is performed to search for pulmonary density, a solitary pulmonary nodule (coin lesion), atelectasis, and infection. CT scans of the chest are used to identify small nodules not easily visualized on the chest x-ray and also to serially examine areas for lymphadenopathy.

Sputum cytology is rarely used to make a diagnosis of lung cancer. Fiberoptic bronchoscopy is more commonly used; it provides a detailed study of the tracheobronchial tree and allows for brushings, washings, and biopsies of suspicious areas. For peripheral lesions not amenable to bronchoscopic biopsy, a transthoracic **fine-needle aspiration** may be performed under CT guidance to aspirate cells from a suspicious area. In some circumstances, an endoscopy with esophageal ultrasound may be used to obtain a transesophageal biopsy of enlarged subcarinal lymph nodes that are not easily accessible by other means.

Figure 23-7 Frequent sites of lung cancer metastasis.

A variety of scans may be used to assess for metastasis of the cancer. These may include bone scans, abdominal scans, positron emission tomography (PET) scans, and liver ultrasound. CT of the brain, magnetic resonance imaging (MRI), and other neurologic diagnostic procedures are used to detect central nervous system metastases. Mediastinoscopy or mediastinotomy may be used to obtain biopsy samples from lymph nodes in the mediastinum.

If surgery is a potential treatment, the patient is evaluated to determine whether the tumor is resectable and whether the patient can tolerate the physiologic impairment resulting from such surgery. Pulmonary function tests, arterial blood gas analysis, V/Q scans, and exercise testing may all be used as part of the preoperative assessment.

Medical Management

The objective of management is to provide a cure, if possible. Treatment depends on the cell type, the stage of the disease, and the patient's physiologic status (particularly cardiac and pulmonary status). In general, treatment may involve surgery, radiation therapy, or chemotherapy—or a combination of these. Newer and more specific therapies to modulate the immune system (gene therapy, therapy with defined tumor antigens) are under study and show promise.

Surgical Management

Surgical resection is the preferred method of treating patients with localized non-small cell tumors, no evidence of metastatic spread, and adequate cardiopulmonary function. If the patient's cardiovascular status, pulmonary function,

Chart 23-10 • Types of Lung Resection

- Lobectomy: a single lobe of the lung is removed
- Bilobectomy: two lobes of the lung are removed
- Sleeve resection: cancerous lobe(s) is removed and a segment of the main bronchus is resected
- Pneumonectomy: removal of entire lung
- Segmentectomy: a segment of the lung is removed*
- Wedge resection: removal of a small, pie-shaped area of the segment*
- Chest wall resection with removal of cancerous lung tissue: for cancers that have invaded the chest wall

*Not recommended as curative resection for lung cancer.

and functional status are satisfactory, surgery is generally well tolerated. However, coronary artery disease, pulmonary insufficiency, and other comorbidities may contraindicate surgical intervention. The cure rate of surgical resection depends on the type and stage of the cancer. Surgery is primarily used for NSCLCs, because small cell cancer of the lung grows rapidly and metastasizes early and extensively. Lesions of many patients with bronchogenic cancer are inoperable at the time of diagnosis.

Several different types of lung resection may be performed (Chart 23-10). The most common surgical procedure for a small, apparently curable tumor of the lung is lobectomy (removal of a lobe of the lung). In some cases, an entire lung may be removed (pneumonectomy) (see Chapter 25 for further details).

Radiation Therapy

Radiation therapy may offer cure in a small percentage of patients. It is useful in controlling neoplasms that cannot be surgically resected but are responsive to radiation. Irradiation also may be used to reduce the size of a tumor, to make an inoperable tumor operable, or to relieve the pressure of the tumor on vital structures. It can reduce symptoms of spinal cord metastasis and superior vena caval compression. Also, prophylactic brain irradiation is used in certain patients to treat microscopic metastases to the brain. Radiation therapy may help relieve cough, chest pain, dyspnea, hemoptysis, and bone and liver pain. Relief of symptoms may last from a few weeks to many months and is important in improving the quality of the remaining period of life.

Radiation therapy usually is toxic to normal tissue within the radiation field, and this may lead to complications such as esophagitis, pneumonitis, and radiation lung fibrosis. These may impair ventilatory and diffusion capacity and significantly reduce pulmonary reserve. The patient's nutritional status, psychological outlook, fatigue level, and signs of anemia and infection are monitored throughout the treatment. See Chapter 16 for management of the patient receiving radiation therapy.

Chemotherapy

Chemotherapy is used to alter tumor growth patterns, to treat distant metastases or small cell cancer of the lung, and as an adjunct to surgery or radiation therapy. Chemotherapy may provide relief, especially of pain, but it does not usually

cure the disease or prolong life to any great degree. Chemotherapy is also accompanied by side effects. It is valuable in reducing pressure symptoms of lung cancer and in treating brain, spinal cord, and pericardial metastasis. See Chapter 16 for a discussion of chemotherapy for the patient with cancer.

The choice of agent depends on the growth of the tumor cell and the specific phase of the cell cycle that the medication affects. In combination with surgery, chemotherapy may be administered before surgery (neoadjuvant therapy) or after surgery (adjuvant therapy). Combinations of two or more medications may be more beneficial than single-dose regimens. A variety of agents are used, including platinum analogues (cisplatin [Platinol] and carboplatin [Paraplatin]) and non-platinum-containing agents—taxanes (paclitaxel [Taxol, Onxol], docetaxel [Taxotere]), vinca alkaloids (vinblastine [Velban] and vindesine [Eldisine]), doxorubicin (Adriamycin, Doxil), gemcitabine (Gemzar), vinorelbine (Navelbine), irinotecan (Camptosar), etoposide (Toposar), and pemetrexed (Alimta). Other approved chemotherapeutic agents in oral form are gefitinib (Iressa) and erlotinib (Tarceva), which are epidermal growth factor tyrosine kinase inhibitors. Numerous new agents with cellular targets, including protein kinase C, vascular endothelial growth factor, cyclo-oxygenase-2, and farnesyl transferase, are being investigated for various types of lung cancer.

Palliative Therapy

Palliative therapy may include radiation therapy to shrink the tumor to provide pain relief, a variety of bronchoscopic interventions to open a narrowed bronchus or airway, and pain management and other comfort measures. Evaluation and referral for hospice care are important in planning for comfortable and dignified end-of-life care for the patient and family.

Treatment-Related Complications

A variety of complications may occur as a result of treatment for lung cancer. Surgical resection may result in respiratory failure, particularly if the cardiopulmonary system is compromised before surgery. Surgical complications and prolonged mechanical ventilation are potential outcomes. Radiation therapy may result in diminished cardiopulmonary function and other complications, such as pulmonary fibrosis, pericarditis, myelitis, and cor pulmonale. Chemotherapy, particularly in combination with radiation therapy, can cause pneumonitis. Pulmonary toxicity is a potential side effect of chemotherapy.

Nursing Management

Nursing care of patients with lung cancer is similar to that for other patients with cancer (see Chapter 16) and addresses the physiologic and psychological needs of the patient. The physiologic problems are primarily due to the respiratory manifestations of the disease. Nursing care includes strategies to ensure relief of pain and discomfort and to prevent complications.

Managing Symptoms

The nurse instructs the patient and family about the potential side effects of the specific treatment and strategies to manage them. Strategies for managing such symptoms as

CHART NURSING RESEARCH PROFILE

23-11 Quality of Life of Women With Lung Cancer and Their Families

Sarna, L., Cooley, M. E., Brown, J. K., et al. (2006). Quality of life and health status of dyads of women with lung cancer and family members. *Oncology Nursing Forum*, 33(6), 1109–1116.

Purpose

The purpose of this study was to describe and compare the quality of life and health status of dyads of women with lung cancer and their family members. Primary outcomes evaluated included quality of life and health status for both patients and family members.

Design

The investigators used a descriptive, cross-sectional research approach in which a convenience sample of 51 dyads of subjects participated. The patient sample consisted of women, and the family sample consisted primarily of men. A one-time assessment was conducted to evaluate quality of life (QOL), with a generic questionnaire, Short Form-36 (SF-36); comorbidities, with the Charlson Comorbidity Index; and depression,

with the Center for Epidemiologic Studies Depression (CES-D). The participants also provided a self-report of smoking and drinking history as well as demographic data.

Findings

Analysis of data from 50 dyads revealed that the QOL of the patients and families was not significantly correlated. Family members of patients with lung cancer reported a significantly higher quality of life than patients with the disease. Poorer physical QOL of family members was related to increased age, comorbid conditions, less education, and alcohol use. Significantly more family members continued to smoke and use alcohol following the patient's diagnosis.

Nursing Implications

Nurses should consider not only the health status of patients with lung cancer but also the health status and QOL of family members. The health and QOL of these caregivers can affect their ability to care for the patient with cancer and to cope with the family member's illness.

dyspnea, fatigue, nausea and vomiting, and anorexia help the patient and family cope with therapeutic measures.

Relieving Breathing Problems

Airway clearance techniques are key to maintaining airway patency through the removal of excess secretions. This may be accomplished through deep-breathing exercises, chest physiotherapy, directed cough, suctioning, and in some instances bronchoscopy. Bronchodilator medications may be prescribed to promote bronchial dilation. As the tumor enlarges or spreads, it may compress a bronchus or involve a large area of lung tissue, resulting in an impaired breathing pattern and poor gas exchange. At some stage of the disease, supplemental oxygen will probably be necessary.

Nursing measures focus on decreasing dyspnea by encouraging the patient to assume positions that promote lung expansion and to perform breathing exercises for lung expansion and relaxation. Patient education about energy conservation and airway clearance techniques is also necessary. Many of the techniques used in pulmonary rehabilitation can be applied to patients with lung cancer. Depending on the severity of disease and the patient's wishes, a referral to a pulmonary rehabilitation program may be helpful in managing respiratory symptoms.

Reducing Fatigue

Fatigue is a devastating symptom that affects quality of life in patients with cancer. It is commonly experienced by patients with lung cancer and may be related to the disease itself, the cancer treatment and complications (eg, anemia), sleep disturbances, pain and discomfort, hypoxemia, poor nutrition, or the psychological ramifications of the disease (eg, anxiety, depression). Nursing strategies to promote energy conservation and reduce fatigue are presented in Chapter 16.

Providing Psychological Support

Another important part of the nursing care of patients with lung cancer is provision of psychological support and identification of potential resources for the patient and family. Often, the nurse must help the patient and family deal with the following:

- The poor prognosis and relatively rapid progression of this disease
- Informed decision making regarding the possible treatment options
- Methods to maintain the patient's quality of life during the course of this disease (Chart 23-11)
- End-of-life treatment options

**Gerontologic Considerations**

At the time of diagnosis of lung cancer, most patients are older than 65 years of age and have stage III or IV disease. Although age is not a significant prognostic factor for overall survival and response to treatment for either NSCLC or small cell lung cancer, older patients have specific needs. Depending on the comorbidities and functional status of elderly patients, chemotherapy agents, doses, and cycles may need to be adjusted to maintain quality of life. Issues that must be considered in care of elderly patients with lung cancer include functional status, comorbid conditions, nutritional status, cognition, concomitant medications, and psychological and social support (ACCP, 2007; Yoder, 2006).

Tumors of the Mediastinum

Tumors of the mediastinum include neurogenic tumors, tumors of the thymus, lymphomas, germ cell tumors, cysts, and mesenchymal tumors. These tumors may be malignant

or benign. They are usually described in relation to location: anterior, middle, or posterior masses or tumors.

Clinical Manifestations

Nearly all symptoms of mediastinal tumors result from the pressure of the mass against important intrathoracic organs. Symptoms may include cough, wheezing, dyspnea, anterior chest or neck pain, bulging of the chest wall, heart palpitations, angina, other circulatory disturbances, central cyanosis, superior vena cava syndrome (ie, swelling of the face, neck, and upper extremities), marked distention of the veins of the neck and the chest wall (evidence of the obstruction of large veins of the mediastinum by extravascular compression or intravascular invasion), and dysphagia and weight loss from pressure or invasion into the esophagus.

Assessment and Diagnostic Findings

Chest x-rays are the major method used initially to diagnose mediastinal tumors and cysts. CT is the standard diagnostic test for assessment of the mediastinum and surrounding structures. MRI, as well as PET, may be used in some circumstances.

Medical Management

If the tumor is malignant and has infiltrated the surrounding tissue and complete surgical removal is not feasible, radiation therapy, chemotherapy, or both are used.

Surgical Management

Many mediastinal tumors are benign and operable. The location of the tumor (anterior, middle, or posterior compartment) in the mediastinum dictates the type of incision. The common incision used is a median sternotomy; however, a thoracotomy may be used, depending on the location of the tumor. Additional approaches include a bilateral anterior thoracotomy (clamshell incision) and video-assisted thoracoscopic surgery (see Chapter 25). The care is the same as for any patient undergoing thoracic surgery. Major complications include hemorrhage, injury to the phrenic or recurrent laryngeal nerve, and infection.

CHEST TRAUMA

Major chest trauma may occur alone or in combination with multiple other injuries. Chest trauma is classified as either blunt or penetrating. Blunt chest trauma results from sudden compression or positive pressure inflicted to the chest wall. Penetrating trauma occurs when a foreign object penetrates the chest wall.

Blunt Trauma

Although blunt chest trauma is more common than penetrating trauma, it is often difficult to identify the extent of the damage because the symptoms may be generalized and vague. In addition, patients may not seek immediate medical attention, which may complicate the problem.

Pathophysiology

The most common causes of blunt chest trauma are motor vehicle crashes (trauma from steering wheel, seat belt), falls, and bicycle crashes (trauma from handlebars). Mechanisms of blunt chest trauma include acceleration (moving object hitting the chest or patient being thrown into an object), deceleration (sudden decrease in rate of speed or velocity, such as a motor vehicle crash), shearing (stretching forces to areas of the chest causing tears, ruptures, or dissections), and compression (direct blow to the chest, such as a crush injury). Injuries to the chest are often life-threatening and result in one or more of the following pathologic states:

- Hypoxemia from disruption of the airway; injury to the lung parenchyma, rib cage, and respiratory musculature; massive hemorrhage; collapsed lung; and pneumothorax
- Hypovolemia from massive fluid loss from the great vessels, cardiac rupture, or hemothorax
- Cardiac failure from cardiac tamponade, cardiac contusion, or increased intrathoracic pressure

These pathologic states frequently result in impaired ventilation and perfusion leading to acute renal failure, hypovolemic shock, and death.

Assessment and Diagnostic Findings

Time is critical in treating chest trauma. Therefore, it is essential to assess the patient immediately to determine the following: time elapsed since injury occurred, mechanism of injury, level of responsiveness, specific injuries, estimated blood loss, recent drug or alcohol use, and prehospital treatment. Initial assessment of thoracic injuries includes assessment for airway obstruction, tension pneumothorax, open pneumothorax, massive hemothorax, flail chest, and cardiac tamponade. These injuries are life-threatening and require immediate treatment. Secondary assessment includes assessment for simple pneumothorax, hemothorax, pulmonary contusion, traumatic aortic rupture, tracheobronchial disruption, esophageal perforation, traumatic diaphragmatic injury, and penetrating wounds to the mediastinum. Although listed as secondary, these injuries may be life-threatening as well.

The physical examination includes inspection of the airway, thorax, neck veins, and breathing difficulty. Specifics include assessing the rate and depth of breathing for abnormalities such as stridor, cyanosis, nasal flaring, use of accessory muscles, drooling, and overt trauma to the face, mouth, or neck. The chest is assessed for symmetric movement, symmetry of breath sounds, open chest wounds, entrance or exit wounds, impaled objects, tracheal shift, distended neck veins, subcutaneous emphysema, and paradoxical chest wall motion. In addition, the chest wall is assessed for bruising, petechiae, lacerations, and burns. The vital signs and skin color are assessed for signs of shock. The thorax is palpated for tenderness and crepitus, and the position of the trachea is also assessed.

The initial diagnostic workup includes a chest x-ray, CT scan, complete blood count, clotting studies, type and cross-match, electrolytes, oxygen saturation, arterial blood gas analysis, and ECG. The patient is completely undressed to avoid missing additional injuries that may complicate care.

Many patients with injuries involving the chest have associated head and abdominal injuries that require attention. Ongoing assessment is essential to monitor the patient's response to treatment and to detect early signs of clinical deterioration.

Medical Management

The goals of treatment are to evaluate the patient's condition and to initiate aggressive resuscitation. An airway is immediately established with oxygen support and, in some cases, intubation and ventilatory support. Reestablishing fluid volume and negative intrapleural pressure and draining intrapleural fluid and blood are essential.

The potential for massive blood loss and exsanguination with blunt or penetrating chest injuries is high because of injury to the great blood vessels. Many patients die at the scene of the injury or are in shock by the time help arrives. Agitation and irrational and combative behavior are signs of decreased oxygen delivery to the cerebral cortex. Strategies to restore and maintain cardiopulmonary function include ensuring an adequate airway and ventilation; stabilizing and reestablishing chest wall integrity; occluding any opening into the chest (open pneumothorax); and draining or removing any air or fluid from the thorax to relieve pneumothorax, hemothorax, or cardiac tamponade. Hypovolemia and low cardiac output must be corrected. Many of these treatment efforts, along with the control of hemorrhage, are carried out simultaneously at the scene of the injury or in the emergency department. Depending on the success of efforts to control the hemorrhage in the emergency department, the patient may be taken immediately to the operating room. Principles of management are essentially those pertaining to care of the postoperative thoracic patient (see Chapter 25).

STERNAL AND RIB FRACTURES

Sternal fractures are most common in motor vehicle crashes with a direct blow to the sternum via the steering wheel. Rib fractures are the most common type of chest trauma, occurring in more than 60% of patients admitted with blunt chest injury (Wilkins, Dexter & Gold, 2007). Most rib fractures are benign and are treated conservatively. Fractures of the first three ribs are rare but can result in a high mortality rate because they are associated with laceration of the subclavian artery or vein. The fifth through ninth ribs are the most common sites of fractures. Fractures of the lower ribs are associated with injury to the spleen and liver, which may be lacerated by fragmented sections of the rib.

Clinical Manifestations

Patients with sternal fractures have anterior chest pain, overlying tenderness, ecchymosis, crepitus, swelling, and possible chest wall deformity. For patients with rib fractures, clinical manifestations are similar: severe pain, point tenderness, and muscle spasm over the area of the fracture that are aggravated by coughing, deep breathing, and movement. The area around the fracture may be bruised. To reduce the pain, the patient splints the chest by breathing in a shallow manner and avoids sighs, deep breaths, coughing, and movement. This reluctance to move or breathe deeply

results in diminished ventilation, atelectasis (collapse of unaerated alveoli), pneumonitis, and hypoxemia. Respiratory insufficiency and failure can be the outcomes of such a cycle.

Assessment and Diagnostic Findings

The patient must be closely evaluated for underlying cardiac injuries. A crackling, grating sound in the thorax (subcutaneous crepitus) may be detected with auscultation. The diagnostic workup may include a chest x-ray, rib films of a specific area, ECG, continuous pulse oximetry, and arterial blood gas analysis.

Medical Management

Medical management is directed toward relieving pain, avoiding excessive activity, and treating any associated injuries. Surgical fixation is rarely necessary unless fragments are grossly displaced and pose a potential for further injury.

The goals of treatment for rib fractures are to control pain and to detect and treat the injury. Sedation is used to relieve pain and to allow deep breathing and coughing. Care must be taken to avoid oversedation and suppression of respiratory drive. Alternative strategies to relieve pain include an intercostal nerve block and ice over the fracture site. A chest binder may be used as supportive treatment to provide stability to the chest wall and may decrease pain. The patient is instructed to apply the binder snugly enough to provide support, but not to impair respiratory excursion. Usually the pain abates in 5 to 7 days, and discomfort can be relieved with epidural analgesia, patient-controlled analgesia, or nonopioid analgesia. Most rib fractures heal in 3 to 6 weeks. The patient is monitored closely for signs and symptoms of associated injuries.

FLAIL CHEST

Flail chest is frequently a complication of blunt chest trauma from a steering wheel injury. It usually occurs when three or more adjacent ribs (multiple contiguous ribs) are fractured at two or more sites, resulting in free-floating rib segments. It may also result as a combination fracture of ribs and costal cartilages or sternum. As a result, the chest wall loses stability, causing respiratory impairment and usually severe respiratory distress.

Pathophysiology

During inspiration, as the chest expands, the detached part of the rib segment (flail segment) moves in a paradoxical manner (pendelluft movement) in that it is pulled inward during inspiration, reducing the amount of air that can be drawn into the lungs. On expiration, because the intrathoracic pressure exceeds atmospheric pressure, the flail segment bulges outward, impairing the patient's ability to exhale. The mediastinum then shifts back to the affected side (Fig. 23-8). This paradoxical action results in increased dead space, a reduction in alveolar ventilation, and decreased compliance. Retained airway secretions and atelectasis frequently accompany flail chest. The patient has hypoxemia, and if gas exchange is greatly compromised, respiratory acidosis develops as a result of carbon dioxide retention. Hypotension, inadequate tissue perfusion, and metabolic acidosis often follow

Figure 23-8 Flail chest is caused by a free-floating segment of rib cage resulting from multiple rib fractures. **A**, Paradoxical movement on inspiration occurs when the flail rib segment is sucked inward and the mediastinal structures shift to the unaffected side. The amount of air drawn into the affected lung is reduced. **B**, On expiration, the flail segment bulges outward and the mediastinal structures shift back to the affected side.

as the paradoxical motion of the mediastinum decreases cardiac output.

Medical Management

As with rib fracture, treatment of flail chest is usually supportive. Management includes providing ventilatory support, clearing secretions from the lungs, and controlling pain. Specific management depends on the degree of respiratory dysfunction. If only a small segment of the chest is involved, the objectives are to clear the airway through positioning, coughing, deep breathing, and suctioning to aid in the expansion of the lung, and to relieve pain by intercostal nerve blocks, high thoracic epidural blocks, or cautious use of IV opioids.

For mild to moderate flail chest injuries, the underlying pulmonary contusion is treated by monitoring fluid intake and appropriate fluid replacement while relieving chest pain. Pulmonary physiotherapy focusing on lung volume expansion, and secretion management techniques are performed. The patient is closely monitored for further respiratory compromise.

For severe flail chest injuries, endotracheal intubation and mechanical ventilation are required to provide internal pneumatic stabilization of the flail chest and to correct abnormalities in gas exchange. This helps treat the underlying pulmonary contusion, serves to stabilize the thoracic cage to allow the fractures to heal, and improves alveolar ventilation and intrathoracic volume by decreasing the work of breathing. This treatment modality requires endotracheal intubation and ventilator support. Differing modes of ventilation are used depending on the patient's underlying disease and specific needs (see Chapter 25).

In rare circumstances, surgery may be required to more quickly stabilize the flail segment. This may be used for patients who are difficult to ventilate or for high-risk patients with underlying lung disease who may be difficult to wean from mechanical ventilation.

Regardless of the type of treatment, the patient is carefully monitored by serial chest x-rays, arterial blood gas analysis, pulse oximetry, and bedside pulmonary function monitoring. Pain management is key to successful treatment. Patient-controlled analgesia, intercostal nerve blocks, epidural analgesia, and intrapleural administration of opioids may be used to relieve or manage thoracic pain.

PULMONARY CONTUSION

Pulmonary contusion is a common thoracic injury and is frequently associated with flail chest. It is defined as damage to the lung tissues resulting in hemorrhage and localized edema. It is associated with chest trauma when there is rapid compression and decompression to the chest wall (ie, blunt trauma). Pulmonary contusion represents a spectrum of lung injury characterized by the development of infiltrates and various degrees of respiratory dysfunction and sometimes respiratory failure. It is often cited as the most common potentially life-threatening chest injury; however, mortality is often attributed to other associated injuries. A contusion is sustained in 30% to 70% of patients who experience blunt force trauma. Pulmonary contusion may not be evident initially on examination but develops in the posttraumatic period; it may involve a small portion of one lung, a massive section of a lung, one entire lung, or both lungs.

Pathophysiology

The primary pathologic defect is an abnormal accumulation of fluid in the interstitial and intra-alveolar spaces. It is thought that injury to the lung parenchyma and its capillary network results in a leakage of serum protein and plasma. The leaking serum protein exerts an osmotic pressure that enhances loss of fluid from the capillaries. Blood, edema, and cellular debris (from cellular response to injury) enter the lung and accumulate in the bronchioles and alveoli, where they interfere with gas exchange. An increase in pulmonary vascular resistance and pulmonary artery pressure occurs. The patient has hypoxemia and carbon dioxide retention. Occasionally, a contused lung occurs on the other side of the point of body impact; this is called a contrecoup contusion.

Clinical Manifestations

Pulmonary contusion may be mild, moderate, or severe. The clinical manifestations vary from decreased breath sounds, tachypnea, tachycardia, chest pain, hypoxemia, and blood-tinged secretions to more severe tachypnea, tachycardia, crackles, frank bleeding, severe hypoxemia (cyanosis), and respiratory acidosis. Changes in sensorium,

including increased agitation or combative irrational behavior, may be signs of hypoxemia.

In addition, patients with moderate pulmonary contusion have a large amount of mucus, serum, and frank blood in the tracheobronchial tree; patients often have a constant cough but cannot clear the secretions. Patients with severe pulmonary contusion have the signs and symptoms of ARDS; these may include central cyanosis, agitation, combativeness, and productive cough with frothy, bloody secretions.

Assessment and Diagnostic Findings

The efficiency of gas exchange is determined by pulse oximetry and arterial blood gas measurements. Pulse oximetry is also used to measure oxygen saturation continuously. The initial chest x-ray may show no changes; changes may not appear for 1 or 2 days after the injury and appear as pulmonary infiltrates on chest x-ray.

Medical Management

Treatment priorities include maintaining the airway, providing adequate oxygenation, and controlling pain. In mild pulmonary contusion, adequate hydration via IV fluids and oral intake is important to mobilize secretions. However, fluid intake must be closely monitored to avoid hypervolemia. Volume expansion techniques, postural drainage, physiotherapy including coughing, and endotracheal suctioning are used to remove the secretions. Pain is managed by intercostal nerve blocks or by opioids via patient-controlled analgesia or other methods. Usually, antimicrobial therapy is administered because the damaged lung is susceptible to infection. Supplemental oxygen is usually given by mask or cannula for 24 to 36 hours.

In patients with moderate pulmonary contusions, bronchoscopy may be required to remove secretions. Intubation and mechanical ventilation with PEEP (see Chapter 25) may also be necessary to maintain the pressure and keep the lungs inflated. Diuretics may be administered to reduce edema. A nasogastric tube is inserted to relieve gastrointestinal distention.

In patients with severe contusion, who may develop respiratory failure, aggressive treatment with endotracheal intubation and ventilatory support, diuretics, and fluid restriction may be necessary. Colloids and crystalloid solutions may be used to treat hypovolemia.

Antimicrobial medications may be prescribed for the treatment of pulmonary infection. This is a common complication of pulmonary contusion (especially pneumonia in the contused segment), because the fluid and blood that extravasates into the alveolar and interstitial spaces serve as an excellent culture medium.

Penetrating Trauma: Gunshot and Stab Wounds

Gunshot and stab wounds are the most common causes of penetrating chest trauma. These wounds are classified according to their velocity. Stab wounds are generally considered

low-velocity trauma because the weapon destroys a small area around the wound. Knives and switchblades cause most stab wounds. The appearance of the external wound may be very deceptive, because pneumothorax, hemothorax, lung contusion, and cardiac tamponade, along with severe and continuing hemorrhage, can occur from any small wound, even one caused by a small-diameter instrument such as an ice pick.

Gunshot wounds may be classified as low, medium, or high velocity. The factors that determine the velocity and resulting extent of damage include the distance from which the gun was fired, the caliber of the gun, and the construction and size of the bullet. A bullet can cause damage at the site of penetration and along its pathway, and a gunshot wound to the chest can produce a variety of pathophysiologic changes. The bullet may ricochet off bony structures and damage the chest organs and great vessels. If the diaphragm is involved in a gunshot wound or a stab wound, injury to the chest cavity must be considered.

Medical Management

The objective of immediate management is to restore and maintain cardiopulmonary function. After an adequate airway is ensured and ventilation is established, examination for shock and intrathoracic and intra-abdominal injuries is necessary. The patient is undressed completely so that additional injuries are not missed. There is a high risk for associated intra-abdominal injuries with stab wounds below the level of the fifth anterior intercostal space. Death can result from exsanguinating hemorrhage or intra-abdominal sepsis.

The diagnostic workup includes a chest x-ray, chemistry profile, arterial blood gas analysis, pulse oximetry, and ECG. The patient's blood is typed and cross-matched in case blood transfusion is required. After the status of the peripheral pulses is assessed, a large-bore IV line is inserted. An indwelling catheter is inserted to monitor urinary output. A nasogastric tube is inserted and connected to low suction to prevent aspiration, minimize leakage of abdominal contents, and decompress the gastrointestinal tract.

Shock is treated simultaneously with colloid solutions, crystalloids, or blood, as indicated by the patient's condition. Diagnostic procedures are carried out as dictated by the needs of the patient (eg, CT scans of chest or abdomen, flat plate x-ray of the abdomen, abdominal tap to check for bleeding).

A chest tube is inserted into the pleural space in most patients with penetrating wounds of the chest to achieve rapid and continuing re-expansion of the lungs. The insertion of the chest tube frequently results in a complete evacuation of the blood and air. The chest tube also allows early recognition of continuing intrathoracic bleeding, which would make surgical exploration necessary. If the patient has a penetrating wound of the heart or great vessels, the esophagus, or the tracheobronchial tree, surgical intervention is required.

Pneumothorax

Pneumothorax occurs when the parietal or visceral pleura is breached and the pleural space is exposed to positive atmospheric pressure. Normally the pressure in the pleural

space is negative or subatmospheric; this negative pressure is required to maintain lung inflation. When either pleura is breached, air enters the pleural space, and the lung or a portion of it collapses.

Types of Pneumothorax

Types of pneumothorax include simple, traumatic, and tension pneumothorax.

Simple Pneumothorax

A simple, or spontaneous, pneumothorax occurs when air enters the pleural space through a breach of either the parietal or visceral pleura. Most commonly, this occurs as air enters the pleural space through the rupture of a bleb or a bronchopleural fistula. A spontaneous pneumothorax may occur in an apparently healthy person in the absence of trauma due to rupture of an air-filled bleb, or blister, on the surface of the lung, allowing air from the airways to enter the pleural cavity. It may be associated with diffuse interstitial lung disease and severe emphysema.

Traumatic Pneumothorax

A traumatic pneumothorax occurs when air escapes from a laceration in the lung itself and enters the pleural space or from a wound in the chest wall. It may result from blunt trauma (eg, rib fractures), penetrating chest or abdominal trauma (eg, stab wounds or gunshot wounds), or diaphragmatic tears. Traumatic pneumothorax may occur during invasive thoracic procedures (ie, thoracentesis, transbronchial lung biopsy, insertion of a subclavian line) in which the pleura is inadvertently punctured, or with barotrauma from mechanical ventilation.

A traumatic pneumothorax resulting from major injury to the chest is often accompanied by hemothorax (collection of blood in the pleural space resulting from torn intercostal vessels, lacerations of the great vessels, or lacerations of the lungs). Often both blood and air are found in the chest cavity (hemopneumothorax) after major trauma. Chest surgery can be classified as a traumatic pneumothorax as a result of the entry into the pleural space and the accumulation of air and fluid in the pleural space.

Open pneumothorax is one form of traumatic pneumothorax. It occurs when a wound in the chest wall is large enough to allow air to pass freely in and out of the thoracic cavity with each attempted respiration. Because the rush of air through the wound in the chest wall produces a sucking sound, such injuries are termed sucking chest wounds. In such patients, not only does the lung collapse, but the structures of the mediastinum (heart and great vessels) also shift toward the uninjured side with each inspiration and in the opposite direction with expiration. This is termed mediastinal flutter or swing, and it produces serious circulatory problems.

NURSING ALERT

Traumatic open pneumothorax calls for emergency interventions. Stopping the flow of air through the opening in the chest wall is a lifesaving measure.

Tension Pneumothorax

A **tension pneumothorax** occurs when air is drawn into the pleural space from a lacerated lung or through a small opening or wound in the chest wall. It may be a complication of other types of pneumothorax. In contrast to open pneumothorax, the air that enters the chest cavity with each inspiration is trapped; it cannot be expelled during expiration through the air passages or the opening in the chest wall. In effect, a one-way valve or ball valve mechanism occurs where air enters the pleural space but cannot escape. With each breath, tension (positive pressure) is increased within the affected pleural space. This causes the lung to collapse and the heart, the great vessels, and the trachea to shift toward the unaffected side of the chest (mediastinal shift). Both respiration and circulatory function are compromised because of the increased intrathoracic pressure, which decreases venous return to the heart, causing decreased cardiac output and impairment of peripheral circulation. In extreme cases, the pulse may be undetectable—this is known as pulseless electrical activity.

NURSING ALERT

Relief of tension pneumothorax is considered an emergency measure.

Clinical Manifestations

The signs and symptoms associated with pneumothorax depend on its size and cause. Pain is usually sudden and may be pleuritic. The patient may have only minimal respiratory distress with slight chest discomfort and tachypnea with a small simple or uncomplicated pneumothorax. If the pneumothorax is large and the lung collapses totally, acute respiratory distress occurs. The patient is anxious, has dyspnea and air hunger, has increased use of the accessory muscles, and may develop central cyanosis from severe hypoxemia.

In assessing the chest for any type of pneumothorax, the nurse assesses tracheal alignment, expansion of the chest, breath sounds, and percussion of the chest. In a simple pneumothorax, the trachea is midline, expansion of the chest is decreased, breath sounds may be diminished, and percussion of the chest may reveal normal sounds or hyperresonance depending on the size of the pneumothorax. In a tension pneumothorax, the trachea is shifted away from the affected side, chest expansion may be decreased or fixed in a hyperexpansion state, breath sounds are diminished or absent, and percussion to the affected side is hyperresonant. The clinical picture is one of air hunger, agitation, increasing hypoxemia, central cyanosis, hypotension, tachycardia, and profuse diaphoresis. Figure 23-9 compares open and tension pneumothorax.

Medical Management

Medical management of pneumothorax depends on its cause and severity. The goal of treatment is to evacuate the air or blood from the pleural space. A small chest tube (28 Fr) is inserted near the second intercostal space; this space is used because it is the thinnest part of the chest wall, minimizes the danger of contacting the thoracic nerve, and

Figure 23-9 Open pneumothorax (*top*) and tension pneumothorax (*bottom*). In open pneumothorax, air enters the chest during inspiration and exits during expiration. A slight shift of the affected lung may occur because of a decrease in pressure as air moves out of the chest. In tension pneumothorax, air enters but cannot leave the chest. As the pressure increases, the heart and great vessels are compressed and the mediastinal structures are shifted toward the opposite side of the chest. The trachea is pushed from its normal midline position toward the opposite side of the chest, and the unaffected lung is compressed.

leaves a less visible scar. If a patient also has a hemothorax, a large-diameter chest tube (32 Fr or greater) is inserted, usually in the fourth or fifth intercostal space at the midaxillary line. The tube is directed posteriorly to drain the fluid and air. Once the chest tube or tubes are inserted and suction is applied (usually to 20 mm Hg suction), effective decompression of the pleural cavity (drainage of blood or air) occurs.

If an excessive amount of blood enters the chest tube in a relatively short period, an autotransfusion may be needed. This technique involves taking the patient's own blood that has been drained from the chest, filtering it, and then transfusing it back into the vascular system.

In such an emergency, anything may be used that is large enough to fill the chest wound—a towel, a handkerchief, or the heel of the hand. If conscious, the patient is instructed to inhale and strain against a closed glottis. This action assists in re-expanding the lung and ejecting the air from the thorax. In the hospital, the opening is plugged by sealing it with gauze impregnated with petrolatum. A pressure dressing is applied. Usually, a chest tube connected to water-seal drainage is inserted to remove air and fluid. Antibiotics usually are prescribed to combat infection from contamination.

The severity of open pneumothorax depends on the amount and rate of thoracic bleeding and the amount of air

in the pleural space. The pleural cavity can be decompressed by needle aspiration (thoracentesis) or by chest tube drainage of the blood or air. The lung is then able to re-expand and resume the function of gas exchange. As a rule of thumb, the chest wall is opened surgically (thoracotomy) if more than 1500 mL of blood is aspirated initially by thoracentesis (or is the initial chest tube output) or if chest tube output continues at greater than 200 mL/h. The urgency with which the blood must be removed is determined by the degree of respiratory compromise. An emergency thoracotomy may also be performed in the emergency department if a cardiovascular injury secondary to chest or penetrating trauma is suspected. The patient with a possible tension pneumothorax should immediately be given a high concentration of supplemental oxygen to treat the hypoxemia, and pulse oximetry should be used to monitor oxygen saturation. In an emergency situation, a tension pneumothorax can be decompressed or quickly converted to a simple pneumothorax by inserting a large-bore needle (14-gauge) at the second intercostal space, midclavicular line on the affected side. This relieves the pressure and vents the positive pressure to the external environment. A chest tube is then inserted and connected to suction to remove the remaining air and fluid, reestablish the negative pressure, and re-expand the lung. If the lung re-expands and air leakage from

the lung parenchyma stops, further drainage may be unnecessary. If a prolonged air leak continues despite chest tube drainage to underwater seal, surgery may be necessary to close the leak.

Cardiac Tamponade

Cardiac tamponade is compression of the heart resulting from fluid or blood within the pericardial sac. It usually is caused by blunt or penetrating trauma to the chest. A penetrating wound of the heart is associated with a high mortality rate. Cardiac tamponade also may follow diagnostic cardiac catheterization, angiographic procedures, and pacemaker insertion, which can produce perforations of the heart and great vessels. Pericardial effusion with fluid compressing the heart also may develop from metastases to the pericardium from malignant tumors of the breast, lung, or mediastinum and may occur with lymphomas and leukemias, renal failure, TB, and high-dose radiation to the chest. Cardiac tamponade is discussed in detail in Chapter 30.

Subcutaneous Emphysema

No matter what kind of chest trauma a patient has, when the lung or the air passages are injured, air may enter the tissue planes and pass for some distance under the skin (eg, neck, chest). The tissues give a crackling sensation when palpated, and the subcutaneous air produces an alarming appearance as the face, neck, body, and scrotum become misshapen by subcutaneous air. Fortunately, subcutaneous emphysema is of itself usually not a serious complication. The subcutaneous air is spontaneously absorbed if the underlying air leak is treated or stops spontaneously. In severe cases in which there is widespread subcutaneous emphysema, a tracheostomy is indicated if airway patency is threatened by pressure of the trapped air on the trachea.

CRITICAL THINKING EXERCISES

1 You are caring for a 42-year-old woman who underwent gastric bypass surgery. After being in the intensive care unit for 3 days, she was transferred to a general surgery unit. She is a former smoker and is taking multiple medications for high blood pressure and diabetes. When you started your shift, she was stable, but she has become increasingly anxious with some shortness of breath in the past hour. What are potential risk factors you might observe or identify in this patient? What assessment strategies would you use to evaluate changes in her respiratory status? What are the potential causes of the shortness of breath? What decision process would you use to determine when the physician should be contacted?

EBP 2 An 89-year-old woman is admitted to your unit from a long-term care facility. She is extremely frail and has multiple comorbidities. She has been diagnosed with community-acquired pneumonia. What evidence-

based nursing interventions are important in her care and recovery? How would you determine the strength of the evidence for the interventions you choose?

EBP 3 A 48-year-old patient is admitted to the hospital with a diagnosis of malnutrition, possible aspiration pneumonia, and stage 4 pressure ulcer. The patient experienced a traumatic brain injury 4 years ago; he is not fully aware of his surroundings and has difficulty swallowing. Tube feedings have been prescribed in an effort to improve his nutritional status prior to débridement and skin grafting to the pressure ulcer. Identify evidence-based nursing interventions appropriate for this patient related to possible aspiration pneumonia. How would you assess the strength of that evidence?

EBP 4 You are on a surgical unit caring for a 68-year-old man who has undergone a left pneumonectomy for lung cancer. The patient has COPD and continues to smoke despite the diagnoses of COPD and lung cancer. What strategies would you use to prevent or minimize pulmonary complications in this patient? What parameters would you use to monitor the patient's postoperative respiratory status? What strategies would you consider to encourage the patient to stop smoking? What is the evidence base for the strategies that you consider? How would you evaluate the strength of the evidence?

5 You are caring for a 34-year-old patient who experienced her third spontaneous pneumothorax. A chest tube was inserted, relieving the patient's acute symptoms. She has, however, become increasingly short of breath during the past hour. What physical assessment skills and strategies would you use to determine potential changes in the patient's respiratory condition? What are potential causes of this increasing shortness of breath? What would you do to prepare for an emergency situation in this patient?

Management of Patients With Chronic Pulmonary Disease

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the pathophysiology of chronic obstructive pulmonary disease (COPD).
- 2 Discuss the major risk factors for developing COPD and nursing interventions to minimize or prevent these risk factors.
- 3 Describe nursing management of patients with COPD.
- 4 Develop a teaching plan for patients with COPD.
- 5 Describe the pathophysiology of bronchiectasis and relate it to signs and symptoms of bronchiectasis.
- 6 Identify medical and nursing management of bronchiectasis.
- 7 Describe the pathophysiology of asthma.
- 8 Discuss the medications used in asthma management.
- 9 Describe asthma self-management strategies.
- 10 Describe the pathophysiology of cystic fibrosis.

GLOSSARY

air trapping: incomplete emptying of alveoli during expiration due to loss of lung tissue elasticity (emphysema), bronchospasm (asthma), or airway obstruction

alpha₁-antitrypsin deficiency: genetic disorder resulting from deficiency of alpha₁ antitrypsin, a protective agent for the lung; increases patient's risk for developing panacinar emphysema even in the absence of smoking

asthma: a disease with multiple precipitating mechanisms resulting in a common clinical outcome of reversible air-flow obstruction; no longer considered a category of COPD

bronchiectasis: chronic dilation of a bronchus or bronchi; the dilated airways become saccular and are a medium for chronic infection; no longer considered a category of COPD

bronchitis: a disease of the airways defined as the presence of cough and sputum production for at least a combined total of 3 months in each of 2 consecutive years; a category of COPD

chronic obstructive pulmonary disease: disease state characterized by airflow limitation that is not fully reversible; sometimes referred to as chronic airway obstruction or chronic obstructive lung disease

emphysema: a disease of the airways characterized by destruction of the walls of overdistended alveoli; a category of COPD

metered-dose inhaler: patient-activated medication canister that provides aerosolized medication that the patient inhales into the lungs

polycythemia: increase in the red blood cell concentration in the blood; in COPD, the body attempts to improve oxygen carrying capacity by producing increasing amounts of red blood cells

spirometry: pulmonary function tests that measure specific lung volumes (eg, FEV₁, FVC) and rates (FEF_{25-75%}); may be measured before and after bronchodilator administration

Chronic pulmonary disorders are a leading cause of morbidity and mortality in the United States. Nurses care for patients with chronic pulmonary disease across the spectrum of care, from outpatient and home care to emergency department, critical care, and hospice settings. To care for these patients, nurses need not only have astute assessment and clinical management skills but also knowledge of how these disorders can affect quality of life. In addition, the nurse's knowledge of palliative and end-of-life care is important for affected patients. Patient and family teaching is an important nursing intervention to enhance self-management in patients with any chronic pulmonary disorder.

Chronic Obstructive Pulmonary Disease

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) has defined **chronic obstructive pulmonary disease** (COPD) as “a preventable and treatable disease with some significant extrapulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases” (GOLD, 2008, p. 2). This updated definition is a broad description that explains COPD and its signs and symptoms. Although previous definitions have categorized emphysema and chronic bronchitis as types of COPD, this was often confusing because most patients with COPD present with overlapping signs and symptoms of these two distinct disease processes.

COPD may include diseases that cause airflow obstruction (eg, emphysema, chronic bronchitis) or any combination of these disorders. Other diseases such as cystic fibrosis, bronchiectasis, and asthma that were previously classified as types of COPD are now classified as chronic pulmonary disorders. Asthma is now considered a distinct, separate disorder and is classified as an abnormal airway condition characterized primarily by reversible inflammation. COPD can coexist with asthma. Both of these diseases have the same major symptoms; however, symptoms are generally more variable in asthma than in COPD. This chapter discusses COPD as a disease and describes chronic bronchitis and emphysema as distinct disease states, providing a foundation for understanding the pathophysiology of COPD. Bronchiectasis, asthma, and cystic fibrosis are discussed separately.

While mortality from other major causes of death has been decreasing, deaths from COPD have continued to rise. Currently, COPD and associated conditions (chronic lower respiratory diseases) are the fourth leading cause of death in the United States and account for the death of almost 125,000 Americans per year (National Heart, Lung, and Blood Institute [NHLBI], 2007). Mortality from COPD among women has dramatically increased since World War II, and in 2005, more women than men died of COPD. Approximately 12 million Americans live with a diagnosis of COPD; however, many patients do not receive optimal treatment. An additional 12 million Americans may have COPD but remain undiagnosed. The annual cost of COPD

(annual expenditures for health and low productivity) is approximately \$42.6 billion with overall health care expenditures (hospital care, physician services, medications, and home health and nursing home care) of \$26.7 billion (NHLBI, 2007).

People with COPD commonly become symptomatic during the middle adult years, and the incidence of the disease increases with age. Although certain aspects of lung function normally decrease with age—for example, vital capacity and forced expiratory volume in 1 second (FEV₁), COPD accentuates and accelerates these physiologic changes.

Pathophysiology

In COPD, the airflow limitation is both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases. The inflammatory response occurs throughout the proximal and peripheral airways, lung parenchyma, and pulmonary vasculature (GOLD, 2008). Because of the chronic inflammation and the body's attempts to repair it, changes and narrowing occur in the airways. In the proximal airways (trachea and bronchi greater than 2 mm in diameter), changes include increased numbers of goblet cells and enlarged submucosal glands, both of which lead to hypersecretion of mucus. In the peripheral airways (bronchioles less than 2 mm diameter), inflammation causes thickening of the airway wall, peribronchial fibrosis, exudate in the airway, and overall airway narrowing (obstructive bronchiolitis). Over time, this ongoing injury-and-repair process causes scar tissue formation and narrowing of the airway lumen (GOLD, 2008). Inflammatory and structural changes also occur in the lung parenchyma (respiratory bronchioles and alveoli). Alveolar wall destruction leads to loss of alveolar attachments and a decrease in elastic recoil. Finally, the chronic inflammatory process affects the pulmonary vasculature and causes thickening of the lining of the vessel and hypertrophy of smooth muscle, which may lead to pulmonary hypertension (GOLD, 2008).

Processes related to imbalances of substances (proteinases and antiproteinases) in the lung may also contribute to airflow limitation. When activated by chronic inflammation, proteinases and other substances may be released, damaging the parenchyma of the lung. These parenchymal changes may also occur as a consequence of inflammation or environmental or genetic factors (eg, alpha₁-antitrypsin deficiency).

Chronic Bronchitis

Chronic **bronchitis**, a disease of the airways, is defined as the presence of cough and sputum production for at least 3 months in each of 2 consecutive years. Although, chronic bronchitis is a clinically and epidemiologically useful term, it does not reflect the major impact of airflow limitation on morbidity and mortality in COPD (GOLD, 2008). In many cases, smoke or other environmental pollutants irritate the airways, resulting in inflammation and hypersecretion of mucus. Constant irritation causes the mucus-secreting glands and goblet cells to increase in number, leading to increased mucus production. Mucus plugging of the airway reduces ciliary function. Bronchial walls also become

Figure 24-1 Pathophysiology of chronic bronchitis as compared to a normal bronchus. The bronchus in chronic bronchitis is narrowed and has impaired air flow due to multiple mechanisms: inflammation, excess mucus production, and potential smooth muscle constriction (bronchospasm).

thickened, further narrowing the bronchial lumen (Fig. 24-1). Alveoli adjacent to the bronchioles may become damaged and fibrosed, resulting in altered function of the alveolar macrophages. This is significant because the macrophages play an important role in destroying foreign particles, including bacteria. As a result, the patient becomes more susceptible to respiratory infection. A wide range of viral, bacterial, and mycoplasmal infections can produce acute episodes of bronchitis. Exacerbations of chronic bronchitis are most likely to occur during the winter when viral and bacterial infections are more prevalent.

Emphysema

In **emphysema**, impaired oxygen and carbon dioxide exchange results from destruction of the walls of overdistended alveoli. *Emphysema* is a pathologic term that describes an abnormal distention of the airspaces beyond the terminal bronchioles and destruction of the walls of the alveoli (GOLD, 2008). This is the end stage of a process that progresses slowly for many years. As the walls of the alveoli are destroyed (a process accelerated by recurrent infections), the alveolar surface area in direct contact with the pulmonary capillaries continually decreases. This causes an increase in dead space (lung area where no gas exchange can occur) and impaired oxygen diffusion, which leads to hypoxemia. In the later stages of disease, carbon dioxide elimination is impaired, resulting in increased carbon dioxide tension in arterial blood (hypercapnia) leading to respiratory acidosis. As the alveolar walls continue to break down, the pulmonary capillary bed is reduced in size. Consequently, resistance to pulmonary blood flow is increased, forcing the right ventricle to maintain a higher blood pressure in the pulmonary artery. Hypoxemia may further increase pulmonary artery pressures. For this reason, right-sided heart failure (*cor pulmonale*) is one of the complications of emphysema. Congestion, dependent edema, distended neck veins, or pain in the region of the liver suggests the development of cardiac failure.

There are two main types of emphysema, based on the changes taking place in the lung (Fig. 24-2). Both types may occur in the same patient. In the panlobular (panacinar) type of emphysema, there is destruction of the respiratory bronchiole, alveolar duct, and alveolus. All airspaces within the lobule are essentially enlarged, but there

is little inflammatory disease. A hyperinflated (hyperexpanded) chest, marked dyspnea on exertion, and weight loss typically occur. To move air into and out of the lungs, negative pressure is required during inspiration, and an adequate level of positive pressure must be attained and maintained during expiration. Instead of being an involuntary passive act, expiration becomes active and requires muscular effort.

In the centrilobular (centroacinar) form, pathologic changes take place mainly in the center of the secondary lobule, preserving the peripheral portions of the acinus. Frequently, there is a derangement of ventilation-perfusion ratios, producing chronic hypoxemia, hypercapnia, **polycythemia**, and episodes of right-sided heart failure. This leads to central cyanosis and respiratory failure. The patient also develops peripheral edema, which is treated with diuretic therapy.

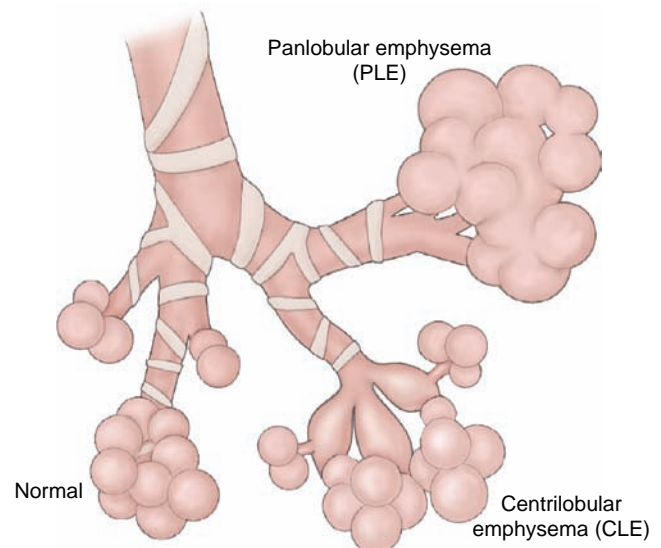

Figure 24-2 Changes in alveolar structure in centrilobular and panlobular emphysema. In panlobular emphysema, the bronchioles, alveolar ducts, and alveoli are destroyed, and the airspaces within the lobule are enlarged. In centrilobular emphysema, the pathologic changes occur in the lobule, whereas the peripheral portions of the acinus are preserved.

CHART
24-1

Risk Factors for Chronic Obstructive Pulmonary Disease (COPD)

- Exposure to tobacco smoke accounts for an estimated 80% to 90% of COPD cases
- Passive smoking
- Occupational exposure—dust, chemicals
- Ambient air pollution
- Genetic abnormalities, including a deficiency of alpha₁-antitrypsin, an enzyme inhibitor that normally counteracts the destruction of lung tissue by certain other enzymes

Risk Factors

Risk factors for COPD include environmental exposures and host factors (Chart 24-1). The most important environmental risk factor for COPD is cigarette smoking. Other environmental risk factors include smoking pipes, cigars, and other types of tobacco. Passive smoking (ie, second-hand smoke) also contributes to respiratory symptoms and COPD (GOLD, 2008). Smoking depresses the activity of scavenger cells and affects the respiratory tract's ciliary cleansing mechanism, which keeps breathing passages free of inhaled irritants, bacteria, and other foreign matter. When smoking damages this cleansing mechanism, airflow is obstructed and air becomes trapped behind the obstruction. The alveoli greatly distend, diminishing lung capacity. Smoking also irritates the goblet cells and mucous glands, causing an increased accumulation of mucus, which in turn produces more irritation, infection, and damage to the lung. In addition, carbon monoxide (a byproduct of smoking) combines with hemoglobin to form carboxyhemoglobin. Hemoglobin that is bound by carboxyhemoglobin cannot carry oxygen efficiently.

Other environmental risk factors for COPD include prolonged and intense exposure to occupational dusts and chemicals, indoor air pollution, and outdoor air pollution (GOLD, 2008). In the United States, it has been estimated that COPD in 19% of smokers and in as many as 31% of nonsmokers may be attributable to such exposure (GOLD, 2008).

One of six Americans with COPD has never smoked (NHLBI, 2007), and COPD involves a gene–environment interaction (GOLD, 2008). The well-documented genetic risk factor is a deficiency of alpha₁-antitrypsin, an enzyme inhibitor that protects the lung parenchyma from injury. This deficiency of alpha₁-antitrypsin predisposes young people to rapid development of lobular emphysema, even if they do not smoke. **α₁-antitrypsin deficiency** is one of the most common genetically linked lethal diseases among Caucasians. There are approximately 25 million carriers of this genetic defect in the United States, and the disease affects approximately 100,000 Americans (American Lung Association, 2007a). Genetically susceptible people are sensitive to environmental factors (eg, smoking, air pollution, infectious agents, allergens) and eventually develop chronic obstructive symptoms. Carriers must be identified so that they can modify environmental risk factors to delay or prevent overt symptoms of disease. Genetics counseling should be offered. Alpha-protease inhibitor replacement therapy, which slows the progression of the disease, is available for patients with this genetic defect and for those with severe disease. However, this intermittent infusion therapy is costly and is required on an ongoing basis.

Clinical Manifestations

Although the natural history of COPD is variable, it is generally a progressive disease characterized by three primary symptoms: chronic cough, sputum production, and dyspnea

on exertion (GOLD, 2008). These symptoms often worsen over time. Chronic cough and sputum production often precede the development of airflow limitation by many years. However, not all people with cough and sputum production develop COPD. The cough may be intermittent and may be unproductive in some patients (GOLD, 2008). Dyspnea may be severe and often interferes with the patient's activities. It is usually progressive, is worse with exercise, and is persistent. As COPD progresses, dyspnea may occur at rest. Weight loss is common, because dyspnea interferes with eating and the work of breathing is energy depleting. As the work of breathing increases over time, the accessory muscles are recruited in an effort to breathe. Patients with COPD are at risk for respiratory insufficiency and respiratory infections, which in turn increase the risk of acute and chronic respiratory failure.

In patients with COPD that has a primary emphysematous component, chronic hyperinflation leads to the “barrel chest” thorax configuration. This configuration results from a more fixed position of the ribs in the inspiratory position (due to hyperinflation) and from loss of lung elasticity (Fig. 24-3).

Figure 24-3 Characteristics of normal chest wall and chest wall in emphysema. **A**, The normal chest wall and its cross-section. **B**, The barrel-shaped chest of emphysema and its cross-section

Figure 24-4 Typical posture of a person with chronic obstructive pulmonary disease (COPD)—primarily emphysema. The person tends to lean forward and uses the accessory muscles of respiration to breathe, forcing the shoulder girdle upward and causing the supraclavicular fossae to retract on inspiration.

Retraction of the supraclavicular fossae occurs on inspiration, causing the shoulders to heave upward (Fig. 24-4). In advanced emphysema, the abdominal muscles may also contract on inspiration.

Assessment and Diagnostic Findings

The nurse should obtain a thorough health history from patients with known or potential COPD. Chart 24-2 lists the key factors to assess. Pulmonary function studies are used to help confirm the diagnosis of COPD, determine disease severity, and monitor disease progression. **Spirometry** is used to evaluate airflow obstruction, which is determined by the ratio of FEV₁ to forced vital capacity (FVC). Spirometric results are expressed as an absolute volume and as a percentage of the predicted value using appropriate normal values for gender, age, and height. With obstruction, the patient either has difficulty exhaling or cannot forcibly exhale air from the lungs, reducing the FEV₁. Spirometry is also used to determine reversibility of obstruction after use of bronchodilators (GOLD, 2008). Spirometry is initially performed, the patient is given an inhaled bronchodilator treatment according to a standard protocol, and then spirometry is repeated. The patient demonstrates a degree of reversibility if the pulmonary function values improve after administration of the bronchodilator. Even patients who do not show a significant response to a short-acting bronchodilator test may benefit symptomatically from long-term bronchodilator treatment.

Arterial blood gas measurements may also be obtained to assess baseline oxygenation and gas exchange and are especially important in advanced COPD. A chest x-ray may be obtained to exclude alternative diagnoses. A computed tomography (CT) chest scan is not routinely obtained in the diagnosis of COPD, but a high-resolution CT scan may help in the differential diagnosis. Lastly, screening for alpha₁-antitrypsin deficiency may be performed for patients younger than 45 years of age and for those with a strong family history of COPD.

COPD is classified into four stages depending upon the severity (measured by pulmonary function tests) and symptoms (GOLD, 2008). Stage I (mild) is defined by an FEV₁/FVC less than 70% and an FEV₁ greater than or equal to 80% predicted, and the patient may be with or without symptoms of cough and sputum production. Stage II (moderate) is defined by an FEV₁/FVC less than 70%, an FEV₁ 50% to 80% predicted, and shortness of breath typically developing upon exertion. Stage III (severe) is defined as an FEV₁/FVC less than 70% and an FEV₁ less than 30% to 50% predicted. Severe COPD symptoms include increased shortness of breath, reduced exercise capacity, and repeated exacerbations. Lastly, stage IV (very severe) is defined as an FEV₁/FVC less than 70%, an FEV₁ less than 30% to 50% predicted, and symptoms/signs of chronic respiratory failure.

Factors that determine the clinical course and survival of patients with COPD include history of cigarette smoking, passive smoking exposure, age, rate of decline of FEV₁, hypoxemia, pulmonary artery pressure, resting heart rate, weight loss, and reversibility of airflow obstruction. See Chart 24-3 for additional information about the assessment of symptoms in COPD.

In diagnosing COPD, several differential diagnoses must be ruled out. The primary differential diagnosis is asthma. It may be difficult to differentiate between a patient with COPD and one with chronic asthma. Other diseases that must be considered in the differential diagnosis include heart failure, bronchiectasis, tuberculosis, obliterative bronchiolitis, and diffuse panbronchiolitis (GOLD, 2008). Key factors in determining the diagnosis are the patient's history and the patient's responsiveness to bronchodilators.

Complications

Respiratory insufficiency and failure are major life-threatening complications of COPD. The acuity of the onset and the severity of respiratory failure depend on baseline pulmonary function, pulse oximetry or arterial blood gas values, comorbid conditions, and the severity of other complications of COPD. Respiratory insufficiency and failure may be chronic (with severe COPD) or acute (with severe bronchospasm or pneumonia in a patient with severe COPD). Acute respiratory insufficiency and failure may necessitate ventilatory support until other acute complications, such as infection, can be treated. Management of the patient requiring ventilatory support is discussed in Chapter 25. Other complications of COPD include pneumonia, chronic atelectasis, pneumothorax, and pulmonary arterial hypertension (cor pulmonale).

CHART
24-2

Assessing Patients With Chronic Obstructive Pulmonary Disease (COPD)

Health History

- Has the patient been exposed to risk factors (types, intensity, duration)?
- Does the patient have a past medical history of respiratory diseases/problems, including asthma, allergy, sinusitis, nasal polyps, or respiratory infections?
- Does the patient have a family history of COPD or other chronic respiratory diseases?
- How long has the patient had respiratory difficulty?
- What is the pattern of symptom development?
- Does exertion increase the dyspnea? What type of exertion?
- What are the limits of the patient's tolerance for exercise?
- At what times during the day does the patient complain most of fatigue and shortness of breath?
- Which eating and sleeping habits have been affected?
- What is the impact of respiratory disease on quality of life?
- What does the patient know about the disease and his or her condition?
- What is the patient's smoking history (primary and secondary)?
- Is there occupational exposure to smoke or other pollutants?
- What are the triggering events (eg, exertion, strong odors, dust, exposure to animals)?
- Does the patient have a history of exacerbations or previous hospitalizations for respiratory problems?
- Are comorbidities present?
- How appropriate are current medical treatments?

- Does the patient have available social and family support?
- What is the potential for reducing risk factors (eg, smoking cessation)?

Physical Assessment

- What position does the patient assume during the interview?
- What are the pulse and the respiratory rates?
- What is the character of respirations? Even and without effort? Other?
- Can the patient complete a sentence without having to take a breath?
- Does the patient contract the abdominal muscles during inspiration?
- Does the patient use accessory muscles of the shoulders and neck when breathing?
- Does the patient take a long time to exhale (prolonged expiration)?
- Is central cyanosis evident?
- Are the patient's neck veins engorged?
- Does the patient have peripheral edema?
- Is the patient coughing?
- What are the color, amount, and consistency of the sputum?
- Is clubbing of the fingers present?
- What types of breath sounds (ie, clear, diminished or distant, crackles, wheezes) are heard? Describe and document findings and locations.
- What is the status of the patient's sensorium?
- Is there short-term or long-term memory impairment?
- Is there increasing stupor?
- Is the patient apprehensive?

CHART
24-3

NURSING RESEARCH PROFILE

Symptom Assessment of Patients With Chronic Obstructive Pulmonary Disease

Jablonski, A., Gift, A. & Cook, K. E. (2007). Symptom assessment of patients with chronic obstructive pulmonary disease. *Western Journal of Nursing Research*, 29(7), 845–863.

Purpose

The purpose of this secondary analysis of data was to evaluate the Memorial Symptom Assessment Scale (MSAS) for use in patients with severe chronic obstructive pulmonary disease (COPD). Although the multidimensional MSAS was developed for patients with cancer, it has potential for assessment of symptoms of people with other diseases.

Design

This descriptive study was a secondary analysis of data that examined the relationship between symptoms and functional status in patients with COPD. The investigators recruited the convenience sample of 72 subjects who met the criteria for severe COPD from an outpatient pulmonary clinic. Ages ranged from 36 to 79 years. The MSAS has 32 items but for the purposes of the study, the researchers shortened it to the 19 items, or symptoms, that patients with COPD most frequently identify. The included symptoms related to prevalence, frequency, severity, and distress.

Findings

The top 10 symptoms identified by this COPD population were shortness of breath, lack of energy, dry mouth, cough, feeling nervous, feeling sad, feeling irritable, worrying, feeling drowsy, and difficulty sleeping. Shortness of breath and lack of energy were the most severe, frequent, and distressful symptoms. When researchers evaluated the prevalence and characteristics of symptoms, they found that both clinical and emotional symptoms (feeling nervous, sad, or irritable; worrying) were equally represented. Reliability of the revised MSAS tool, with 19 items, remained high (Cronbach's alpha = 0.86), and this study also confirmed content and convergent validity.

Nursing Implications

Although many tools are available to measure the frequency of symptoms, few tools are available to evaluate symptoms on a multidimensional perspective; the MSAS enables assessment of symptom prevalence, severity, frequency, and distress. Nursing implications of this study include not only a potential new tool to evaluate patients with severe COPD but also the need to recognize that emotional symptoms are as important as clinical symptoms in people with this disease. Nursing interventions need to focus not only on patients' clinical symptoms but also on their emotional needs.

Medical Management

Risk Reduction

Smoking cessation is the single most cost-effective intervention to reduce the risk of developing COPD and to stop its progression (GOLD, 2008). However, smoking cessation is difficult to achieve and even more difficult to sustain in the long term. Nurses are key in promoting smoking cessation and educating patients about its importance. Patients diagnosed with COPD who continue to smoke must be encouraged and assisted to quit. Factors associated with continued smoking vary among patients and may include the strength of the nicotine addiction, continued exposure to smoking-associated stimuli (at work or in social settings), stress, depression, and habit. Continued smoking is also more prevalent among those with low incomes, low levels of education, or psychosocial problems (CDC, 2007b).

Because multiple factors are associated with continued smoking, successful cessation often requires multiple strategies. Health care providers should promote cessation by explaining the risks of smoking and personalizing the “at-risk” message to the patient. After giving a strong warning about smoking, health care providers should work with the patient to set a definite “quit date.” Referral to a smoking cessation program may be helpful. Follow-up within 3 to 5 days after the “quit date” to review progress and to address any problems is associated with an increased rate of success; this should be repeated as needed. Continued reinforcement with telephone calls or clinic visits is extremely beneficial. Relapses should be analyzed, and the patient and health care provider should jointly identify possible solutions to prevent future backsliding. It is important to emphasize successes rather than failures. Nicotine replacement, first-line pharmacotherapy that reliably increases long-term smoking abstinence rates, comes in a variety of forms (gum, inhaler, nasal spray, transdermal patch, sublingual tablet, or lozenges). Bupropion SR (Wellbutrin, Zyban) and nortriptyline (Aventyl), both antidepressants, may also increase long-term quit rates. Other pharmacologic agents include the antihypertensive agent clonidine (Catapres); however, its side effects limit its use. Varenicline (Chantix), a nicotinic acetylcholine receptor partial agonist, may assist in smoking cessation (GOLD, 2008). Patients who are not appropriate candidates for the use of pharmacotherapy include those with medical contraindications, light smokers (less than 10 cigarettes per day), and pregnant and adolescent smokers.

Smoking cessation can begin in a variety of health care settings—outpatient clinic, nursing center, pulmonary rehabilitation, community, hospital, and in the home. Regardless of the setting, nurses have the opportunity to teach patients about the risks of smoking and the benefits of smoking cessation. Various materials, resources, and programs developed by several organizations (eg, Agency for Healthcare Research and Quality, U.S. Public Health Service, CDC, National Cancer Institute, American Lung Association, American Cancer Society) are available to assist with this effort.

Pharmacologic Therapy

Bronchodilators

Bronchodilators relieve bronchospasm by altering smooth muscle tone and reduce airway obstruction by allowing increased oxygen distribution throughout the lungs and

improving alveolar ventilation. Although regular use of bronchodilators that act primarily on the airway smooth muscle does not modify the decline of function or the prognosis of COPD, their use is central in the management of COPD (GOLD, 2008). These agents can be delivered through a metered-dose inhaler or other type of inhaler, by nebulization, or via the oral route in pill or liquid form. Bronchodilators are often administered regularly throughout the day as well as on an as-needed basis. They may also be used prophylactically to prevent breathlessness by having the patient use them before participating in or completing an activity, such as eating or walking.

Several devices are available to deliver medication via an aerosolized method. These include **metered-dose inhalers** (MDIs), breath-actuated MDIs, dry powder inhalers, spacer or valved-holding chambers, and nebulizers. Key aspects of each are described in Table 24-1. An MDI is a pressurized device that contains an aerosolized powder of medication. A precise amount of medication is released with each activation of the canister. Patients must be instructed on the correct use of the device. A spacer or valved-holding chamber may also be used to enhance deposition of the medication in the lung and help the patient coordinate activation of the MDI with inspiration. Spacers come in several designs, but all are attached to the MDI and have a mouthpiece on the opposite end (Fig. 24-5). Specific package insert information is available for different types of aerosol delivery devices.

Several classes of bronchodilators are used, including beta-adrenergic agonists (short- and long-acting), anticholinergic agents (short- and long-acting), methylxanthines, and combination agents. These medications may be used in combination to optimize bronchodilation. Long-acting bronchodilators are more convenient for patient use. Examples of these medications are described in Table 24-2. Nebulized medications also known as wet nebulizers (nebulization of medication via an air compressor) may also be effective in patients who cannot use an MDI properly or who prefer this method of administration. However, wet nebulizers are more expensive than other devices and require appropriate maintenance (GOLD, 2008).

Bronchodilators are key to symptom management in stable COPD. Before these agents are used, the following information should be considered: Inhaled therapy is preferred, choice of bronchodilator is dependent on availability and individual response in terms of symptom relief and side effects, they may be prescribed on an as-needed or regular basis to reduce symptoms, long-acting bronchodilators are more convenient for patient use, and combining bronchodilators with different durations of action and different mechanisms may optimize symptom management (GOLD, 2008).

Corticosteroids

Although inhaled and systemic corticosteroids may improve the symptoms of COPD, they do not slow the decline in lung function. Their effects are less dramatic than in asthma. A short trial course of oral corticosteroids may be prescribed for patients to determine whether pulmonary function improves and symptoms decrease. Long-term

Devices/Drugs	Optimal Technique	Therapeutic Issues
Metered-dose inhaler (MDI) Beta ₂ -agonists Corticosteroids Cromolyn sodium Anticholinergics	Actuation during a slow (30 L/min or 3–5 sec) deep inhalation, followed by 10-sec breathhold	Slow inhalation and coordination of actuation may be difficult for some patients. Patients may incorrectly stop inhalation at actuation. Deposition of 50–80% of actuated dose in the oropharynx. Mouth washing and spitting is effective in reducing the amount of drug swallowed and absorbed systemically.
Breath-actuated MDI Beta ₂ -agonists	Tight seal around mouthpiece and slightly more rapid inhalation than standard MDI (see above) followed by 10-sec breathhold	May be particularly useful for patients unable to coordinate inhalation and actuation. May also be useful for elderly patients. Patients may incorrectly stop inhalation at actuation. Cannot be used with currently available spacer/valved-holding chamber devices.
Dry powder inhaler (DPI) Beta ₂ -agonists Corticosteroids Anticholinergics	Rapid (1–2 sec) deep inhalation. Minimally effective inspiratory flow is device dependent.	Dose is lost if patient exhales through device after actuating. Delivery may be greater or lesser than MDIs, depending on device and technique. Delivery is more flow dependent in devices with highest internal resistance. Rapid inhalation promotes greater deposition in larger central airways. Mouth washing and spitting are effective in reducing amount of drug swallowed and absorbed systemically.
Spacer or valved-holding chamber (VHC)	Slow (30 L/min or 3–5 sec) deep inhalation, followed by 10-sec breathhold immediately following actuation. Actuate only once into spacer/VHC per inhalation. Rinse plastic VHCs once a month with low concentration of liquid household dishwashing detergent (1:5000 or 1–2 drops per cup of water) and let drip dry.	Indicated for patients who have difficult performing adequate MDI technique. May be bulky. Simple tubes do not obviate coordinating actuation and inhalation. VHCs are preferred. Spacers or VHCs may increase delivery of inhaled corticosteroids to the lungs.
Nebulizer Beta ₂ -agonists Corticosteroids Cromolyn sodium Anticholinergics	Slow tidal breathing with occasional deep breaths. Tightly fitting face mask for those unable to use mouthpiece.	Less dependent on patient's coordination and cooperation. May be expensive, time consuming, and bulky; output is dependent on device and operating parameters (fill volume, driving gas flow); internebulizer and intranebulizer output variances are significant. Use of a face mask reduces delivery to lungs by 50%. Choice of delivery system is dependent on resources, availability, and clinical judgment of clinician caring for patient. There is potential for infections if device is not cleaned properly.

From Expert Panel Report 3. (2007). *Guidelines for the diagnosis and management of asthma* (pp. 31–32). NIH Publication Number 08-5846. National Asthma Education and Prevention Program. Summary Report. Bethesda, MD: U.S. Department of Health and Human Services, National Heart, Lung and Blood Institute.

treatment with oral corticosteroids is not recommended in COPD and can cause steroid myopathy, leading to muscle weakness, decreased ability to function, and, in advanced disease, respiratory failure (GOLD, 2008).

Medication regimens used to manage COPD are based on disease severity. For stage I (mild) COPD, a short-acting bronchodilator may be prescribed. For stage II or III COPD, a short-acting bronchodilator along with regular treatment of one or more long-acting bronchodilators may be used. For stage III or IV (severe or very severe) COPD, medication therapy includes regular treatment with one or more bronchodilators and inhaled corticosteroids for repeated exacerbations. Combination long-term beta₂-agonists plus corticosteroids in one inhaler may be appropriate; examples

include formoterol/budesonide (Symbicort) and salmeterol/fluticasone (Seretide).

Other Medications

Other pharmacologic treatments that may be used in COPD include alpha₁-antitrypsin augmentation therapy, antibiotic agents, mucolytic agents, antitussive agents, vasodilators, and narcotics. Vaccines may also be effective. Influenza vaccines can reduce serious morbidity and death in patients with COPD by approximately 50% (GOLD, 2008). It is recommended that people limit their risk through influenza vaccination and smoking cessation. Pneumococcal vaccination also reduces the incidence of pneumonia, hospitalizations for cardiac conditions, and deaths in the

Figure 24-5 A, Examples of metered-dose inhalers and spacers. B, A metered-dose inhaler and spacer in use.

general elderly population. Pneumococcal pneumonia is responsible for approximately 175,000 hospitalized cases per year (National Pneumonia Medicare Quality Improvement Project, 2007). Vaccination is recommended in patients 65 years or older who have COPD (GOLD, 2008).

Management of Exacerbations

An exacerbation of COPD is defined as an event in the natural course of the disease characterized by an acute change in the patient's baseline dyspnea, cough, or sputum production beyond the normal day-to-day variations. It may warrant a change in regular medications (GOLD, 2008). Primary causes of an acute exacerbation include tracheobronchial infection and air pollution. However, the cause of approximately one third of severe exacerbations cannot be identified (GOLD, 2008). If possible, the primary cause of the exacerbation is identified, and specific treatment is adminis-

tered. Optimization of bronchodilator medications is first-line therapy and involves identifying the best medication or combinations of medications taken on a regular schedule for a specific patient. Depending on the signs and symptoms, corticosteroids, antibiotic agents, oxygen therapy, and intensive respiratory interventions may also be used. Indications for hospitalization for acute exacerbation of COPD include severe dyspnea that does not respond adequately to initial therapy, confusion or lethargy, respiratory muscle fatigue, paradoxical chest wall movement, peripheral edema, worsening or new onset of central cyanosis, persistent or worsening hypoxemia, and need for noninvasive or invasive assisted mechanical ventilation (GOLD, 2008). The outcome from an exacerbation of COPD is closely related to the development of respiratory acidosis, the presence of significant comorbidities, and the need for noninvasive or invasive positive pressure ventilatory support.

Table 24-2 COMMON TYPES OF BRONCHODILATOR MEDICATIONS FOR COPD

Class/Drug (Trade Name)	Method of Administration			Duration of Action [†]
	Inhaler*	Nebulizer	Oral	
Beta₂-Adrenergic Agonist Agents				
salbutamol, albuterol (Proventil, Ventolin)	X	X	X	Short
fenoterol (Alupent, Isuprel)	X	X	X	Short
terbutaline (Brethine)	X			Short
formoterol (Foradil)	X			Long
salmeterol (Serevent Diskus)	X			Long
Anticholinergic Agents				
Ipratropium bromide (Atrovent)	X	X		Short
Combination Short-Acting Beta-2 Adrenergic Agonist and Anticholinergic Agents				
fenoterol/ipratropium (Duovent)	X	X		
salbutamol/ipratropium (Combivent)	X	X		
Methylxanthines				
aminophylline (Phyllocontin, Truphylline)			X	Variable
theophylline (Theo-Dur, Slo-Bid)			X	Variable

*Inhaler may include metered-dose inhaler, powdered inhalation with inhaler, or discus.

[†]Short-acting, 4–6 h; long-acting, 12+ h.

The GOLD guidelines (2008) provide indications for assessment, hospital admission, and intensive care admission for patients with exacerbations of COPD. These include signs of increasing severity on physical examination (use of accessory muscles, paradoxical chest wall movement, worsening or new onset of central cyanosis, peripheral edema, signs of right heart failure, reduced alertness).

On the patient's arrival at the emergency department, the first line of treatment is supplemental oxygen therapy and rapid assessment to determine if the exacerbation is life-threatening (GOLD, 2008). A short-acting inhaled bronchodilator may be used to assess response to treatment. Oral or intravenous corticosteroids, in addition to bronchodilators, are recommended in the hospital management of a COPD exacerbation. Antibiotics have been shown to be of some benefit in patients with increased dyspnea, increased sputum volume, and increased sputum purulence, and in those needing mechanical ventilation (GOLD, 2008).

Oxygen Therapy

Oxygen therapy can be administered as long-term continuous therapy, during exercise, or to prevent acute dyspnea during an exacerbation. The goal of supplemental oxygen therapy is to increase the baseline resting partial arterial pressure of oxygen (PaO_2) to at least 60 mm Hg at sea level and an arterial oxygen saturation (SaO_2) at least 90% (GOLD, 2008). Long-term oxygen therapy (more than 15 hours per day) has also been shown to improve quality of life, reduce pulmonary arterial pressure and dyspnea, and improve survival (GOLD, 2008). Long-term oxygen therapy is usually introduced in very severe COPD, and indications generally include a PaO_2 of 55 mm Hg or less or evidence of tissue hypoxia and organ damage such as cor pulmonale, secondary polycythemia, edema from right-sided heart failure, or impaired mental status (GOLD, 2008). For patients with exercise-induced hypoxemia, oxygen supplementation during exercise may improve performance. There is no evidence to support the idea that short bursts of oxygen before or after exercise provide any symptomatic relief (GOLD, 2008). Patients who are hypoxemic while awake are likely to be so during sleep. Therefore, nighttime oxygen therapy is recommended as well, and the prescription for oxygen therapy is for continuous, 24-hour use. Intermittent oxygen therapy is indicated for patients who desaturate only during exercise or sleep.

The main objective in treating patients with hypoxemia and hypercapnia is to give sufficient oxygen to improve oxygenation. Patients with COPD who require oxygen may have respiratory failure that is caused primarily by a ventilation-perfusion mismatch. These patients respond to oxygen therapy and should be treated to keep the resting oxygen saturation above 90%. However, a small subset of patients with COPD and chronic hypercapnia (elevated partial pressure of arterial carbon dioxide [PaCO_2] levels) may be more oxygen sensitive; their respiratory failure is caused more by alveolar hypoventilation. Administering too much oxygen can result in the retention of carbon dioxide. Patients with alveolar hypoventilation cannot increase ventilation to adjust for this increased load, and increasing

hypercapnia occurs. Monitoring and assessment are key in the care of patients with COPD on supplemental oxygen. Pulse oximetry is helpful in assessing response to therapy but does not assess PaCO_2 levels. Optimal oxygenation of patients is important while monitoring for any possible complications of oxygen supplementation.

NURSING ALERT

Oxygen therapy is variable in COPD patients; its aim in COPD is to achieve an acceptable oxygen level without a fall in the pH (increasing hypercapnia).

Surgical Management

Bullectomy

A bullectomy is a surgical option for select patients with bullous emphysema. Bullae are enlarged airspaces that do not contribute to ventilation but occupy space in the thorax; these areas may be surgically excised. These bullae compress areas of the lung and may impair gas exchange. Bullectomy may help reduce dyspnea and improve lung function. It can be performed via a video-assisted thoracoscope or a limited thoracotomy incision (see Chapter 25).

Lung Volume Reduction Surgery

Treatment options for patients with end-stage COPD (stage IV) with a primary emphysematous component are limited, although lung volume reduction surgery is a palliative surgical option in a selected subset of patients. This subset includes patients with homogenous disease or disease that is focused in one area and not widespread throughout the lungs. Lung volume reduction surgery involves the removal of a portion of the diseased lung parenchyma. This reduces hyperinflation and allows the functional tissue to expand, resulting in improved elastic recoil of the lung and improved chest wall and diaphragmatic mechanics. This type of surgery does not cure the disease or improve life expectancy, but it may decrease dyspnea, improve lung function, and improve the patient's overall quality of life (GOLD, 2008).

Careful selection of patients for lung volume reduction surgery is essential to decrease morbidity and mortality. A large multisite trial, the National Emphysema Treatment Trial, found that the addition of lung volume reduction surgery to optimal medical management and rehabilitation led to overall improvement in exercise tolerance and survival in a very select subgroup of patients with predominantly upper lobe disease (American Lung Association, 2007b; GOLD, 2008).

Lung Transplantation

Lung transplantation is a viable option for definitive surgical treatment of end-stage emphysema. It has been shown to improve quality of life and functional capacity in a selected group of patients with COPD. Limited not only by the shortage of donor organs, it is also a costly procedure with financial implications for months to years because of complications and the need for costly immunosuppressive medication regimens (GOLD, 2008).

Pulmonary Rehabilitation

Pulmonary rehabilitation for patients with COPD is well established and widely accepted as a means to alleviate symptoms and optimize functional status (Ries, Bauldoff, Carlin, et al., 2007). The primary goals of rehabilitation are to reduce symptoms, improve quality of life, and increase physical and emotional participation in everyday activities (GOLD, 2008). The benefits of this therapy include improvement of exercise capacity, reduction of the perceived intensity of breathlessness, improvement in health-related quality of life, reduction in the number of hospitalizations and days in the hospital, and reduction of the anxiety and depression associated with COPD (GOLD, 2008). Pulmonary rehabilitation services are multidisciplinary and include assessment, education, smoking cessation, physical reconditioning, nutritional counseling, skills training, and psychological support. Patients are taught methods to alleviate symptoms. Breathing exercises as well as retraining and exercise programs are used to improve functional status.

Pulmonary rehabilitation is appropriate for stages II through IV (GOLD, 2008). The minimum length of an effective program is 6 weeks; the longer the program, the more effective the results (GOLD, 2008; Ries, et al., 2007). It may be conducted in inpatient, outpatient, or home settings, and the lengths of programs vary. Program selection depends on the patient's physical, functional, and psychosocial status; insurance coverage; availability of programs; and preference. Pulmonary rehabilitation may also be used therapeutically in other disorders besides COPD, including asthma, cystic fibrosis, lung cancer, interstitial lung disease, thoracic surgery, and lung transplantation.

Patient Education

Nurses play a key role in identifying potential candidates for pulmonary rehabilitation and in facilitating and reinforcing the material learned in the rehabilitation program. Not all patients have access to a formal rehabilitation program. However, nurses can be instrumental in teaching patients and families as well as facilitating specific services, such as respiratory therapy education, physical therapy for exercise and breathing retraining, occupational therapy for conserving energy during activities of daily living, and nutritional counseling. Patient education is a major component of pulmonary rehabilitation and includes a broad variety of topics.

Depending on the length and setting of the educational program, topics may include normal anatomy and physiology of the lung, pathophysiology and changes with COPD, medications and home oxygen therapy, nutrition, respiratory therapy treatments, symptom alleviation, smoking cessation, sexuality and COPD, coping with chronic disease, communicating with the health care team, and planning for the future (advance directives, living wills, informed decision making about health care alternatives). Education, including that relating to smoking cessation, should be incorporated into all aspects of care for COPD and in many settings (physicians' offices, clinics, hospitals, home and community health care settings, and comprehensive rehabilitation programs).

Breathing Exercises

The breathing pattern of most people with COPD is shallow, rapid, and inefficient; the more severe the disease, the more inefficient the breathing pattern. With practice, this type of upper chest breathing can be changed to diaphragmatic breathing, which reduces the respiratory rate, increases alveolar ventilation, and sometimes helps expel as much air as possible during expiration (see Chapter 25 for technique). Pursed-lip breathing helps slow expiration, prevents collapse of small airways, and helps the patient control the rate and depth of respiration. It also promotes relaxation, enabling the patient to gain control of dyspnea and reduce feelings of panic.

Activity Pacing

People with COPD have decreased exercise tolerance during specific periods of the day, especially in the morning on arising, because bronchial secretions have collected in the lungs during the night while the person was lying down. The patient may have difficulty bathing or dressing and may become fatigued. Activities that require the arms to be supported above the level of the thorax may produce fatigue or respiratory distress but may be tolerated better after the patient has been up and moving around for an hour or more. The nurse can help the patient reduce these limitations by planning self-care activities and determining the best times for bathing, dressing, and other daily activities.

Self-Care Activities

As gas exchange, airway clearance, and the breathing pattern improve, the patient is encouraged to assume increasing participation in self-care activities. The patient is taught to coordinate diaphragmatic breathing with activities such as walking, bathing, bending, or climbing stairs. The patient should bathe, dress, and take short walks, resting as needed to avoid fatigue and excessive dyspnea. Fluids should always be readily available, and the patient should begin to drink fluids without having to be reminded. If management of secretions is a problem and some type of postural drainage or airway clearance maneuver is to be performed at home, the nurse or respiratory therapist instructs and supervises the patient before discharge or in an outpatient setting.

Physical Conditioning

People with COPD of all stages benefit from exercise training programs, which result in increased exercise tolerance and decreased dyspnea and fatigue (GOLD, 2008). Physical conditioning techniques include breathing exercises and general exercises intended to conserve energy and increase pulmonary ventilation. Graded exercises and physical conditioning programs using treadmills, stationary bicycles, and measured level walks can improve symptoms and increase work capacity and exercise tolerance. Any physical activity that can be performed regularly is helpful. Walking aids may be beneficial (GOLD, 2008). Lightweight portable oxygen systems are available for ambulatory patients who require oxygen therapy during physical activity.

Oxygen Therapy

Oxygen supplied to the home comes in compressed gas, liquid, or concentrator systems. Portable oxygen systems allow the patient to exercise, work, and travel. To help the patient

adhere to the oxygen prescription, the nurse explains the proper flow rate and required number of hours for oxygen use as well as the dangers of arbitrary changes in flow rate or duration of therapy. The nurse should caution the patient that smoking with or near oxygen is extremely dangerous. The nurse also reassures the patient that oxygen is not “addictive” and explains the need for regular evaluations of blood oxygenation by pulse oximetry or arterial blood gas analysis.

Nutritional Therapy

Nutritional assessment and counseling are important aspects in the rehabilitation process for patients with COPD. Nutritional status is important in COPD and is reflected in severity of symptoms, degree of disability, and prognosis. Significant weight loss is often a major problem, but excessive weight can also be problematic although it occurs less often. Most people have difficulty gaining and maintaining weight. A thorough assessment of caloric needs and counseling about meal planning and supplementation is part of the rehabilitation process. Continual monitoring of weight and interventions as necessary are important parts of the care of patients with COPD.

Coping Measures

Any factor that interferes with normal breathing quite naturally induces anxiety, depression, and changes in behavior. Constant shortness of breath and fatigue may make the patient irritable and apprehensive to the point of panic. Restricted activity (and reversal of family roles due to loss of employment), the frustration of having to work to breathe, and the realization that the disease is prolonged and unrelenting may cause the patient to become angry, depressed, and demanding. Sexual function may be compromised, which also diminishes self-esteem. The nurse should provide education and support to spouses or significant others and families, because the caregiver role in end-stage COPD can be difficult.

Nursing Management

Assessing the Patient

Assessment involves obtaining information about current symptoms as well as previous disease manifestations. See Chart 24-2 for sample questions that may be used to obtain a clear history of the disease process. In addition to the history, nurses review the results of available diagnostic tests.

Achieving Airway Clearance

Bronchospasm, which occurs in many pulmonary diseases, reduces the caliber of the small bronchi and may cause dyspnea, static secretions, and infection. Bronchospasm can sometimes be detected on auscultation with a stethoscope when wheezing or diminished breath sounds are heard. Increased mucus production, along with decreased mucociliary action, contributes to further reduction in the caliber of the bronchi and results in decreased airflow and decreased gas exchange. This is further aggravated by the loss of lung elasticity that occurs with COPD (GOLD, 2008). These changes in the airway require that the nurse monitor the patient for dyspnea and hypoxemia. If bronchodilators or

corticosteroids are prescribed, the nurse must administer the medications properly and be alert for potential side effects. The relief of bronchospasm is confirmed by measuring improvement in expiratory flow rates and volumes (the force of expiration, how long it takes to exhale, and the amount of air exhaled) as well as by assessing the dyspnea and making sure that it has lessened.

Diminishing the quantity and viscosity of sputum can clear the airway and improve pulmonary ventilation and gas exchange. All pulmonary irritants should be eliminated or reduced, particularly cigarette smoking, which is the most persistent source of pulmonary irritation. The nurse instructs the patient in directed or controlled coughing, which is more effective and reduces the fatigue associated with undirected forceful coughing. Directed coughing consists of a slow, maximal inspiration followed by breath-holding for several seconds and then two or three coughs. “Huff” coughing may also be effective. The technique consists of one or two forced exhalations (“huffs”) from low to medium lung volumes with the glottis open.

Chest physiotherapy with postural drainage, intermittent positive pressure breathing, increased fluid intake, and bland aerosol mists (with normal saline solution or water) may be useful for some patients with COPD. The use of these measures must be based on the response and tolerance of each patient.

Improving Breathing Patterns

Ineffective breathing patterns and shortness of breath are due to the ineffective respiratory mechanics of the chest wall and lung resulting from **air trapping**, ineffective diaphragmatic movement, airway obstruction, the metabolic cost of breathing, and stress. Inspiratory muscle training and breathing retraining may help improve breathing patterns. Training in diaphragmatic breathing reduces the respiratory rate, increases alveolar ventilation, and sometimes helps expel as much air as possible during expiration. Pursed-lip breathing helps slow expiration, prevent collapse of small airways, and control the rate and depth of respiration. It also promotes relaxation, which allows patients to gain control of dyspnea and reduce feelings of panic.

Improving Activity Tolerance

Patients with COPD experience progressive activity and exercise intolerance and disability. Education is focused on rehabilitative therapies to promote independence in executing activities of daily living. These may include pacing activities throughout the day or using supportive devices to decrease energy expenditure. The nurse evaluates the patient’s activity tolerance and limitations and uses teaching strategies to promote independent activities of daily living. The patient may be a candidate for exercise training to strengthen the muscles of the upper and lower extremities and to improve exercise tolerance and endurance. Use of walking aids may be recommended to improve activity levels and ambulation (GOLD, 2008). Other health care professionals (rehabilitation therapist, occupational therapist, physical therapist) may be consulted as additional resources.

Monitoring and Managing Potential Complications

The nurse must assess for various complications of COPD, such as life-threatening respiratory insufficiency and failure, as well as respiratory infection and chronic atelectasis, which may increase the risk of respiratory failure. The nurse monitors for cognitive changes (personality and behavioral changes, memory impairment), increasing dyspnea, tachypnea, and tachycardia, which may indicate increasing hypoxemia and impending respiratory failure.

The nurse monitors pulse oximetry values to assess the patient's need for oxygen and administers supplemental oxygen as prescribed. The nurse also instructs the patient about signs and symptoms of respiratory infection that may worsen hypoxemia and reports changes in the patient's physical and cognitive status to the physician.

Bronchopulmonary infections must be controlled to diminish inflammatory edema and to permit recovery of normal ciliary action. Minor respiratory infections that are of no consequence to people with normal lungs can be life-threatening to people with COPD. Infection compromises lung function and is a common cause of respiratory failure in people with COPD. In COPD, infection may be accompanied by subtle changes. The nurse instructs the patient to report any signs of infection, such as a fever or change in sputum color, character, consistency, or amount. Any worsening of symptoms (increased tightness of the chest, increased dyspnea, and fatigue) also suggests infection and must be reported. Viral infections are hazardous to the patient because they are often followed by infections caused by bacterial organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*.

To prevent infection, the nurse should encourage the patient with COPD to be immunized against influenza and *S. pneumoniae*, because the patient is prone to respiratory infection. It is important to caution the patient to avoid going outdoors if the pollen count is high or if there is significant air pollution, because of the risk of bronchospasm. The patient also should avoid exposure to high outdoor temperatures with high humidity.

Pneumothorax is a potential complication of COPD and can be life-threatening in patients with COPD who have minimal pulmonary reserve. Patients with severe emphysematous changes can develop large bullae, which may rupture and cause a pneumothorax. Development of a pneumothorax may be spontaneous or related to an activity such as severe coughing or large intrathoracic pressure changes. If a rapid onset of shortness of breath occurs, the nurse should quickly evaluate the patient for potential pneumothorax by assessing the symmetry of chest movement, differences in breath sounds, and pulse oximetry.

Over time, pulmonary hypertension may occur as a result of chronic hypoxemia. The pulmonary arteries respond to hypoxemia by constricting, which results in pulmonary hypertension. The complication may be prevented by maintaining adequate oxygenation through an adequate hemoglobin level, improved ventilation-perfusion of the lungs, or continuous administration of supplemental oxygen (if needed).

Promoting Home and Community-Based Care

Teaching Patients Self-Care

When providing instructions about self-management, it is important for the nurse to assess the knowledge of patients and family members about self-care and the therapeutic regimen. The nurse should also consider whether they are comfortable with this knowledge. Familiarity with prescribed medications' potential side effects is essential. In addition, patients and family members need to learn the early signs and symptoms of infection and other complications so that they seek appropriate health care promptly.

NURSING ALERT

Teaching is essential and should be tailored to the stage of COPD.

A major area of teaching involves setting and accepting realistic short-term and long-range goals. If the COPD is mild, the objectives of treatment are to increase exercise tolerance and prevent further loss of pulmonary function. If the COPD is severe, these objectives are to preserve current pulmonary function and relieve symptoms as much as possible. It is important to plan and share the goals and expectations of treatment with the patient. Both the patient and the care provider need patience to achieve these goals.

The nurse instructs the patient to avoid extremes of heat and cold. Heat increases the body temperature, thereby raising oxygen requirements, and cold tends to promote bronchospasm. Air pollutants such as fumes, smoke, dust, and even talcum, lint, and aerosol sprays may initiate bronchospasm. High altitudes aggravate hypoxemia.

A patient with COPD should adopt a lifestyle of moderate activity, ideally in a climate with minimal shifts in temperature and humidity. As much as possible, the patient should avoid emotional disturbances and stressful situations that might trigger a coughing episode. The medication regimen can be quite complex; patients receiving aerosol medications by an MDI or other type of inhaler may be particularly challenged. It is crucial to review educational information and to have the patient demonstrate correct MDI use before discharge, during follow-up visits to a caregiver's office or clinic, and during home visits (Chart 24-4).

Smoking cessation goes hand in hand with lifestyle changes, and reinforcement of the patient's efforts is a key nursing activity. Smoking cessation is the single most important therapeutic intervention for patients with COPD. There are many strategies, including prevention, cessation with or without oral or topical patch medications, and behavior modification techniques.

Numerous educational materials are available to assist nurses in teaching patients with COPD. Potential resources include those of organizations such as the American Lung Association, the American Association of Cardiovascular and Pulmonary Rehabilitation, the American Thoracic Society, the American College of Chest Physicians, and the American Association for Respiratory Therapy.

CHART
24-4

PATIENT EDUCATION

Use of Metered-Dose Inhaler (MDI)

To administer medication:

- Remove the cap and hold the inhaler upright.
- Shake the inhaler.
- Tilt your head back slightly and breathe out slowly and all the way.
- Position the inhaler approximately 1–2 inches away from the open mouth, or use a spacer/holding chamber. When using a medicine chamber, place the lips around the mouthpiece.
- Start breathing in slowly through your mouth, and press down on the inhaler one time. If using a chamber, first

press down on the inhaler and within 5 seconds, begin to breathe in slowly.

- Breathe in slowly and deeply for as long as possible.
- Hold your breath as you count to 10 slowly to allow the medication to reach down into your airways.
- Repeat puffs as directed, allowing 15–30 seconds between puffs for quick-acting medications. There is no need to wait for other medications.
- Apply the cap to the MDI for storage.
- After inhalation, rinse mouth with water when using a corticosteroid-containing MDI.

Expert Panel Report 3. (2007). *Guidelines for the diagnosis and management of asthma*. Bethesda, MD: National Asthma Education and Prevention Program, National Institutes of Health.

Continuing Care

Referral for home care is important to enable the nurse to assess the patient's home environment and physical and psychological status, to evaluate the patient's adherence to a prescribed regimen, and to assess the patient's ability to cope with changes in lifestyle and physical status. Home care visits provide an opportunity to reinforce the information and activities learned in the inpatient or outpatient pulmonary rehabilitation program and to have the patient and family demonstrate correct administration of medications and oxygen, if indicated, and performance of exercises. If the patient does not have access to a formal pulmonary rehabilitation program, it is important to provide the education and breathing retraining necessary to optimize the patient's functional status.

The nurse may direct the patient to community resources such as pulmonary rehabilitation programs and smoking cessation programs to help improve the patient's ability to cope with his or her chronic condition and the therapeutic regimen and to give the patient a sense of worth, hope, and well-being. In addition, the nurse reminds the patient and family about the importance of participating in general health promotion activities and health screening.

It is important to address quality of life and issues surrounding the end of life in patients with end-stage COPD. Patients with COPD have indicated that information about their end-of-life needs is limited. Based on a structured literature review, the following end-of-life care issues are important: symptom management, quality of life, satisfaction with care, information/communication, use of care professionals, use of care facilities, hospital admission, and place of death (Habraken, Willems, de Kort, et al., 2007). It is crucial that patients know what to expect as the disease progresses. In addition, they should have information about their role in decisions regarding aggressiveness of care near the end of life and access to specialists who may help them and their families. As the disease course progresses, a holistic assessment of physical and psychological needs should be undertaken at each hospitalization, clinic visit, or home visit. This helps gauge the patient's assessment of the progression of the disease and its impact on quality of life and guides planning for future interventions and management.

Chart 24-5 provides further information on providing nursing care for the patient with COPD.

Bronchiectasis

Bronchiectasis is a chronic, irreversible dilation of the bronchi and bronchioles. Under the new definition of COPD, it is considered a disease process separate from COPD (GOLD, 2008). Bronchiectasis may be caused by a variety of conditions, including

- Airway obstruction
- Diffuse airway injury
- Pulmonary infections and obstruction of the bronchus or complications of long-term pulmonary infections
- Genetic disorders such as cystic fibrosis
- Abnormal host defense (eg, ciliary dyskinesia or humoral immunodeficiency)
- Idiopathic causes

People may be predisposed to bronchiectasis as a result of recurrent respiratory infections in early childhood, measles, influenza, tuberculosis, or immunodeficiency disorders.

Pathophysiology

The inflammatory process associated with pulmonary infections damages the bronchial wall, causing a loss of its supporting structure and resulting in thick sputum that ultimately obstructs the bronchi. The walls become permanently distended and distorted, impairing mucociliary clearance. In saccular bronchiectasis, each dilated peribronchial tube virtually amounts to a lung abscess, the exudate of which drains freely through the bronchus. Bronchiectasis is usually localized, affecting a segment or lobe of a lung, most frequently the lower lobes.

The retention of secretions and subsequent obstruction ultimately cause the alveoli distal to the obstruction to collapse (atelectasis). Inflammatory scarring or fibrosis replaces functioning lung tissue. In time, the patient develops respiratory insufficiency with reduced vital capacity, decreased ventilation, and an increased ratio of residual volume to total lung capacity. There is impairment in the match of ventilation to perfusion (ventilation–perfusion imbalance) and hypoxemia.

**CHART
24-5**
PLAN OF NURSING CARE
Care of the Patient With COPD
NURSING DIAGNOSIS: Impaired gas exchange and airway clearance due to chronic inhalation of toxins

GOAL: Improvement in gas exchange

Nursing Interventions

1. Evaluate current smoking status, educate regarding smoking cessation, and facilitate efforts to quit.
 - a. Evaluate current smoking habits of patient and family.
 - b. Educate regarding hazards of smoking and relationship to COPD.
 - c. Evaluate previous smoking cessation attempts.
 - d. Provide educational materials.
 - e. Refer to a smoking cessation program or resource.
2. Evaluate current exposure to occupational toxins or pollutants and indoor/outdoor pollution.
 - a. Evaluate current exposures to occupational toxins, indoor and outdoor air pollution (eg, smog, toxic fumes, chemicals).
 - b. Emphasize primary prevention to occupational exposures. This is best achieved by elimination or reduction of exposures in the workplace.
 - c. Educate regarding types of indoor and outdoor air pollution (eg, biomass fuel burned for cooking and heating in poorly ventilated buildings, outdoor air pollution).
 - d. Advise patient to monitor public announcements regarding air quality.

Rationale

1. Smoking causes permanent damage to the lung and diminishes the lungs' protective mechanisms. Airflow is obstructed, secretions are increased, and lung capacity is reduced. Continued smoking increases morbidity and mortality in COPD and is also a risk factor for lung cancer.
2. Chronic inhalation of both indoor and outdoor toxins causes damage to the airways and impairs gas exchange.

Expected Outcomes

- Identifies the hazards of cigarette smoking
- Identifies resources for smoking cessation
- Enrolls in smoking cessation program
- Reports success in stopping smoking
- Verbalizes types of inhaled toxins
- Minimizes or eliminates exposures
- Monitors public announcements regarding air quality and minimizes or eliminates exposures during episodes of severe pollution

NURSING DIAGNOSIS: Impaired gas exchange related to ventilation–perfusion inequality

GOAL: Improvement in gas exchange

Nursing Interventions

1. Administer bronchodilators as prescribed:
 - a. Inhalation is the preferred route.
 - b. Observe for side effects: tachycardia, dysrhythmias, central nervous system excitation, nausea, and vomiting.
 - c. Assess for correct technique of metered-dose inhaler (MDI) or other type of administration.
2. Evaluate effectiveness of nebulizer or MDI treatments.
 - a. Assess for decreased shortness of breath, decreased wheezing or crackles, loosened secretions, and decreased anxiety.
 - b. Ensure that treatment is given before meals to avoid nausea and to reduce fatigue that accompanies eating.

Rationale

1. Bronchodilators dilate the airways. The medication dosage is carefully adjusted for each patient, in accordance with clinical response.
2. Combining medication with aerosolized bronchodilators is typically used to control bronchoconstriction in an acute exacerbation. Generally, however, the MDI with spacer is the preferred route (less cost and time to treatment).

Expected Outcomes

- Verbalizes need for bronchodilators and for taking them as prescribed
- Evidences minimal side effects; heart rate near normal, absence of dysrhythmias, normal mentation
- Reports a decrease in dyspnea
- Shows an improved expiratory flow rate
- Uses and cleans respiratory therapy equipment as applicable
- Demonstrates diaphragmatic breathing and coughing
- Uses oxygen equipment appropriately when indicated
- Evidences improved arterial blood gases or pulse oximetry
- Demonstrates correct technique for use of MDI

 CHART
24-5

PLAN OF NURSING CARE
Care of the Patient With COPD (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 3. Instruct and encourage patient in diaphragmatic breathing and effective coughing. 4. Administer oxygen by the method prescribed. <ol style="list-style-type: none"> a. Explain rationale and importance to patient. b. Evaluate effectiveness; observe for signs of hypoxemia. Notify physician if restlessness, anxiety, somnolence, cyanosis, or tachycardia is present. c. Analyze arterial blood gases and compare with baseline values. When arterial puncture is performed and a blood sample is obtained, hold puncture site for 5 minutes to prevent arterial bleeding and development of ecchymoses. d. Initiate pulse oximetry to monitor oxygen saturation. e. Explain that no smoking is permitted by patient or visitors while oxygen is in use. 	<ol style="list-style-type: none"> 3. These techniques improve ventilation by opening airways to facilitate clearing the airways of sputum. Gas exchange is improved and fatigue is minimized. 4. Oxygen will correct the hypoxemia. Careful observation of the liter flow or the percentage administered and its effect on the patient is important. These patients generally require low-flow oxygen rates of 1 to 2 L/min. Monitor and titrate to achieve desired PaO₂. Periodic arterial blood gases and pulse oximetry help evaluate adequacy of oxygenation. Smoking may render pulse oximetry inaccurate because the carbon monoxide from cigarette smoke also saturates hemoglobin. 	
<p>NURSING DIAGNOSIS: Ineffective airway clearance related to bronchoconstriction, increased mucus production, ineffective cough, bronchopulmonary infection, and other complications</p> <p>GOAL: Achievement of airway clearance</p>		
Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Adequately hydrate the patient. 2. Teach and encourage the use of diaphragmatic breathing and coughing techniques. 3. Assist in administering nebulizer or MDI. 4. If indicated, perform postural drainage with percussion and vibration in the morning and at night as prescribed. 5. Instruct patient to avoid bronchial irritants such as cigarette smoke, aerosols, extremes of temperature, and fumes. 6. Teach early signs of infection that are to be reported to the clinician immediately: <ol style="list-style-type: none"> a. Increased sputum production b. Change in color of sputum c. Increased thickness of sputum d. Increased shortness of breath, tightness in chest, or fatigue e. Increased coughing f. Fever or chills 	<ol style="list-style-type: none"> 1. Systemic hydration keeps secretions moist and easier to expectorate. Fluids must be given with caution if right- or left-sided heart failure is present. 2. These techniques help to improve ventilation and mobilize secretions without causing breathlessness and fatigue. 3. This ensures adequate delivery of medication to the airways. 4. This uses gravity to help raise secretions so they can be more easily expectorated or suctioned. 5. Bronchial irritants cause bronchoconstriction and increased mucus production, which then interfere with airway clearance. 6. Minor respiratory infections that are of no consequence to the person with normal lungs can produce fatal disturbances in the lungs of the person with emphysema. Early recognition is crucial. 	<ul style="list-style-type: none"> • Verbalizes need to drink fluids • Demonstrates diaphragmatic breathing and coughing • Performs postural drainage correctly • Coughing is minimized • Does not smoke • Verbalizes that pollens, fumes, gases, dusts, and extremes of temperature and humidity are irritants to be avoided • Identifies signs of early infection • Is free of infection (no fever, no change in sputum, lessening of dyspnea) • Verbalizes need to notify health care provider at the earliest sign of infection • Verbalizes need to stay away from crowds or people with colds in flu season • Discusses flu and pneumonia vaccines with clinician to help prevent infection

Continued

**CHART
24-5**
PLAN OF NURSING CARE**Care of the Patient With COPD (Continued)****Nursing Interventions**

7. Administer antibiotics as prescribed.
8. Encourage patient to be immunized against influenza and *Streptococcus pneumoniae*.

Rationale

7. Antibiotics may be prescribed to prevent or treat infection.
8. People with respiratory conditions are prone to respiratory infections and are encouraged to be immunized.

Expected Outcomes

NURSING DIAGNOSIS: Ineffective breathing pattern related to shortness of breath, mucus, bronchoconstriction, and airway irritants

GOAL: Improvement in breathing pattern

Nursing Interventions

1. Teach patient diaphragmatic and pursed-lip breathing.
2. Encourage alternating activity with rest periods. Allow patient to make some decisions (bath, shaving) about care based on tolerance level.
3. Encourage use of an inspiratory muscle trainer if prescribed.

Rationale

1. This helps patient prolong expiration time and decreases air trapping. With these techniques, patient will breathe more efficiently and effectively.
2. Pacing activities permit patient to perform activities without excessive distress.
3. This strengthens and conditions the respiratory muscles.

Expected Outcomes

- Practices pursed-lip and diaphragmatic breathing and uses them when short of breath and with activity
- Shows signs of decreased respiratory effort and paces activities
- Uses inspiratory muscle trainer as prescribed

NURSING DIAGNOSIS: Self-care deficits related to fatigue secondary to increased work of breathing and insufficient ventilation and oxygenation

GOAL: Independence in self-care activities

Nursing Interventions

1. Teach patient to coordinate diaphragmatic breathing with activity (eg, walking, bending).
2. Encourage patient to begin to bathe self, dress self, walk, and drink fluids. Discuss energy conservation measures.
3. Teach postural drainage if appropriate.

Rationale

1. This will allow the patient to be more active and to avoid excessive fatigue or dyspnea during activity.
2. As condition resolves, patient will be able to do more but needs to be encouraged to avoid increasing dependence.
3. This encourages patient to become involved in own care and prepares patient to manage at home.

Expected Outcomes

- Uses controlled breathing while bathing, bending, and walking
- Paces activities of daily living to alternate with rest periods to reduce fatigue and dyspnea
- Describes energy conservation strategies
- Performs same self-care activities as before
- Performs postural drainage correctly

NURSING DIAGNOSIS: Activity intolerance due to fatigue, hypoxemia, and ineffective breathing patterns

GOAL: Improvement in activity tolerance

Nursing Interventions

1. Support patient in establishing a regular regimen of exercise using treadmill and exercise bicycle, walking, or other appropriate exercises, such as mall walking.
 - a. Assess the patient's current level of functioning and develop exercise plan based on baseline functional status.
 - b. Suggest consultation with a physical therapist or pulmonary rehabilitation program to determine an exercise program specific to the patient's capability. Have portable oxygen unit available if oxygen is prescribed for exercise.

Rationale

1. Muscles that are deconditioned consume more oxygen and place an additional burden on the lungs. Through regular, graded exercise, these muscle groups become more conditioned, and the patient can do more without getting as short of breath. Graded exercise breaks the cycle of debilitation.

Expected Outcomes

- Performs activities with less shortness of breath
- Verbalizes need to exercise daily and demonstrates an exercise plan to be carried out at home
- Walks and gradually increases walking time and distance to improve physical condition
- Exercises both upper and lower body muscle groups

Continued on following page

 CHART
24-5

PLAN OF NURSING CARE
Care of the Patient With COPD (Continued)

NURSING DIAGNOSIS: Ineffective coping related to reduced socialization, anxiety, depression, lower activity level, and the inability to work

GOAL: Attainment of an optimal level of coping

Nursing Interventions

1. Help the patient develop realistic goals.
2. Encourage activity to level of symptom tolerance.
3. Teach relaxation technique or provide a relaxation tape for patient.
4. Enroll patient in pulmonary rehabilitation program where available.

Rationale

1. Developing realistic goals will promote a sense of hope and accomplishment rather than defeat and hopelessness.
2. Activity reduces tension and decreases degree of dyspnea as patient becomes conditioned.
3. Relaxation reduces stress, anxiety, and dyspnea and helps patient to cope with disability.
4. Pulmonary rehabilitation programs have been shown to promote a subjective improvement in a patient's status and self-esteem as well as increased exercise tolerance and decreased hospitalizations.

Expected Outcomes

- Expresses interest in the future
- Participates in the discharge plan
- Discusses activities or methods that can be performed to ease shortness of breath
- Uses relaxation techniques appropriately
- Expresses interest in a pulmonary rehabilitation program

NURSING DIAGNOSIS: Deficient knowledge about self-management to be performed at home

GOAL: Adherence to therapeutic program and home care

Nursing Interventions

1. Help patient identify/develop short- and long-term goals.
 - a. Teach the patient about disease, medications, procedures, and how and when to seek help.
 - b. Refer patient to pulmonary rehabilitation.
2. Give strong message to stop smoking. Discuss smoking cessation strategies. Provide information about resource groups (eg, SmokEnders, American Cancer Society, American Lung Association).

Rationale

1. Patient needs to be a partner in developing the plan of care and needs to know what to expect. Teaching about the condition is one of the most important aspects of care; it will prepare the patient to live and cope with the condition and improve quality of life.
2. Smoking causes permanent damage to the lung and diminishes the lungs' protective mechanisms. Air flow is obstructed and lung capacity is reduced. Smoking increases morbidity and mortality and is also a risk factor for lung cancer.

Expected Outcomes

- Understands disease and what affects it
- Verbalizes the need to preserve existing lung function by adhering to the prescribed program
- Understands purposes and proper administration of medications
- Stops smoking or enrolls in a smoking cessation program
- Identifies when and whom to call for assistance

COLLABORATIVE PROBLEM: Atelectasis

GOAL: Absence of atelectasis on x-ray and physical examination

Nursing Interventions

1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, signs and symptoms of respiratory distress, and pulse oximetry.
2. Instruct in and encourage diaphragmatic breathing and effective coughing techniques.
3. Promote use of lung expansion techniques (eg, deep-breathing exercises, incentive spirometry) as prescribed.

Rationale

1. A change in respiratory status, including tachypnea, dyspnea, and diminished or absent breath sounds, may indicate atelectasis.
2. These techniques improve ventilation and lung expansion and ideally improve gas exchange.
3. Deep-breathing exercises and incentive spirometry promote maximal lung expansion.

Expected Outcomes

- Normal (baseline for patient) respiratory rate and pattern
- Normal breath sounds for patient
- Demonstrates diaphragmatic breathing and effective coughing
- Performs deep-breathing exercises, incentive spirometry as prescribed
- Pulse oximetry is $\geq 90\%$

Continued

CHART
24-5

PLAN OF NURSING CARE

Care of the Patient With COPD (Continued)

COLLABORATIVE PROBLEM: Pneumothorax

GOAL: Absence of signs and symptoms of pneumothorax

Nursing Interventions

1. Monitor respiratory status, including rate and pattern of respirations, symmetry of chest wall movement, breath sounds, signs and symptoms of respiratory distress, and pulse oximetry.
2. Assess pulse.
3. Assess for chest pain and precipitating factors.
4. Palpate for tracheal deviation/ shift away from the affected side.
5. Monitor pulse oximetry and, if indicated, arterial blood gases.
6. Administer supplemental oxygen therapy, as indicated.
7. Administer analgesics agents, as indicated, for chest pain.
8. Assist with chest tube insertion and use pleural drainage system, as prescribed.

Rationale

1. Dyspnea, tachypnea, tachycardia, acute pleuritic chest pain, tracheal deviation away from the affected side, absence of breath sounds on the affected side, and decreased tactile fremitus may indicate pneumothorax.
2. Tachycardia is associated with pneumothorax and anxiety.
3. Pain may accompany pneumothorax.
4. Early detection of pneumothorax and prompt intervention will prevent other serious complications.
5. Recognition of a deterioration in respiratory function will prevent serious complications.
6. Oxygen will correct hypoxemia; administer it with caution.
7. Pain interferes with deep breathing, resulting in a decrease in lung expansion.
8. Removal of air from the pleural space will re-expand the lung.

Expected Outcomes

- Normal respiratory rate and pattern for patient
- Normal breath sounds bilaterally
- Normal pulse for patient
- Normal tactile fremitus
- Absence of pain
- Tracheal position is midline
- Pulse oximetry $\geq 90\%$
- Maintains normal oxygen saturation and arterial blood gas measurements
- Exhibits no hypoxemia and hypercapnia (or returns to baseline values)
- Absence of pain
- Symmetric chest wall movement
- Lung is re-expanded on chest x-ray
- Breath sounds are heard on the affected side

COLLABORATIVE PROBLEM: Respiratory failure

GOAL: Absence of signs and symptoms of respiratory failure; no evidence of respiratory failure on laboratory tests

Nursing Interventions

1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, and signs and symptoms of acute respiratory distress.
2. Monitor pulse oximetry and arterial blood gases.
3. Administer supplemental oxygen and initiate mechanisms for mechanical ventilation, as prescribed.

Rationale

1. Early recognition of a deterioration in respiratory function will avert further complications, such as respiratory failure, severe hypoxemia, and hypercapnia.
2. Recognition of changes in oxygenation and acid-base balance will guide in correcting and preventing complications.
3. Acute respiratory failure is a medical emergency. Hypoxemia is a hallmark sign. Administration of oxygen therapy and mechanical ventilation (if indicated) are critical to survival.

Expected Outcomes

- Normal respiratory rate and pattern for patient with no acute distress
- Recognizes symptoms of hypoxemia and hypercapnia
- Maintains normal arterial blood gases/pulse oximetry or returns to baseline values

COLLABORATIVE PROBLEM: Pulmonary arterial hypertension

GOAL: Absence of evidence of pulmonary arterial hypertension on physical examination or laboratory tests

Nursing Interventions

1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, pulse oximetry, and signs and symptoms of acute respiratory distress.
2. Assess for signs and symptoms of right-sided heart failure, including peripheral edema, ascites, distended neck veins, crackles, and heart murmur.
3. Administer oxygen therapy, as prescribed.

Rationale

1. Dyspnea is the primary symptom of pulmonary arterial hypertension. Other symptoms include fatigue, angina, near syncope, edema, and palpitations.
2. Right-sided heart failure is a common clinical manifestation of pulmonary arterial hypertension due to increased right ventricular workload.
3. Continuous oxygen therapy is a major component of management of pulmonary arterial hypertension by preventing hypoxemia and thereby reducing pulmonary vascular constriction (resistance) secondary to hypoxemia.

Expected Outcomes

- Normal respiratory rate and pattern for patient
- Exhibits no signs and symptoms of right-sided failure
- Maintains baseline pulse oximetry values and arterial blood gases

Clinical Manifestations

Characteristic symptoms of bronchiectasis include chronic cough and the production of purulent sputum in copious amounts. Many patients with this disease have hemoptysis. Clubbing of the fingers also is common because of respiratory insufficiency. Patients usually have repeated episodes of pulmonary infection. Even with modern treatment approaches, the average age at death is approximately 55 years.

Assessment and Diagnostic Findings

Bronchiectasis is not readily diagnosed because the symptoms can be mistaken for those of simple chronic bronchitis. A definite sign is a prolonged history of productive cough, with sputum consistently negative for tubercle bacilli. The diagnosis is established by a CT scan, which reveals bronchial dilation.

Medical Management

Treatment objectives are to promote bronchial drainage to clear excessive secretions from the affected portion of the lungs and to prevent or control infection. Postural drainage is part of all treatment plans, because draining of the bronchiectatic areas by gravity reduces the amount of secretions and the degree of infection. Sometimes mucopurulent sputum must be removed by bronchoscopy. Chest physiotherapy, including percussion and postural drainage, is important in the management of secretions. Smoking cessation is important, because smoking impairs bronchial drainage by paralyzing ciliary action, increasing bronchial secretions, and causing inflammation of the mucous membranes, resulting in hyperplasia of the mucous glands.

Antimicrobial therapy based on the results of sensitivity studies on organisms cultured from sputum is used to control infection. A year-round regimen of antibiotic agents may be prescribed, with different types of antibiotics at intervals. Some clinicians prescribe antibiotic agents throughout the winter or when acute upper respiratory tract infections occur. Patients should be vaccinated against influenza and pneumococcal pneumonia. Bronchodilators, which may be prescribed for patients who also have reactive airway disease, may also assist with secretion management.

Surgical intervention, although used infrequently, may be indicated for patients who continue to expectorate large amounts of sputum and have repeated bouts of pneumonia and hemoptysis despite adherence to treatment regimens. The disease must involve only one or two areas of the lung that can be removed without producing respiratory insufficiency. The goals of surgical treatment are to conserve normal pulmonary tissue and to avoid infectious complications. Diseased tissue is removed, provided that postoperative lung function will be adequate. It may be necessary to remove a segment of a lobe (segmental resection), a lobe (lobectomy), or rarely an entire lung (pneumonectomy). (See Chart 25-18 in Chapter 25 for further information.) Segmental resection is the removal of an anatomic subdivision of a pulmonary lobe. The chief advantage is that only diseased tissue is removed, and healthy lung tissue is conserved.

The surgery is preceded by a period of careful preparation. The objective is to obtain a dry (free of infection) tracheobronchial tree to prevent complications (atelectasis,

pneumonia, bronchopleural fistula, and empyema). This is accomplished by postural drainage or, depending on the location, by direct suction through a bronchoscope. A course of antibacterial therapy may be prescribed. After surgery, care is the same as for any patient who has undergone chest surgery (see Chapter 25).

Nursing Management

Nursing management focuses on alleviating symptoms and helping patients clear pulmonary secretions. Patient teaching targets smoking and other factors that increase the production of mucus and hamper its removal. Patients and families are taught to perform postural drainage and to avoid exposure to people with upper respiratory or other infections. If the patient experiences fatigue and dyspnea, he or she is informed about strategies to conserve energy while maintaining as active a lifestyle as possible. The patient is taught about the early signs of respiratory infection and the progression of the disorder, so that appropriate treatment can be implemented promptly. The presence of a large amount of mucus may decrease the patient's appetite and result in an inadequate dietary intake; therefore, the patient's nutritional status is assessed and strategies are implemented to ensure an adequate diet.

Asthma

Asthma is a chronic inflammatory disease of the airways that causes airway hyperresponsiveness, mucosal edema, and mucus production. This inflammation ultimately leads to recurrent episodes of asthma symptoms: cough, chest tightness, wheezing, and dyspnea (Fig. 24-6). In the United

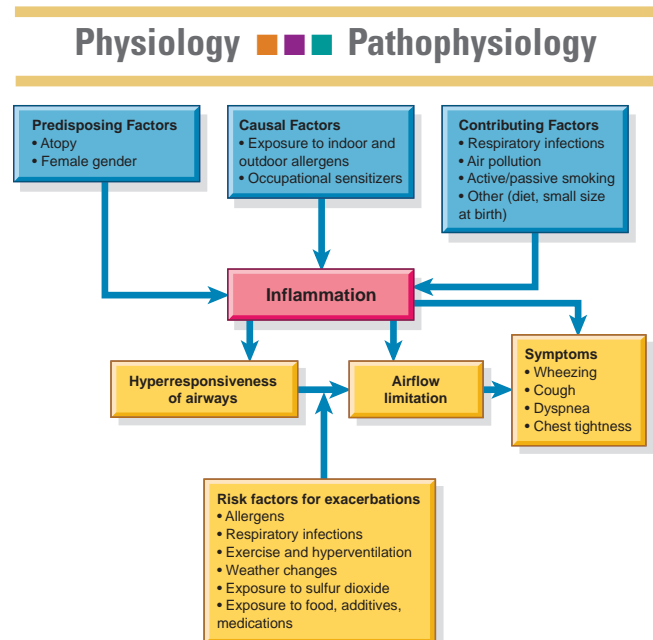

Figure 24-6 Pathophysiology of asthma. Adapted from materials developed for the Global Initiative for Asthma (GINA). *Global Strategy for Asthma Management and Prevention*, Global Initiative for Asthma (GINA) 2008. Available from: <http://www.ginasthma.org>.

States, asthma affects more than 22 million people (Expert Panel Report 3, 2007). Asthma accounts for more than 497,000 hospitalizations annually (Agency for Healthcare Research and Quality [AHRQ, 2007]). The total economic cost of asthma exceeds \$27.6 billion (AHRQ, 2007).

The most common chronic disease of childhood, asthma can occur at any age. For most patients, asthma is a disruptive disease, affecting school and work attendance, occupational choices, physical activity, and general quality of life.

Despite increased knowledge regarding the pathology of asthma and the development of improved medications and management plans, the death rate from the disease continues to rise. Ethnic and racial disparities affect morbidity and mortality in asthma, which are higher in inner-city African Americans and Latinos (Wright & Subramanian, 2007). Contributing to these disparities are epidemiology and risk factors; genetics and molecular aspects; inner-city environments; limited community assets; health care access, delivery, and quality; and lack of insurance coverage.

Unlike other obstructive lung diseases, asthma is largely reversible, either spontaneously or with treatment. Patients with asthma may experience symptom-free periods alternating with acute exacerbations that last from minutes to hours or days.

Allergy is the strongest predisposing factor for asthma. Chronic exposure to airway irritants or allergens also increases the risk of asthma. Common allergens can be seasonal (grass, tree, and weed pollens) or perennial (eg, mold, dust, roaches, animal dander). Common triggers for asthma symptoms and exacerbations include airway irritants (eg, air pollutants, cold, heat, weather changes, strong odors or perfumes, smoke), exercise, stress or emotional upset, rhinosinusitis with postnasal drip, medications, viral respiratory tract infections, and gastroesophageal reflux. Most people who have asthma are sensitive to a variety of triggers.

Pathophysiology

The underlying pathology in asthma is reversible and diffuse airway inflammation that leads to airway narrowing. This narrowing, which is exacerbated by a variety of changes in the airway, includes bronchoconstriction, airway edema, airway hyperresponsiveness, and airway remodeling. The interaction of these factors determines the clinical manifestations and severity of asthma (Expert Panel Report 3, 2007).

Mast cells, neutrophils, eosinophils, and lymphocytes play a key role in the inflammation of asthma. When activated, mast cells release several chemicals called mediators. These chemicals, which include histamine, bradykinin, prostaglandins, and leukotrienes, perpetuate the inflammatory response, causing increased blood flow, vasoconstriction, fluid leak from the vasculature, attraction of white blood cells to the area, and bronchoconstriction (Expert Panel Report 3, 2007).

In acute exacerbations of asthma, bronchial smooth muscle contraction or bronchoconstriction occurs quickly to narrow the airway in response to an exposure. Acute bronchoconstriction due to allergens results from an immunoglobulin E (IgE)-dependent release of mediators from mast cells; these mediators include histamine, tryptase, leukotrienes, and prostaglandins that directly contract the

airway. There are also non-IgE-mediated responses and proinflammatory cytokines (Expert Panel Report 3, 2007). In addition, alpha- and beta₂-adrenergic receptors of the sympathetic nervous system located in the bronchi play a role. When the alpha-adrenergic receptors are stimulated, bronchoconstriction occurs. When the beta₂-adrenergic receptors are stimulated, bronchodilation occurs. The balance between alpha- and beta₂-adrenergic receptors is controlled primarily by cyclic 3',5'-adenosine monophosphate (cAMP). Beta₂-adrenergic stimulation results in increased levels of cAMP, which inhibits the release of chemical mediators and causes bronchodilation.

As asthma becomes more persistent, the inflammation progresses and other factors may be involved in airflow limitation. These include airway edema, mucus hypersecretion, and the formation of mucous plugs. Also, airway “remodeling” may occur in response to chronic inflammation, causing further airway narrowing.

Clinical Manifestations

The three most common symptoms of asthma are cough, dyspnea, and wheezing. In some instances, cough may be the only symptom. An asthma attack often occurs at night or early in the morning, possibly because of circadian variations that influence airway receptor thresholds.

An asthma exacerbation may begin abruptly but most frequently is preceded by increasing symptoms over the previous few days. There is cough, with or without mucus production. At times, the mucus is so tightly wedged in the narrowed airway that the patient cannot cough it up. There may be generalized wheezing (the sound of airflow through narrowed airways), first on expiration and then possibly during inspiration as well. Generalized chest tightness and dyspnea occur. Expiration requires effort and becomes prolonged. As the exacerbation progresses, diaphoresis, tachycardia, and a widened pulse pressure may occur along with hypoxemia and central cyanosis (a late sign of poor oxygenation). Although severe, life-threatening hypoxemia can occur in asthma, it is relatively uncommon. The hypoxemia is secondary to a ventilation-perfusion mismatch and readily responds to supplemental oxygenation.

Symptoms of exercise-induced asthma include maximal symptoms during exercise, absence of nocturnal symptoms, and sometimes only a description of a “choking” sensation during exercise.

Assessment and Diagnostic Findings

To establish the diagnosis, the clinician must determine that episodic symptoms of airflow obstruction are present, airflow is at least partially reversible, and other causes have been excluded. A positive family history and environmental factors, including seasonal changes, high pollen counts, mold, pet dander, climate changes (particularly cold air), and air pollution, are primarily associated with asthma. In addition, asthma is associated with a variety of occupation-related chemicals and compounds. Comorbid conditions that may accompany asthma include gastroesophageal reflux disease (GERD), drug-induced asthma, and allergic bronchopulmonary aspergillosis. Other possible allergic reactions that may accompany asthma include eczema, rashes, and temporary edema.

During acute episodes, sputum and blood tests may disclose eosinophilia (elevated levels of eosinophils). Serum levels of IgE may be elevated if allergy is present. Arterial blood gas analysis and pulse oximetry reveal hypoxemia during acute attacks. Initially, hypocapnia and respiratory alkalosis are present. As the patient's condition worsens and he or she becomes more fatigued, the PaCO₂ may increase. Because carbon dioxide is 20 times more diffusible than oxygen, it is rare for PaCO₂ to be normal or elevated in a person who is breathing very rapidly.

NURSING ALERT

Normal PaCO₂ during an asthma attack may be a signal of impending respiratory failure.

During an exacerbation, the FEV₁ and FVC are markedly decreased but improve with bronchodilator administration (demonstrating reversibility). Pulmonary function is usually normal between exacerbations. The occurrence of a severe, continuous reaction is referred to as status asthmaticus and is considered life-threatening (see later discussion).

Asthma severity is considered in the selection of the initial type, amount, and schedule of treatment (Expert Panel Report 3, 2007). The severity of disease is classified by current impairment and future risk of adverse events. Impairment is defined by the following factors: nighttime awakenings, need for short-acting bronchodilators for relief of symptoms, work/school days missed, ability to engage in normal activities, and quality of life. Lung function is evaluated by spirometry. Assessment of risk of future adverse events is evaluated by numbers of exacerbations, need for emergency department care or hospitalizations in the past year, demographic data (gender, ethnicity, nonuse of prescribed inhaled corticosteroid therapy, existing smoking), psychosocial factors and attitudes, and beliefs about taking medication (Expert Panel Report 3, 2007).

Prevention

Patients with recurrent asthma should undergo tests to identify the substances that precipitate the symptoms. Possible causes are dust, dust mites, roaches, certain types of cloth, pets, horses, detergents, soaps, certain foods, molds, and pollens. If the attacks are seasonal, pollens can be strongly suspected. Patients are instructed to avoid the causative agents whenever possible. Knowledge is the key to quality asthma care. Evaluation of impairment and risk are key in the control.

Complications

Complications of asthma may include status asthmaticus, respiratory failure, pneumonia, and atelectasis. Airway obstruction, particularly during acute asthmatic episodes, often results in hypoxemia, requiring the administration of oxygen and the monitoring of pulse oximetry and arterial blood gases. Fluids are administered, because people with asthma are frequently dehydrated from diaphoresis and insensible fluid loss with hyperventilation.

Medical Management

Immediate intervention may be necessary, because continuing and progressive dyspnea leads to increased anxiety, aggravating the situation. The Expert Panel 3 Guidelines for

the Diagnosis and Management of Asthma (2007) are based on the concept of severity and control of asthma along with the domains of impairment and risk as keys to improving care. Primary concerns in the treatment of patients are impairment of lung function and normal life and risk of exacerbations, decline in lung function, and adverse effects from medications (Expert Panel Report 3, 2007).

Pharmacologic Therapy

Figure 24-7 shows the pharmacologic treatment of asthma using a stepwise approach. There are two general classes of asthma medications: quick-relief medications for immediate treatment of asthma symptoms and exacerbations and long-acting medications to achieve and maintain control of persistent asthma (Tables 24-3 and 24-4). Because the underlying pathology of asthma is inflammation, control of persistent asthma is accomplished primarily with regular use of anti-inflammatory medications. These medications have systemic side effects when used over the long term. The route of choice for administration of these medications is an MDI or other type of inhaler, because it allows for topical administration (see Chart 24-4 and Table 24-1).

Quick-Relief Medications

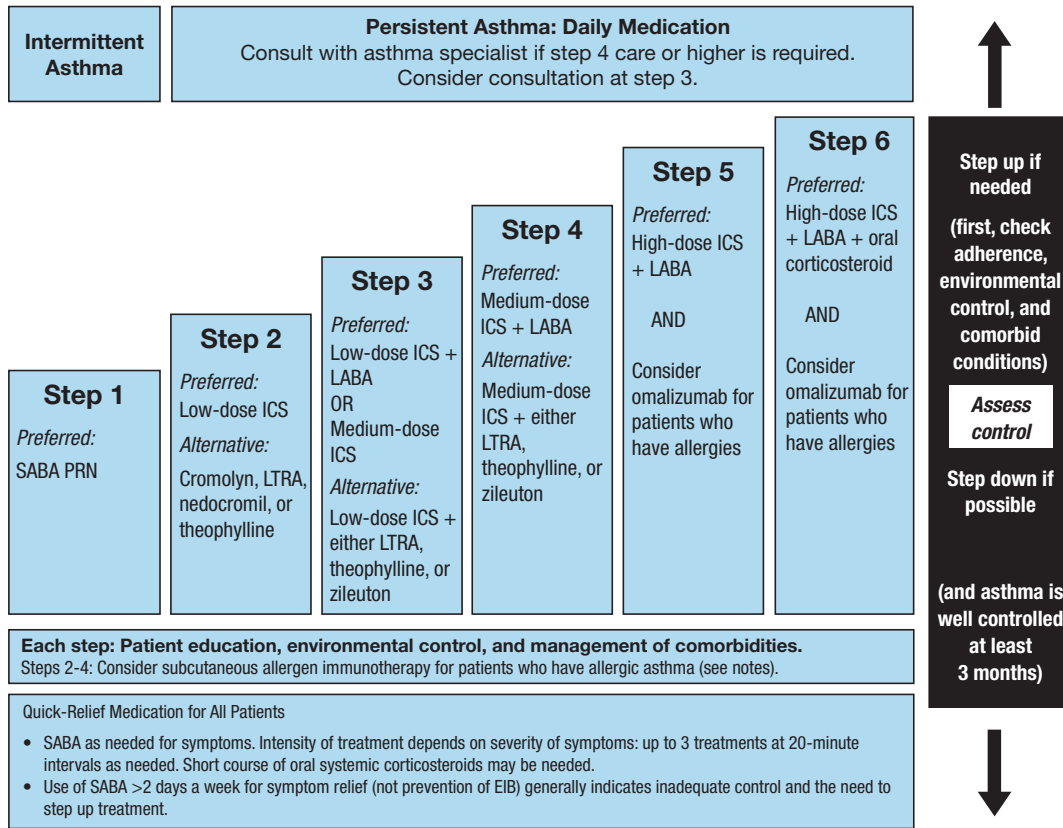

Short-acting beta₂-adrenergic agonists (albuterol [Proventil, Ventolin], levalbuterol [Xopenex], and pirbuterol [Maxair]) are the medications of choice for relief of acute symptoms and prevention of exercise-induced asthma. They are used to relax smooth muscle.

Anticholinergics (eg, ipratropium bromide [Atrovent]) inhibit muscarinic cholinergic receptors and reduce intrinsic vagal tone of the airway. These may be used in patients who do not tolerate short-acting beta₂-adrenergic agonists.

Long-Acting Control Medications

Corticosteroids are the most potent and effective anti-inflammatory medications currently available. They are broadly effective in alleviating symptoms, improving airway function, and decreasing peak flow variability. Initially, an inhaled form is used. A spacer should be used with inhaled corticosteroids, and patients should rinse their mouth after administration to prevent thrush, a common complication associated with use of inhaled corticosteroids. A systemic preparation may be used to gain rapid control of the disease; to manage severe, persistent asthma; to treat moderate to severe exacerbations; to accelerate recovery; and to prevent recurrence. Cromolyn sodium (Crolom, NasalCrom) and nedocromil (Alocril, Tilade) are mild to moderate anti-inflammatory agents and are considered alternative medications for treatment. These medications stabilize mast cells. They also are effective on a prophylactic basis to prevent exercise-induced asthma or in unavoidable exposure to known triggers. These medications are contraindicated in acute asthma exacerbations.

Long-acting beta₂-adrenergic agonists are used with anti-inflammatory medications to control asthma symptoms, particularly those that occur during the night. These agents are also effective in the prevention of exercise-induced asthma. Long-acting beta₂-adrenergic agonists are not indicated for immediate relief of symptoms. Theophylline (Slo-Bid, Theo-Dur) is a mild to moderate bronchodilator that is

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, inhaled long-acting beta₂-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta₂-agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Steps 1, 2, and 3 preferred therapies are based on evidence A; step 3 alternative therapy is based on evidence A for LTRA, evidence B for theophylline, and evidence D for zileuton. Step 4 preferred therapy is based on evidence B, and alternative therapy is based on evidence B for LTRA and theophylline and evidence D for zileuton. Step 5 preferred therapy is based on evidence B. Step 6 preferred therapy is based on (EPR—2 1997) and evidence B for omalizumab.
- Immunotherapy for steps 2-4 is based on evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

Figure 24-7 Stepwise approach for managing asthma in youths 12 years of age and older and adults. Redrawn from Expert Panel Report 3. (2007). *Guidelines for the diagnosis and management of asthma* (p. 343). NIH Publication Number 08-5846. National Asthma Education and Prevention Program. Summary Report. Bethesda, MD: U.S. Department of Health and Human Services, National Heart, Lung and Blood Institute.

Table 24-3 LONG-TERM MEDICATIONS FOR TREATMENT OF ASTHMA (CONTROLLER MEDICATIONS)			
Medication	Indications/Mechanisms	Potential Adverse Effects	Nursing Considerations
Inhaled Corticosteroids (ICs)			
beclomethasone dipropionate (QVAR) beclomethasone (Beconase-AQ) budesonide (Pulmicort) ciclesonide (Alvesco) flunisolide (AeroBid) fluticasone (Flovent) mometasone furoate (Asmanex) triamcinolone acetonide (Azmacort)	<p><i>Indications</i> Long-term prevention of symptoms; suppression, control, and reversal of inflammation Reduce need for oral corticosteroid.</p> <p><i>Mechanisms</i> Anti-inflammatory. Block late reaction to allergen and reduce airway hyperresponsiveness. Inhibit cytokine production, adhesion protein activation, and inflammatory cell migration and activation. Reverse beta-2 receptor down-regulation. Inhibit microvascular leakage.</p>	Cough, dysphonia, oral thrush (candidiasis), headache. In high doses, systemic effects may occur (eg, adrenal suppression, osteoporosis, skin thinning, and easy bruising).	Instruct patient in correct use of metered-dose inhaler (MDI) and use of spacer/holding chamber devices. Instruct patient to rinse mouth after inhalation to reduce local side effects.
Systemic Corticosteroids			
methylprednisolone (Medrol) prednisolone (Prelone) prednisone (Deltasone, Orasone)	<p><i>Indications</i> For short-term (3–10 days) “burst” to gain prompt control of inadequately controlled persistent asthma. For long-term prevention of symptoms in severe persistent asthma: suppression, control, and reversal of inflammation.</p> <p><i>Mechanisms</i> Same as inhaled corticosteroids.</p>	<p>Short-term use: reversible abnormalities in glucose metabolism, increased appetite, fluid retention, weight gain, mood alteration, hypertension, peptic ulcer, and rarely aseptic necrosis.</p> <p>Long-term use: adrenal axis suppression, growth suppression, dermal thinning, hypertension, diabetes, Cushing’s syndrome, cataracts, muscle weakness, and—in rare instances—impaired immune function. Consideration should be given to comorbidities that could be worsened by systemic corticosteroids.</p>	Instruct patient about possible side effects and the importance of taking the medication as prescribed (usually a single dose in the morning daily or on an alternate-day schedule, which may produce less adrenal suppression).
Long-Acting Beta₂-Agonists (LABAs)			
<p><i>Inhaled:</i> salmeterol (Serevent Diskus) formoterol (Foradil Aerolizer)</p> <p><i>Oral:</i> albuterol (Proventil) sustained-release</p>	<p><i>Indications</i> Long-term prevention of symptoms, added to ICS. Prevention of exercise-induced bronchospasm.</p> <p><i>Mechanisms</i> Bronchodilation. Smooth muscle relaxation following adenylate cyclase activation and increase in cyclic AMP, producing functional antagonism of bronchoconstriction. Compared to SABA, salmeterol (but not formoterol) has slower onset of action (15–30 min). Both salmeterol and formoterol have longer duration (>12 h) compared to SABA.</p>	<p>Should <i>not</i> be used to treat acute symptoms or exacerbations. Decreased protection against exercise-induced bronchospasm may occur with regular use. Tachycardia, muscle tremor, hypokalemia, ECG changes with overdose. A diminished bronchoprotective effect may occur within 1 wk of chronic therapy. Potential risk of uncommon, severe, life-threatening or fatal exacerbation.</p> <p>Inhaled route is preferred to oral route because LABAs are longer acting and have fewer side effects than oral sustained-release agents.</p>	Reinforce to patient that these medications should <i>not</i> be used to treat acute asthma symptoms or exacerbations. Instruct patient about correct use of MDI or aerolizer inhaler.
Methylxanthines			
theophylline (Theo-Dur) sustained-release tablets and capsules	<p><i>Indications</i> Long-term control and prevention of symptoms in mild persistent asthma or as adjunctive with ICS, in moderate or persistent asthma.</p>	Dose-related acute toxicities include tachycardia, nausea and vomiting, tachyarrhythmias (SVT), central nervous system stimulation, headache, seizures, hematemesis, hyperglycemia, and hypokalemia.	Maintain steady-state serum concentrations between 5 and 15 µg/mL.

Continued

Table 24-3

**LONG-TERM MEDICATIONS FOR TREATMENT OF ASTHMA
(CONTROLLER MEDICATIONS) (Continued)**

Medication	Indications/Mechanisms	Potential Adverse Effects	Nursing Considerations
	<p><i>Mechanisms</i> Bronchodilation. Smooth muscle relaxation from phosphodiesterase inhibition and possibly adenosine antagonism. May affect eosinophilic infiltration into bronchial mucosa as well as decrease T-lymphocyte numbers in epithelium. Increases diaphragm contractility and mucociliary clearance.</p>	<p>Adverse effects at usual therapeutic doses include insomnia, gastric upset, aggravation of ulcer or reflux, difficulty in urination in elderly males who have prostatism. Not generally recommended for exacerbations. There is minimal evidence for added benefit to optimal doses of SABA. Serum concentration monitoring is mandatory. Available as sustained-release tablets and capsules.</p>	<p>Absorption and metabolism may be affected by numerous factors that can produce significant changes in steady-state serum theophylline concentrations. Instruct patients to discontinue if they experience toxicity. Inform patients about the importance of blood tests to monitor serum concentration. Instruct patient to check with primary health care provider before taking any new medication.</p>
Combined Medication			
fluticasone/salmeterol (Advair)	<p>DPI 100 µg/50 µg 250 µg/50 µg 500 µg/50 µg</p>	<p>Lowest dose of DPI or HFA used for patients whose asthma is not controlled on low- to medium-dose ICS.</p>	
budesonide/formoterol (Symbicort)	<p>HFA 45 µg/21 µg 115 µg/21 µg 230 µg/21 µg HFA MDI 80 µg/4.5 µg 160 µg/4.5 µg</p>	<p>Higher doses of DPI or HFA used for patients whose asthma is not controlled on medium- to high-dose ICS. Lower dose used for patients who have asthma not controlled on low- to medium-dose ICS. Higher dose used for patients who have asthma not controlled on medium- to high-dose ICS.</p>	
Cromolyn and Nedocromil			
Cromolyn sodium (Intal)	<p><i>Indications</i> Long-term prevention of symptoms in mild persistent asthma; may modify inflammation. Preventive treatment prior to exposure to exercise or known allergen.</p>	<p>Cough and irritation. 15–20% of patients complain of an unpleasant taste from nedocromil. Dose of cromolyn by MDI may be inadequate to affect airway hyperresponsiveness. Nebulizer delivery may be preferred for some patients. Safety is the primary advantage of these agents.</p>	<p>Inform patient that 4–6-wk trial may be needed to determine maximum benefit. Instruct patient about correct use of inhaler.</p>
nedocromil (Tilade)	<p><i>Mechanisms</i> Anti-inflammatory. Blocks early and late reaction to allergen. Stabilizes mast cell membranes and inhibits activation and release of mediators from eosinophils and epithelial cells. Inhibits acute response to exercise, cold dry air, and SO₂.</p>	<p>One dose before exercise or exposure to allergen provides effective prophylaxis for 1–2 h. Not as effective for exercise-induced bronchospasm as short-acting beta₂-agonist.</p>	
Leukotriene Modifiers			
Leukotriene Receptor Antagonists			
montelukast (Singulair)	<p><i>Mechanism</i> Selective competitive inhibitor of CysLT₁ receptor.</p> <p><i>Indications</i> Long-term control and prevention of symptoms in mild persistent asthma for patients ≥1 yr of age. May also be used with ICS as combination therapy in moderate persistent asthma.</p>	<p>May attenuate EIB in some patients, but less effective than ICS therapy. LTRA + LABA should not be used as a substitute for ICS + LABA. No specific adverse effects have been identified. Available in tablets and granules.</p>	<p>Instruct patient to take at least 1 h before meals or 2 h after meals. Inform patient that zafirlukast can inhibit the metabolism of warfarin. INRs should be monitored if patient is taking both medications.</p>
zafirlukast (Accolate)	<p>Long-term control and prevention of symptoms in mild persistent asthma. May also be used with ICS as combination therapy in moderate persistent asthma.</p>	<p>Cases of reversible hepatitis have been reported along with rare cases of irreversible hepatic failure resulting in death and liver transplantation. Available in tablets.</p>	<p>Instruct patients to discontinue use if they experience signs and symptoms of liver dysfunction (right upper quadrant pain, pruritus, lethargy, jaundice, nausea), and to notify their primary health care provider.</p>

Continued on following page

Table 24-3 LONG-TERM MEDICATIONS FOR TREATMENT OF ASTHMA (CONTROLLER MEDICATIONS) (Continued)

Medication	Indications/Mechanisms	Potential Adverse Effects	Nursing Considerations
5-Lipoxygenase Inhibitor zileuton (Zyflo)	<p><i>Mechanism</i> Inhibits the production of leukotrienes from arachidonic acid, both LTB and the cysteinyl leukotrienes.</p> <p><i>Indications</i> Long-term control and prevention of symptoms in mild persistent asthma for patients. May be used with ICS as combination therapy in moderate persistent asthma in patients.</p>	Elevation of liver enzymes has been reported. Limited case reports of reversible hepatitis and hyperbilirubinemia.	Inform patient that zileuton can inhibit the metabolism of warfarin and theophylline. Therefore, the doses of these medications should be monitored accordingly. Teach patient the importance of monitoring medication levels and tests of liver function.
Immunomodulators omalizumab (Xolair)	<p><i>Indications</i> Long-term control and prevention of symptoms in adults with moderate or severe persistent allergic asthma inadequately controlled with ICS.</p> <p><i>Mechanisms</i> Monoclonal antibody (anti-IgE) that binds to circulating IgE, preventing it from binding to the high-affinity receptors on basophils and mast cells. Decreases mast cell mediator release from allergen exposure.</p>	Administered by subcutaneous injection. Anaphylaxis has been reported in 0.2% of treated patients. Pain, bruising and skin reactions (itching, redness, stinging) at injection sites. The dose is administered either every 2 or 4 wk and is dependent on the patient's body weight and IgE level before therapy. A maximum of 150 mg can be administered in one injection. Medication needs to be stored under refrigeration at 2–8°C. It is unknown if patients will develop significant antibody titers to the drug with long-term administration.	Monitor patients for allergic reactions or anaphylaxis following administration. Be prepared to initiate emergency treatment if anaphylaxis occurs. Instruct patient about signs and symptoms that indicate allergic reaction and immediate action to take. Remind patient to continue to take other medications prescribed for treatment of asthma.

AMP, 3',5'-adenosine monophosphate; DPI, dry powder inhaler; ECG, electrocardiogram; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; ICS, inhaled corticosteroid; INR, international normalized ratio; LTB, leukotriene B; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta₂-agonist; SVT, supraventricular tachycardia.

usually used in addition to inhaled corticosteroids, mainly for relief of nighttime asthma symptoms. Salmeterol (Serevent) and formoterol (Foradil) have a duration of bronchodilation for at least 12 hours. They are used with other medications in long-term control of asthma.

Leukotriene modifiers (inhibitors), or *antileukotrienes*, are a class of medications that include montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo). Leukotrienes, which are synthesized from membrane phospholipids through a cascade of enzymes, are potent bronchoconstrictors that also dilate blood vessels and alter permeability. Leukotriene inhibitors act either by interfering with leukotriene synthesis or by blocking the receptors where leukotrienes exert their action. They may provide an alternative to inhaled corticosteroids for mild persistent asthma, or they may be added to a regimen of inhaled corticosteroids in more severe asthma to attain further control.

Immunomodulators prevent binding of IgE to the high-affinity receptors of basophils and mast cells. Omalizumab

(Xolair) is a monoclonal antibody and may be used for patients with allergies and severe persistent asthma.

Management of Exacerbations

Asthma exacerbations are best managed by early treatment and education, including the use of written action plans as part of any overall effort to educate patients about self-management techniques, especially those with moderate or severe persistent asthma or with a history of severe exacerbations (Expert Panel Report 3, 2007). Quick-acting beta₂-adrenergic agonist medications are first used for prompt relief of airflow obstruction. Systemic corticosteroids may be necessary to decrease airway inflammation in patients who fail to respond to inhaled beta-adrenergic medications. In some patients, oxygen supplementation may be required to relieve hypoxemia associated with moderate to severe exacerbations. In addition, response to treatment may be monitored by serial measurements of lung function.

Evidence from clinical trials suggests that antibiotic therapy, whether administered routinely or when suspicion

Table 24-4 QUICK-RELIEF MEDICATIONS FOR TREATMENT OF ASTHMA

Medication	Indications/Mechanisms	Potential Adverse Effects	Nursing Considerations
Inhaled Short-Acting Beta₂-Agonists (SABAs)			
albuterol (Proventil HFA, Ventolin HFA) levalbuterol HFA (Xopenex) pirbuterol CFC (Maxair) metaproterenol sulfate (Alupent)	<i>Indications:</i> Relief of acute symptoms; quick-relief medication. Preventive treatment for exercise-induced bronchospasm. <i>Mechanisms:</i> Bronchodilation. Binds to the beta-2 adrenergic receptor, producing smooth muscle relaxation and decreased bronchoconstriction.	Tachycardia, muscle tremor, hypokalemia, increased lactic acid, headache, and hyperglycemia. Inhaled route causes few systematic adverse effects. Patients with preexisting cardiovascular disease, especially the elderly, may have adverse cardiovascular reactions with inhaled therapy. Lack of effect or need for regular use indicates inadequate asthma control.	Patients need to be instructed in correct use of inhaled agents and understanding of how to evaluate amount of remaining medication in MDI. Periodic cleaning of device recommended. Patient is informed about possible side effects and need to inform health care provider about increased use of medication to control symptoms.
Anticholinergics			
ipratropium (Atrovent)	<i>Indications:</i> Relief of acute bronchospasm. <i>Mechanisms:</i> Bronchodilation. Inhibition of muscarinic cholinergic receptors. Reduction of vagal tone of airways. May decrease mucous gland secretion.	Dryness of mouth and respiratory secretions. May cause increased wheezing in some patients. Does not block exercise-induced bronchospasm. Is not effective in long-term control of asthma.	Instruct patient in correct use of inhaled agents. Ensure adequate fluid intake. Assess patient for hypersensitivity to atropine, soybeans, peanuts; glaucoma, prostatic hypertrophy.
Corticosteroids			
Systemic: methylprednisolone (Medrol) prednisolone (Prelone) prednisone (Deltasone, Orasone)	<i>Indications:</i> For moderate or severe exacerbations to prevent progression of exacerbation, reverse inflammation, speed recovery, and reduce rate of relapse. <i>Mechanisms:</i> Anti-inflammatory. Block reaction to allergen and reduce hyperresponsiveness. Inhibit cytokine production, adhesion protein activation, and inflammatory cell migration and activation. Reverses beta-2 receptor down-regulation.	Short-term use: reversible blood glucose abnormalities, increased appetite, fluid retention, weight gain, mood alteration, hypertension, peptic ulcer. Consideration must be given to comorbidities that may be worsened by systemic corticosteroids.	Explain to patient that action is often rapid in onset, although resolution of symptoms may take 3–10 days. Instruct patient about possible side effects and the importance of taking the medication as prescribed.

CFC, chlorofluorocarbons; HFA, hydrofluoroalkane; MDI, metered-dose inhaler.

of bacterial infection is low, is not beneficial for asthma exacerbations (Expert Panel Report 3, 2007). Antibiotics may be appropriate in the treatment of acute asthma exacerbations in patients with comorbid conditions (eg, fever and purulent sputum, evidence of pneumonia, suspected bacterial sinusitis).

Despite insufficient data supporting or refuting the benefits of using a written asthma action plan as compared to medical management alone, the 2007 Expert Panel Report 3 recommends the use of a written asthma action plan to educate patients about self-management (Fig. 24-8). Plans can be based on either symptoms or peak flow measurements. They should focus on daily management as well as the recognition and handling of worsening symptoms. Patient self-management and early recognition of problems lead to more efficient communication with health care providers about asthma exacerbations (Expert Panel Report 3, 2007).

Peak Flow Monitoring

Peak flow meters measure the highest airflow during a forced expiration (Fig. 24-9). Daily peak flow monitoring is recommended for patients who meet one or more of the following criteria: have moderate or severe persistent asthma, have poor perception of changes in airflow or worsening symptoms, have unexplained response to environmental or occupational exposures, or at the discretion of the clinician and patient (Expert Panel Report 3, 2007). If peak flow monitoring is used, it helps measure asthma severity and, when added to symptom monitoring, indicates the current degree of asthma control.

The patient is instructed in the proper technique (Chart 24-6), particularly about using maximal effort; peak flows are monitored for 2 or 3 weeks after receipt of optimal asthma therapy. Then the patient's "personal best" value is measured. The green (80% to 100% of personal best), yellow (60% to 80%), and red (less than 60%) zones are

Peak flow: _____ to _____
 (50% to 79% of my best peak flow)

First Add: quick-relief medicine—and keep taking your GREEN ZONE medicine.

_____ 2 or 4 puffs, every 20 minutes for up to 1 hour
 (short-acting beta₂-agonist) Nebulizer, once

If applicable, remove yourself from the thing that made your asthma worse.

Second If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:
 Continue monitoring to be sure you stay in the green zone.

-Or-
 If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:

Take: _____ 2 or 4 puffs or Nebulizer
 (short-acting beta₂-agonist)

Add: _____ mg per day For _____ (3-10) days
 (oral corticosteroid)

Call the doctor: _____, before/ within _____ hours after taking the oral corticosteroid.
 (phone)

RED ZONE

Medical Alert!

- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

-Or-
Peak flow: less than _____
 (50% of my best peak flow)

Take this medicine:

_____ 4 or 6 puffs or Nebulizer
 (short-acting beta₂-agonist)

_____ mg
 (oral corticosteroid)

Then call your doctor NOW. Go to the hospital or call an ambulance if:

- You are still in the red zone after 15 minutes AND
- You have not reached your doctor.

DANGER SIGNS

- Trouble walking and talking due to shortness of breath
- Lips or fingernails are blue

Take 4 or 6 puffs of your quick-relief medicine AND

Go to the hospital or call for an ambulance _____ NOW!
 (phone)

Figure 24-8 Asthma action plan. Redrawn from Expert Panel Report 3. (2007). *Guidelines for the diagnosis and management of asthma* (p. 119). NIH Publication Number 08-5846. National Asthma Education and Prevention Program. Bethesda, MD: U.S. Department of Health and Human Services, National Heart, Lung and Blood Institute.

determined, and specific actions are delineated for each zone, enabling the patient to monitor and manipulate his or her own therapy after careful instruction (Expert Panel Report 3, 2007).

The Expert Panel Report 3 (2007) recommends that peak flow monitoring be considered an adjunct to asthma management for patients with moderate to severe persistent asthma. Peak flow monitoring plans may enhance communication between the patient and health care providers and may increase the patient's awareness of disease status and control.

Nursing Management

The immediate nursing care of patients with asthma depends on the severity of symptoms. The patient may be treated successfully as an outpatient if asthma symptoms are relatively mild or may require hospitalization and intensive care if symptoms are acute and severe. The patient and family are often frightened and anxious because of the patient's dyspnea. Therefore, a calm approach is an important aspect

of care. The nurse assesses the patient's respiratory status by monitoring the severity of symptoms, breath sounds, peak flow, pulse oximetry, and vital signs.

The nurse generally performs the following interventions:

- Obtains a history of allergic reactions to medications before administering medications
- Identifies medications the patient is currently taking
- Administers medications as prescribed and monitors the patient's responses to those medications. These medications may include an antibiotic if the patient has an underlying respiratory infection.
- Administers fluids if the patient is dehydrated

If the patient requires intubation because of acute respiratory failure, the nurse assists with the intubation procedure, continues close monitoring of the patient, and keeps the patient and family informed about procedures. Intubation and mechanical ventilation are discussed in Chapter 25.

Figure 24-9 Peak flow meters measure the highest volume of air flow during a forced expiration (*left*). Volume is measured in color-coded zones (*right*): the green zone signifies 80% to 100% of personal best; yellow, 60% to 80%; and red, less than 60%. If peak flow falls below the red zone, the patient should take the appropriate actions prescribed by his or her health care provider.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

A major challenge is to implement basic asthma management principles at the community level. Strategies include education of health care providers, establishment of programs for asthma education (for patients and providers), use of outpatient follow-up care for patients, and a focus on chronic management versus acute episodic care. Nurses are pivotal to achievement of these objectives.

Patient teaching is a critical component of care for patients with asthma. Multiple inhalers, different types of inhalers, antiallergy therapy, antireflux medications, and avoidance measures are essential for long-term control.

This complex therapy requires a partnership between the patient and the health care providers to determine the desired outcomes and to formulate a plan to achieve those outcomes. The patient then carries out daily therapy as part of self-care management, with input and guidance by his or her health care providers. Before a partnership can be established, the patient must understand the following:

- The nature of asthma as a chronic inflammatory disease
- The definitions of inflammation and bronchoconstriction
- The purpose and action of each medication
- Triggers to avoid, and how to do so
- Proper inhalation technique

CHART
24-6

HOME CARE CHECKLIST Use of Peak Flow Meter

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe the rationale for using a peak flow meter in asthma management.	✓	✓
• Explain how peak flow monitoring is used along with symptoms to determine severity of asthma.	✓	✓
• Demonstrate steps for using the peak flow meter correctly.	✓	✓
• Move the indicator to the bottom of the numbered scale.	✓	✓
• Stand up.	✓	✓
• Take a deep breath and fill the lungs completely.	✓	✓
• Place mouthpiece in mouth and close lips around mouthpiece. (do not put tongue inside opening).	✓	✓
• Blow out hard and fast with a single blow.	✓	✓
• Record the number achieved on the indicator. If patient coughs or a mistake is made in the process, do it over.	✓	✓
• Repeat steps 1–5 two more times and write the highest number in the asthma diary.	✓	✓
• Explain how to determine the “personal best” peak flow reading.	✓	✓
• Describe the significance of the color zones for peak flow monitoring.	✓	✓
• Demonstrate how to clean the peak flow meter.	✓	✓
• Discuss how and when to contact the health care provider about changes or decreases in peak flow values.	✓	✓

- How to perform peak flow monitoring (see Chart 24-6)
- How to implement an action plan
- When to seek assistance, and how to do so

An assortment of excellent educational materials is available from the NHLBI and other sources. The nurse should obtain current educational materials for the patient based on the patient's diagnosis, causative factors, educational level, and cultural background. If a patient has a coexisting sensory impairment (ie, vision loss or hearing impairment), materials should be provided in an alternative format.

Continuing Care

Nurses who have contact with patients in the hospital, clinic, school, or office use the opportunity to assess the patient's respiratory status and ability to manage self-care to prevent serious exacerbations. Nurses emphasize adherence to the prescribed therapy, preventive measures, and the need to keep follow-up appointments with health care providers. Home visits to assess the home environment for allergens may be indicated for patients with recurrent exacerbations. Nurses refer patients to community support groups. In addition, nurses remind patients and families about the importance of health promotion strategies and recommended health screening.

Status Asthmaticus

Status asthmaticus is severe and persistent asthma that does not respond to conventional therapy. The attacks can occur with little or no warning and can progress rapidly to asphyxiation. Infection, anxiety, nebulizer abuse, dehydration, increased adrenergic blockage, and nonspecific irritants may contribute to these episodes. An acute episode may be precipitated by hypersensitivity to aspirin.

Pathophysiology

The basic characteristics of asthma (inflammation of bronchial mucosa, constriction of the bronchiolar smooth muscle, and thickened secretions) decrease the diameter of the bronchi and occur in status asthmaticus. The most common scenario is severe bronchospasm, with mucus plugging leading to asphyxia. A ventilation-perfusion abnormality results in hypoxemia. There is a reduced PaO₂ and initial respiratory alkalosis, with a decreased PaCO₂ and an increased pH. As status asthmaticus worsens, the PaCO₂ increases and the pH decreases, reflecting respiratory acidosis.

Clinical Manifestations

The clinical manifestations are the same as those seen in severe asthma; signs and symptoms include labored breathing, prolonged exhalation, engorged neck veins, and wheezing. However, the extent of wheezing does not indicate the severity of the attack. As the obstruction worsens, the wheezing may disappear; this is frequently a sign of impending respiratory failure.

Assessment and Diagnostic Findings

Pulmonary function studies are the most accurate means of assessing acute airway obstruction. Arterial blood gas measurements are obtained if the patient cannot perform pul-

monary function maneuvers because of severe obstruction or fatigue, or if the patient does not respond to treatment. Respiratory alkalosis (low PaCO₂) is the most common finding in patients with asthma.

NURSING ALERT

Frequently, increasing PaCO₂ (to normal levels or levels indicating respiratory acidosis) is a danger sign signifying impending respiratory failure.

Medical Management

Close monitoring of the patient and objective reevaluation for response to therapy are key in status asthmaticus. In the emergency setting, the patient is treated initially with a short-acting beta₂-adrenergic agonist and subsequently a short course of systemic corticosteroids, especially if the patient does not respond to the short-acting beta₂-adrenergic agonist. Corticosteroids are critical in the therapy of status asthmaticus and are used to decrease the intense airway inflammation and swelling. Short-acting inhaled beta₂-adrenergic agonists provide the most rapid relief from bronchospasm. An MDI with or without a spacer may be used for nebulization of the medications. The patient usually requires supplemental oxygen and intravenous (IV) fluids for hydration. Oxygen therapy is initiated to treat dyspnea, central cyanosis, and hypoxemia. High-flow supplemental oxygen is best delivered using a partial or complete non-rebreather mask with the objective of maintaining the PaO₂ at a minimum of 92 mm Hg or O₂ saturation greater than 95%. Sedatives are contraindicated. Magnesium sulfate, a calcium antagonist, may be administered to induce smooth muscle relaxation; the magnesium can relax smooth muscle and hence cause bronchodilation by competing with calcium at calcium-mediated smooth muscle binding sites. Adverse effects of magnesium sulfate may include facial warmth, flushing, tingling, nausea, central nervous system depression, respiratory depression, and hypotension.

If there is no response to repeated treatments, hospitalization is required. Other criteria for hospitalization include poor pulmonary function test results and deteriorating blood gas levels (respiratory acidosis), which may indicate that the patient is tiring and will require mechanical ventilation. Most patients do not need mechanical ventilation, but it is used for patients in respiratory failure, for those who tire and are too fatigued by the attempt to breathe, and for those whose condition does not respond to initial treatment.

Death from asthma is associated with several risk factors, including the following (Expert Panel Report 3, 2007):

- Past history of severe exacerbation (eg, intubation or intensive care unit admission)
- Two or more hospitalizations for asthma within the past year
- Three or more emergency care visits for asthma in the past year
- Hospitalization or emergency care visit for asthma in the past month
- Use of more than two canisters of short-acting beta-agonist inhalers per month

- Difficulty in perceiving asthma symptoms or severity of exacerbations
- Lack of written asthma action plan
- Concurrent cardiovascular disease, COPD, or chronic psychiatric disease
- Low socioeconomic status or inner-city residence
- Illicit drug use

Nursing Management

The main focus of nursing management is to actively assess the airway and the patient's response to treatment. The nurse should be prepared for the next intervention if the patient does not respond to treatment.

The nurse constantly monitors the patient for the first 12 to 24 hours, or until status asthmaticus is under control. The nurse also assesses the patient's skin turgor for signs of dehydration. Fluid intake is essential to combat dehydration, to loosen secretions, and to facilitate expectoration. Nurses administer IV fluids as prescribed, up to 3 to 4 L/day, unless contraindicated. Blood pressure and cardiac rhythm should be monitored continuously during the acute phase and until the patient stabilizes and responds to therapy. The patient's energy needs to be conserved, and his or her room should be quiet and free of respiratory irritants, including flowers, tobacco smoke, perfumes, or odors of cleaning agents. Nonallergenic pillows should be used.

Cystic Fibrosis

Cystic fibrosis (CF) is the most common fatal autosomal recessive disease among the Caucasian population. A person must inherit a defective copy of the CF gene (one from each parent) to have CF. One in 31 Americans is an unknowing carrier of this gene, and approximately 30,000 children and adults in the United States have CF (Cystic Fibrosis Foundation, 2007). CF is less frequently found among Hispanic, Asian, and African Americans. CF was once considered a fatal childhood disease, but the median expected survival age is now 37 years (Flume, O'Sullivan, Robinson, et al., 2007). Patients' quality of life has also improved.

This multisystem genetic disease is usually diagnosed in infancy or early childhood but may be diagnosed later in life. Respiratory symptoms are frequently the major manifestation of CF when it is diagnosed later in life. However, a good number of patients will not demonstrate the classic symptoms of CF, which may potentially cause a diagnostic dilemma (Boyle, 2007).

Pathophysiology

CF is caused by mutations or dysfunction in the protein cystic fibrosis transmembrane conductance regulator (CFTR), which normally transports chloride ions across epithelial cell membranes. Gene mutations affect transport of these ions, leading to CF, which is characterized by thick, viscous secretions in the lungs, pancreas, liver, intestine, and reproductive tract as well as increased salt content in sweat gland secretions. More than 1500 mutations of the CFTR gene have been identified, thus creating multiple variations in presentation and progression of the disease (Boyle, 2007).

The ability to detect the common mutations of this gene allows for routine screening for CF and the detection

of carriers of the disease. Genetics counseling is an important part of health care for couples at risk. People who are heterozygous for CF (ie, have one defective gene and one normal gene) do not have the disease but can be carriers and pass the defective gene on to their children. If both parents are carriers, their risk of having a child with CF is one in four (25%) with each pregnancy. Genetic testing should be offered to adults with a positive family history of CF and to partners of people with CF who are planning a pregnancy or seeking prenatal counseling. Currently, genetic testing for CF is not recommended for the general population.

The hallmark pathology of CF is bronchial mucus plugging, inflammation, and eventual bronchiectasis. Commonly, the bronchiectasis begins in the upper lobes and progresses to involve all lobes. Progressive loss of lung function averaging from 1% to 4% per year begins in the teenage years (Boyle, 2007).

Clinical Manifestations

The pulmonary manifestations of CF include a productive cough, wheezing, hyperinflation of the lung fields on chest x-ray, and pulmonary function test results consistent with obstructive disease of the airways. Chronic respiratory inflammation and infection are caused by impaired mucus clearance. Colonization of the airways with pathogenic bacteria usually occurs early in life. *Staphylococcus aureus* and *H. influenzae* are common organisms during early childhood. As the disease progresses, *Pseudomonas aeruginosa* is ultimately isolated from the sputum of most patients. Upper respiratory manifestations of the disease include sinusitis and nasal polyps.

Nonpulmonary manifestations include gastrointestinal problems (eg, pancreatic insufficiency, recurrent abdominal pain, biliary cirrhosis, vitamin deficiencies, recurrent pancreatitis, weight loss), CF-related diabetes, genitourinary problems (male and female infertility), and clubbing of the digits (fingers and toes). (See Chapter 40 for a discussion of pancreatitis.)

Assessment and Diagnostic Findings

The diagnosis of CF requires a clinical picture consistent with the CF phenotype and laboratory evidence of CFTR dysfunction. The consensus statement of the Cystic Fibrosis Foundation on the diagnosis of CF identifies key aspects of the phenotype (Boyle, 2007):

- Chronic sinopulmonary disease as manifested by chronic cough and sputum production, persistent infection consistent with typical CF pathogens, and x-ray evidence of bronchiectasis and chronic sinusitis, often with nasal polyps
- Gastrointestinal tract and nutritional abnormalities (pancreatic insufficiency, meconium ileus or distal intestinal obstruction syndrome, failure to thrive or chronic malnutrition)
- Male urogenital problems as manifested by congenital bilateral absence of the vas deferens and obstructive azoospermia

Medical Management

CF requires both acute and chronic therapy. Because chronic bacterial infection of the airways occurs in CF, control of infections is essential to treatment. For acute airway

exacerbations, aggressive therapy involves airway clearance and antibiotics based on results of sputum cultures. The majority of patients are colonized with *P. aeruginosa*, and antibiotics are usually given for 14 to 21 days. Because patients with CF may be infected with bacteria that are resistant to multiple antibiotics, they may require several courses of antibiotic agents over long periods. In an acute exacerbation, airway clearance treatments may be used three to four times per day.

For chronic disease, the therapeutic options for CF have undergone tremendous changes. Cornerstones of treatment include airway clearance measures, mucolytic dornase alpha, nebulized antibiotics, oral antibiotics, inhaled hypertonic saline, nutritional support, and exercise (Boyle, 2007).

Airway clearance is a key intervention in the care of patients with CF, and various pulmonary techniques are used to enhance secretion clearance. Examples include manual postural drainage and chest physical therapy, high-frequency chest wall oscillation, autogenic drainage (a combination of breathing techniques at different lung volume levels to move the secretions to where they can be “huff”-coughed out), and other devices that assist in airway clearance, such as masks that generate positive expiratory pressure (PEP masks) and “flutter devices” (devices that provide an oscillatory expiratory pressure pattern with positive expiratory pressure and assist with expectoration of secretions).

Dornase alpha (Pulmozyme) is a nebulized medication administered to degrade the large amount of deoxyribonucleic acid (DNA) that accumulates within CF mucus. This agent helps decrease the viscosity of the sputum and promotes expectoration of secretions. It is recommended for patients with moderate to severe disease (severity of lung disease classification is based on predicted FEV₁ percentage) (Flume, et al., 2007).

Nebulized antibiotics include tobramycin (TOBI), colistin (Colimycin), gentamicin (Garamycin), and ceftazidime (Fortaz, Ceptaz) (Flume, et al., 2007). Inhaled antibiotics provide the advantage of high intrapulmonary drug concentrations and minimal systemic absorption.

Acute infections are treated with a variety of antibiotics. Such infections remain a major cause of mortality related to pulmonary exacerbations in adults with CF (Elpern, Patel & Balk, 2007). Antibiotics such as the macrolide azithromycin (Zithromax) may also be used. Inhaled hypertonic saline may also be used in the chronic treatment of CF. Inhalations increase hydration of the airway surface liquid in patients with CF and improve airway clearance. Regular inhalations have been shown to improve FEV₁ and decreased frequency of pulmonary exacerbations (Boyle, 2007).

Approximately 90% of patients with CF have pancreatic exocrine insufficiency and require oral pancreatic enzyme supplementation with meals (Boyle, 2007). Given the fat malabsorption in CF and increased caloric needs due to the work of breathing, nutritional counseling and monitoring of weight are extremely important. Supplements of fat-soluble vitamins A, D, E, and K are necessary (Boyle, 2007).

Other therapeutic measures may also be necessary. Anti-inflammatory agents may also be used to treat inflammatory response in the airways. The Cystic Fibrosis Foundation states that there is insufficient evidence for the use of routine inhaled or oral corticosteroids. However, chronic use of

nonsteroidal anti-inflammatory agents is recommended to slow the loss of lung function (Flume, et al., 2007). Inhaled bronchodilators may be used in patients who have a significant bronchoconstrictive component as indicated by spirometry pre- and post-bronchodilator therapy.

Supplemental oxygen is used to treat the progressive hypoxemia that occurs with CF. It helps correct the hypoxemia and may minimize the complications seen with chronic hypoxemia (pulmonary hypertension).

Lung transplantation is an option for a small, selected population of patients with CF. A double-lung transplantation technique is used because of chronic infection of both lungs in end-stage CF. Because there is a long waiting list for lung transplants, many patients die while waiting for suitable lungs for transplantation.

Nursing Management

Nursing management is crucial to the interdisciplinary approach required for care of adults with CF. Nursing care includes helping patients manage pulmonary symptoms and prevent complications of CF. Specific measures include strategies that promote removal of pulmonary secretions; chest physiotherapy (including postural drainage, chest percussion, and vibration); and breathing exercises, which are implemented and are taught to the patient and family when the patient is very young. The patient is reminded of the need to reduce risk factors associated with respiratory infections (eg, exposure to crowds or to people with known infections). In addition, the patient is taught the early signs and symptoms of respiratory infection and disease progression that indicate the need to notify a primary health care provider.

Nurses emphasize the importance of an adequate fluid and dietary intake to promote removal of secretions and to ensure an adequate nutritional status. Because CF is a lifelong disorder, patients often have learned to modify their daily activities to accommodate their symptoms and treatment modalities. However, as the disease progresses, assessment of the home environment may be warranted to identify modifications required to address changes in the patient’s needs, increasing dyspnea and fatigue, and nonpulmonary symptoms.

As with any chronic disease, palliative care and end-of-life issues and concerns need to be addressed with the patient when warranted. For the patient whose disease is progressing and who is developing increasing hypoxemia, preferences for end-of-life care should be discussed, documented, and honored (see Chapter 17). Patients and family members require support as they face a shortened lifespan and an uncertain future.

CRITICAL THINKING EXERCISES

1 A 71-year-old white man presents to the clinic for follow-up of end-stage COPD and weight loss. He has been seen regularly for 5 years in the clinic, and his wife usually accompanies him. Today he is anxious and short of breath. He is receiving supplemental oxygen at 2 L/min, and his wife states he is unable to lie flat to sleep. What tests or examinations might be appropriate to assess the severity of his shortness of breath, oxygenation status, and

inability to lie flat? What information or tests would be helpful in assessing his weight loss? What are potential causes and interventions for his weight loss?

EBP 2 A 68-year-old retired businessman with COPD reports that he has been using continuous oxygen for the past 5 years. He reports increasing shortness of breath and asks you to increase his oxygen flow. How do you respond to his request? What evidence base would you use to determine your intervention? How would you determine the strength of the evidence?

EBP 3 A 35-year-old Mexican American single mother presents to the emergency department extremely short of breath. She is only able to speak in short phrases in broken English and is extremely anxious. It is noted in her chart that she has been in the hospital three times in the past year for asthma exacerbations. What are the key aspects of your physical examination, and what laboratory tests might you anticipate? What treatments may be used? What other aspects of care of this patient are important to assess and what resources may be necessary? Identify evidence-based interventions for this patient and the evidence used to select those interventions.

4 A 46-year-old woman newly diagnosed with asthma has come to your clinic for the first time. She is a smoker and has had asthmatic symptoms for the last 36 hours. Previous diagnoses have included acute bronchitis, sinusitis, and GERD. She has been prescribed a short-acting bronchodilator via inhaler and a long-acting medication with a return appointment in 1 month. What key educational topics need to be covered during this initial clinic visit? Describe an educational plan you would develop to implement at her next clinic visit.

5 A 21-year-old male college student with CF is admitted to your unit from the emergency department. He obtains his routine CF care closer to home. He has become progressively short of breath over the past week, and his roommate accompanied him to the hospital. In short and choppy phrases, the young man tells you that he is extremely short of breath; he is having paroxysms of coughing. You note the cough is productive of thick, yellow sputum. His roommate says that he has not been following his usual routine of CF care (airway clearance and nebulized medications) for the past 2 weeks. What pathophysiology is associated with these signs and symptoms? What medical and nursing interventions might be used to decrease or alleviate these signs and symptoms? What members of the health care team would you consult and why?

chapter 25

Respiratory Care Modalities

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the nursing management for patients receiving oxygen therapy, intermittent positive-pressure breathing, mini-nebulizer therapy, intermittent spirometry, chest physiotherapy, and breathing retraining.
- 2 Describe the patient education and home care considerations for patients receiving oxygen therapy.
- 3 Describe the nursing care for a patient with an endotracheal tube and for a patient with a tracheostomy.
- 4 Demonstrate the procedure of tracheal suctioning.
- 5 Use the nursing process as a framework for care of patients who are mechanically ventilated.
- 6 Describe the process of weaning the patient from mechanical ventilation.
- 7 Describe the significance of preoperative nursing assessment and patient teaching for the patient who is going to have thoracic surgery.
- 8 Explain the principles of chest drainage and the nursing responsibilities related to the care of the patient with a chest drainage system.
- 9 Describe the patient education and home care considerations for patients who have had thoracic surgery.

GLOSSARY

airway pressure release ventilation (APRV): mode of mechanical ventilation that allows unrestricted, spontaneous breaths throughout the ventilatory cycle; on inspiration patient receives preset level of continuous positive airway pressure, and pressure is periodically released to aid expiration

assist-control ventilation (A/C): mode of mechanical ventilation in which the patient's breathing pattern may trigger the ventilator to deliver a preset tidal volume; in the absence of spontaneous breathing, the machine delivers a controlled breath at a preset minimum rate and tidal volume

chest drainage system: use of a chest tube and closed drainage system to re-expand the lung and to remove excess air, fluid, and blood

chest percussion: manually cupping over the chest wall to mobilize secretions by mechanically dislodging viscous or adherent secretions in the lungs

chest physiotherapy (CPT): therapy used to remove bronchial secretions, improve ventilation, and increase the efficiency of the respiratory muscles; types include postural drainage, chest percussion, and vibration

GLOSSARY (Continued)

continuous positive airway pressure (CPAP): positive pressure applied throughout the respiratory cycle to a spontaneously breathing patient to promote alveolar and airway stability; may be administered with endotracheal or tracheostomy tube or by mask

controlled ventilation: mode of mechanical ventilation in which the ventilator completely controls the patient's ventilation according to preset tidal volumes and respiratory rate; because of problems with synchrony, it is rarely used except in paralyzed or anesthetized patients

endotracheal intubation: insertion of a breathing tube through the nose or mouth into the trachea

fraction of inspired oxygen (FiO₂): concentration of oxygen delivered (1.0 = 100% oxygen)

hypoxemia: decrease in arterial oxygen tension in the blood

hypoxia: decrease in oxygen supply to the tissues and cells

incentive spirometry: method of deep breathing that provides visual feedback to help the patient inhale deeply and slowly and achieve maximum lung inflation

intermittent mandatory ventilation (IMV): mode of mechanical ventilation that provides a combination of mechanically assisted breaths and spontaneous breaths

mechanical ventilator: a positive- or negative-pressure breathing device that supports ventilation and oxygenation

pneumothorax: partial or complete collapse of the lung due to positive pressure in the pleural space

positive end-expiratory pressure (PEEP): positive pressure maintained by the ventilator at the end of exhalation (instead of a normal zero pressure) to increase functional residual capacity and open collapsed alveoli; improves oxygenation with lower fraction of inspired oxygen

postural drainage: positioning the patient to allow drainage from all the lobes of the lungs and airways

pressure support ventilation (PSV): mode of mechanical ventilation in which preset positive pressure is delivered with spontaneous breaths to decrease work of breathing

proportional assist ventilation (PAV): mode of mechanical ventilation that provides partial ventilatory support in proportion to the patient's inspiratory efforts; decreases the work of breathing

respiratory weaning: process of gradual, systematic withdrawal or removal of ventilator, breathing tube, and oxygen

synchronized intermittent mandatory ventilation (SIMV): mode of mechanical ventilation in which the ventilator allows the patient to breathe spontaneously while providing a preset number of breaths to ensure adequate ventilation; ventilated breaths are synchronized with spontaneous breathing

thoracotomy: surgical opening into the chest cavity

tracheostomy tube: indwelling tube inserted directly into the trachea to assist with ventilation

tracheotomy: surgical opening into the trachea

vibration: a type of massage administered by quickly tapping the chest with the fingertips or alternating the fingers in a rhythmic manner, or by using a mechanical device to assist in mobilizing lung secretions

Numerous treatment modalities are used when caring for patients with various respiratory conditions. The choice of modality is based on the oxygenation disorder and whether there is a problem with gas ventilation, diffusion, or both. Therapies range from simple and noninvasive (oxygen and nebulizer therapy, chest physiotherapy, breathing retraining) to complex and highly invasive treatments (intubation, mechanical ventilation, surgery). Assessment and management of the patient with respiratory disorders are best accomplished when the approach is multidisciplinary and collaborative.

NONINVASIVE RESPIRATORY THERAPIES

Oxygen Therapy

Oxygen therapy is the administration of oxygen at a concentration greater than that found in the environmental atmosphere. At sea level, the concentration of oxygen in room air is 21%. The goal of oxygen therapy is to provide adequate transport of oxygen in the blood while decreasing the work of breathing and reducing stress on the myocardium.

Oxygen transport to tissues depends on factors such as cardiac output, arterial oxygen content, concentration of hemoglobin, and metabolic requirements. These factors must be kept in mind when oxygen therapy is considered. (Respiratory physiology and oxygen transport are discussed in Chapter 21.)

Indications

A change in the patient's respiratory rate or pattern may be one of the earliest indicators of the need for oxygen therapy. These changes may result from hypoxemia or hypoxia. **Hypoxemia**, a decrease in the arterial oxygen tension in the blood, is manifested by changes in mental status (progressing through impaired judgment, agitation, disorientation, confusion, lethargy, and coma), dyspnea, increase in blood pressure, changes in heart rate, dysrhythmias, central cyanosis (late sign), diaphoresis, and cool extremities. Hypoxemia usually leads to **hypoxia**, a decrease in oxygen supply to the tissues, which can also be caused by problems outside the respiratory system. Severe hypoxia can be life-threatening.

The signs and symptoms signaling the need for oxygen may depend on how suddenly this need develops. With rapidly developing hypoxia, changes occur in the central nervous system because the higher neurologic centers are very sensitive to oxygen deprivation. The clinical picture may resemble that of alcohol intoxication, with the patient exhibiting lack of coordination and impaired judgment. With long-standing hypoxia (as seen in chronic obstructive pulmonary disease [COPD] and chronic heart failure), fatigue, drowsiness, apathy, inattentiveness, and delayed reaction time may occur. The need for oxygen is assessed by arterial blood gas analysis, pulse oximetry, and clinical evaluation. More information about hypoxia is presented in Chart 25-1.

Complications

As with other medications, the nurse administers oxygen with caution and carefully assesses its effects on each patient. Oxygen is a medication, and except in emergency situations it is administered only when prescribed by a physician.

Chart 25-1 • Types of Hypoxia

Hypoxia can occur from either severe pulmonary disease (inadequate oxygen supply) or from extrapulmonary disease (inadequate oxygen delivery) affecting gas exchange at the cellular level. The four general types of hypoxia are hypoxemic hypoxia, circulatory hypoxia, anemic hypoxia, and histotoxic hypoxia.

Hypoxemic Hypoxia

Hypoxemic hypoxia is a decreased oxygen level in the blood resulting in decreased oxygen diffusion into the tissues. It may be caused by hypoventilation, high altitudes, ventilation-perfusion mismatch (as in pulmonary embolism), shunts in which the alveoli are collapsed and cannot provide oxygen to the blood (commonly caused by atelectasis), and pulmonary diffusion defects. It is corrected by increasing alveolar ventilation or providing supplemental oxygen.

Circulatory Hypoxia

Circulatory hypoxia is hypoxia resulting from inadequate capillary circulation. It may be caused by decreased cardiac output, local vascular obstruction, low-flow states such as shock, or cardiac arrest. Although tissue partial pressure of oxygen (PO_2) is reduced, arterial oxygen (PaO_2) remains normal. Circulatory hypoxia is corrected by identifying and treating the underlying cause.

Anemic Hypoxia

Anemic hypoxia is a result of decreased effective hemoglobin concentration, which causes a decrease in the oxygen-carrying capacity of the blood. It is rarely accompanied by hypoxemia. Carbon monoxide poisoning, because it reduces the oxygen-carrying capacity of hemoglobin, produces similar effects but is not strictly anemic hypoxia because hemoglobin levels may be normal.

Histotoxic Hypoxia

Histotoxic hypoxia occurs when a toxic substance, such as cyanide, interferes with the ability of tissues to use available oxygen.

In general, patients with respiratory conditions are given oxygen therapy only to increase the arterial oxygen pressure (PaO_2) back to the patient's normal baseline, which may vary from 60 to 95 mm Hg. In terms of the oxyhemoglobin dissociation curve (see Chapter 21), the blood at these levels is 80% to 98% saturated with oxygen; higher **fraction of inspired oxygen (FiO_2)** flow values add no further significant amounts of oxygen to the red blood cells or plasma. Instead of helping, increased amounts of oxygen may produce toxic effects on the lungs and central nervous system or may depress ventilation (see later discussion).

It is important to observe for subtle indicators of inadequate oxygenation when oxygen is administered by any method. Therefore, the nurse assesses the patient frequently for confusion, restlessness progressing to lethargy, diaphoresis, pallor, tachycardia, tachypnea, and hypertension. Intermittent or continuous pulse oximetry is used to monitor oxygen levels.

Oxygen Toxicity

Oxygen toxicity may occur when too high a concentration of oxygen (greater than 50%) is administered for an extended period (longer than 48 hours). It is caused by overproduction

of oxygen free radicals, which are by-products of cell metabolism.

If oxygen toxicity is untreated, these radicals can severely damage or kill cells. Antioxidants such as vitamin E, vitamin C, and beta-carotene may help defend against oxygen free radicals. The dietitian can adjust the patient's diet so that it is rich in antioxidants; supplements are also available for patients who have a decreased appetite or who are unable to eat.

Signs and symptoms of oxygen toxicity include substernal discomfort, paresthesias, dyspnea, restlessness, fatigue, malaise, progressive respiratory difficulty, refractory hypoxemia, alveolar atelectasis, and alveolar infiltrates evident on chest x-rays.

Prevention of oxygen toxicity is achieved by using oxygen only as prescribed. If high concentrations of oxygen are necessary, it is important to minimize the duration of administration and reduce its concentration as soon as possible. Often, **positive end-expiratory pressure (PEEP)** or **continuous positive airway pressure (CPAP)** is used with oxygen therapy to reverse or prevent microatelectasis, thus allowing a lower percentage of oxygen to be used. The level of PEEP that allows the best oxygenation without hemodynamic compromise is known as "best PEEP."

Suppression of Ventilation

In many patients with COPD, the stimulus for respiration is a decrease in blood oxygen rather than an elevation in carbon dioxide levels. The administration of a high concentration of oxygen removes the respiratory drive that has been created largely by the patient's chronic low oxygen tension. The resulting decrease in alveolar ventilation can cause a progressive increase in arterial carbon dioxide pressure (PaCO₂). This hypoventilation can, in rare cases, lead to acute respiratory failure secondary to carbon dioxide narcosis,

acidosis, and death. Oxygen-induced hypoventilation is prevented by administering oxygen at low flow rates (1 to 2 L/min) and by closely monitoring the respiratory rate and the oxygen saturation as measured by pulse oximetry (SpO₂).

Other Complications

Because oxygen supports combustion, there is always a danger of fire when it is used. It is important to post "No Smoking" signs when oxygen is in use. Oxygen therapy equipment is also a potential source of bacterial cross-infection; therefore, the nurse (or respiratory therapist) changes the tubing according to infection control policy and the type of oxygen delivery equipment.

Methods of Oxygen Administration

Oxygen is dispensed from a cylinder or a piped-in system. A reduction gauge is necessary to reduce the pressure to a working level, and a flow meter regulates the flow of oxygen in liters per minute. When oxygen is used at high flow rates, it should be moistened by passing it through a humidification system to prevent it from drying the mucous membranes of the respiratory tract.

The use of oxygen concentrators is another means of providing varying amounts of oxygen, especially in the home setting. These devices are relatively portable, easy to operate, and cost-effective. However, they require more maintenance than tank or liquid systems and probably cannot deliver oxygen flows in excess of 4 L/min, which provides an FiO₂ of about 36%.

Many different oxygen devices are used, and all deliver oxygen if they are used as prescribed and maintained correctly (Table 25-1). The amount of oxygen delivered is expressed as

Table 25-1 OXYGEN ADMINISTRATION DEVICES

Device	Suggested Flow Rate (L/min)	O ₂ Percentage Setting	Advantages	Disadvantages
Low-Flow Systems				
Cannula	1–2	23–30	Lightweight, comfortable, inexpensive, continuous use with meals and activity	Nasal mucosal drying, variable FiO ₂
	3–5	30–40		
	6	42		
Oropharyngeal catheter	1–6	23–42	Inexpensive, does not require a tracheostomy	Nasal mucosa irritation; catheter should be changed frequently to alternate nostril
Mask, simple	6–8	40–60	Simple to use, inexpensive	Poor fitting, variable FiO ₂ , must remove to eat
Mask, partial rebreather	8–11	50–75	Moderate O ₂ concentration	Warm, poorly fitting, must remove to eat
Mask, non-rebreather	12	80–100	High O ₂ concentration	Poorly fitting, must remove to eat
High-Flow Systems				
Transtracheal catheter	¼–4	60–100	More comfortable, concealed by clothing, less oxygen liters per minute needed than nasal cannula	Requires frequent and regular cleaning, requires surgical intervention
Mask, Venturi	4–6	24, 26, 28	Provides low levels of supplemental O ₂ Precise FiO ₂ , additional humidity available	Must remove to eat
	6–8	30, 35, 40		
Mask, aerosol	8–10	30–100	Good humidity, accurate FiO ₂	Uncomfortable for some
Tracheostomy collar	8–10	30–100	Good humidity, comfortable, fairly accurate FiO ₂	
T-piece	8–10	30–100	Same as tracheostomy collar	Heavy with tubing
Face tent	8–10	30–100	Good humidity, fairly accurate FiO ₂	Bulky and cumbersome
Oxygen Conserving Devices				
Pulse dose (or demand)	10–40 mL/breath		Deliver O ₂ only on inspiration, conserve 50% to 75% of O ₂ used	Must carefully evaluate function individually

a percentage concentration (eg, 70%). The appropriate form of oxygen therapy is best determined by arterial blood gas levels, which indicate the patient's oxygenation status.

Oxygen delivery systems are classified as low-flow or high-flow delivery systems. Low-flow systems contribute partially to the inspired gas the patient breathes, which means that the patient breathes some room air along with the oxygen. These systems do not provide a constant or known concentration of inspired oxygen. The amount of inspired oxygen changes as the patient's breathing changes. Examples of low-flow systems include nasal cannula, oropharyngeal catheter, simple mask, partial-rebreather, and non-rebreather masks. In contrast, high-flow systems provide the total inspired air. A specific percentage of oxygen is delivered independent of the patient's breathing. High-flow systems are indicated for patients who require a constant and precise amount of oxygen. Examples of such systems include transtracheal catheters, Venturi masks, aerosol masks, tracheostomy collars, T-pieces, and face tents.

A nasal cannula is used when the patient requires a low to medium concentration of oxygen for which precise accuracy is not essential. This method is relatively simple and allows the patient to move about in bed, talk, cough, and eat without interrupting oxygen flow. Flow rates in excess of 6 to 8 L/min may lead to swallowing of air or may cause irritation and drying of the nasal and pharyngeal mucosa.

The oropharyngeal catheter is rarely used but may be prescribed for short-term therapy to administer low to moderate concentrations of oxygen. The catheter should be changed every 8 hours, alternating nostrils to prevent nasal irritation and infection.

When oxygen is administered via cannula or catheter, the percentage of oxygen reaching the lungs varies with

the depth and rate of respirations, particularly if the nasal mucosa is swollen or if the patient is a mouth breather.

Oxygen masks come in several forms. Each is used for different purposes (Fig. 25-1). *Simple masks* are used to administer low to moderate concentrations of oxygen. The body of the mask itself gathers and stores oxygen between breaths. The patient exhales directly through openings or ports in the body of the mask. If oxygen flow ceases, the patient can draw air in through these openings around the mask edges. Although widely used, these masks cannot be used for controlled oxygen concentrations and must be adjusted for proper fit. They should not press too tightly against the skin because this can cause a sense of claustrophobia as well as skin breakdown; adjustable elastic bands are provided to ensure comfort and security.

Partial-rebreathing masks have a reservoir bag that must remain inflated during both inspiration and expiration. The nurse adjusts the oxygen flow to ensure that the bag does not collapse during inhalation. A high concentration of oxygen can be delivered because both the mask and the bag serve as reservoirs for oxygen. Oxygen enters the mask through small-bore tubing that connects at the junction of the mask and bag. As the patient inhales, gas is drawn from the mask, from the bag, and potentially from room air through the exhalation ports. As the patient exhales, the first third of the exhalation fills the reservoir bag. This is mainly dead space and does not participate in gas exchange in the lungs. Therefore, it has a high oxygen concentration. The remainder of the exhaled gas is vented through the exhalation ports. The actual percentage of oxygen delivered is influenced by the patient's ventilatory pattern (Kacmarek, Dimas & Mack, 2005).

Figure 25-1 Types of oxygen masks used to deliver varying concentrations of oxygen. **A**, Venturi mask. **B**, Non-rebreathing mask. **C**, Partial-rebreathing mask.

Non-rebreathing masks are similar in design to partial-rebreathing masks except that they have additional valves. A one-way valve located between the reservoir bag and the base of the mask allows gas from the reservoir bag to enter the mask on inhalation but prevents gas in the mask from flowing back into the reservoir bag during exhalation. One-way valves located at the exhalation ports prevent room air from entering the mask during inhalation. They also allow the patient's exhaled gases to exit the mask on exhalation. As with the partial-rebreathing mask, it is important to adjust the oxygen flow so that the reservoir bag does not completely collapse on inspiration. In theory, if the non-rebreathing mask fits the patient snugly and both side exhalation ports have one-way valves, it is possible for the patient to receive 100% oxygen, making the non-rebreathing mask a high-flow oxygen system. However, because it is difficult to get an exact fit from the mask on every patient, and some non-rebreathing masks have only one one-way exhalation valve, it is almost impossible to ensure 100% oxygen delivery, making it a low-flow oxygen system.

The *Venturi mask* is the most reliable and accurate method for delivering precise concentrations of oxygen through non-invasive means. The mask is constructed in a way that allows a constant flow of room air blended with a fixed flow of oxygen. It is used primarily for patients with COPD because it can accurately provide appropriate levels of supplemental oxygen, thus avoiding the risk of suppressing the hypoxic drive.

The Venturi mask uses the Bernoulli principle of air entrainment (trapping the air like a vacuum), which provides a high airflow with controlled oxygen enrichment. For each liter of oxygen that passes through a jet orifice, a fixed proportion of room air is entrained. A precise volume of oxygen can be delivered by varying the size of the jet orifice and adjusting the flow of oxygen. Excess gas leaves the mask through the two exhalation ports, carrying with it the exhaled carbon dioxide. This method allows a constant oxygen concentration to be inhaled regardless of the depth or rate of respiration.

The mask should fit snugly enough to prevent oxygen from flowing into the patient's eyes. The nurse checks the patient's skin for irritation. It is necessary to remove the mask so that the patient can eat, drink, and take medications, at which time supplemental oxygen is provided through a nasal cannula.

The *transtracheal oxygen catheter* is inserted directly into the trachea and is indicated for patients with chronic oxygen therapy needs. These catheters are more comfortable, less dependent on breathing patterns, and less obvious than other oxygen delivery methods. Because no oxygen is lost into the surrounding environment, the patient achieves adequate oxygenation at lower rates, making this method less expensive and more efficient.

The *T-piece* connects to the endotracheal tube and is useful in weaning patients from mechanical ventilation (Fig. 25-2).

Other oxygen devices include *aerosol masks*, *tracheostomy collars*, and *face tents*, all of which are used with aerosol devices (nebulizers) that can be adjusted for oxygen concentrations from 27% to 100% (0.27 to 1.00). If the gas mixture flow falls below patient demand, room air is pulled in, diluting the concentration. The aerosol mist must be available for the patient during the entire inspiratory phase.

Figure 25-2 T-pieces and tracheostomy collars are devices used when weaning patients from mechanical ventilation.

Although most oxygen therapy is administered as continuous flow oxygen, new methods of oxygen conservation are coming into use. The *demand oxygen delivery system* (DODS) interrupts the flow of oxygen during exhalation, when it is otherwise mostly wasted. Several versions of the DODS are being evaluated for their effectiveness. Studies show that DODS models conserve oxygen and maintain oxygen saturation better than continuous-flow oxygen systems when the respiratory rate increases (Langenhof & Fichter, 2005).

Hyperbaric oxygen therapy is the administration of oxygen at pressures greater than 1 atm. As a result, the amount of oxygen dissolved in plasma is increased, which increases oxygen levels in the tissues. During therapy, the patient is placed in a small (single patient use) or large (multiple patient use) cylinder chamber. Hyperbaric oxygen therapy is used to treat conditions such as air embolism, carbon monoxide poisoning, gangrene, tissue necrosis, and hemorrhage. Although controversial, hyperbaric oxygen has also been used to treat multiple sclerosis, diabetic foot ulcers (Londahl, Katzman, Nilsson, et al., 2006; McMillan, Glover, McMillan, et al., 2007), closed head trauma, acute myocardial infarction, and unstable angina (Bennett, Jepson & Lehm, 2005), as well as slow-to-heal bone fractures (Bennett, Stanford & Turner, 2005). Potential side effects include ear trauma, central nervous system disorders, oxygen toxicity, and claustrophobia.

Gerontologic Considerations

The respiratory system changes throughout the aging process, and it is important for nurses to be aware of these changes when assessing patients who are receiving oxygen therapy. As the respiratory muscles weaken and the large bronchi and alveoli become enlarged, the available surface area of the lungs decreases, resulting in reduced ventilation and respiratory gas exchange. The number of functional cilia is also reduced, decreasing ciliary action and the cough reflex. As a result of osteoporosis and calcification of the costal cartilages, chest wall compliance is decreased. Patients may display increased chest rigidity and respiratory rate and decreased PaO₂ and lung expansion. Nurses should be aware that the older adult is at risk for aspiration and infection related to these changes. In addition, patient education regarding adequate nutrition is essential because appropriate dietary intake can help diminish the excess buildup of carbon dioxide and maintain optimal respiratory functioning.

Nursing Management

Promoting Home and Community-Based Care

Teaching Patients Self-Care

At times oxygen must be administered to the patient at home. The nurse instructs the patient or family in the methods for administering oxygen safely and informs the patient and family that oxygen is available in gas, liquid, and concentrated forms. The gas and liquid forms come in portable devices so that the patient can leave home while receiving oxygen therapy. Humidity must be provided while

oxygen is used (except with portable devices) to counteract the dry, irritating effects of compressed oxygen on the airway (Chart 25-2).

Continuing Care

Home visits by a home health nurse or respiratory therapist may be arranged based on the patient's status and needs. It is important to assess the patient's home environment, the patient's physical and psychological status, and the need for further teaching. The nurse reinforces the teaching points on how to use oxygen safely and effectively, including fire safety tips. To maintain a consistent quality of care and to maximize the patient's financial reimbursement for home oxygen therapy, the nurse ensures that the physician's prescription includes the diagnosis, the prescribed oxygen flow, and conditions for use (eg, continuous use, nighttime use only). Because oxygen is a medication, the nurse reminds the patient receiving long-term oxygen therapy and the family about the importance of keeping follow-up appointments with the physician. The patient is instructed to see the physician every 6 months or more often, if indicated. Arterial blood gas measurements and laboratory tests are repeated annually or more often if the patient's condition changes.

Incentive Spirometry (Sustained Maximal Inspiration)

Incentive spirometry is a method of deep breathing that provides visual feedback to encourage the patient to inhale slowly and deeply to maximize lung inflation and prevent or

CHART

| • Identify causes of malfunction of equipment and when to call for replacement of equipment | ✓ | ✓ |
| • Describe the importance of determining that all electrical outlets are working properly | ✓ | ✓ |

reduce atelectasis. The purpose of an incentive spirometer is to ensure that the volume of air inhaled is increased gradually as the patient takes deeper and deeper breaths.

Incentive spirometers are available in two types: volume or flow. In the volume type, the tidal volume is set using the manufacturer's instructions. The patient takes a deep breath through the mouthpiece, pauses at peak lung inflation, and then relaxes and exhales. Taking several normal breaths before attempting another with the incentive spirometer helps avoid fatigue. The volume is periodically increased as tolerated.

In the flow type, the volume is not preset. The spirometer contains a number of movable balls that are pushed up by the force of the breath and held suspended in the air while the patient inhales. The amount of air inhaled and the flow of the air are estimated by how long and how high the balls are suspended.

Indications

Incentive spirometry is used after surgery, especially thoracic and abdominal surgery, to promote the expansion of the alveoli and to prevent or treat atelectasis.

Nursing Management

Nursing management of the patient using incentive spirometry includes placing the patient in the proper position, teaching the technique for using the incentive spirometer, setting realistic goals for the patient, and recording the results of the therapy (Chart 25-3). Ideally, the patient assumes a sitting or semi-Fowler's position to enhance diaphragmatic excursion; however, this procedure may be performed with the patient in any position.

Mini-Nebulizer Therapy

The mini-nebulizer is a handheld apparatus that disperses a moisturizing agent or medication, such as a bronchodilator or mucolytic agent, into microscopic particles and delivers it to the lungs as the patient inhales. The mini-nebulizer is usually air driven by means of a compressor through connecting tubing. In some instances, the nebulizer is oxygen

driven rather than air driven. To be effective, a visible mist must be available for the patient to inhale.

Indications

The indications for use of a mini-nebulizer include difficulty in clearing respiratory secretions, reduced vital capacity with ineffective deep breathing and coughing, and unsuccessful trials of simpler and less costly methods for clearing secretions, delivering aerosol, or expanding the lungs. The patient must be able to generate a deep breath. Diaphragmatic breathing (Chart 25-4) is a helpful technique to prepare for proper use of the mini-nebulizer. Mini-nebulizers are frequently used for

CHART
25-4

PATIENT EDUCATION Breathing Exercises

General Instructions

- Breathe slowly and rhythmically to exhale completely and empty the lungs completely.
- Inhale through the nose to filter, humidify, and warm the air before it enters the lungs.
- If you feel out of breath, breathe more slowly by prolonging the exhalation time.
- Keep the air moist with a humidifier.

Diaphragmatic Breathing

Goal: To use and strengthen the diaphragm during breathing

- Place one hand on the abdomen (just below the ribs) and the other hand on the middle of the chest to increase the awareness of the position of the diaphragm and its function in breathing.
- Breathe in slowly and deeply through the nose, letting the abdomen protrude as far as possible.
- Breathe out through pursed lips while tightening (contracting) the abdominal muscles.
- Press firmly inward and upward on the abdomen while breathing out.
- Repeat for 1 minute; follow with a rest period of 2 minutes.
- Gradually increase duration up to 5 minutes, several times a day (before meals and at bedtime).

Pursed-Lip Breathing

Goal: To prolong exhalation and increase airway pressure during expiration, thus reducing the amount of trapped air and the amount of airway resistance.

- Inhale through the nose while slowly counting to 3—the amount of time needed to say "Smell a rose."
- Exhale slowly and evenly against pursed lips while tightening the abdominal muscles. (Pursing the lips increases intratracheal pressure; exhaling through the mouth offers less resistance to expired air.)
- Count to 7 slowly while prolonging expiration through pursed lips—the length of time to say "Blow out the candle."
- While sitting in a chair:
Fold arms over the abdomen.
Inhale through the nose while counting to 3 slowly.
Bend forward and exhale slowly through pursed lips while counting to 7 slowly.
- While walking:
Inhale while walking two steps.
Exhale through pursed lips while walking four or five steps.

CHART
25-3

PATIENT EDUCATION Performing Incentive Spirometry

- The inspired air helps inflate the lungs. The ball or weight in the spirometer rises in response to the intensity of the intake of air. The higher the ball rises, the deeper the breath.
- Assume a semi-Fowler's position or an upright position before initiating therapy.
- Use diaphragmatic breathing.
- Place the mouthpiece of the spirometer firmly in the mouth, breathe air in (inspire) through the mouth, and hold the breath at the end of inspiration for about 3 seconds. Exhale slowly through the mouthpiece.
- Coughing during and after each session is encouraged. Splint the incision when coughing postoperatively.
- Perform the procedure approximately 10 times in succession, repeating the 10 breaths with the spirometer each hour during waking hours.

patients with COPD to dispense inhaled medications, and they are commonly used at home on a long-term basis.

Nursing Management

The nurse instructs the patient to breathe through the mouth, taking slow, deep breaths, and then to hold the breath for a few seconds at the end of inspiration to increase intrapleural pressure and reopen collapsed alveoli, thereby increasing functional residual capacity. The nurse encourages the patient to cough and to monitor the effectiveness of the therapy. The nurse instructs the patient and family about the purpose of the treatment, equipment setup, medication additive, and proper cleaning and storage of the equipment.

Intermittent Positive-Pressure Breathing

Intermittent positive-pressure breathing (IPPB) is an older form of assisted or controlled respiration in which compressed gas is delivered under positive pressure into a person's airways until a preset pressure is reached. Passive exhalation is allowed through a valve. It is infrequently used today.

Chest Physiotherapy

Chest physiotherapy (CPT) includes **postural drainage**, **chest percussion**, and **vibration**, and breathing retraining. In addition, teaching the patient effective coughing technique is an important part of CPT. The goals of CPT are to remove bronchial secretions, improve ventilation, and increase the efficiency of the respiratory muscles.

Postural Drainage (Segmented Bronchial Drainage)

Postural drainage allows the force of gravity to assist in the removal of bronchial secretions. The secretions drain from the affected bronchioles into the bronchi and trachea and are removed by coughing or suctioning. Postural drainage is used to prevent or relieve bronchial obstruction caused by accumulation of secretions.

Because the patient usually sits in an upright position, secretions are likely to accumulate in the lower parts of the lungs. Several other positions (Fig. 25-3) are used so that the force of gravity helps move secretions from the smaller bronchial airways to the main bronchi and trachea. Each position contributes to effective drainage of a different lobe of the lungs; lower and middle lobe bronchi drain more effectively when the head is down, while the upper lobe bronchi drain more effectively when the head is up. The secretions then are removed by coughing. The nurse instructs the patient to inhale bronchodilators and mucolytic agents, if prescribed, before postural drainage, because these medications improve drainage of the bronchial tree.

Nursing Management

The nurse should be aware of the patient's diagnosis as well as the lung lobes or segments involved, the cardiac status, and any structural deformities of the chest wall and spine. Auscultating the chest before and after the procedure is used to iden-

tify the areas that need drainage and assess the effectiveness of treatment. The nurse teaches family members who will assist the patient at home to evaluate breath sounds before and after treatment. The nurse explores strategies that will enable the patient to assume the indicated positions at home. This may require the creative use of objects readily available at home, such as pillows, cushions, or cardboard boxes.

Postural drainage is usually performed two to four times daily, before meals (to prevent nausea, vomiting, and aspiration) and at bedtime. Prescribed bronchodilators, water, or saline may be nebulized and inhaled before postural drainage to dilate the bronchioles, reduce bronchospasm, decrease the thickness of mucus and sputum, and combat edema of the bronchial walls. The recommended sequence starts with positions to drain the lower lobes, followed by positions to drain the upper lobes.

The nurse makes the patient as comfortable as possible in each position and provides an emesis basin, sputum cup, and paper tissues. The nurse instructs the patient to remain in each position for 10 to 15 minutes and to breathe in slowly through the nose and out slowly through pursed lips to help keep the airways open so that secretions can drain while in each position. If a position cannot be tolerated, the nurse helps the patient assume a modified position. When the patient changes position, the nurse explains how to cough and remove secretions (Chart 25-5).

If the patient cannot cough, the nurse may need to suction the secretions mechanically. It also may be necessary to use chest percussion and vibration or a high-frequency chest wall oscillation (HFCWO) vest to loosen bronchial secretions and mucus plugs that adhere to the bronchioles and bronchi and to propel sputum in the direction of gravity drainage (see later discussion). If suctioning is required at home, the nurse instructs caregivers in safe suctioning technique and care of the suctioning equipment.

After the procedure, the nurse notes the amount, color, viscosity, and character of the expelled sputum. It is important to evaluate the patient's skin color and pulse the first few times the procedure is performed. It may be necessary to administer oxygen during postural drainage.

If the sputum is foul-smelling, it is important to perform postural drainage in a room away from other patients or family members. (Deodorizers may be used to counter-

CHART
25-5

PATIENT EDUCATION

Effective Coughing Technique

- Assume a sitting position and bend slightly forward. This upright position permits a stronger cough.
- Flex your knees and hips to promote relaxation and reduce the strain on the abdominal muscles while coughing.
- Inhale slowly through the nose and exhale through pursed lips several times.
- Cough twice during each exhalation while contracting (pulling in) the abdomen sharply with each cough.
- Splint the incisional area, if any, with firm hand pressure or support it with a pillow or rolled blanket while coughing (see Fig. 25-12). (The nurse can initially demonstrate this by using the patient's hands.)

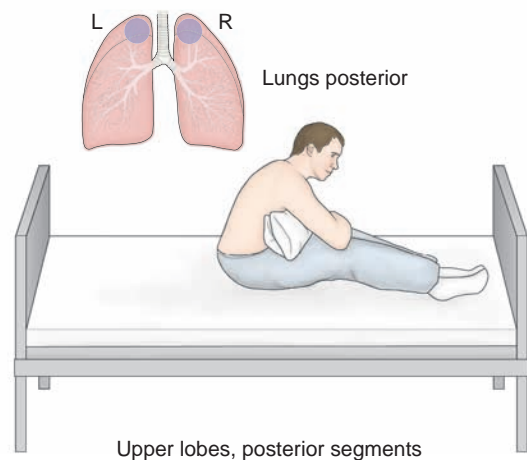

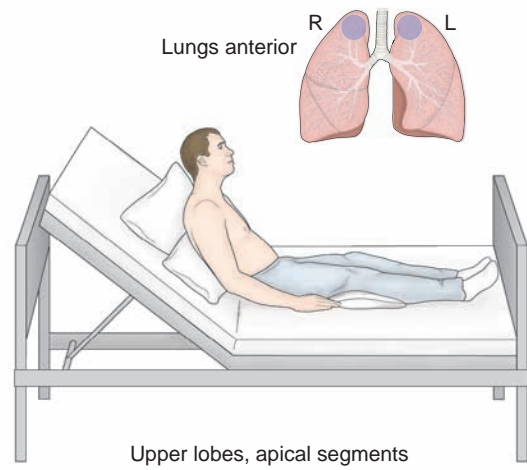

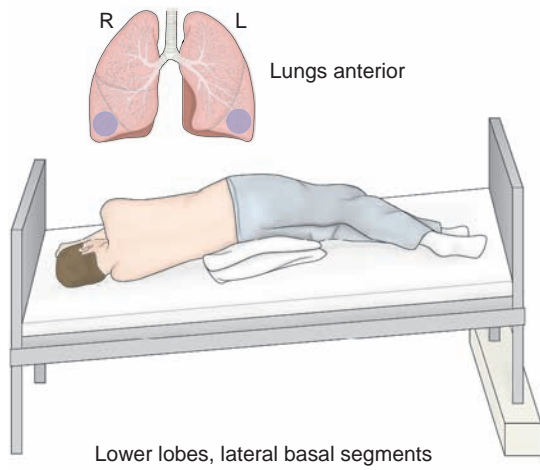

Figure 25-3 Postural drainage positions and the areas of lung drained by each position.

Figure 25-4 Percussion and vibration. **A**, Proper hand position for vibration. **B**, Proper technique for vibration. The wrists and elbows remain stiff; the vibrating motion is produced by the shoulder muscles. **C**, Proper hand position for percussion.

act the odor. Because aerosol sprays can cause bronchospasm and irritation, they should be used sparingly and with caution.) After the procedure, the patient may find it refreshing to brush the teeth and use a mouthwash before resting.

Chest Percussion and Vibration

Thick secretions that are difficult to cough up may be loosened by tapping (percussing) and vibrating the chest or through use of an HFCWO vest. Chest percussion and vibration help dislodge mucus adhering to the bronchioles and bronchi. A scheduled program of coughing and clearing sputum, together with hydration, reduces the amount of sputum in most patients.

Percussion is carried out by cupping the hands and lightly striking the chest wall in a rhythmic fashion over the lung segment to be drained. The wrists are alternately flexed and extended so that the chest is cupped or clapped in a painless manner (Fig. 25-4). A soft cloth or towel may be placed over the segment of the chest that is being cupped to prevent skin irritation and redness from direct contact. Percussion, alternating with vibration, is performed for 3 to 5 minutes for each position. The patient uses diaphragmatic breathing during this procedure to promote relaxation (see later discussion). As a precaution, percussion over chest drainage tubes, the sternum, spine, liver, kidneys, spleen, or breasts (in women) is avoided. Percussion is performed cautiously in the elderly because of their increased incidence of osteoporosis and risk of rib fracture.

Vibration is the technique of applying manual compression and tremor to the chest wall during the exhalation phase of respiration (see Fig. 25-4). This helps increase the velocity of the air expired from the small airways, thus freeing the mucus. After three or four vibrations, the patient is encouraged to cough, contracting the abdominal muscles to increase the effectiveness of the cough.

The number of times the percussion and coughing cycle is repeated depends on the patient's tolerance and clinical

response. It is important to evaluate breath sounds before and after the procedures.

An inflatable HFCWO vest (Fig. 25-5) may be used to provide chest therapy. The vest uses air pulses to compress the chest wall 8 to 18 times/sec, causing secretions to detach from the airway wall and enabling the patient to expel them by coughing. Vest therapy is considered more effective than manual percussion because it is gentler and acts on all lobes of the lung simultaneously. Research has shown that the vest is equally effective to manual CPT, and some patients prefer it (Main, Prasad & van der Schans, 2005).

To increase the effectiveness of coughing, a flutter valve is sometimes used, especially by people who have cystic fibrosis. The flutter valve looks like a pipe but has a cap covering the bowl, which contains a steel ball. When the patient exhales actively into the valve, movement of the ball causes pressure oscillations, thereby decreasing mucus viscosity, allowing it to move within the airways and be coughed out.

Nursing Management

When performing CPT, the nurse ensures that the patient is comfortable, is not wearing restrictive clothing, and has not just eaten. The nurse gives medication for pain, as prescribed, before percussion and vibration and splints any incision and provides pillows for support as needed. The positions are varied, but focus is placed on the affected areas. On completion of the treatment, the nurse assists the patient to assume a comfortable position.

If an HFCWO vest is being used, the patient may assume whatever position is most comfortable and may even continue to perform light activity during therapy within the length of the compressed air hose. It is not necessary for the patient to assume specific positions for the vest to be effective.

The nurse must stop treatment if any of the following occur: increased pain, increased shortness of breath, weakness, lightheadedness, or hemoptysis. Therapy is indicated until the patient has normal respirations, can mobilize secretions, and has normal breath sounds, and until the chest x-ray findings are normal.

Promoting Home and Community-Based Care

Teaching Patients Self-Care. CPT is frequently indicated at home for patients with COPD, bronchiectasis, or cystic fibrosis. The techniques are the same as described previously, but gravity drainage is achieved by placing the hips over a box, a stack of magazines, or pillows (unless a hospital bed is available). The nurse instructs the patient and family in the positions and techniques of percussion and vibration so that therapy can be continued in the home. In addition, the nurse instructs the patient to maintain an adequate fluid intake and air humidity to prevent secretions from becoming thick and tenacious. It also is important to teach the patient to recognize early signs of infection, such as fever and a change in the color or character of sputum. Resting 5 to 10 minutes in each postural drainage position before CPT maximizes the amount of secretions obtained.

Continuing Care. CPT may be carried out during visits by a home care nurse. The nurse also assesses the patient's physical status, understanding of the treatment plan, compliance with recommended therapy, and the effectiveness of therapy. It is important to reinforce patient and family teaching during these visits. The nurse reports to the patient's physician any deterioration in the patient's physical status or inability to clear secretions.

Breathing Retraining

Breathing retraining consists of exercises and breathing practices that are designed to achieve more efficient and controlled ventilation and to decrease the work of breathing. Breathing retraining is especially indicated in patients with COPD and dyspnea. These exercises promote maximal alveolar inflation and muscle relaxation; relieve anxiety; eliminate ineffective, uncoordinated patterns of respiratory muscle activity; slow the respiratory rate; and decrease the work of breathing. Slow, relaxed, rhythmic breathing also helps to control the anxiety that occurs with dyspnea. Specific breathing exercises include diaphragmatic and pursed-lip breathing (see Chart 25-4).

Diaphragmatic breathing can become automatic with sufficient practice and concentration. Pursed-lip breathing,

which improves oxygen transport, helps induce a slow, deep breathing pattern and assists the patient to control breathing, even during periods of stress. This type of breathing helps prevent airway collapse secondary to loss of lung elasticity in emphysema. The nurse instructs the patient in diaphragmatic breathing and pursed-lip breathing, as described in Chart 25-4. Breathing exercises should be practiced in several positions because air distribution and pulmonary circulation vary with the position of the chest.

Many patients require additional oxygen, using a low-flow method, while performing breathing exercises. Emphysema-like changes in the lung occur as part of the natural aging process of the lung; therefore, breathing exercises are appropriate for all elderly patients, whether hospitalized or not, who are sedentary, even without primary lung disease.

Nursing Management

The nurse instructs the patient to breathe slowly and rhythmically in a relaxed manner and to exhale completely to empty the lungs. The patient is instructed to always inhale through the nose because this filters, humidifies, and warms the air. If short of breath, the patient should be instructed to concentrate on prolonging the length of exhalation; this helps avoid initiating a cycle of increasing shortness of breath and panic. Minimizing the amount of dust or particles in the air and providing adequate humidification may also make it easier for the patient to breathe. Dust and particles in the air can be decreased by removing drapes and upholstered furniture, using air filters, and washing floors, dusting, and vacuuming frequently.

The nurse instructs the patient that an adequate dietary intake promotes gas exchange and increases energy levels. It is important to obtain adequate nutrition without overeating by consuming small, frequent meals and snacks. Having ready-prepared meals and favorite foods available helps encourage nutrient consumption. Gas-producing foods such as beans, legumes, broccoli, cabbage, and brussels sprouts should be avoided to prevent gastric distress. Because many patients lack the energy to eat, they should be taught to rest before and after meals to conserve energy.

AIRWAY MANAGEMENT

Adequate ventilation is dependent on free movement of air through the upper and lower airways. In many disorders, the airway becomes narrowed or blocked as a result of disease, bronchoconstriction (narrowing of airway by contraction of muscle fibers), a foreign body, or secretions. Maintaining a patent (open) airway is achieved through meticulous airway management, whether in an emergency situation such as airway obstruction or in long-term management, as in caring for a patient with an endotracheal or a tracheostomy tube.

Emergency Management of Upper Airway Obstruction

Upper airway obstruction has a variety of causes. Acute upper airway obstruction may be caused by food particles, vomitus, blood clots, or anything that obstructs the larynx or

trachea. It also may occur from enlargement of tissue in the wall of the airway, as in epiglottitis, obstructive sleep apnea, laryngeal edema, laryngeal carcinoma, or peritonsillar abscess, or from thick secretions. Pressure on the walls of the airway, as occurs in retrosternal goiter, enlarged mediastinal lymph nodes, hematoma around the upper airway, and thoracic aneurysm, also may result in upper airway obstruction.

The patient with an altered level of consciousness from any cause is at risk for upper airway obstruction because of loss of the protective reflexes (cough and swallowing) and loss of the tone of the pharyngeal muscles, which causes the tongue to fall back and block the airway.

The nurse makes the following rapid observations to assess for signs and symptoms of upper airway obstruction:

- **Inspection:** Is the patient conscious? Is there any inspiratory effort? Does the chest rise symmetrically? Is there use or retraction of accessory muscles? What is the skin color? Are there any obvious signs of deformity or obstruction (trauma, food, teeth, vomitus)? Is the trachea midline?
- **Palpation:** Do both sides of the chest rise equally with inspiration? Are there any specific areas of tenderness, fracture, or subcutaneous emphysema (crepitus)?
- **Auscultation:** Is there any audible air movement, stridor (inspiratory sound), or wheezing (expiratory sound)? Are breath sounds present over the lower trachea and all lobes?
- As soon as an upper airway obstruction is identified, the nurse takes emergency measures (Chart 25-6). (See Chapter 22 or Chapter 71 for more details on managing a foreign body airway obstruction.)

Endotracheal Intubation

Endotracheal intubation involves passing an endotracheal tube through the mouth or nose into the trachea (Fig. 25-6). Intubation provides a patent airway when the patient is having respiratory distress that cannot be treated with simpler methods and is the method of choice in emergency care. Endotracheal intubation is a means of providing an airway for

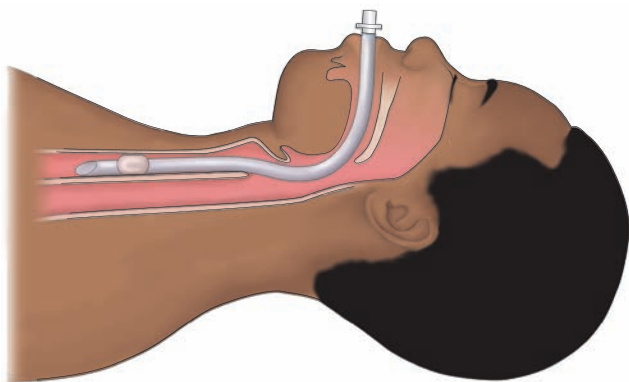

Figure 25-6 Endotracheal tube in place. The tube has been inserted using the oral route. The cuff has been inflated to maintain the tube's position and to minimize the risk of aspiration.

patients who cannot maintain an adequate airway on their own (e.g., comatose patients, patients with upper airway obstruction), for patients needing mechanical ventilation, and for suctioning secretions from the pulmonary tree.

An endotracheal tube usually is passed with the aid of a laryngoscope by specifically trained medical, nursing, or respiratory therapy personnel (see Chapter 71). Once the tube is inserted, a cuff is inflated to prevent air from leaking around the outer part of the tube, to minimize the possibility of aspiration, and to prevent movement of the tube. Chart 25-7 discusses the nursing care of the patient with an endotracheal tube.

Complications can occur from pressure exerted by the cuff on the tracheal wall. Cuff pressures should be maintained between 15 and 20 mm Hg (Morton, Fontaine, Hudak, et al., 2009). High cuff pressure can cause tracheal bleeding, ischemia, and pressure necrosis, whereas low cuff pressure can increase the risk of aspiration pneumonia. Routine deflation of the cuff is not recommended because of the increased risk of aspiration and hypoxia. Tracheobronchial secretions are suctioned through the tube. Warmed, humidified oxygen should always be introduced through the tube, whether the patient is breathing spontaneously or is receiving ventilatory support. Endotracheal intubation may be used for no longer than 3 weeks, by which time a tracheostomy must be considered to decrease irritation of and trauma to the tracheal lining, to reduce the incidence of vocal cord paralysis (secondary to laryngeal nerve damage), and to decrease the work of breathing.

Endotracheal and tracheostomy tubes have several disadvantages. The tubes cause discomfort. The cough reflex is depressed because glottis closure is hindered. Secretions tend to become thicker because the warming and humidifying effect of the upper respiratory tract has been bypassed. The swallowing reflexes (glottic, pharyngeal, and laryngeal reflexes) are depressed because of prolonged disuse and the mechanical trauma produced by the endotracheal or tracheostomy tube, increasing the risk of aspiration. In addition, ulceration and stricture of the larynx or trachea may develop. Of great concern to the patient is the inability to talk and to communicate needs.

Unintentional or premature removal of the tube is a potentially life-threatening complication of endotracheal intubation. Removal of the tube is a frequent problem in intensive care units and occurs mainly during nursing care or by the patient. It is important that nurses instruct and remind patients and family members about the purpose of the tube and the dangers of removing it. Baseline and ongoing assessment of the patient and of the equipment ensures effective care. Providing comfort measures, including opioid analgesia and sedation, can improve the patient's tolerance of the endotracheal tube.

NURSING ALERT

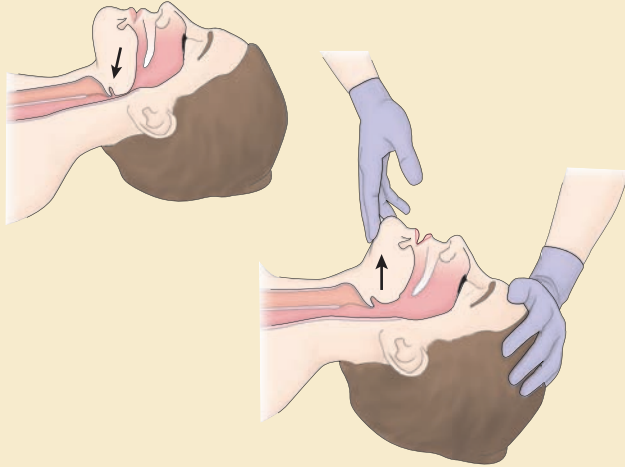

Inadvertent removal of an endotracheal tube can cause laryngeal swelling, hypoxemia, bradycardia, hypotension, and even death. Measures must be taken to prevent premature or inadvertent removal.

To prevent tube removal by the patient, the nurse should explain to the patient and family the purpose of the tube, distract the patient through one-to-one interaction or with

Chart 25-6 • Clearing an Upper Airway Obstruction

Clearing the Airway

Hyperextend the patient's neck by placing one hand on the forehead and placing the fingers of the other hand underneath the jaw and lifting upward and forward. This action pulls the tongue away from the back of the pharynx.

Opening the airway.

- Assess the patient by observing the chest and listening and feeling for the movement of air.
- Use a cross-finger technique to open the mouth and observe for obvious obstructions such as secretions, blood clots, or food particles.
- If no passage of air is detected, apply five quick sharp abdominal thrusts just below the xiphoid process to expel the

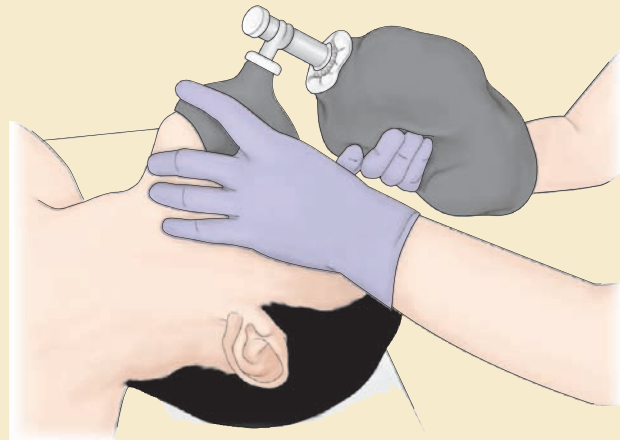

Abdominal thrust (Heimlich) maneuver administered to unconscious patient.

obstruction. Repeat this procedure until the obstruction is expelled.

- After the obstruction is expelled, roll the patient as a unit onto the side for recovery.
- When the obstruction is relieved, if the patient can breathe spontaneously but not cough, swallow, or gag, insert an oral or nasopharyngeal airway.

Bag and Mask Resuscitation

- Apply the mask to the patient's face and create a seal by pressing the thumb of the nondominant hand on the bridge of the nose and the index finger on the chin.
- Using the rest of the fingers on that hand, pull on the chin and the angle of the mandible to maintain the head in extension.
- Use the dominant hand to inflate the lungs by squeezing the bag to its full volume.

Resuscitation via bag and mask apparatus.

Chart 25-7 • Care of the Patient With an Endotracheal Tube

Immediately After Intubation

1. Check symmetry of chest expansion.
2. Auscultate breath sounds of anterior and lateral chest bilaterally.
3. Obtain order for chest x-ray to verify proper tube placement.
4. Check cuff pressure every 6–8 hours.
5. Monitor for signs and symptoms of aspiration.
6. Ensure high humidity; a visible mist should appear in the T-piece or ventilator tubing.
7. Administer oxygen concentration as prescribed by physician.
8. Secure the tube to the patient's face with tape, and mark the proximal end for position maintenance.
 - a. Cut proximal end of tube if it is longer than 7.5 cm (3 inches) to prevent kinking.
 - b. Insert an oral airway or mouth device to prevent the patient from biting and obstructing the tube.
9. Use sterile suction technique and airway care to prevent iatrogenic contamination and infection.
10. Continue to reposition patient every 2 hours and as needed to prevent atelectasis and to optimize lung expansion.
11. Provide oral hygiene and suction the oropharynx whenever necessary.

Extubation (Removal of Endotracheal Tube)

1. Explain procedure.
2. Have self-inflating bag and mask ready in case ventilatory assistance is required immediately after extubation.
3. Suction the tracheobronchial tree and oropharynx, remove tape, and then deflate the cuff.
4. Give 100% oxygen for a few breaths, then insert a new, sterile suction catheter inside tube.
5. Have the patient inhale. At peak inspiration remove the tube, suctioning the airway through the tube as it is pulled out.

Note: In some hospitals this procedure can be performed by respiratory therapists; in others, by nurses. Check hospital policy.

Care of Patient Following Extubation

1. Give heated humidity and oxygen by face mask and maintain the patient in a sitting or high Fowler's position.
2. Monitor respiratory rate and quality of chest excursions. Note stridor, color change, and change in mental alertness or behavior.
3. Monitor the patient's oxygen level using a pulse oximeter.
4. Keep NPO or give only ice chips for next few hours.
5. Provide mouth care.
6. Teach patient how to perform coughing and deep-breathing exercises.

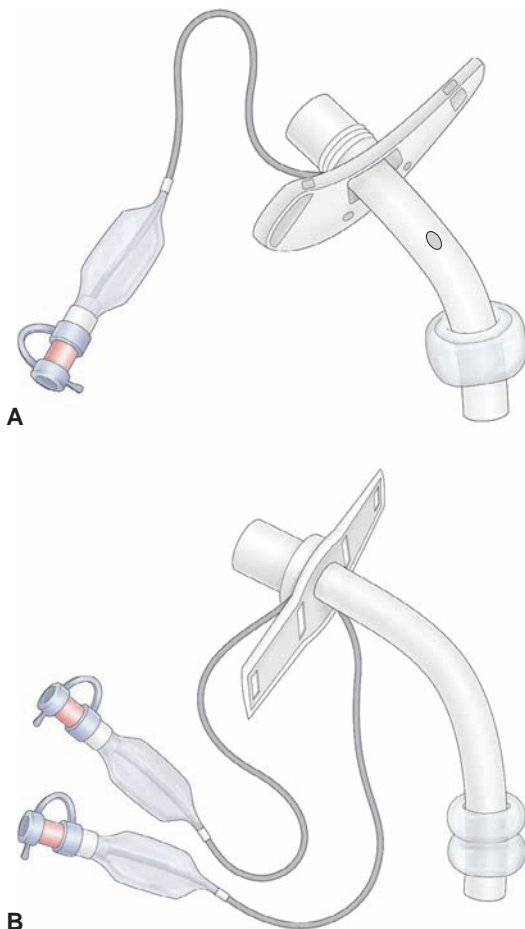

Figure 25-7 Tracheostomy tubes. **A**, Fenestrated tube, which allows patient to talk. **B**, Double-cuffed tube. Inflating the two cuffs alternately can help prevent tracheal damage.

television, and maintain comfort measures. As a last resort, soft wrist restraints may be used. Discretion and caution must always be used before applying any restraint. If the patient cannot move the arms and hands to the endotracheal tube, restraints are not needed. If the patient is alert, oriented, able to follow directions, and cooperative to the point that it is highly unlikely that he or she will remove the endotracheal tube, restraints are not needed. However, if the nurse determines there is a risk that the patient may try to remove the tube, soft wrist restraints are appropriate with a physician's order (check agency policy). Close monitoring of the patient is essential to ensure safety and prevent harm.

Tracheostomy

A **tracheotomy** is a surgical procedure in which an opening is made into the trachea. The indwelling tube inserted into the trachea is called a **tracheostomy tube** (Fig. 25-7). A tracheostomy may be either temporary or permanent.

A tracheotomy is used to bypass an upper airway obstruction, to allow removal of tracheobronchial secretions, to permit the long-term use of mechanical ventilation, to prevent aspiration of oral or gastric secretions in the unconscious or paralyzed patient (by closing off the trachea from the esophagus), and to replace an endotracheal tube. Many disease processes and emergency conditions make a tracheotomy necessary.

Procedure

The surgical procedure is usually performed in the operating room or in an intensive care unit, where the patient's ventilation can be well controlled and optimal aseptic technique can be maintained. A surgical opening is made between the

second and third tracheal rings. After the trachea is exposed, a cuffed tracheostomy tube of an appropriate size is inserted. The cuff is an inflatable attachment to the tracheostomy tube that is designed to occlude the space between the tracheal walls and the tube, to permit effective mechanical ventilation, and to minimize the risk of aspiration. See Figure 25-7 for the different types of tracheostomy tubes.

The tracheostomy tube is held in place by tapes fastened around the patient's neck. Usually a square of sterile gauze is placed between the tube and the skin to absorb drainage and reduce the risk for infection.

Complications

Complications may occur early or late in the course of tracheostomy tube management. They may even occur years after the tube has been removed. Early complications include bleeding, pneumothorax, air embolism, aspiration, subcutaneous or mediastinal emphysema, recurrent laryngeal nerve damage, and posterior tracheal wall penetration. Long-term complications include airway obstruction from accumulation of secretions or protrusion of the cuff over the opening of the tube, infection, rupture of the innominate artery, dysphagia, tracheoesophageal fistula, tracheal dilation, tracheal ischemia, and necrosis. Tracheal stenosis may develop after the tube is removed. Chart 25-8 outlines measures nurses can take to prevent complications.

Nursing Management

The patient requires continuous monitoring and assessment. The newly made opening must be kept patent by proper suctioning of secretions. After the vital signs are stable, the patient is placed in a semi-Fowler's position to facilitate ventilation, promote drainage, minimize edema, and prevent strain on the suture lines. Analgesia and sedative agents must be administered with caution because of the risk of suppressing the cough reflex.

Major objectives of nursing care are to alleviate the patient's apprehension and to provide an effective means of communication. The nurse keeps paper and pencil or a Magic Slate and the call light within the patient's reach at all times to ensure a means of communication. Chart 25-9 summarizes the care of the patient with a tracheostomy tube.

Chart 25-8 • Preventing Complications Associated With Endotracheal and Tracheostomy Tubes

- Administer adequate warmed humidity.
- Maintain cuff pressure at appropriate level.
- Suction as needed per assessment findings.
- Maintain skin integrity. Change tape and dressing as needed or per protocol.
- Auscultate lung sounds.
- Monitor for signs and symptoms of infection, including temperature and white blood cell count.
- Administer prescribed oxygen and monitor oxygen saturation.
- Monitor for cyanosis.
- Maintain adequate hydration of the patient.
- Use sterile technique when suctioning and performing tracheostomy care.

Suctioning the Tracheal Tube (Tracheostomy or Endotracheal Tube)

When a tracheostomy or endotracheal tube is in place, it is usually necessary to suction the patient's secretions because of the decreased effectiveness of the cough mechanism. Tracheal suctioning is performed when adventitious breath sounds are detected or whenever secretions are obviously present. Unnecessary suctioning can initiate bronchospasm and cause mechanical trauma to the tracheal mucosa.

All equipment that comes into direct contact with the patient's lower airway must be sterile to prevent overwhelming pulmonary and systemic infections. Chart 25-10 presents the procedure for suctioning a patient with a tracheostomy tube. In mechanically ventilated patients, an in-line suction catheter may be used to allow rapid suction when needed and to minimize cross-contamination by airborne pathogens. An in-line suction device allows the patient to be suctioned without being disconnected from the ventilator circuit. In-line suctioning (also called closed suctioning) decreases hypoxemia, sustains PEEP, and can decrease patient anxiety associated with suctioning. Because it protects staff from patient secretions, it can be performed without using personal protective gear.

Managing the Cuff

The cuff on an endotracheal or tracheostomy tube should be inflated if the patient requires mechanical ventilation or is at high risk for aspiration. The pressure within the cuff should be the lowest possible pressure that allows delivery of adequate tidal volumes and prevents pulmonary aspiration. Usually the pressure is maintained at less than 25 mm Hg to prevent injury and at more than 15 mm Hg to prevent aspiration. Cuff pressure must be monitored at least every 8 hours by attaching a handheld pressure gauge to the pilot balloon of the tube or by using the minimal leak volume or minimal occlusion volume technique. With long-term intubation, higher pressures may be needed to maintain an adequate seal.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

If the patient is at home with a tracheostomy tube, the nurse instructs the patient and family about daily care, including techniques to prevent infection, as well as measures to take in an emergency. The nurse provides the patient and family with a list of community contacts for education and support needs.

Continuing Care

A referral for home care is indicated for ongoing assessment of the patient and of the ability of the patient and family to provide appropriate and safe care. The home care nurse assesses the patient's and family's ability to cope with the physical changes and psychological issues associated with having a tracheostomy. The nurse also identifies resources and makes referrals for appropriate services to assist the patient and family to manage the tracheostomy tube at home.

 CHART
25-9

Guidelines for Care of the Patient With a Tracheostomy Tube

Equipment

- Sterile gloves
- Hydrogen peroxide
- Normal saline solution or sterile water
- Cotton-tipped applicators
- Dressing
- Twill tape
- Type of tube prescribed, if the tube is to be changed

Implementation

Actions

1. Provide patient and family instruction on the key points for tracheostomy care, beginning with how to inspect the tracheostomy dressing for moisture or drainage. A cuffed tube (air injected into cuff) is required during mechanical ventilation. A low-pressure cuff is most commonly used. Patients requiring long-term use of a tracheostomy tube and who can breathe spontaneously commonly use an uncuffed, metal tube.
2. Perform hand hygiene.
3. Explain procedure to patient and family as appropriate.
4. Put on clean gloves; remove and discard the soiled dressing in a biohazard container.
5. Prepare sterile supplies, including hydrogen peroxide, normal saline solution or sterile water, cotton-tipped applicators, dressing, and tape.
6. Put on sterile gloves. (Some physicians approve clean technique for long-term tracheostomy patients in the home.)
7. Cleanse the wound and the plate of the tracheostomy tube with sterile cotton-tipped applicators moistened with hydrogen peroxide. Rinse with sterile saline solution.
8. Soak inner cannula in peroxide or sterile saline, per manufacturer's instructions; rinse with saline solution; and inspect to be sure all dried secretions have been removed. Dry and reinsert inner cannula or replace with a new disposable inner cannula.
9. Place clean twill tape in position to secure the tracheostomy tube by inserting one end of the tape through the side opening of the outer cannula. Take the tape around the back of the patient's neck and thread it through the opposite opening of the outer cannula. Bring both ends around so that they meet on one side of the neck. Tighten the tape until only two fingers can be comfortably inserted under it. Secure with a knot. For a new tracheostomy, two people should assist with tape changes. Remove soiled twill tape after the new tape is in place.
10. Remove old tapes and discard in a biohazard container after the new tape is in place.
11. Although some long-term tracheostomies with healed stomas may not require a dressing, other tracheostomies do. In such cases, use a sterile tracheostomy dressing, fitting it securely under the twill tapes and flange of tracheostomy tube so that the incision is covered, as shown below.

Rationale

The tracheostomy dressing is changed as needed to keep the skin clean and dry. To prevent potential breakdown, moist or soiled dressings should not remain on the skin. A cuffed tube prevents air from leaking during positive-pressure ventilation and also prevents tracheal aspiration of gastric contents. An adequate seal is indicated by the disappearance of any air leakage from the mouth or tracheostomy or by the disappearance of the harsh, gurgling sound of air coming from the throat. Low-pressure cuffs exert minimal pressure on the tracheal mucosa and thus reduce the danger of tracheal ulceration and stricture.

Hand hygiene reduces bacteria on hands.

A patient with a tracheostomy is apprehensive and requires ongoing assurance and support.

Observing body substance isolation reduces cross-contamination from soiled dressings.

Having necessary supplies and equipment readily available allows the procedure to be completed efficiently.

Sterile equipment minimizes transmission of surface flora to the sterile respiratory tract. Clean technique may be used in the home because of decreased exposure to potential pathogens.

Hydrogen peroxide is effective in loosening crusted secretions. Rinsing prevents skin residue.

Soaking loosens and removes secretions from the inner lumen of the tracheostomy tube. Retained secretions could harbor bacteria, leading to infection. Some plastic tracheostomy tubes may be damaged by using peroxide.

This taping technique provides a double thickness of tape around the neck, which is needed because the tracheostomy tube can be dislodged by movement or by a forceful cough if left unsecured. A dislodged tracheostomy tube is difficult to reinsert, and respiratory distress may occur. Dislodgement of the tube with a new tracheostomy is a medical emergency.

Tapes with old secretions may harbor bacteria.

Healed tracheostomies with minimal secretions do not need a dressing. Dressings that will shred are not used around a tracheostomy because of the risk that pieces of material, lint, or thread may get into the tube, and eventually into the trachea, causing obstruction or abscess formation. Special dressings that do not have a tendency to shred are used.

Continued on following page

CHART
25-9

Guidelines for Care of the Patient With a Tracheostomy Tube (Continued)

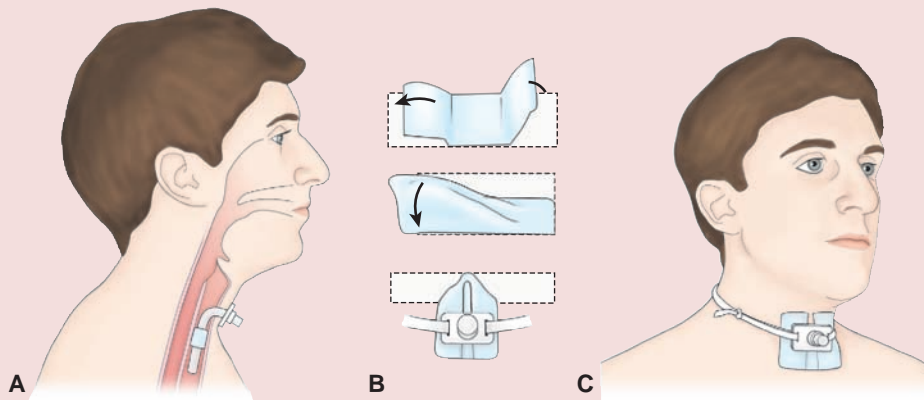

Figure 25-9.1 **A**, The cuff of the tracheostomy tube fits smoothly and snugly in the trachea in a way that promotes circulation but seals off the escape of secretions and air surrounding the tube. **B**, For a dressing change, a 4- by 4-inch gauze pad may be folded (cutting would promote shredding, placing the patient at risk for aspiration) around the tracheostomy tube and **C**, stabilized by slipping the neck tape ties through the neck plate slots of the tracheostomy tube. The ties may be fastened to the side of the neck to eliminate the discomfort of lying on the knot.

Mechanical Ventilation

Mechanical ventilation may be required for a variety of reasons: to control the patient's respirations during surgery or during treatment of severe head injury, to oxygenate the blood when the patient's ventilatory efforts are inadequate, and to rest the respiratory muscles, among others. Many patients placed on a ventilator can breathe spontaneously, but the effort needed to do so may be exhausting.

A **mechanical ventilator** is a positive- or negative-pressure breathing device that can maintain ventilation and oxygen delivery for a prolonged period. Caring for a patient on mechanical ventilation has become an integral part of nursing care in critical care or general medical-surgical units, extended care facilities, and the home. Nurses, physicians, and respiratory therapists must understand each patient's specific pulmonary needs and work together to set realistic goals. Positive patient outcomes depend on an understanding of the principles of mechanical ventilation and the patient's care needs as well as open communication among members of the health care team about the goals of therapy, weaning plans, and the patient's tolerance of changes in ventilator settings.

Indications

If a patient has a continuous decrease in oxygenation (PaO_2), an increase in arterial carbon dioxide levels (PaCO_2), and a persistent acidosis (decreased pH), mechanical ventilation may be necessary. Conditions such as thoracic or abdominal surgery, drug overdose, neuromuscular disorders, inhalation injury, COPD, multiple trauma, shock, multisystem failure, and coma all may lead to respiratory failure and the need for mechanical ventilation. The criteria for mechanical ventilation guide the decision to place a patient on a ventilator (Chart 25-11). A patient with apnea that is not readily reversible also is a candidate for mechanical ventilation.

Classification of Ventilators

Mechanical ventilators are classified according to the method by which they support ventilation. The two general categories are negative-pressure and positive-pressure ventilators.

Negative-Pressure Ventilators

Negative-pressure ventilators exert a negative pressure on the external chest. Decreasing the intrathoracic pressure during inspiration allows air to flow into the lung, filling its volume. Physiologically, this type of assisted ventilation is similar to spontaneous ventilation. It is used mainly in chronic respiratory failure associated with neuromuscular conditions, such as poliomyelitis, muscular dystrophy, amyotrophic lateral sclerosis, and myasthenia gravis. It is inappropriate for the patient whose condition is unstable or complex or who requires frequent ventilatory changes. Negative-pressure ventilators are simple to use and do not require intubation of the airway; consequently, they are especially adaptable for home use.

There are several types of negative-pressure ventilators: iron lung, body wrap, and chest cuirass.

Iron Lung (Drinker Respirator Tank)

The iron lung is a negative-pressure chamber used for ventilation. It was used extensively during polio epidemics in the past and currently is used by a few polio survivors and patients with other neuromuscular disorders (eg, amyotrophic lateral sclerosis, muscular dystrophy).

Body Wrap (Pneumo-Wrap) and Chest Cuirass (Tortoise Shell)

The body wrap and chest cuirass are portable devices that require a rigid cage or shell to create a negative-pressure chamber around the thorax and abdomen. Because of problems with proper fit and system leaks, these types of ventilators are used only with carefully selected patients.

 CHART
25-10

Guidelines for Performing Tracheal Suction

Equipment

- Suction catheters
- Gloves (sterile and nonsterile), gown, mask, and goggles for eye protection
- Basin for sterile normal saline solution for irrigation
- Manual resuscitation bag with supplemental oxygen
- Suction source

Implementation

Step

1. Assess the patient's lung sounds and oxygen saturation via pulse oximeter.
2. Explain the procedure to the patient before beginning and offer reassurance during suctioning.
3. Performing hand hygiene. Put on nonsterile gloves, goggles, gown, and mask.
4. Turn on suction source (pressure should not exceed 120 mm Hg).
5. Open suction catheter kit.
6. Fill basin with sterile water.
7. Put sterile glove on dominant hand.
8. Ventilate the patient with manual resuscitation bag and high-flow oxygen for about 30 seconds or turn on suction mode of ventilator (if available) to hyperoxygenate the patient. Instill normal saline solution into airway only if there are thick, tenacious secretions.
9. Instill normal saline solution into airway if there are thick, tenacious secretions.
10. Pick up suction catheter in sterile gloved hand and connect to suction.
11. Insert suction catheter at least as far as the end of the tube without applying suction, just far enough to stimulate the cough reflex.
12. Apply suction while withdrawing and gently rotating the catheter 360 degrees (no longer than 10 to 15 seconds).
13. Reoxygenate and inflate the patient's lungs for several breaths with manual resuscitation bag, or allow ventilator to reoxygenate patient for several breaths using suction mode.
14. Rinse catheter by suctioning a few milliliters of sterile saline solution from the basin between suction attempts.
15. Repeat steps 9 to 14 until the airway is clear.
16. Suction oropharyngeal cavity after completing tracheal suctioning.
17. Rinse suction tubing and discard catheter, gloves, and basin appropriately.
18. Assess the patient's lung sounds and oxygen saturation via pulse oximeter after procedure.
19. Document the amount, color, and consistency of secretions.

Rationale

- Assessment data indicate the need for suctioning and allow the nurse to monitor the effect of suction on the patient's level of oxygenation.
- The patient may be apprehensive about choking and about an inability to communicate.
- Hand hygiene reduces bacteria on hands.
- Suction pressure should be set high enough to be effective without causing trauma to the tissues.
- Having equipment ready prevents interruption of the procedure.
- This provides sterile solution for clearing suction catheter of secretions.
- Equipment that will contact the patient's lower airway must remain sterile to prevent infection.
- This prevents hypoxia during suctioning.
- Solution facilitates their removal.
- Prevents contamination of sterile catheter.
- Inserting the catheter without applying suction permits insertion without causing trauma to the tissues.
- Prolonged suctioning may result in hypoxia and dysrhythmias, leading to cardiac arrest.
- Prevents hypoxia during procedure and restores oxygen supply.
- Keeps suction catheter patent.
- This ensures removal of all tracheal secretions.
- Avoids contamination of trachea with oropharyngeal secretions and organisms.
- Safe disposal of equipment avoids cross-contamination.
- Provides information about effectiveness of procedure.
- Documentation allows monitoring of patient's status over time.

Positive-Pressure Ventilators

Today, the most common ventilators use positive pressure. Positive-pressure ventilators inflate the lungs by exerting positive pressure on the airway, pushing air in, similar to a bellows mechanism, forcing the alveoli to expand during in-

spiration. Expiration occurs passively. Endotracheal intubation or tracheostomy is usually necessary. These ventilators are widely used in the hospital setting and are increasingly used in the home for patients with primary lung disease. Three types of positive-pressure ventilators are classified by the method of ending the inspiratory phase of respiration:

Chart 25-11 • Indications for Mechanical Ventilation

PaO₂ <50 mm Hg with FiO₂ >0.60
 PaO₂ >50 mm Hg with pH <7.25
 Vital capacity <2 times tidal volume
 Negative inspiratory force <25 cm H₂O
 Respiratory rate >35/min

pressure-cycled, time-cycled, and volume-cycled. The fourth type, noninvasive positive-pressure ventilation, does not require intubation.

Pressure-Cycled Ventilators

When the pressure-cycled ventilator cycles on, it delivers a flow of air (inspiration) until it reaches a preset pressure, and then cycles off, and expiration occurs passively. Its major limitation is that the volume of air or oxygen can vary as the patient's airway resistance or compliance changes. As a result, the tidal volume delivered may be inconsistent, possibly compromising ventilation. Consequently, in adults, pressure-cycled ventilators are intended only for short-term use. The most common type is the IPPB machine (see earlier discussion).

Time-Cycled Ventilators

Time-cycled ventilators terminate or control inspiration after a preset time. The volume of air the patient receives is regulated by the length of inspiration and the flow rate of the air. Most ventilators have a rate control that determines the respiratory rate, but pure time cycling is rarely used for adults. These ventilators are used in newborns and infants.

Volume-Cycled Ventilators

Volume-cycled ventilators are by far the most commonly used positive-pressure ventilators today (Fig. 25-8). The

Figure 25-8 Positive-pressure ventilators. **A**, The AVEA can be used to both ventilate and monitor neonatal, pediatric, and adult patients. It can also deliver noninvasive ventilation with Heliox to adult and pediatric patients. Courtesy of VIASYS Healthcare, Inc., Yorba Linda, CA. **B**, The Puritan-Bennett 840 Ventilator System has volume, pressure, and mixed modes designed for adult, pediatric, and infant ventilation. Courtesy of Tyco Healthcare/Nelicor Puritan Bennett, Pleasanton, CA.

volume of air delivered with each inspiration is preset. Once this preset volume is delivered to the patient, the ventilator cycles off and exhalation occurs passively. From breath to breath, the volume of air delivered by the ventilator is relatively constant, ensuring consistent, adequate breaths despite varying airway pressures.

Noninvasive Positive-Pressure Ventilation

Noninvasive positive-pressure ventilation (NIPPV) is a method of positive-pressure ventilation that can be given via face masks that cover the nose and mouth, nasal masks, or other oral or nasal devices such as the nasal pillow (a small nasal cannula that seals around the nares to maintain the prescribed pressure). It eliminates the need for endotracheal intubation or tracheostomy and decreases the risk of nosocomial infections such as pneumonia. The most comfortable mode for the patient is pressure-controlled ventilation with pressure support. This eases the work of breathing and enhances gas exchange. The ventilator can be set with a minimum backup rate for patients with periods of apnea.

Patients are candidates for NIPPV if they have acute or chronic respiratory failure, acute pulmonary edema, COPD, chronic heart failure, or a sleep-related breathing disorder. The technique also may be used at home to improve tissue oxygenation and to rest the respiratory muscles while patients sleep at night. NIPPV is contraindicated for those who have experienced respiratory arrest, serious dysrhythmias, cognitive impairment, or head or facial trauma. NIPPV may also be used for obstructive sleep apnea, for patients at the end of life, and for those who do not want endotracheal intubation but may need short- or long-term ventilatory support (Bauman, 2009).

Continuous positive airway pressure (CPAP) provides positive pressure to the airways throughout the respiratory cycle. Although it can be used as an adjunct to mechanical ventilation with a cuffed endotracheal tube or tracheostomy tube to open the alveoli, it is also used with a leak-proof mask to keep alveoli open, thereby preventing respiratory failure. CPAP is the most effective treatment for obstructive sleep apnea because the positive pressure acts as a splint, keeping the upper airway and trachea open during sleep. To use CPAP, the patient must be breathing independently.

Bilevel positive airway pressure (bi-PAP) ventilation offers independent control of inspiratory and expiratory pressures while providing pressure support ventilation. It delivers two levels of positive airway pressure provided via a nasal or oral mask, nasal pillow, or mouthpiece with a tight seal and a portable ventilator. Each inspiration can be initiated either by the patient or by the machine if it is programmed with a backup rate. The backup rate ensures that the patient receives a set number of breaths per minute. Bi-PAP is most often used for patients who require ventilatory assistance at night, such as those with severe COPD or sleep apnea. Tolerance is variable; bi-PAP usually is most successful with highly motivated patients.

Ventilator Modes

Ventilator mode refers to how breaths are delivered to the patient. The most commonly used modes are assist-control, intermittent mandatory ventilation, synchronized intermittent

A. Controlled ventilation

E. Continuous positive airway pressure (CPAP)

B. Assist-control (A/C) ventilation

F. Pressure support with SIMV

C. Synchronized intermittent mandatory ventilation (SIMV)

G. Airway pressure release ventilation (APRV)

D. Positive end expiratory pressure (PEEP)

Figure 25-9 Modes of mechanical ventilation with airflow waveforms. Inhalations marked with an asterisk (*) are spontaneous.

mandatory ventilation, pressure support ventilation, and airway pressure release ventilation (Fig. 25-9).

Assist-control (A/C) ventilation provides full ventilatory support by delivering a preset tidal volume and respiratory rate. If the patient initiates a breath between the machine's breaths, the ventilator delivers at the preset volume

(assisted breath). Therefore, every breath is the preset volume.

Intermittent mandatory ventilation (IMV) provides a combination of mechanically assisted breaths and spontaneous breaths. Mechanical breaths are delivered at preset intervals and a preselected tidal volume, regardless of the patient's

efforts. Although the patient can increase the respiratory rate by initiating inspiration between ventilator-delivered breaths, these spontaneous breaths are limited to the tidal volume generated by the patient. IMV allows patients to use their own muscles for ventilation to help prevent muscle atrophy. It lowers mean airway pressure, which can assist in preventing barotrauma. However, bucking the ventilator (trying to exhale when the ventilator is delivering a breath) may be increased.

Synchronized intermittent mandatory ventilation (SIMV) also delivers a preset tidal volume and number of breaths per minute. Between ventilator-delivered breaths, the patient can breathe spontaneously with no assistance from the ventilator on those extra breaths. Because the ventilator senses patient breathing efforts and does not initiate a breath in opposition to the patient's efforts, bucking the ventilator is reduced. As the patient's ability to breathe spontaneously increases, the preset number of ventilator breaths is decreased and the patient does more of the work of breathing. Like IMV, SIMV can be used to provide full or partial ventilatory support. Nursing interventions for patients receiving IMV or SIMV include monitoring progress by recording respiratory rate, minute volume, spontaneous and machine-generated tidal volume, FiO_2 , and arterial blood gas levels.

Pressure support ventilation (PSV) applies a pressure plateau to the airway throughout the patient-triggered inspiration to decrease resistance within the tracheal tube and ventilator tubing. Pressure support is reduced gradually as the patient's strength increases. A SIMV backup rate may be added for extra support. The nurse must closely observe the patient's respiratory rate and tidal volumes on initiation of PSV. It may be necessary to adjust the pressure support to avoid tachypnea or large tidal volumes.

Airway pressure release ventilation (APRV) is a time-triggered, pressure-limited, time-cycled mode of mechanical ventilation that allows unrestricted, spontaneous breathing throughout the ventilatory cycle. The inflation period is long, and breaths may be initiated spontaneously as well as by the ventilator. APRV allows alveolar gas to be expelled through the lungs' natural recoil. Further research is needed on the effectiveness of this mode of mechanical ventilation, but it has been suggested that APRV has the important advantages of causing less ventilator-induced lung injury and fewer adverse effects on cardiocirculatory function and being associated with lower need for sedation and neuromuscular blockade (MacIntyre, 2007).

A relatively new mode of support, **proportional assist ventilation (PAV)**, provides partial ventilatory support in which the ventilator generates pressure in proportion to the patient's inspiratory efforts. With every breath, the ventilator synchronizes with the patient's ventilatory efforts. The more inspiratory pressure the patient generates, the more pressure the ventilator generates, amplifying the patient's inspiratory effort without any specific preselected target pressure or volume. It generally adds "additional muscle" to the patient's effort; the depth and frequency of breaths are controlled by the patient (Ambrosino & Rossi, 2002).

New modes of mechanical ventilation that incorporate computerized control of ventilation are being developed. In some of these modes, the ventilator constantly monitors many variables and adjusts gas delivery during individual breaths; these within-breath adjustment systems include automatic tube compensation, volume-ensured pressure sup-

port, and proportional support ventilation. In other modes, the ventilator evaluates gas delivery during one breath and uses that information to adjust the next breath; these between-breath adjustment systems can be made to ensure a preset tidal volume by adjusting pressure, up to a preset maximum, and include pressure volume support, pressure-regulated volume control, and adaptive support ventilation.

High-frequency oscillatory ventilators deliver small breaths approximately equal to the ventilatory dead space, at rates up to more than 100 times a minute. These small pulses of oxygen-enriched air move down the center of the airways, allowing alveolar air to exit the lungs along the margins of the airways. This ventilatory mode is used to open the alveoli in situations characterized by closed small airways, such as atelectasis and acute respiratory distress syndrome (ARDS), and it is also thought to protect the lung from pressure injury (MacIntyre, 2007).

Adjusting the Ventilator

The ventilator is adjusted so that the patient is comfortable and breathes "in sync" with the machine. Minimal alteration of the normal cardiovascular and pulmonary dynamics is desired. Figure 25-9 describes modes of mechanical ventilation. If the volume ventilator is adjusted appropriately, the patient's arterial blood gas values will be satisfactory and there will be little or no cardiovascular compromise. Chart 25-12 describes initial ventilator settings.

Chart 25-12 • Initial Ventilator Settings

The following guide is an example of the steps involved in operating a mechanical ventilator. The nurse, in collaboration with the respiratory therapist, always reviews the manufacturer's instructions, which vary according to the equipment, before beginning mechanical ventilation.

1. Set the machine to deliver the tidal volume required (10 to 15 mL/kg).
2. Adjust the machine to deliver the lowest concentration of oxygen to maintain normal PaO_2 (80 to 100 mm Hg). This setting may be high initially but will gradually be reduced based on arterial blood gas results.
3. Record peak inspiratory pressure.
4. Set mode (assist-control or synchronized intermittent mandatory ventilation) and rate according to physician order. (See the glossary for definitions of modes of mechanical ventilation.) Set PEEP and pressure support if ordered.
5. Adjust sensitivity so that the patient can trigger the ventilator with a minimal effort (usually 2 mm Hg negative inspiratory force).
6. Record minute volume and obtain ABGs to measure carbon dioxide partial pressure (PaCO_2), pH, and PaO_2 after 20 minutes of continuous mechanical ventilation.
7. Adjust setting (FiO_2 and rate) according to results of arterial blood gas analysis to provide normal values or those set by the physician.
8. If the patient suddenly becomes confused or agitated or begins bucking the ventilator for some unexplained reason, assess for hypoxia and manually ventilate on 100% oxygen with a resuscitation bag.

Assessing the Equipment

The ventilator needs to be assessed to make sure that it is functioning properly and that the settings are appropriate. Although the nurse may not be primarily responsible for adjusting the settings on the ventilator or measuring ventilator parameters (these are usually responsibilities of the respiratory therapist), the nurse is responsible for the patient and therefore needs to evaluate how the ventilator affects the patient's overall status.

When monitoring the ventilator, the nurse notes the following:

- Type of ventilator (eg, volume-cycled, pressure-cycled, negative-pressure)
- Controlling mode (eg, **controlled ventilation**, assist-control ventilation, synchronized intermittent mandatory ventilation)
- Tidal volume and rate settings (tidal volume is usually set at 6 to 12 mL/kg [ideal body weight]; rate is usually set at 12 to 16 breaths/min)
- FiO₂ setting
- Inspiratory pressure reached and pressure limit (normal is 15 to 20 cm H₂O; this increases if there is increased airway resistance or decreased compliance)
- Sensitivity (a 2-cm H₂O inspiratory force should trigger the ventilator)
- Inspiratory-to-expiratory ratio (usually 1:3 [1 second of inspiration to 3 seconds of expiration] or 1:2)

- Minute volume (tidal volume × respiratory rate, usually 6 to 8 L/min)
- Sigh settings (usually set at 1.5 times the tidal volume and ranging from 1 to 3 per hour), if applicable
- Water in the tubing, disconnection or kinking of the tubing
- Humidification (humidifier filled with water) and temperature
- Alarms (turned on and functioning properly)
- PEEP and pressure support level, if applicable (PEEP is usually set at 5 to 15 cm H₂O)

Problems With Mechanical Ventilation

Because of the seriousness of the patient's condition and the highly complex and technical nature of mechanical ventilation, a number of problems or complications can occur. Such situations fall into two categories: ventilator problems and patient problems (Table 25-2). In either case, the patient must be supported while the problem is identified and corrected.

NURSING ALERT

If the ventilator system malfunctions and the problem cannot be identified and corrected immediately, the nurse must ventilate the patient with a manual resuscitation bag until the problem is resolved.

Table 25-2 TROUBLESHOOTING PROBLEMS WITH MECHANICAL VENTILATION

Problem	Cause	Solution
Ventilator Problems		
Increase in peak airway pressure	Coughing or plugged airway tube	Suction airway for secretions, empty condensation fluid from circuit
	Patient "bucking" ventilator	Adjust sensitivity
	Decreasing lung compliance	Manually ventilate patient
Decrease in pressure or loss of volume	Tubing kinked	Assess for hypoxia or bronchospasm
	Pneumothorax	Check arterial blood gas values
	Atelectasis or bronchospasm	Sedate only if necessary
	Increase in compliance	Check tubing; reposition patient; insert oral airway if necessary
Patient Problems	Leak in ventilator or tubing; cuff on tube/humidifier not tight	Manually ventilate patient; notify physician
	Decrease in venous return due to application of positive pressure to lungs	Clear secretions
	Application of positive pressure to lungs; high mean airway pressures lead to alveolar rupture	None
Cardiovascular compromise	Bypass of normal defense mechanisms; frequent breaks in ventilator circuit; decreased mobility; impaired cough reflex	Check entire ventilator circuit for patency
Barotrauma/pneumothorax	Optimize nutritional status	Correct leak
Pulmonary infection	Assess for adequate volume status by measuring heart rate, blood pressure, central venous pressure, pulmonary capillary wedge pressure, and urine output; notify physician if values are abnormal	Notify physician
	Prepare patient for chest tube insertion	Prepare patient for chest tube insertion
	Avoid high pressure settings for patients with COPD, ARDS, or history of pneumothorax	Avoid high pressure settings for patients with COPD, ARDS, or history of pneumothorax
	Use meticulous aseptic technique	Use meticulous aseptic technique
	Provide frequent mouth care	Provide frequent mouth care
	Optimize nutritional status	Optimize nutritional status

ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease.

Bucking the Ventilator

The patient is “in sync” with the ventilator when thoracic expansion coincides with the inspiratory phase of the machine and exhalation occurs passively. The patient is said to fight or buck the ventilator when he or she is out of phase with the machine. This is manifested when the patient attempts to breathe out during the ventilator’s mechanical inspiratory phase or when there is jerky and increased abdominal muscle effort. Anxiety, hypoxia, increased secretions, hypercapnia, inadequate minute volume, long expiratory time, and pulmonary edema can all contribute to this problem. These problems must be corrected before resorting to the use of paralyzing agents to reduce bucking; otherwise, the underlying problem is simply masked and the patient’s condition will continue to deteriorate.

Muscle relaxants, tranquilizers, analgesic agents, and paralyzing agents are sometimes administered to patients receiving mechanical ventilation. Their purpose is ultimately to increase the patient–machine synchrony by decreasing the patient’s anxiety, hyperventilation, or excessive muscle activity. The selection and dose of the appropriate medication are determined by the patient’s requirements and the cause of his or her restlessness. Paralyzing agents are always used as a last resort, and they are administered with a sedative medication and often an analgesic medication.

NURSING PROCESS

THE PATIENT RECEIVING MECHANICAL VENTILATION

Assessment

The nurse plays a vital role in assessing the patient’s status and the functioning of the ventilator. In assessing the patient, the nurse evaluates the patient’s physiologic status and how he or she is coping with mechanical ventilation. Physical assessment includes systematic assessment of all body systems, with an in-depth focus on the respiratory system. Respiratory assessment includes vital signs, respiratory rate and pattern, breath sounds, evaluation of spontaneous ventilatory effort, and potential evidence of hypoxia (eg, skin color). Increased adventitious breath sounds may indicate a need for suctioning. The nurse also evaluates the settings and functioning of the mechanical ventilator, as described previously.

Assessment also addresses the patient’s neurologic status and effectiveness of coping with the need for assisted ventilation and the changes that accompany it. The nurse assesses the patient’s comfort level and ability to communicate as well. Because weaning from mechanical ventilation requires adequate nutrition, it is important to assess the patient’s gastrointestinal system and nutritional status.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient’s major nursing diagnoses may include:

- Impaired gas exchange related to underlying illness, ventilator setting adjustments, or weaning.
- Ineffective airway clearance related to increased mucus production associated with presence of the tube in trachea or continuous positive-pressure mechanical ventilation
- Risk for trauma and infection related to endotracheal intubation or tracheostomy
- Impaired physical mobility related to ventilator dependency
- Impaired verbal communication related to endotracheal tube or tracheostomy tube and attachment to ventilator
- Defensive coping and powerlessness related to ventilator dependency

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include the following:

- Alterations in cardiac function
- Barotrauma (trauma to the trachea or alveoli secondary to positive pressure) and pneumothorax
- Pulmonary infection
- Sepsis

Planning and Goals

The major goals for the patient may include achievement of optimal gas exchange, maintenance of a patent airway, absence of trauma or infection, attainment of optimal mobility, adjustment to nonverbal methods of communication, acquisition of successful coping measures, and absence of complications.

Nursing Interventions

Nursing care of the mechanically ventilated patient requires expert technical and interpersonal skills. Nursing interventions are similar regardless of the setting; however, the frequency of interventions and the stability of the patient vary from setting to setting. Nursing interventions for the mechanically ventilated patient are not uniquely different from those for patients with other pulmonary disorders; but astute nursing assessment and a therapeutic nurse–patient relationship are critical. The specific interventions used by the nurse are determined by the underlying disease process and the patient’s response.

Two general nursing interventions that are important in the care of the mechanically ventilated patient are pulmonary auscultation and interpretation of arterial blood gas measurements. The nurse is often the first to note changes in physical assessment findings or significant trends in blood gases that signal the development of a serious problem (eg, pneumothorax, tube displacement, pulmonary embolus).

Enhancing Gas Exchange

The purpose of mechanical ventilation is to optimize gas exchange by maintaining alveolar ventilation and oxygen delivery. The alteration in gas exchange may be caused by the underlying illness or by mechanical factors related to adjustment of the machine to the patient. The health care team, including the nurse, physician, and respiratory therapist,

continually assesses the patient for adequate gas exchange, signs and symptoms of hypoxia, and response to treatment. Therefore, the nursing diagnosis of impaired gas exchange is, by its complex nature, multidisciplinary and collaborative. The team members must share goals and information freely. All other goals directly or indirectly relate to this primary goal.

Nursing interventions to promote optimal gas exchange include judicious administration of analgesic agents to relieve pain without suppressing the respiratory drive and frequent repositioning to diminish the pulmonary effects of immobility. The nurse also monitors for adequate fluid balance by assessing for the presence of peripheral edema, calculating daily intake and output, and monitoring daily weights. The nurse administers medications prescribed to control the primary disease and monitors for their side effects.

Promoting Effective Airway Clearance

Continuous positive-pressure ventilation increases the production of secretions regardless of the patient's underlying condition. The nurse assesses for the presence of secretions by lung auscultation at least every 2 to 4 hours. Measures to clear the airway of secretions include suctioning, CPT, frequent position changes, and increased mobility as soon as possible. Frequency of suctioning should be determined by patient assessment. If excessive secretions are identified by inspection or auscultation techniques, suctioning should be performed. Sputum is not produced continuously or every 1 to 2 hours but as a response to a pathologic condition. Therefore, there is no rationale for routine suctioning of all patients every 1 to 2 hours. Although suctioning is used to aid in the clearance of secretions, it can damage the airway mucosa and impair cilia action.

The sigh mechanism on the ventilator may be adjusted to deliver at least 1 to 3 sighs per hour at 1.5 times the tidal volume if the patient is receiving assist-control ventilation. Periodic sighs prevent atelectasis and the further retention of secretions. Because of the risk for hyperventilation and trauma to pulmonary tissue from excess ventilator pressure (barotrauma, pneumothorax), the sigh feature is not used frequently. If the SIMV mode is being used, the mandatory ventilations act as sighs because they are of greater volume than the patient's spontaneous breaths.

Humidification of the airway via the ventilator is maintained to help liquefy secretions so that they are more easily removed. Bronchodilators are administered to dilate the bronchioles and are classified as adrenergic or anticholinergic. Adrenergic bronchodilators (see Chapter 24) are mostly inhaled and work by stimulating the beta-receptor sites, mimicking the effects of epinephrine in the body. The desired effect is smooth muscle relaxation, which dilates the constricted bronchial tubes. Anticholinergic bronchodilators produce airway relaxation by blocking cholinergic-induced bronchoconstriction. Patients receiving bronchodilator therapy of either type should be monitored for adverse effects, including dizziness, nausea, decreased oxygen saturation, hypokalemia, increased heart rate, and urine retention. Mucolytic agents are administered to liquefy secretions so that they are more easily mobilized. Nursing management of patients receiving mucolytic therapy includes assessment for an adequate cough reflex, sputum characteristics, and (in patients not receiving mechanical

ventilation) improvement in incentive spirometry. Side effects include nausea, vomiting, bronchospasm, stomatitis (oral ulcers), urticaria, and rhinorrhea (runny nose).

Preventing Trauma and Infection

Maintaining the endotracheal or tracheostomy tube is an essential part of airway management. The nurse positions the ventilator tubing so that there is minimal pulling or distortion of the tube in the trachea, reducing the risk of trauma to the trachea. Cuff pressure is monitored every 6 to 8 hours to maintain the pressure at less than 25 mm Hg (optimal cuff pressure is 15 to 20 mm Hg). The nurse assesses for the presence of a cuff leak at the same time.

Patients with an endotracheal or tracheostomy tube do not have the normal defenses of the upper airway. In addition, these patients frequently have multiple additional body system disturbances that lead to immunocompromise. Tracheostomy care is performed at least every 8 hours, and more frequently if needed, because of the increased risk for infection. The ventilator circuit tubing and in-line suction tubing are replaced periodically, according to infection control guidelines, to decrease the risk for infection.

The nurse administers oral hygiene frequently because the oral cavity is a primary source of contamination of the lungs in the intubated and compromised patient (American Thoracic Society, 2005). The presence of a nasogastric tube in the intubated patient can increase the risk for aspiration, leading to nosocomial pneumonia. The nurse positions the patient with the head elevated above the stomach as much as possible. Although antiulcer medications such as cimetidine (Tagamet) or ranitidine (Zantac) are sometimes administered, an oral antiulcer medication such as sucralfate (Carafate) is preferable because it maintains normal gastric pH, decreasing the incidence of aspiration pneumonia.

Promoting Optimal Level of Mobility

Being connected to a ventilator limits the patient's mobility. The nurse helps the patient whose condition has become stable to get out of bed and move to a chair as soon as possible. Mobility and muscle activity are beneficial because they stimulate respirations and improve morale. If the patient is unable to get out of bed, the nurse encourages performance of active range-of-motion exercises every 6 to 8 hours. If the patient cannot perform these exercises, the nurse performs passive range-of-motion exercises every 8 hours to prevent contractures and venous stasis.

Promoting Optimal Communication

It is important to develop alternative methods of communication for the patient who is receiving mechanical ventilation. The nurse assesses the patient's communication abilities to evaluate for limitations. Questions to consider when assessing the ventilator-dependent patient's ability to communicate include the following:

- Is the patient conscious and able to communicate?
Can the patient nod or shake his or her head?
- Is the patient's mouth unobstructed by the tube so that words can be mouthed?

- Is the patient's dominant hand strong and available for writing? For example, if the patient is right-handed, the intravenous (IV) line should be placed in the left arm if possible so that the right hand is free.
- Is the patient a candidate for a fenestrated tracheostomy tube or a one-way speaking valve (such as Passy-Muir valve or Olympic Trach-Talk) that permit talking?

Once the patient's limitations are known, the nurse offers several appropriate communication approaches: lip or speech reading (use single key words), pad and pencil or Magic Slate, communication board, gesturing, sign language, or electric larynx. Use of a "talking" or fenestrated tracheostomy tube or one-way valve may be suggested to the physician; these allow the patient to talk while on the ventilator. The nurse makes sure that the patient's eyeglasses, hearing aid, sign interpreter, and language translator are available if needed to enhance the patient's ability to communicate.

Some communication methods may be frustrating to the patient, family, and nurse; these need to be identified and minimized. A speech therapist can assist in determining the most appropriate method.

Promoting Coping Ability

Dependence on a ventilator is frightening to both the patient and the family and disrupts even the most stable fam-

ilies. Encouraging the family to verbalize their feelings about the ventilator, the patient's condition, and the environment in general is beneficial. Explaining procedures every time they are performed helps reduce anxiety and familiarizes the patient with ventilator procedures. To restore a sense of control, the nurse encourages the patient to participate in decisions about care, schedules, and treatment when possible. The patient may become withdrawn or depressed while receiving mechanical ventilation, especially if its use is prolonged (Chart 25-13). To promote effective coping, the nurse informs the patient about progress when appropriate. It is important to provide diversions such as watching television, playing music, or taking a walk (if appropriate and possible). Stress reduction techniques (eg, a back rub, relaxation measures) relieve tension and help the patient deal with anxieties and fears about both the condition and the dependence on the ventilator.

Monitoring and Managing Potential Complications

ALTERATIONS IN CARDIAC FUNCTION. Alterations in cardiac output may occur as a result of positive-pressure ventilation. The positive intrathoracic pressure during inspiration compresses the heart and great vessels, thereby reducing venous return and cardiac output. This is usually corrected during exhalation when the positive pressure is off. The patient

CHART 25-13

NURSING RESEARCH PROFILE *What It's Like to Live on a Ventilator*

Johnson, P., St. John, W. & Moyle, W. (2006). Long-term mechanical ventilation in a critical care unit: Existing in an uneveryday world. *Journal of Advanced Nursing*, 53(5), 551–558.

Purpose

Because of the aging of the population and improvements in health care technology, more patients are undergoing mechanical ventilation for long periods—that is, for 7 or more days. This use of technology may be uncomfortable and frightening to the patient, who may also feel helpless and anxious; the patient may even experience episodes of panic, nightmares, or hallucinations. Researchers conducted this study to learn what it means to the patient to be dependent on long-term mechanical ventilation.

Design

Data collection for this qualitative study consisted of interviews with nine people, 21 to 69 years of age, who had required mechanical ventilation for at least 7 days while in a critical care unit. Participants had been conscious for some of the time while on the ventilator and were able to recall and discuss their experience. The interviews lasted 45 to 140 minutes. The investigators read transcriptions of the interviews several times and found four major themes that ran through the interviews. The investigators then went back to five of the participants and reviewed their preliminary findings to ensure that they had interpreted the data correctly.

Findings

Participants' reactions had four themes, including "existing in an uneveryday world." The participants' fluctuating levels of

consciousness, difficulty distinguishing reality, and losing track of time caused them to feel removed from the real world. Hallucinations and unpleasant dreams remained vivid even following discharge. Their bodies felt strange and unfamiliar, and their inability to communicate effectively was frustrating. The technology that they depended on was irritating at times and made them feel vulnerable; they wondered if they would survive.

Nursing Implications

Despite the near universal complaint of discomfort, there was little mention of pain in this sample. This may be related to adequate management of pain. However, participants described other unpleasant sensations, such as those associated with suctioning. Therefore, it is vital that nurses caring for patients on long-term mechanical ventilation comfort and support them; in addition, the nurses must carry out interventions with sensitivity and gentleness. Because participants had not been able to make sense of what occurred while they were in the critical care unit, they found the interviews therapeutic; discussing their memories of the critical care unit helped them understand what had happened. The authors recommend, therefore, that nurses provide opportunities for patients to discuss their hospitalization following discharge. More research is needed to determine optimal care and postdischarge services for people who need to be mechanically ventilated while in intensive care.

may have decreased cardiac output and resultant decreased tissue perfusion and oxygenation.

To evaluate cardiac function, the nurse first observes for signs and symptoms of hypoxia (restlessness, apprehension, confusion, tachycardia, tachypnea, pallor progressing to cyanosis, diaphoresis, transient hypertension, and decreased urine output). If a pulmonary artery catheter is in place, cardiac output, cardiac index, and other hemodynamic values can be used to assess the patient's status.

BAROTRAUMA AND PNEUMOTHORAX. Excessive positive pressure can cause lung damage, or barotrauma, which may result in a spontaneous **pneumothorax**, which may quickly develop into a tension pneumothorax, further compromising venous return, cardiac output, and blood pressure. The nurse considers any sudden changes in oxygen saturation or the onset of respiratory distress to be a life-threatening emergency requiring immediate action.

PULMONARY INFECTION. The patient is at high risk for infection, as described earlier. The nurse reports fever or a change in the color or odor of sputum to the physician for follow-up.

Promoting Home and Community-Based Care

Increasingly, patients are being cared for in extended care facilities or at home while receiving mechanical ventilation, with a tracheostomy tube, or receiving oxygen therapy. Patients receiving home ventilator care usually have a chronic neuromuscular condition or COPD. Providing the opportunity for ventilator-dependent patients to return home to live with their families in familiar surroundings can be a positive experience. The ultimate goal of home ventilator therapy is to enhance the patient's quality of life, not simply to support or prolong life.

TEACHING PATIENTS SELF-CARE. Caring for the patient with mechanical ventilator support at home can be accomplished successfully. A home care team consisting of the nurse, physician, respiratory therapist, social service or home care agency, and equipment supplier is needed. The home is evaluated to determine whether the electrical equipment needed can be operated safely. Chart 25-14 summarizes the basic assessment criteria needed for successful home care.

Once the decision to initiate mechanical ventilation at home is made, the nurse prepares the patient and family for home care. The nurse teaches the patient and family about the ventilator, suctioning, tracheostomy care, signs of pulmonary infection, cuff inflation and deflation, and assessment of vital signs. Teaching begins in the hospital and continues at home. Nursing responsibilities include evaluating the patient's and family's understanding of the information presented.

The nurse teaches the family cardiopulmonary resuscitation, including mouth-to-tracheostomy tube (instead of mouth-to-mouth) breathing. The nurse also explains how to handle a power failure, which usually involves converting the ventilator from an electrical power source to a battery power source. Conversion is automatic in most types of home ventilators and lasts

Chart 25-14 • Criteria for Successful Home Ventilator Care

The decision to proceed with home ventilation therapy is usually based on the following parameters.

Patient Criteria

- The patient has a chronic underlying pulmonary or neuromuscular disorder.
- The patient's clinical pulmonary status is stable.
- The patient is willing to go home on mechanical ventilation.

Home Criteria

- The home environment is conducive to care of the patient.
- The electrical facilities are adequate to operate all equipment safely.
- The home environment is controlled, without drafts in cold weather and with proper ventilation in warm weather.
- Space is available for cleaning and storing ventilator equipment.

Family Criteria

- Family members are competent, dependable, and willing to spend the time required for proper training as primary caregivers.
- Family members understand the diagnosis and prognosis.
- Family has sufficient financial and supportive resources and can obtain professional support if necessary.

approximately 1 hour. The nurse instructs the family on the use of a manual self-inflation bag should it be necessary. Chart 25-15 lists some of the patient's and family's responsibilities.

CONTINUING CARE. A home care nurse monitors and evaluates how well the patient and family are adapting to providing care in the home. The nurse assesses the adequacy of the patient's ventilation and oxygenation as well as airway patency. The nurse addresses any unique adaptation problems the patient may have and listens to the patient's and family's anxieties and frustrations, offering support and encouragement where possible. The home care nurse helps identify and contact community resources that may assist in home management of the patient with mechanical ventilation.

The technical aspects of the ventilator are managed by vendor follow-up. A respiratory therapist usually is assigned to the patient and makes frequent home visits to evaluate the patient and perform a maintenance check of the ventilator.

Transportation services are identified in case the patient requires transportation in an emergency. These arrangements must be made before an emergency arises.

Evaluation

Expected patient outcomes may include the following:

1. Exhibits adequate gas exchange, as evidenced by normal breath sounds, acceptable arterial blood gas levels, and vital signs

CHART
25-15  **HOME CARE CHECKLIST**
Ventilator Care

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
<ul style="list-style-type: none"> State proper care of patient on ventilator <ul style="list-style-type: none"> Observe physical signs such as color, secretions, breathing pattern, and state of consciousness. Perform physical care such as suctioning, postural drainage, and ambulation. Observe the tidal volume and pressure manometer regularly. Intervene when they are abnormal (ie, suction if airway pressure increases). Provide a communication method for the patient (eg, pad and pencil, electric larynx, talking tracheostomy tube, sign language). Monitor vital signs as directed. - Demonstrates adequate ventilation with minimal mucus accumulation
- Is free of injury or infection, as evidenced by normal temperature, white blood cell count, and clear sputum
- Is mobile within limits of ability
 - Gets out of bed to chair, bears weight, or ambulates as soon as possible
 - Performs range-of-motion exercises every 6 to 8 hours
- Communicates effectively through written messages, gestures, or other communication strategies
- Copes effectively
 - Verbalizes fears and concerns about condition and equipment
 - Participates in decision making when possible
 - Uses stress reduction techniques when necessary
- Absence of complications
 - Absence of cardiac compromise, as evidenced by stable vital signs and adequate urine output
 - Absence of pneumothorax, as evidenced by bilateral chest excursion, normal chest x-ray, and adequate oxygenation
 - Absence of pulmonary infection, as evidenced by normal temperature, clear pulmonary secretions, and negative sputum cultures

Weaning the Patient From the Ventilator

Respiratory weaning, the process of withdrawing the patient from dependence on the ventilator, takes place in three stages: the patient is gradually removed from the ventilator, then

from the tube, and finally from oxygen. Weaning from mechanical ventilation is performed at the earliest possible time consistent with patient safety. The decision must be made from a physiologic rather than a mechanical viewpoint. A thorough understanding of the patient’s clinical status is required in making this decision. Weaning is started when the patient is recovering from the acute stage of medical and surgical problems and when the cause of respiratory failure is sufficiently reversed. Chart 25-16 presents information about patient care during weaning from mechanical ventilation.

Successful weaning involves collaboration among the physician, respiratory therapist, and nurse. Each health care provider must understand the scope and function of other team members in relation to patient weaning to conserve the patient’s strength, use resources efficiently, and maximize successful outcomes.

Criteria for Weaning

Careful assessment is required to determine whether the patient is ready to be removed from mechanical ventilation. If the patient is stable and showing signs of improvement or reversal of the disease or condition that caused the need for mechanical ventilation, weaning indices should be assessed (see Chart 25-16).

Stable vital signs and arterial blood gases are also important predictors of successful weaning. Once readiness has been determined, the nurse records baseline measurements of weaning indices to monitor progress.

Patient Preparation

To maximize the chances of success of weaning, the nurse must consider the patient as a whole, taking into account factors that impair the delivery of oxygen and elimination

Chart 25-16 • Care of the Patient Being Weaned From Mechanical Ventilation

- Assess patient for weaning criteria:
 - a. Vital capacity: 10 to 15 mL/kg
 - b. Maximum inspiratory pressure (MIP) at least -20 cm H₂O
 - c. Tidal volume: 7 to 9 mL/kg
 - d. Minute ventilation: 6 L/min
 - e. Rapid/shallow breathing index: below 100 breaths/minute/L; PaO₂ >60 mm Hg with FiO₂ less than 40%
- Monitor activity level, assess dietary intake, and monitor results of laboratory tests of nutritional status. Reestablishing independent spontaneous ventilation can be physically exhausting. It is crucial that the patient have enough energy reserves to succeed.
- Assess the patient's and family's understanding of the weaning process and address any concerns about the process. Explain that the patient may feel short of breath initially and provide encouragement as needed. Reassure the patient that he or she will be attended closely and that if the weaning attempt is not successful, it can be tried again later.
- Implement the weaning method prescribed: A/C ventilation, IMV, SIMV, PSV, PAV, CPAP, or T-piece.
- Monitor vital signs, pulse oximetry, ECG, and respiratory pattern constantly for the first 20 to 30 minutes and every 5 minutes after that until weaning is complete. Monitoring the patient closely provides ongoing indications of success or failure.
- Maintain a patent airway; monitor arterial blood gas levels and pulmonary function tests. Suction the airway as needed.
- In collaboration with the physician, terminate the weaning process if adverse reactions occur. These include a heart rate increase of 20 beats/min, systolic blood pressure increase of 20 mm Hg, a decrease in oxygen saturation to less than 90%, respiratory rate less than 8 or greater than 20 breaths/min, ventricular dysrhythmias, fatigue, panic, cyanosis, erratic or labored breathing, paradoxical chest movement.
- If the weaning process continues, measure tidal volume and minute ventilation every 20 to 30 minutes; compare with the patient's desired values, which have been determined in collaboration with the physician.
- Assess for psychological dependence if the physiologic parameters indicate weaning is feasible and the patient still resists. Possible causes of psychological dependence include fear of dying and depression from chronic illness. It is important to address this issue before the next weaning attempt.

of carbon dioxide as well as those that increase oxygen demand (eg, sepsis, seizures, thyroid imbalances) or decrease the patient's overall strength (eg, inadequate nutrition, neuromuscular disease). Adequate psychological preparation is necessary before and during the weaning process.

Methods of Weaning

Successful weaning depends on the combination of adequate patient preparation, available equipment, and an interdisciplinary approach to solve patient problems (see Chart 25-16). All usual modes of ventilation can be used for weaning.

When assist-control (A/C) ventilation is used, the control rate is decreased, so that the patient strengthens the respiratory muscles by triggering progressively more breaths. The nurse assesses the patient for signs of distress: rapid or shallow breathing, use of accessory muscles, reduced level of consciousness, increase in carbon dioxide levels, decrease in oxygen saturation, and tachycardia.

SIMV is indicated if the patient satisfies all the criteria for weaning but cannot sustain adequate spontaneous ventilation for long periods. As the patient's respiratory muscles become stronger, the rate is decreased until the patient is breathing spontaneously.

The PAV mode of partial ventilatory support allows the ventilator to generate pressure in proportion to the patient's efforts. With every breath, the ventilator synchronizes with the patient's ventilatory efforts. Nursing assessment includes careful monitoring of the patient's respiratory rate, arterial blood gases, tidal volume, minute ventilation, and breathing pattern.

CPAP allows the patient to breathe spontaneously while applying positive pressure throughout the respiratory cycle to keep the alveoli open and promote oxygenation. Providing CPAP during spontaneous breathing also offers the advantage of an alarm system and may reduce patient anxiety if the patient has been taught that the machine is keeping track of breathing. It also maintains lung volumes and improves the patient's oxygenation status. CPAP is often used in conjunction with PSV. Nurses should carefully assess for tachypnea, tachycardia, reduced tidal volumes, decreasing oxygen saturations, and increasing carbon dioxide levels.

When the patient can breathe spontaneously, weaning trials using a T-piece or tracheostomy mask (see Fig. 25-2) are normally conducted with the patient disconnected from the ventilator, receiving humidified oxygen only and performing all work of breathing. Because patients do not have to overcome the resistance of the ventilator, they may find this mode more comfortable, or they may become anxious as they breathe with no support from the ventilator. During T-piece trials, the nurse monitors the patient closely and provides encouragement. This method of weaning is usually used when the patient is awake and alert, is breathing without difficulty, has good gag and cough reflexes, and is hemodynamically stable. During the weaning process, the patient is maintained on the same or a higher oxygen concentration than when receiving mechanical ventilation. While the patient is using the T-piece, he or she is observed for signs and symptoms of hypoxia, increasing respiratory muscle fatigue, or systemic fatigue. These include rest-

lessness, increased respiratory rate (greater than 35 breaths/min), use of accessory muscles, tachycardia with premature ventricular contractions, and paradoxical chest movement (asynchronous breathing, chest contraction during inspiration and expansion during expiration). Fatigue or exhaustion is initially manifested by an increased respiratory rate associated with a gradual reduction in tidal volume; later there is a slowing of the respiratory rate.

If the patient appears to be tolerating the T-piece trial, a second set of arterial blood gas measurements is drawn 20 minutes after the patient has been on spontaneous ventilation at a constant FiO_2 pressure support ventilation. (Alveolar–arterial equilibration takes 15 to 20 minutes to occur.)

Signs of exhaustion and hypoxia correlated with deterioration in the blood gas measurements indicate the need for ventilatory support. The patient is placed back on the ventilator each time signs of fatigue or deterioration develop.

If clinically stable, the patient usually can be extubated within 2 or 3 hours after weaning and allowed spontaneous ventilation by means of a mask with humidified oxygen. Patients who have had prolonged ventilatory assistance usually require more gradual weaning; it may take days or even weeks. They are weaned primarily during the day and placed back on the ventilator at night to rest.

Because patients respond in different manners to weaning methods, there is no definitive way to assess which method is best. Regardless of the weaning method being used, ongoing assessment of respiratory status is essential to monitor patient progress.

Successful weaning from the ventilator is supplemented by intensive pulmonary care. The following methods are used: oxygen therapy; arterial blood gas evaluation; pulse oximetry; bronchodilator therapy; CPT; adequate nutrition, hydration, and humidification; blood pressure measurement; and incentive spirometry. Daily spontaneous breathing trials may be used to evaluate the patient's ability to breathe without ventilatory support. There is some evidence that such trials are best performed if sedation is temporarily withdrawn for the trial (MacIntyre, 2007). A patient may still have borderline pulmonary function and need vigorous supportive therapy before his or her respiratory status returns to a level that supports activities of daily living.

Weaning From the Tube

Weaning from the tube is considered when the patient can breathe spontaneously, maintain an adequate airway by effectively coughing up secretions, swallow, and move the jaw. If frequent suctioning is needed to clear secretions, tube weaning may be unsuccessful. Secretion clearance and aspiration risks are assessed to determine whether active pharyngeal and laryngeal reflexes are intact.

Once the patient can clear secretions adequately, a trial period of mouth breathing or nose breathing is conducted. This can be accomplished by several methods. The first method requires changing to a smaller size tube to increase

the resistance to airflow or plugging the tracheostomy tube (deflating the cuff first). The smaller tube is sometimes replaced by a cuffless tracheostomy tube, which allows the tube to be plugged at lengthening intervals to monitor patient progress. A second method involves changing to a fenestrated tube (a tube with an opening or window in its bend). This permits air to flow around and through the tube to the upper airway and enables talking. A third method involves switching to a smaller tracheostomy button (stoma button). A tracheostomy button is a plastic tube approximately 1 inch long that helps keep the windpipe open after the larger tracheostomy tube has been removed. Finally, when the patient demonstrates the ability to maintain a patent airway, the tube can be removed. An occlusive dressing is placed over the stoma, which heals in several days to weeks.

Weaning From Oxygen

The patient who has been successfully weaned from the ventilator, cuff, and tube and has adequate respiratory function is then weaned from oxygen. The FiO_2 is gradually reduced until the PaO_2 is in the range of 70 to 100 mm Hg while the patient is breathing room air. If the PaO_2 is less than 70 mm Hg on room air, supplemental oxygen is recommended. To be eligible for financial reimbursement from the Centers for Medicare and Medicaid Services for in-home oxygen, the patient must have a PaO_2 of less than 60 mm Hg while awake and at rest.

Nutrition

Success in weaning the long-term ventilator-dependent patient requires early and aggressive but judicious nutritional support. The respiratory muscles (diaphragm and especially intercostals) become weak or atrophied after just a few days of mechanical ventilation and may be catabolized for energy, especially if nutrition is inadequate. Compensation for inadequate nutrition must be undertaken with care; excessive intake can increase production of carbon dioxide and the demand for oxygen and lead to prolonged ventilator dependence and difficulty in weaning (O'Leary-Kelley, Puntillo, Barr, et al., 2005). Because the metabolism of fat produces less carbon dioxide than the metabolism of carbohydrates, a high-fat diet, in which 50% of daily kilocalories are from fat, may assist patients with respiratory failure, both during mechanical ventilation and while being weaned. The evidence on the value of a limited carbohydrate intake versus a carbohydrate-enriched diet is uncertain. Adequate protein intake is important in increasing respiratory muscle strength. Protein intake should be approximately 25% of total daily kilocalories, or 1.2 to 1.5 g/kg/day. Daily nutrition should be closely monitored.

Soon after the patient is admitted, a consultation with a dietitian or nutrition support team should be arranged to plan the best form of nutritional replacement. Adequate nutrition may decrease the duration of mechanical ventilation and prevent other complications, especially sepsis. Sepsis can occur if bacteria enter the bloodstream and release toxins that, in turn, cause vasodilation and

hypotension, fever, tachycardia, increased respiratory rate, and coma. Aggressive treatment of sepsis is essential to reverse this threat to survival and to promote weaning from the ventilator when the patient's condition improves.

THE PATIENT UNDERGOING THORACIC SURGERY

Assessment and management are particularly important for the patient undergoing thoracic surgery. Frequently, patients undergoing such surgery also have obstructive pulmonary disease or other chronic disease. Preoperative preparation and careful postoperative management are crucial for successful patient outcomes because these patients may have a narrow range between their physical tolerance for certain activities and their limitations, which, if exceeded, can lead to distress. Various types of thoracic surgical procedures are performed to relieve disease conditions such as lung abscesses, lung cancer, cysts, benign tumors, and emphysema (Chart 25-17). An exploratory **thoracotomy** (creation of a surgical opening into the thoracic cavity) may be performed to diagnose lung or chest disease. A biopsy may be performed in this procedure with a small amount of lung tissue removed for analysis; the chest incision is then closed.

The objectives of preoperative care for the patient undergoing thoracic surgery are to ascertain the patient's functional reserve, to determine whether the patient is likely to survive and recover from the surgery, and to ensure that the patient is in optimal condition for surgery.

Preoperative Management

Assessment and Diagnostic Findings

The nurse performs chest auscultation to assess breath sounds in all regions of the lungs (see Chapter 21). It is important to note whether breath sounds are normal, indicating a free flow of air in and out of the lungs. (In the patient with emphysema, the breath sounds may be markedly decreased or even absent on auscultation.) The nurse notes crackles and wheezes and assesses for hyperresonance and decreased diaphragmatic motion. Unilateral diminished breath sounds and rhonchi can be the result of occlusion of the bronchi by mucus plugs. The nurse assesses for retained secretions during auscultation by asking the patient to cough. It is important to note any signs of rhonchi or wheezing. The patient history and assessment should include the following questions:

- What signs and symptoms (cough, sputum expectorated [amount and color], hemoptysis, chest pain, dyspnea) are present?
- If there is a smoking history, how long has the patient smoked? Does the patient smoke currently? How many packs a day?

- What is the patient's cardiopulmonary tolerance while resting, eating, bathing, and walking?
- What is the patient's breathing pattern? How much exertion is required to produce dyspnea?
- Does the patient need to sleep in an upright position or with more than two pillows?
- What is the patient's general physiologic status (eg, general appearance, mental alertness, behavior, nutritional status)?
- What other medical conditions exist (eg, allergies, cardiac disorders, diabetes)?

A number of tests are performed to determine the patient's preoperative status and to assess the patient's physical assets and limitations. Many patients are seen by their surgeons in the office, and many tests and examinations are performed on an outpatient basis. The decision to perform any pulmonary resection is based on the patient's cardiovascular status and pulmonary reserve. Pulmonary function studies (especially lung volume and vital capacity) are performed to determine whether the planned resection will leave sufficient functioning lung tissue. Arterial blood gas values are assessed to provide a more complete picture of the functional capacity of the lung. Exercise tolerance tests are useful to determine whether the patient who is a candidate for pneumonectomy can tolerate removal of one of the lungs.

Preoperative studies are performed to provide a baseline for comparison during the postoperative period and to detect any unsuspected abnormalities. These studies may include a bronchoscopic examination (a lighted scope is inserted into the airways to examine the bronchi), chest x-ray, magnetic resonance imaging (MRI), electrocardiogram (ECG) for arteriosclerotic heart disease, conduction defects), nutritional assessment, determination of blood urea nitrogen and serum creatinine levels (to assess renal function), determination of glucose tolerance or blood glucose level (to check for diabetes), serum electrolytes and protein levels, blood volume determinations, and complete blood cell count.

Preoperative Nursing Management

Improving Airway Clearance

The underlying lung condition often is associated with increased respiratory secretions. Before surgery, the airway is cleared of secretions to reduce the possibility of postoperative atelectasis or infection. Chart 25-18 lists the risk factors for postoperative atelectasis and pneumonia. Strategies to reduce the risk for atelectasis and infection include humidification, postural drainage, and chest percussion after bronchodilators are administered, if prescribed. The nurse estimates the volume of sputum if the patient expectorates large amounts of secretions. Such measurements are carried out to determine whether and when the amount decreases. Antibiotics are administered as prescribed for infection, which can cause excessive secretions.

Teaching the Patient

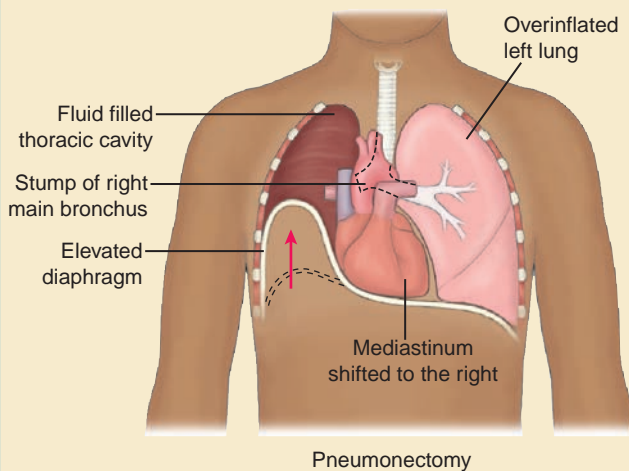

Increasingly, patients are admitted on the day of surgery, which does not provide much time for preoperative assessment or teaching. Nurses in all settings must take an active role in educating the patient and relieving anxiety. The

Chart 25-17 • Thoracic Surgeries and Procedures

Pneumonectomy

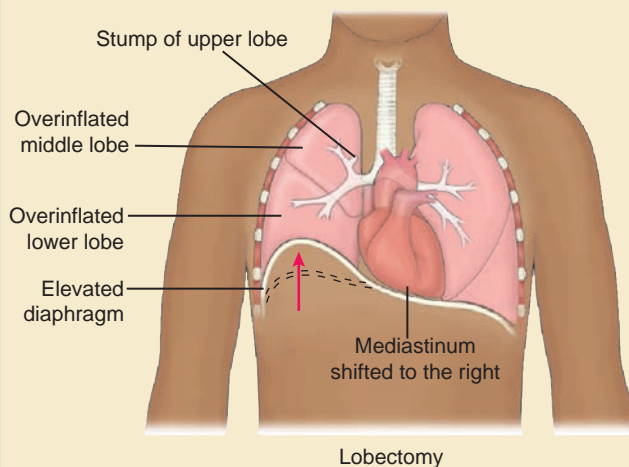

The removal of an entire lung (pneumonectomy) is performed chiefly for cancer when the lesion cannot be removed by a less extensive procedure. It also may be performed for lung abscesses, bronchiectasis, or extensive unilateral tuberculosis. The removal of the right lung is more dangerous than the removal of the left, because the right lung has a larger vascular bed and its removal imposes a greater physiologic burden.

A posterolateral or anterolateral thoracotomy incision is made, sometimes with resection of a rib. The pulmonary artery and the pulmonary veins are ligated and severed. The main bronchus is divided and the lung removed. The bronchial stump is stapled, and usually no drains are used because the accumulation of fluid in the empty hemithorax prevents mediastinal shift.

Lobectomy

When the pathology is limited to one area of a lung, a lobectomy (removal of a lobe of a lung) is performed. Lobectomy, which is more common than pneumonectomy, may be carried out for bronchogenic carcinoma, giant emphysematous blebs or bullae, benign tumors, metastatic malignant tumors, bronchiectasis, and fungus infections.

The surgeon makes a thoracotomy incision: its exact location depends on the lobe to be resected. When the pleural space is entered, the involved lung collapses and the lobar vessels and the bronchus are ligated and divided. After the lobe is removed, the remaining lobes of the lung are re-expanded. Usually, two chest catheters are inserted for drainage. The upper tube is for air removal; the lower one is for fluid drainage. Sometimes, only one catheter is needed. The chest tube is connected to a chest drainage apparatus for several days.

Segmentectomy (Segmental Resection)

Some lesions are located in only one segment of the lung. Bronchopulmonary segments are subdivisions of the lung that function as individual units. They are held together by delicate connective tissue. Disease processes may be limited to a single segment. Care is used to preserve as much healthy and functional lung tissue as possible, especially in patients who already have limited cardiopulmonary reserve. Single segments can be removed from any lobe; the right middle lobe, which has only two small segments, invariably is removed entirely. On the left side, corresponding to a middle lobe, is a "lingular" segment of the upper lobe. This can be removed as a single segment or by lingulectomy. This segment frequently is involved in bronchiectasis.

Wedge Resection

A wedge resection of a small, well-circumscribed lesion may be performed without regard for the location of the intersegmental planes. The pleural cavity usually is drained because of the possibility of an air or blood leak. This procedure is performed for diagnostic lung biopsy and for the excision of small peripheral nodules.

Bronchoplastic or Sleeve Resection

Bronchoplastic resection is a procedure in which only one lobar bronchus, together with a part of the right or left bronchus, is excised. The distal bronchus is reanastomosed to the proximal bronchus or trachea.

Lung Volume Reduction

Lung volume reduction is a surgical procedure involving the removal of 20% to 30% of a patient's lung through a midsternal incision or video thoracoscopy. The diseased lung tissue is identified on a lung perfusion scan. This surgery leads to significant improvements in dyspnea, exercise capacity, quality of life, and survival of a subgroup of people with end-stage emphysema (Naunheim, 2004).

Video Thoracoscopy

A video thoracoscopy is an endoscopic procedure that allows the surgeon to look into the thorax without making a large incision. The procedure is performed to obtain specimens of tissue for biopsy, to treat recurrent spontaneous pneumothorax, and to diagnose either pleural effusions or pleural masses. Thoracoscopy has also been found to be an effective diagnostic and therapeutic alternative for the treatment of mediastinal disorders (Cirino, Campos, Jatene, et al., 2000). Some advantages of video thoracoscopy are rapid diagnosis and treatment of some conditions, a decrease in postoperative complications, and a shortened hospital stay (see Chapter 21).

CHART
25-18

Risk Factors for Surgery-Related Atelectasis and Pneumonia

Preoperative Risk Factors

- Increased age
- Obesity
- Poor nutritional status
- Smoking history
- Abnormal pulmonary function tests
- Preexisting lung disease
- Emergency surgery
- History of aspiration
- Comorbid states
- Preexisting disability

Intraoperative Risk Factors

- Thoracic incision
- Prolonged anesthesia

Postoperative Risk Factors

- Immobilization
- Supine position
- Decreased level of consciousness
- Inadequate pain management
- Prolonged intubation/mechanical ventilation
- Presence of nasogastric tube
- Inadequate preoperative education

nurse informs the patient what to expect, from administration of anesthesia to thoracotomy and the likely use of chest tubes and a drainage system in the postoperative period. The patient is also informed about the usual postoperative administration of oxygen to facilitate breathing and the possible use of a ventilator. It is essential to explain the importance of frequent turning to promote drainage of lung secretions. Instruction in the use of incentive spirometry begins before surgery to familiarize the patient with its correct use. The nurse teaches diaphragmatic and pursed-lip breathing, and the patient should begin practicing these techniques (see Charts 25-3 and 25-4).

Because a coughing schedule is necessary in the postoperative period to promote the clearance or removal of secretions, the nurse instructs the patient in the technique of coughing and warns the patient that the coughing routine may be uncomfortable. The nurse teaches the patient to splint the incision with the hands, a pillow, or a folded towel (see Chart 25-5).

Another technique, “huffing,” may be helpful for the patient with diminished expiratory flow rates or for the patient who refuses to cough because of severe pain. Huffing is the expulsion of air through an open glottis. This type of forced expiration technique (FET) stimulates pulmonary expansion and assists in alveolar inflation. The nurse instructs the patient as follows:

- Take a deep diaphragmatic breath and exhale forcefully against your hand in a quick, distinct pant, or huff.
- Practice doing small huffs and progress to one strong huff during exhalation.

Patients should be informed preoperatively that blood and other fluids may be administered, oxygen will be ad-

ministered, and vital signs will be checked often for several hours after surgery. If a chest tube is needed, the patient should be informed that it will drain the fluid and air that normally accumulate after chest surgery. The patient and family are informed that the patient may be admitted to the intensive care unit for 1 to 2 days after surgery, that the patient may experience pain at the incision site, and that medication is available to relieve pain and discomfort.

Relieving Anxiety

The nurse listens to the patient to evaluate his or her feelings about the illness and proposed treatment. The nurse also determines the patient’s motivation to return to normal or baseline function. The patient may reveal significant concerns: fear of hemorrhage because of bloody sputum, fear of discomfort from a chronic cough and chest pain, fear of ventilator dependence, or fear of death because of dyspnea and the underlying disease (eg, tumor).

The nurse helps the patient to overcome these fears and to cope with the stress of surgery by correcting any misconceptions, supporting the patient’s decision to undergo surgery, reassuring the patient that the incision will “hold,” and dealing honestly with questions about pain and discomfort and the patient’s treatment. The management and control of pain begin before surgery, when the nurse informs the patient that many postoperative problems can be overcome by following certain routines related to deep breathing, coughing, turning, and moving. If patient-controlled analgesia (PCA) or epidural analgesia is to be used after surgery, the nurse instructs the patient in its use.

Postoperative Management

After surgery, the vital signs are checked frequently. Oxygen is administered by a mechanical ventilator, nasal cannula, or mask for as long as necessary. A reduction in lung capacity requires a period of physiologic adjustment, and fluids may be given at a low hourly rate to prevent fluid overload and pulmonary edema. After the patient is conscious and the vital signs have stabilized, the head of the bed may be elevated 30 to 45 degrees. Careful positioning of the patient is important. After pneumonectomy, a patient is usually turned every hour from the back to the operative side and should not be completely turned to the unoperated side. This allows the fluid left in the space to consolidate and prevents the remaining lung and the heart from shifting (mediastinal shift) toward the operative side. The patient with a lobectomy may be turned to either side, and a patient with a segmental resection usually is not turned onto the operative side unless the surgeon prescribes this position.

Medication for pain is needed for several days after surgery; it is usually a combination of epidural analgesia, PCA, and scheduled or as-needed oral analgesics (Gottschalk, Cohen, Yang, et al., 2006). Because coughing can be painful, the patient should be taught to splint the chest. Exercises are resumed early in the postoperative period to facilitate lung ventilation. The nurse assesses for signs of complications, including cyanosis, dyspnea, and acute chest pain. These may indicate atelectasis and should be reported immediately.

Increased temperature or white blood cell count may indicate an infection, and pallor and increased pulse may indicate internal hemorrhage. Dressings are assessed for fresh bleeding.

Mechanical Ventilation

Depending on the nature of the surgery, the patient's underlying condition, the intraoperative course, and the depth of anesthesia, the patient may require mechanical ventilation after surgery. The physician is responsible for determining the ventilator settings and modes, as well as determining the overall method and pace of weaning. It is important to assess the patient's tolerance and weaning progress. Early extubation from mechanical ventilation can lead to earlier removal of arterial lines.

Chest Drainage

A crucial intervention for improving gas exchange and breathing in the postoperative period is the proper management of chest drainage and the **chest drainage system**. After thoracic surgery, chest tubes and a closed drainage system are used to re-expand the involved lung and to remove excess air, fluid, and blood. Chest drainage systems also are used in treatment of spontaneous pneumothorax and trauma resulting in pneumothorax. Table 25-3 describes and compares the main features of these systems, and Chart 25-19 explains the management of chest drainage systems. Chart 25-20 discusses actions that may prevent cardiopulmonary complications after thoracic surgery.

The normal breathing mechanism operates on the principle of negative pressure; that is, the pressure in the chest cavity normally is lower than the pressure of the atmosphere, causing air to move into the lungs during inspiration. Whenever the chest is opened, there is a loss of negative pressure, which results in collapse of the lung. The collec-

tion of air, fluid, or other substances in the chest can compromise cardiopulmonary function and can also cause the lung to collapse. Pathologic substances that collect in the pleural space include fibrin or clotted blood, liquids (serous fluids, blood, pus, chyle), and gases (air from the lung, tracheobronchial tree, or esophagus).

Chest tubes may be inserted to drain fluid or air from any of the three compartments of the thorax (the right and left pleural spaces and the mediastinum). The pleural space, located between the visceral and parietal pleura, normally contains 20 mL or less of fluid, which helps lubricate the visceral and parietal pleura. Surgical incision of the chest wall almost always causes some degree of pneumothorax (air accumulating in the pleural space) or hemothorax (buildup of serous fluid or blood in the pleural space). Air and fluid collect in the pleural space, restricting lung expansion and reducing gas exchange. Placement of a chest tube in the pleural space restores the negative intrathoracic pressure needed for lung re-expansion after surgery or trauma.

The mediastinal space is an extrapleural space that lies between the right and left thoracic cavities and contains the large blood vessels, heart, mainstem bronchus, and thymus gland. If fluid accumulates here, the heart can become compressed and stop beating, causing death. Mediastinal chest tubes can be inserted either anteriorly or posteriorly to the heart to drain blood after surgery.

There are two types of chest tubes: small-bore and large-bore catheters. Small-bore catheters (7 Fr to 12 Fr) have a one-way valve apparatus to prevent air from moving back into the chest. They can be inserted through a small skin incision. Large-bore catheters, which range in size up to 40 Fr, are usually connected to a chest drainage system to collect any pleural fluid and monitor for air leaks. After the

Table 25-3 COMPARISON OF CHEST DRAINAGE SYSTEMS*

Types of Chest Drainage Systems	Description	Comments
Traditional Water Seal		
Also referred to as wet suction	Has three chambers: a collection chamber, water seal chamber (middle chamber), and wet suction control chamber	Requires that sterile fluid be instilled into water seal and suction chambers Has positive- and negative-pressure release valves Intermittent bubbling indicates that the system is functioning properly Additional suction can be added by connecting system to a suction source
Dry Suction Water Seal		
Also referred to as dry suction	Has three chambers: a collection chamber, water seal chamber (middle chamber), and wet suction control chamber	Requires that sterile fluid be instilled in water seal chamber at 2-cm level No need to fill suction chamber with fluid Suction pressure is set with a regulator Has positive- and negative-pressure release valves Has an indicator to signify that the suction pressure is adequate Quieter than traditional water seal systems
Dry Suction		
Also referred to as one-way valve system	Has a one-way mechanical valve that allows air to leave the chest and prevents air from moving back into the chest	No need to fill suction chamber with fluid; thus, can be set up quickly in an emergency Works even if knocked over, making it ideal for patients who are ambulatory

*If no fluid drainage is expected, a drainage collection device may not be needed.

CHART
25-19

Guidelines for Managing Chest Drainage Systems

Equipment

- Chest tube insertion tray (contains chest tube, scalpel, gloves)
- Antiseptic solution
- Local anesthetic agent
- Chest drainage system
- Adhesive tape

Implementation

Actions

1. If using a chest drainage system with a water seal, fill the water seal chamber with sterile water to the level specified by the manufacturer.
2. When using suction in chest drainage systems with a water seal, fill the suction control chamber with sterile water to the 20-cm level or as prescribed. In systems without a water seal, set the regulator dial at the appropriate suction level.
3. Attach the drainage catheter exiting the thoracic cavity to the tubing coming from the collection chamber. Tape securely with adhesive tape.
4. If suction is used, connect the suction control chamber tubing to the suction unit. If using a wet suction system, turn on the suction unit and increase pressure until slow but steady bubbling appears in the suction control chamber. If using a chest drainage system with a dry suction control chamber, turn the regulator dial to 20 cm H₂O.

Rationale

Water seal drainage allows air and fluid to escape into a drainage chamber. The water acts as a seal and keeps the air from being drawn back into the pleural space.

The water level regulator dial setting determines the degree of suction applied.

In chest drainage units, the system is closed. The only connection is the one to the patient's catheter.

With a wet suction system, the degree of suction is determined by the amount of water in the suction control chamber and is not dependent on the rate of bubbling or the pressure gauge setting on the suction unit.

With a dry suction control chamber, the regulator dial replaces the water.

Example of a disposable chest drainage system.

5. Mark the drainage from the collection chamber with tape on the outside of the drainage unit. Mark hourly/daily increments (date and time) at the drainage level.

This marking shows the amount of fluid loss and how fast fluid is collecting in the drainage chamber. It serves as a basis for determining the need for blood replacement, if the fluid is blood. Visibly bloody drainage will appear in the chamber in the immediate postoperative period but should gradually become serous. If the patient is bleeding as heavily as 100 mL every 15 minutes, check the drainage every few minutes. A reoperation or autotransfusion may be needed. The transfusion of blood collected in the drainage chamber must be reinfused within 4 to 6 hours. Usually, however, drainage decreases progressively in the first 24 hours.

Continued

CHART
25-19

Guidelines for Managing Chest Drainage Systems (Continued)

Actions

6. Ensure that the drainage tubing does not kink, loop, or interfere with the patient's movements.
7. Encourage the patient to assume a comfortable position with good body alignment. With the lateral position, make sure that the patient's body does not compress the tubing. The patient should be turned and repositioned every 1.5 to 2 hours. Provide adequate analgesia.
8. Assist the patient with range-of-motion exercises for the affected arm and shoulder several times daily. Provide adequate analgesia.
9. Gently "milk" the tubing in the direction of the drainage chamber as needed.
10. Make sure there is fluctuation ("tidaling") of the fluid level in the water seal chamber (in wet systems), or check the air leak indicator for leaks (in dry systems with a one-way valve). *Note:* Fluid fluctuations in the water seal chamber or air leak indicator area will stop when:
 - a. The lung has re-expanded
 - b. The tubing is obstructed by blood clots, fibrin, or kinks
 - c. A loop of tubing hangs below the rest of the tubing
 - d. Suction motor or wall suction is not working properly
11. With a dry system, assess for the presence of the indicator (bellows or float device) when setting the regulator dial to the desired level of suction.
12. Observe for air leaks in the drainage system; they are indicated by constant bubbling in the water seal chamber, or by the air leak indicator in dry systems with a one-way valve. Also assess the chest tube system for correctable external leaks. Notify the physician immediately of excessive bubbling in the water seal chamber not due to external leaks.
13. When turning down the dry suction, depress the manual high-negativity vent, and assess for a rise in the water level of the water seal chamber.
14. Observe and immediately report rapid and shallow breathing, cyanosis, pressure in the chest, subcutaneous emphysema, symptoms of hemorrhage, or significant changes in vital signs.
15. Encourage the patient to breathe deeply and cough at frequent intervals. Provide adequate analgesia. If needed, request an order for patient-controlled analgesia. Also teach the patient how to perform incentive spirometry.
16. If the patient is lying on a stretcher and must be transported to another area, place the drainage system below the chest level. If the tubing disconnects, cut off the contaminated tips of the chest tube and tubing, insert a sterile connector in the cut ends, and reattach to the drainage system. Do *not* clamp the chest tube during transport.
17. When assisting in the chest tube's removal, instruct the patient to perform a gentle Valsalva maneuver or to breathe quietly. The chest tube is then clamped and quickly removed. Simultaneously, a small bandage is applied and made airtight with petrolatum gauze covered by a 4 × 4-inch gauze pad and thoroughly covered and sealed with nonporous tape.

Rationale

- Kinking, looping, or pressure on the drainage tubing can produce back-pressure, which may force fluid back into the pleural space or impede its drainage.
- Frequent position changes promote drainage, and good body alignment helps prevent postural deformities and contractures. Proper positioning also helps breathing and promotes better air exchange. Analgesics may be needed to promote comfort.
- Exercise helps to prevent ankylosis of the shoulder and to reduce postoperative pain and discomfort. Analgesics may be needed to relieve pain.
- "Milking" prevents the tubing from becoming obstructed by clots and fibrin. Constant attention to maintaining the patency of the tube facilitates prompt expansion of the lung and minimizes complications.
- Fluctuation of the water level in the water seal shows effective connection between the pleural cavity and the drainage chamber and indicates that the drainage system remains patent. Fluctuation is also a gauge of intrapleural pressure in systems with a water seal (wet and dry, but not with the one-way valve).
- An air leak indicator shows changes in intrathoracic pressure in dry systems with a one-way valve. Bubbles will appear if a leak is present. The air leak indicator takes the place of fluid fluctuations in the water seal chamber.
- The indicator shows that the vacuum is adequate to maintain the desired level of suction.
- Leaking and trapping of air in the pleural space can result in tension pneumothorax.
- A rise in the water level of the water seal chamber indicates high negative pressure in the system that could lead to increased intrathoracic pressure.
- Many clinical conditions can cause these signs and symptoms, including tension pneumothorax, mediastinal shift, hemorrhage, severe incisional pain, pulmonary embolus, and cardiac tamponade. Surgical intervention may be necessary.
- Deep breathing and coughing help to raise the intrapleural pressure, which promotes drainage of accumulated fluid in the pleural space. Deep breathing and coughing also promote removal of secretions from the tracheobronchial tree, which in turn promotes lung expansion and prevents atelectasis (alveolar collapse).
- The drainage apparatus must be kept at a level lower than the patient's chest to prevent fluid from flowing backward into the pleural space. Clamping can result in a tension pneumothorax.
- The chest tube is removed as directed when the lung is re-expanded (usually 24 hours to several days), depending on the cause of the pneumothorax. During tube removal, the chief priorities are preventing air from entering the pleural cavity as the tube is withdrawn and preventing infection.

Chart 25-20 • Preventing Postoperative Cardiopulmonary Complications After Thoracic Surgery**Patient Management**

- Auscultate lung sounds and assess for rate, rhythm, and depth.
- Monitor oxygenation with pulse oximetry.
- Monitor electrocardiogram for rate and rhythm changes.
- Assess capillary refill, skin color, and status of the surgical dressing.
- Encourage and assist the patient to turn, cough, and take deep breaths.

Chest Drainage Management

- Verify that all connection tubes are patent and connected securely.
- Assess that the water seal is intact when using a wet suction system and assess the regulator dial in dry suction systems.

- Monitor characteristics of drainage including color, amount, and consistency. Assess for significant increases or decreases in drainage output.
- Note fluctuations in the water seal chamber for wet suction systems and the air leak indicator for dry suction systems.
- Keep system below the patient's chest level.
- Assess suction control chamber for bubbling in wet suction systems.
- Keep suction at prescribed level.
- Maintain appropriate fluid in water seal for wet suction systems.
- Keep air vent open when suction is off.

chest tube is positioned, it is sutured to the skin and connected to a drainage apparatus (Fig. 25-10) to remove the residual air and fluid from the pleural or mediastinal space. This results in the re-expansion of remaining lung tissue.

Chest Drainage Systems

Chest drainage systems have a suction source, a collection chamber for pleural drainage, and a mechanism to prevent air from re-entering the chest with inhalation. Various types of chest drainage systems are available for use in removal of air and fluid from the pleural space and re-expansion of the lungs. Chest drainage systems come with either wet (water seal) or dry suction control. In wet suction systems, the amount of suction is determined by the amount of water instilled in the suction chamber. The amount of bubbling in the suction chamber indicates how strong the suction is. Wet systems use a water seal to prevent air from moving back into the chest on inspiration. Dry systems use a one-way valve and may have a suction control dial in place of the water. Both systems can operate by gravity drainage, without a suction source.

NURSING ALERT

When the wall vacuum is turned off, the drainage system must be open to the atmosphere so that intrapleural air can escape from the system. This can be done by detaching the tubing from the suction port to provide a vent.

Water Seal Systems

The traditional water seal system (or wet suction) for chest drainage has three chambers: a collection chamber, a water seal chamber, and a wet suction control chamber. The collection chamber acts as a reservoir for fluid draining from the chest tube. It is graduated to permit easy measurement of drainage. Suction may be added to create negative pressure and promote drainage of fluid and removal of air. The suction control chamber regulates the amount of negative pressure applied to the chest. The amount of suction is determined by the water level. It is usually set at 20 cm H₂O; adding more fluid re-

sults in more suction. After the suction is turned on, bubbling appears in the suction chamber. A positive-pressure valve is located at the top of the suction chamber that automatically opens with increases in positive pressure within the system. Air is automatically released through a positive-pressure relief valve if the suction tubing is inadvertently clamped or kinked.

The water seal chamber has a one-way valve or water seal that prevents air from moving back into the chest when the patient inhales. There is an increase in the water level with inspiration and a return to the baseline level during exhalation; this is referred to as tidaling. Intermittent bubbling in the water seal chamber is normal, but continuous bubbling can indicate an air leak. Bubbling and tidaling do not occur when the tube is placed in the mediastinal space; however, fluid may pulsate with the patient's heartbeat. If the chest tube is connected to gravity drainage only, suction is not used. The pressure is equal to the water seal only. Two-chamber chest drainage systems (water seal chamber and collection chamber) are available for use with patients who need only gravity drainage.

The water level in the water seal chamber reflects the negative pressure present in the intrathoracic cavity. A rise in the water level indicates negative pressure in the pleural or mediastinal space. Excessive negative pressure can cause trauma to tissue. Most chest drainage systems have an automatic means to prevent excessive negative pressure. By pressing and holding a manual high-negativity vent (usually located on the top of the chest drainage system) until the water level in the water seal chamber returns to the 2-cm mark, excessive negative pressure is avoided, preventing damage to tissue.

NURSING ALERT

If the chest tube and drainage system become disconnected, air can enter the pleural space, producing a pneumothorax. To prevent pneumothorax if the chest tube is inadvertently disconnected from the drainage system, a temporary water seal can be established by immersing the chest tube's open end in a bottle of sterile water.

Figure 25-10 Chest drainage systems. **A**, The Atrium Ocean is an example of a water seal chest drain system composed of a drainage chamber and water seal chamber. The suction control is determined by the height of the water column in that chamber (usually 20 cm). (A, suction control chamber; B, water seal chamber; C, air leak zone; D, collection chamber.) **B**, The Atrium Oasis is an example of a dry suction water seal system that uses a mechanical regulator for vacuum control, a water seal chamber, and a drainage chamber. (A, dry suction regulator; B, water seal chamber; C, air leak monitor; D, collection chamber; E, suction monitor bellows.) Art redrawn with permission from Atrium Medical Corporation, Hudson, NH.

Dry Suction Water Seal Systems

Dry suction water seal systems, also referred to as dry suction, have a collection chamber for drainage, a water seal chamber, and a dry suction control chamber. The water seal chamber is filled with water to the 2-cm level. Bubbling in this area can indicate an air leak. The dry suction control chamber contains a regulator dial that conveniently regulates vacuum to the chest drain. Water is not needed for suction in these systems. Without the bubbling in the suction chamber, the machine is quieter. However, if the container is knocked over, the water seal may be lost.

Once the tube is connected to the suction source, the regulator dial allows the desired level of suction to be set; the suction is increased until an indicator appears. The indicator has the same function as the bubbling in the traditional water seal system; that is, it indicates that the vacuum is adequate to maintain the desired level of suction. Some drainage systems use a bellows (a chamber that can

be expanded or contracted) or an orange-colored float device as an indicator of when the suction control regulator is set.

When the water in the water seal rises above the 2-cm level, intrathoracic pressure increases. Dry suction water seal systems have a manual high-negativity vent located on top of the drain. The manual high-negativity vent is pressed until the indicator appears (either a float device or bellows), and the water level in the water seal returns to the desired level, indicating that the intrathoracic pressure is decreased.

NURSING ALERT

The manual vent should not be used to lower the water level in the water seal when the patient is on gravity drainage (no suction) because intrathoracic pressure is equal to the pressure in the water seal.

Dry Suction Systems With a One-Way Valve

A third type of chest drainage system is dry suction with a one-way mechanical valve. This system has a collection chamber, a one-way mechanical valve, and a dry suction control chamber. The valve permits air and fluid to leave the chest but prevents their movement back into the pleural space. This model lacks a water seal chamber and therefore can be set up quickly in emergency situations, and the dry control drain still works even if it is knocked over. This makes the dry suction systems useful for the patient who is ambulating or being transported. However, without the water seal chamber, there is no way to tell by inspection whether the pressure in the chest has changed, even though an air leak indicator is present so that the system can be checked. If an air leak is suspected, 30 mL of water is injected into the air leak indicator or the container is tipped so that fluid enters the air leak detection chamber. Bubbles will appear if a leak is present.

If the chest tube has been inserted to re-expand a lung after pneumothorax, or if very little fluid drainage is expected, a one-way valve (Heimlich valve) may be connected to the chest tube. This valve may be attached to a collection bag (Fig. 25-11) or covered with a sterile dressing if no drainage is expected.

Postoperative Nursing Management

Postoperative nursing care of the patient who has undergone thoracic surgery addresses close monitoring of the patient's respiratory and cardiovascular status, interventions to prevent complications, and the psychological reactions that often occur in response to this major surgical procedure and the fears that it often engenders in patients and their families.

Figure 25-11 One-way (Heimlich) valve, a disposable, single-use chest drainage system with 30 mL collection volume. Used when minimal volume of chest drainage is expected.

Monitoring Respiratory and Cardiovascular Status

The nurse monitors the heart rate and rhythm by auscultation and ECG because episodes of major dysrhythmias are common after thoracic and cardiac surgery. In the immediate postoperative period, an arterial line may be maintained to allow frequent monitoring of arterial blood gases, serum electrolytes, hemoglobin and hematocrit values, and arterial pressure. Central venous pressure may be monitored to detect early signs of fluid volume disturbances; however, central venous pressure monitoring devices are being used less than in the past. Early extubation from mechanical ventilation can also lead to earlier removal of arterial lines. Another important component of postoperative assessment is to note the results of the preoperative evaluation of the patient's lung reserve by pulmonary function testing. A preoperative FEV₁ (the volume of air that the patient can forcibly exhale in 1 second) of more than 2 L or more than 70% of predicted value indicates a good lung reserve. Patients who have a postoperative FEV₁ of less than 40% of predicted value have decreased tidal volume, which places them at risk for respiratory failure, other morbidity, and death.

Improving Gas Exchange and Breathing

Gas exchange is determined by evaluating oxygenation and ventilation. In the immediate postoperative period, this is achieved by measuring vital signs (blood pressure, pulse, and respirations) at least every 15 minutes for the first 1 to 2 hours, and then less frequently as the patient's condition stabilizes. Pulse oximetry is used for continuous monitoring of the adequacy of oxygenation. Arterial blood gas measurements are obtained early in the postoperative period to establish a baseline to assess the adequacy of oxygenation and ventilation and the possible retention of carbon dioxide. The frequency with which postoperative arterial blood gases are measured depends on whether the patient is mechanically ventilated and whether he or she exhibits signs of respiratory distress; these measurements can help determine appropriate therapy. It also is common practice for patients to have an arterial line in place to obtain blood for blood gas measurements and to monitor blood pressure closely. Hemodynamic monitoring may be used to assess hemodynamic stability.

Breathing techniques, such as diaphragmatic and pursed-lip breathing, taught prior to surgery should be performed by the patient every 2 hours to expand the alveoli and prevent atelectasis. Sustained maximal inspiration therapy or incentive spirometry promotes lung inflation, improves the cough mechanism, and allows early assessment of acute pulmonary changes. (See Charts 25-3 and 25-4 for more information.)

If the patient is oriented and blood pressure is stabilized, the head of the bed is elevated 30 to 40 degrees during the immediate postoperative period. This position facilitates ventilation, promotes chest drainage from the lower chest tube, and helps residual air to rise in the upper portion of the pleural space, where it can be removed through the upper chest tube.

The nurse consults with the surgeon about patient positioning to determine the best side-lying position. In general, the patient should be positioned from back to side

frequently and moved from a flat to a semiupright position as soon as tolerated. Most commonly, the patient is instructed to lie on the operative side. However, the patient with unilateral lung pathology may not be able to turn well onto that side because of pain. In addition, positioning the patient with the “good lung” (the nonoperated lung) down allows a better match of ventilation and perfusion and therefore may actually improve oxygenation. The patient’s position is changed from flat to semiupright as soon as possible because remaining in one position tends to promote the retention of secretions in the dependent portion of the lungs, and the upright position increases diaphragmatic excursion, enhancing lung expansion. After a pneumonectomy, the operated side should be dependent so that fluid in the pleural space remains below the level of the bronchial stump and the other lung can fully expand.

Improving Airway Clearance

Retained secretions are a threat to the patient after thoracotomy surgery. Trauma to the tracheobronchial tree during surgery, diminished lung ventilation, and diminished cough reflex all result in the accumulation of excessive secretions. If the secretions are retained, airway obstruction occurs. This, in turn, causes the air in the alveoli distal to the obstruction to become absorbed and the affected portion of the lung to collapse. Atelectasis, pneumonia, and respiratory failure may result.

To maintain a patent airway, secretions are suctioned from the tracheobronchial tree before the endotracheal tube is discontinued. Secretions continue to be removed by suctioning until the patient can cough up secretions effectively. Nasotracheal suctioning may be needed to stimulate a deep cough and aspirate secretions that the patient cannot clear by coughing. However, it should be used only after other methods to raise secretions have been unsuccessful (Chart 25-21).

The patient is encouraged to cough effectively to maintain a patent airway; ineffective coughing results in exhaustion and retention of secretions (see Chart 25-5). To be effective, the cough must be low-pitched, deep, and controlled. Because it is difficult to cough in a supine position, the patient is helped to a sitting position on the edge of the bed, with the feet resting on a chair. The patient should cough at least every hour during the first 24 hours and when necessary thereafter. If audible crackles are present, it may be necessary to use chest percussion with the cough routine until the lungs are clear. Aerosol therapy is helpful in humidifying and mobilizing secretions so that they can easily be cleared with coughing. To minimize incisional pain during coughing, the nurse supports the incision or encourages the patient to do so (Fig. 25-12). If a patient is identified as being at high risk for postoperative pulmonary complications, then CPT is started immediately (perhaps even before surgery). The techniques of postural drainage, vibration, and percussion help loosen and mobilize the secretions so that they can be coughed up or suctioned.

Following the use of these measures, the nurse listens to both lungs, anteriorly and posteriorly, to determine whether there are any changes in breath sounds. Diminished breath sounds may indicate collapsed or hypoventilated alveoli.

Chart 25-21 • Performing Nasotracheal Suction

- Explain procedure to the patient.
- Medicate patient for pain if necessary.
- Place the patient in a sitting or semi-Fowler’s position. Make sure the patient’s head is not flexed forward. Remove excess pillows if necessary.
- Oxygenate the patient several minutes before initiating the suctioning procedure. Have oxygen source ready nearby during procedure.
- Put on sterile gloves.
- Lubricate catheter with water-soluble gel.
- Gently pass catheter through the patient’s nose to the pharynx. If it is difficult to pass the catheter, and repeated suctioning is expected, a soft rubber nasal trumpet may be placed nasopharyngeally to provide easier catheter passage. Check the position of the tip of the catheter by asking the patient to open the mouth to inspect it; the tip of the catheter should be in the lower pharynx.
- Instruct the patient to take a deep breath or stick out the tongue. This action opens the epiglottis and promotes downward movement of the catheter.
- Advance the catheter into the trachea only during inspiration. Listen for cough or for passage of air through the catheter.
- Attach the catheter to suction apparatus. Apply intermittent suction while slowly withdrawing the catheter. Do not let suction exceed 120 mm Hg.
- Do not suction for longer than 10 to 15 seconds, as dysrhythmias, bradycardia, or cardiac arrest may occur in patients with borderline oxygenation.
- If additional suctioning is needed, withdraw the catheter to the back of the pharynx. Reassure patient and oxygenate for several minutes before resuming suctioning.

Relieving Pain and Discomfort

Pain after a thoracotomy may be severe, depending on the type of incision and the patient’s reaction and ability to cope with pain. Pain can impair the patient’s ability to breathe deeply and cough. Immediately after the surgical procedure and before the incision is closed, the surgeon may perform a nerve block with a long-acting local anesthetic such as bupivacaine (Marcaine, Sensorcaine). Bupivacaine is titrated to relieve postoperative pain while allowing the patient to cooperate in deep breathing, coughing, and mobilization. An epidural catheter may be placed for continuous or PCA using a combination of a long-acting local anesthetic and an opioid, or a continuous epidural infusion may be combined with IV PCA using an opioid (Gottschalk, et al., 2006). Opioid analgesic agents such as morphine are commonly used in PCA, which allows the patient to control the frequency and total dosage. Preset limits on the pump avoid overdosage. With proper instruction, PCA is well tolerated and allows earlier mobilization and cooperation with the treatment regimen. (See Chapter 13 for a more extensive discussion of PCA and pain management.)

It is important to avoid depressing the respiratory system with excessive analgesia: the patient should not be so sedated as to be unable to cough. Inadequate treatment of

A. Nurse's hands should support the chest incision anteriorly and posteriorly. The patient is instructed to take several deep breaths, inhale, and then cough forcibly.

B. With one hand, the nurse exerts downward pressure on the shoulder of the affected side while firmly supporting the area beneath the wound. The patient is instructed to take several deep breaths, inhale, and then cough forcibly.

C. The nurse can wrap a towel or sheet around the patient's chest and hold the ends together, pulling slightly as the patient coughs, and releasing during deep breaths.

D. The patient can be taught to hold a pillow firmly against the incision while coughing. This can be done while lying down or sitting in an upright position.

Figure 25-12 Techniques for supporting incision while a patient recovering from thoracic surgery coughs.

pain, however, may also lead to hypoventilation and decreased coughing.

NURSING ALERT

It is important not to confuse the restlessness of hypoxia with the restlessness caused by pain. Dyspnea, restlessness, increasing respiratory rate, increasing blood pressure, and tachycardia are warning signs of impending respiratory insufficiency. Pulse oximetry is used to monitor oxygenation and to differentiate causes of restlessness.

Lidocaine (Xylocaine) and prilocaine (Citanest) are local anesthetic agents that may be used to treat pain at the site of the chest tube insertion. These medications are administered as topical transdermal analgesics that penetrate the skin; they have also been found to be effective when used together. EMLA cream, which is a mixture of the two medications, may be effective in treating pain from chest tube removal. However, many physicians prefer not to use analgesia when removing chest tubes because the pain, although severe, is of short duration (usually less than a few minutes) and the analgesia might interfere with respiratory effort.

Promoting Mobility and Shoulder Exercises

Because large shoulder girdle muscles are transected during a thoracotomy, the arm and shoulder must be mobilized by full range of motion of the shoulder. As soon as physiologically possible, usually within 8 to 12 hours, the patient is helped to get out of bed. Although this may be painful initially, the earlier the patient moves, the sooner the pain will subside. In addition to getting out of bed, the patient begins arm and

shoulder exercises to restore movement and prevent painful stiffening of the affected arm and shoulder (Chart 25-22). Regular doses of acetaminophen can help relieve shoulder pain (Gottschalk, et al., 2006).

Maintaining Fluid Volume and Nutrition

During the surgical procedure or immediately after, the patient may receive a transfusion of blood products, followed by a continuous IV infusion. Because a reduction in lung capacity often occurs after thoracic surgery, a period of physiologic adjustment is needed. Fluids should be administered at a low hourly rate and titrated (as prescribed) to prevent overloading the vascular system and precipitating pulmonary edema. The nurse performs careful respiratory and cardiovascular assessments and monitors intake and output, vital signs, and jugular vein distention. The nurse also monitors the infusion site for signs of infiltration, including swelling, tenderness, and redness.

Patients undergoing thoracotomy may have poor nutritional status before surgery because of dyspnea, sputum production, and poor appetite. Therefore, it is especially important that adequate nutrition be provided. A liquid diet is provided as soon as bowel sounds return, and the patient is progressed to a full diet as soon as possible. Small, frequent meals are better tolerated and are crucial to the recovery and maintenance of lung function.

Monitoring and Managing Potential Complications

Complications after thoracic surgery are always a possibility and must be identified and managed early. In addition, the nurse monitors the patient at regular intervals for signs of respiratory distress or developing respiratory failure,

CHART
25-22

PATIENT EDUCATION

Performing Arm and Shoulder Exercises

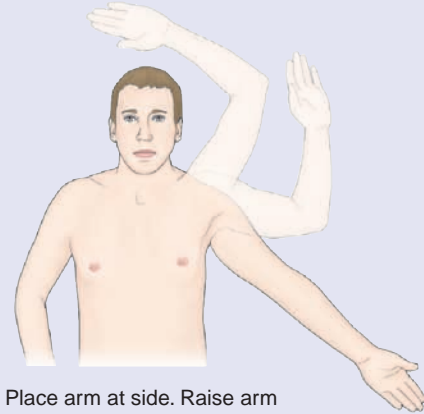

Arm and shoulder exercises are performed after thoracic surgery to restore movement, prevent painful stiffening of the shoulder, and improve muscle power.

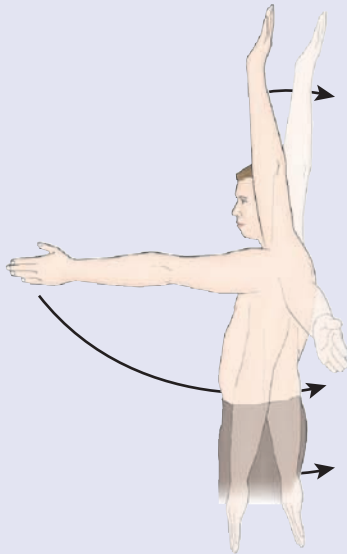

Hold hand of the affected side with the other hand, palms facing in. Raise the arms forward, upward, and then overhead, while taking a deep breath. Exhale while lowering the arms. Repeat five times.

Raise arm sideward, upward, and downward in a waving motion

Place arm at side. Raise arm sideward, upward, and then overhead. Repeat five times. These exercises can also be performed while lying in bed.

Extend the arm up and back, out to the side and back, down at the side, and back.

Place hands in small of back. Push elbows as far back as possible.

Sit erect in an armchair; place the hands on arms of the chair. Press down on hands, consciously pulling the abdomen in and stretching up from the waist. Inhale while raising the body until elbows are extended completely. Hold this position a moment, and begin exhaling while lowering the body slowly to the original position.

dysrhythmias, bronchopleural fistula, hemorrhage and shock, atelectasis, and incisional or pulmonary infection.

Respiratory distress is treated by identifying and eliminating its cause while providing supplemental oxygen. If the patient progresses to respiratory failure, intubation and mechanical ventilation are necessary.

Dysrhythmias are often related to the effects of hypoxia or the surgical procedure. They are treated with antiarrhyth-

mic medication and supportive therapy (see Chapter 27). Pulmonary infections or effusion, often preceded by atelectasis, may occur a few days into the postoperative course.

Pneumothorax may occur after thoracic surgery if there is an air leak from the surgical site to the pleural cavity or from the pleural cavity to the environment. Failure of the chest drainage system prevents return of negative pressure in the pleural cavity and results in pneumothorax. In the

CHART

HOME CARE CHECKLIST

The Patient With a Thoracotomy

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Use local heat and oral analgesia to relieve intercostal pain.	✓	✓
• Alternate walking and other activities with frequent rest periods, expecting weakness and fatigue for the first 3 weeks.	✓	✓
• Perform breathing exercises several times daily for the first few weeks at home.	✓	
• Avoid lifting more than 20 pounds until complete healing has taken place; the chest muscles and incision may be weaker than normal for 3 to 6 months after surgery.	✓	
• Walk at a moderate pace, gradually and persistently extending walking time and distance.	✓	
• Immediately stop any activity that causes undue fatigue, increased shortness of breath, or chest pain.	✓	
• Avoid bronchial irritants (smoke, fumes, air pollution, aerosol sprays).	✓	✓
• Avoid others with known colds or lung infections.	✓	✓
• Obtain an annual influenza vaccine and discuss vaccination against pneumonia with the physician.	✓	
• Report for follow-up care by the surgeon or clinic as necessary.	✓	✓
• Stop smoking, if applicable, and avoid exposure to secondhand smoke.	✓	✓

postoperative patient, pneumothorax is often accompanied by hemothorax. The nurse maintains the chest drainage system and monitors the patient for signs and symptoms of pneumothorax: increasing shortness of breath, tachycardia, increased respiratory rate, and increasing respiratory distress.

Bronchopleural fistula is a serious but rare complication that prevents the return of negative intrathoracic pressure and lung re-expansion. Depending on its severity, it is treated with closed chest drainage, mechanical ventilation, and possibly talc pleurodesis (described in Chapter 23).

Hemorrhage and shock are managed by treating the underlying cause, whether by reoperation or by administration of blood products or fluids. Pulmonary edema from overinfusion of IV fluids is a significant danger. Early symptoms are dyspnea, crackles, bubbling sounds in the chest, tachycardia, and pink, frothy sputum. This constitutes an emergency and must be reported and treated immediately.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The nurse instructs the patient and family about postoperative care that will be continued at home. The nurse explains signs and symptoms that should be reported to the physician. These include the following:

- Change in respiratory status: increasing shortness of breath, fever, increased restlessness or other changes in mental or cognitive status, increased respiratory rate, change in respiratory pattern, change in amount or color of sputum
- Bleeding or other drainage from the surgical incision or chest tube exit sites
- Increased chest pain

In addition, respiratory care and other treatment modalities (oxygen, incentive spirometry, CPT, and oral, inhaled, or IV medications) may be continued at

home. Therefore, the nurse needs to instruct the patient and family in their correct and safe use.

The nurse emphasizes the importance of progressively increased activity. The nurse instructs the patient to ambulate within limits and explains that return of strength is likely to be very gradual. Another important aspect of patient teaching addresses shoulder exercises. The patient is instructed to do these exercises five times daily. Additional patient teaching is described in Chart 25-23.

Continuing Care

Depending on the patient's physical status and the availability of family assistance, a home care referral may be indicated. The home care nurse assesses the patient's recovery from surgery, with special attention to respiratory status, the surgical incision, chest drainage, pain control, ambulation, and nutritional status. The patient's use of respiratory modalities is assessed to ensure that they are being used correctly and safely. In addition, the nurse assesses the patient's adherence to the postoperative treatment plan and identifies acute or late postoperative complications.

The recovery process may take longer than the patient had expected, and providing support to the patient is an important task for the home care nurse. Because of shorter hospital stays, follow-up appointments with the physician are essential. The nurse teaches the patient about the importance of keeping follow-up appointments and completing laboratory tests as prescribed to assist the physician in evaluating recovery. The home care nurse provides continuous encouragement and education to the patient and family during the process. As recovery progresses, the nurse also reminds the patient and family about the importance of participating in health promotion activities and recommended health screening.

For a detailed plan of nursing care for the patient who has had a thoracotomy, see Chart 25-24.

CHART
25-24

PLAN OF NURSING CARE

Care of the Patient After Thoracotomy

NURSING DIAGNOSIS: Impaired gas exchange related to lung impairment and surgery

GOAL: Improvement of gas exchange and breathing

Nursing Interventions

1. Monitor pulmonary status as directed and as needed:
 - a. Auscultate breath sounds.
 - b. Check rate, depth, and pattern of respirations.
 - c. Assess blood gases for signs of hypoxemia or CO₂ retention.
 - d. Evaluate patient's color for cyanosis.
2. Monitor and record blood pressure, apical pulse, and temperature every 2–4 hours, central venous pressure (if indicated) every 2 hours.
3. Monitor continuous electrocardiogram for pattern and dysrhythmias.
4. Elevate head of bed 30–40 degrees when patient is oriented and hemodynamic status is stable.
5. Encourage deep-breathing exercises (see section on Breathing Retraining) and effective use of incentive spirometer (sustained maximal inspiration).
6. Encourage and promote an effective cough routine to be performed every 1–2 hours during first 24 hours.
7. Assess and monitor the chest drainage system*
 - a. Assess for leaks and patency as needed (See Chart 25–19).
 - b. Monitor amount and character of drainage and document every 2 hours. Notify physician if drainage is 150 mL/h or greater.

Rationale

1. Changes in pulmonary status indicate improvement or onset of complications.
2. Aid in evaluating effect of surgery on cardiac status.
3. Dysrhythmias (especially atrial fibrillation and atrial flutter) are more frequently seen after thoracic surgery. A patient with total pneumonectomy is especially prone to cardiac irregularity.
4. Maximum lung excursion is achieved when patient is as close to upright as possible.
5. Helps to achieve maximal lung inflation and to open closed airways.
6. Coughing is necessary to remove retained secretions.
7. System is used to eliminate any residual air or fluid after thoracotomy.

Expected Outcomes

- Lungs are clear on auscultation
- Respiratory rate is within acceptable range with no episodes of dyspnea
- Vital signs are stable
- Dysrhythmias are not present or are under control
- Demonstrates deep, controlled, effective breathing to allow maximal lung expansion
- Uses incentive spirometer every 2 hours while awake
- Demonstrates deep, effective coughing technique
- Lungs are expanded to capacity (evidenced by chest x-ray)

NURSING DIAGNOSIS: Ineffective airway clearance related to lung impairment, anesthesia, and pain

GOAL: Improvement of airway clearance and achievement of a patent airway

Nursing Interventions

1. Maintain an open airway.
2. Perform endotracheal suctioning until patient can raise secretions effectively.
3. Assess and medicate for pain. Encourage deep-breathing and coughing exercises. Help splint incision during coughing.

Rationale

1. Provides for adequate ventilation and gas exchange.
2. Endotracheal secretions are present in excessive amounts in postthoracotomy patients due to trauma to the tracheo-bronchial tree during surgery, diminished lung ventilation, and cough reflex.
3. Helps to achieve maximal lung inflation and to open closed airways. Coughing is painful; incision needs to be supported.

Expected Outcomes

- Airway is patent
- Coughs effectively
- Splints incision while coughing
- Sputum is clear or colorless
- Lungs are clear on auscultation

*A patient with a pneumonectomy usually does not have water seal chest drainage because it is desirable that the pleural space fill with an effusion, which eventually obliterates this space. Some surgeons do use a modified water seal system.

 CHART
25-24

PLAN OF NURSING CARE
Care of the Patient After Thoracotomy (Continued)

Nursing Interventions	Rationale	Expected Outcomes
4. Monitor amount, viscosity, color, and odor of sputum. Notify physician if sputum is excessive or contains bright-red blood. 5. Administer humidification and mini-nebulizer therapy as prescribed. 6. Perform postural drainage, percussion, and vibration as prescribed. Do not percuss or vibrate directly over operative site. 7. Auscultate both sides of chest to determine changes in breath sounds.	4. Changes in sputum suggest presence of infection or change in pulmonary status. Colorless sputum is not unusual; opacification or coloring of sputum may indicate dehydration or infection. 5. Secretions must be moistened and thinned if they are to be raised from the chest with the least amount of effort. 6. Chest physiotherapy uses gravity to help remove secretions from the lung. 7. Indications for tracheal suctioning are determined by chest auscultation.	
NURSING DIAGNOSIS: Acute pain related to incision, drainage tubes, and the surgical procedure GOAL: Relief of pain and discomfort		
Nursing Interventions	Rationale	Expected Outcomes
1. Evaluate location, character, quality, and severity of pain. Administer analgesic medication as prescribed and as needed. Observe for respiratory effect of opioid. Is patient too somnolent to cough? Are respirations depressed? 2. Maintain care postoperatively in positioning the patient: a. Place patient in semi-Fowler's position. b. Patients with limited respiratory reserve may not be able to turn on unoperated side. c. Assist or turn patient every 2 hours. 3. Assess incision area every 8 hours for redness, heat, induration, swelling, separation, and drainage. 4. Request order for patient-controlled analgesia pump if appropriate for patient.	1. Pain limits chest excursions and thereby decreases ventilation. 2. The patient who is comfortable and free of pain will be less likely to splint the chest while breathing. A semi-Fowler's position permits residual air in the pleural space to rise to upper portion of pleural space and be removed via the upper chest catheter. 3. These signs indicate possible infection. 4. Allowing patient control over frequency and dose improves comfort and compliance with treatment regimen.	<ul style="list-style-type: none"> • Asks for pain medication, but verbalizes that he or she expects some discomfort while deep breathing and coughing • Verbalizes that he or she is comfortable and not in acute distress • No signs of incisional infection evident
NURSING DIAGNOSIS: Anxiety related to outcomes of surgery, pain, technology GOAL: Reduction of anxiety to a manageable level		
Nursing Interventions	Rationale	Expected Outcomes
1. Explain all procedures in understandable language. 2. Assess for pain and medicate, especially before potentially painful procedures. 3. Silence all <i>unnecessary</i> alarms on technology (monitors, ventilators).	1. Explaining what can be expected in understandable terms decreases anxiety and increases cooperation. 2. Premedication before painful procedures or activities improves comfort and minimizes undue anxiety. 3. <i>Unnecessary</i> alarms increase the risk of sensory overload and may increase anxiety. <i>Essential</i> alarms must be turned on at all times.	<ul style="list-style-type: none"> • States that anxiety is at a manageable level • Participates with health care team in treatment regimen • Uses appropriate coping skills (verbalization, pain relief strategies, use of support systems such as family, clergy) • Demonstrates basic understanding of technology used in care

Continued

 CHART
25-24

PLAN OF NURSING CARE
Care of the Patient After Thoracotomy (Continued)

Nursing Interventions 4. Encourage and support patient while increasing activity level. 5. Mobilize resources (family, clergy, social worker) to help patient cope with outcomes of surgery (diagnosis, change in functional abilities).	Rationale 4. Positive reinforcement improves patient motivation and independence. 5. A multidisciplinary approach promotes the patient's strengths and coping mechanisms.	Expected Outcomes
NURSING DIAGNOSIS: Impaired physical mobility of the upper extremities related to thoracic surgery GOAL: Increased mobility of the affected shoulder and arm		
Nursing Interventions 1. Assist patient with normal range of motion and function of shoulder and trunk: a. Teach breathing exercises to mobilize thorax. b. Encourage skeletal exercises to promote abduction and mobilization of shoulder (see Chart 25-22). c. Assist out of bed to chair as soon as pulmonary and circulatory systems are stable (usually by evening of surgery). 2. Encourage progressive activities according to level of fatigue.	Rationale 1. Necessary to regain normal mobility of arm and shoulder and to speed recovery and minimize discomfort. 2. Increases patient's use of affected shoulder and arm.	Expected Outcomes <ul style="list-style-type: none"> • Demonstrates arm and shoulder exercises and verbalizes intent to perform them on discharge • Regains previous range of motion in shoulder and arm
NURSING DIAGNOSIS: Risk for imbalanced fluid volume related to the surgical procedure GOAL: Maintenance of adequate fluid volume		
Nursing Interventions 1. Monitor and record hourly intake and output. Urine output should be at least 30 mL/h after surgery. 2. Administer blood component therapy and parenteral fluids and/or diuretics as prescribed to restore and maintain fluid volume.	Rationale 1. Fluid management may be altered before, during, and after surgery, and patient's response to and need for fluid management must be assessed. 2. Pulmonary edema due to transfusion or fluid overload is an ever-present threat; after pneumonectomy, the pulmonary vascular system has been greatly reduced.	Expected Outcomes <ul style="list-style-type: none"> • Patient is adequately hydrated, as evidenced by: <ul style="list-style-type: none"> • Urine output greater than 30 mL/h • Vital signs stable, heart rate, and central venous pressure approaching normal • No excessive peripheral edema
NURSING DIAGNOSIS: Deficient knowledge of home care procedures GOAL: Increased ability to carry out care procedures at home		
Nursing Interventions 1. Encourage patient to practice arm and shoulder exercises five times daily at home. 2. Instruct patient to practice assuming a functionally erect position in front of a full-length mirror. 3. Instruct patient about home care (see chart 25-3).	Rationale 1. Exercise accelerates recovery of muscle function and reduces long-term pain and discomfort. 2. Practice will help restore normal posture. 3. Knowing what to expect facilitates recovery.	Expected Outcomes <ul style="list-style-type: none"> • Demonstrates arm and shoulder exercises • Verbalizes need to try to assume an erect posture • Verbalizes the importance of relieving discomfort, alternating walking and rest, performing breathing exercises, avoiding heavy lifting, avoiding undue fatigue, avoiding bronchial irritants, preventing colds or lung infections, getting influenza vaccine, keeping follow-up visits, and stopping smoking

CRITICAL THINKING EXERCISES

1 A 20-year-old woman who was admitted to your unit because of sudden onset of severe chest pain is diagnosed with spontaneous pneumothorax. A physician will insert a chest tube with a Heimlich valve shortly. What do your patient and her family need to know about the procedure? What supplies do you think you will need in the room for the chest tube insertion? What assessments will be necessary immediately after chest tube insertion? In 1 hour?

2 A 72-year-old man who has COPD from working as a coal miner has pneumonia in his right lower and middle lobes. To help mobilize and drain the secretions, CPT is prescribed. The patient only wants to sit in bed because it is easier for him to breathe when in the semi-Fowler's position. What positions are the most important for successful CPT? What can you do to aid him during the treatments?

3 Oxygen therapy is required for the following patients: a 59-year-old patient who has just been diagnosed with severe COPD and will need lifelong supplemental oxygen; a 21-year-old patient who was rescued from a house fire and needs short-term oxygen therapy because of exposure to smoke; and a 65-year-old patient with terminal metastatic cancer. Compare and contrast the similarities and differences in the oxygen therapy necessary for each patient, and discuss teaching and safety precautions indicated for each patient and his or her family. Describe the patient teaching that will be required for the patients who will be discharged from the hospital with a prescription for oxygen therapy.

4 **EBP** Following an episode of flu, a 50-year-old woman developed respiratory failure and was intubated. Three weeks later, because of complications that prevented extubation, a tracheostomy was performed. She has been relying on the ventilator for more than 2 months and is now strong enough to begin weaning. However, whenever the respiratory technician adjusts the ventilator settings, she becomes extremely anxious and starts hyperventilating. How will you explain the weaning process to her? What other antianxiety measures may be helpful? Develop an evidence-based practice weaning plan for this patient.

5 Your patient has just returned from the operating room after thoracic surgery. She has an endotracheal tube, two chest tubes, two IV lines, an epidural catheter, and an indwelling urinary catheter in place. The surgeon's orders include ventilator settings, a cardiac monitor, "stat" complete blood cell (CBC) count on arrival to the intensive care unit, and arterial blood gases in 1 hour. What are your immediate priorities for assessment for this patient? What observations need to be reported to the surgeon immediately? What other nursing interventions are warranted immediately? In 8 hours? At 24 hours and 48 hours postoperatively?

unit 6

Cardiovascular, Circulatory, and Hematologic Function

Case Study • Applying Concepts From NANDA, NIC,
and NOC

A Patient Who Has Intermittent Claudication and Ulceration

Mr. Black, age 63 years, has a history of peripheral arterial occlusive disease (2 years), hypertension, hypercholesterolemia, type 2 diabetes, and smoking. He eats low-fat foods and cut back on smoking to half a pack a day. His home-monitored blood glucose levels range from 180 to 215 mg/dL. Because he has severe calf pain after walking, he now walks only two blocks a day—one block from home and one block back. He now receives medical treatment for a nonhealing ulcer on the plantar aspect of his left foot.

Visit the Point to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
INEFFECTIVE PERIPHERAL TISSUE PERFUSION —Decrease in oxygen resulting in the failure to nourish tissues at the capillary level	CIRCULATORY CARE: ARTERIAL INSUFFICIENCY —Promotion of arterial circulation CIRCULATORY PRECAUTIONS —Protection of localized area with limited perfusion	CIRCULATION STATUS —Unobstructed, unidirectional blood flow at an appropriate pressure through large vessels of the systemic and pulmonary circuits PERIPHERAL TISSUE PERFUSION —Adequacy of blood flow through the small vessels of the extremities to maintain tissue function
CHRONIC PAIN —Unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage; sudden or slow onset of any intensity from mild to severe, constant or recurring without an anticipated or predictable end and a duration of greater than 6 months	PAIN MANAGEMENT —Alleviation of pain or reduction in pain to a level of comfort that is acceptable to the patient	SYMPTOM CONTROL —Personal actions to minimize perceived adverse changes in physical and emotional functioning COMFORT LEVEL —Extent of positive perception of physical and psychological ease
ACTIVITY INTOLERANCE —Insufficient physiological or psychological energy to endure or complete required or desired daily activities	EXERCISE THERAPY: AMBULATION —Promotion and assistance with walking to maintain or restore autonomic and voluntary body functions during treatment and recovery from illness or injury	ACTIVITY TOLERANCE —Physiologic response to energy-consuming movements with daily activities

chapter 26

Assessment of Cardiovascular Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Explain cardiac physiology in relation to cardiac anatomy and the conduction system of the heart.
- 2 Incorporate assessment of cardiac risk factors into the health history and physical assessment of the patient with cardiovascular disease.
- 3 Discuss the clinical indications, patient preparation, and other related nursing implications for common tests and procedures used to assess cardiovascular function and diagnose cardiovascular diseases.
- 4 Compare the various methods of hemodynamic monitoring (eg, central venous pressure, pulmonary artery pressure, and arterial pressure monitoring) with regard to indications for use, potential complications, and nursing responsibilities.

GLOSSARY

acute coronary syndrome: refers to rupture of an atheromatous plaque in a diseased coronary artery, which rapidly forms an obstructive thrombus

afterload: the amount of resistance to ejection of blood from the ventricle

apical impulse (also called **point of maximum impulse**): impulse normally palpated at the fifth intercostal space, left midclavicular line; caused by contraction of the left ventricle

atrioventricular (AV) node: secondary pacemaker of the heart, located in the right atrial wall near the tricuspid valve

baroreceptors: nerve fibers located in the aortic arch and carotid arteries that are responsible for reflex control of the blood pressure

cardiac catheterization: an invasive procedure used to measure cardiac chamber pressures and assess patency of the coronary arteries

cardiac conduction system: specialized heart cells strategically located throughout the heart that are responsible for methodically generating and coordinating the transmission of electrical impulses to the myocardial cells

cardiac output: amount of blood pumped by each ventricle in liters per minute

cardiac stress test: a test used to evaluate the functioning of the heart during a period of increased oxygen demand

contractility: ability of the cardiac muscle to shorten in response to an electrical impulse

depolarization: electrical activation of a cell caused by the influx of sodium into the cell while potassium exits the cell

diastole: period of ventricular relaxation resulting in ventricular filling

ejection fraction: percentage of the end-diastolic blood volume ejected from the ventricle with each heartbeat

GLOSSARY (Continued)

hemodynamic monitoring: use of pressure monitoring devices to directly measure cardiovascular function

hypertension: blood pressure that is persistently greater than 140/90 mm Hg

hypotension: a decrease in blood pressure to less than 100/60 mm Hg that compromises systemic perfusion

murmurs: sounds created by abnormal, turbulent flow of blood in the heart

myocardial ischemia: condition in which heart muscle cells receive less oxygen than needed

myocardium: muscle layer of the heart responsible for the pumping action of the heart

normal heart sounds: sounds produced when the valves close; normal heart sounds are S₁ (atrioventricular valves) and S₂ (semilunar valves)

opening snaps: abnormal diastolic sound generated during opening of a rigid AV valve leaflet

postural (orthostatic) hypotension: a significant drop in blood pressure (usually 10 mm Hg systolic or more) after an upright posture is assumed

preload: degree of stretch of the cardiac muscle fibers at the end of diastole

pulmonary vascular resistance: resistance to right ventricular ejection of blood

radioisotopes: unstable atoms that emit small amounts of energy in the form of gamma rays; used in cardiac nuclear medicine studies

repolarization: return of the cell to resting state, caused by reentry of potassium into the cell while sodium exits the cell

S₁: the first heart sound produced by closure of the atrioventricular (mitral and tricuspid) valves

S₂: the second heart sound produced by closure of the semilunar (aortic and pulmonic) valves

S₃: an abnormal heart sound detected early in diastole as resistance is met to blood entering either ventricle; most often due to volume overload associated with heart failure

S₄: an abnormal heart sound detected late in diastole as resistance is met to blood entering either ventricle during atrial contraction; most often caused by hypertrophy of the ventricle

sinoatrial (SA) node: primary pacemaker of the heart, located in the right atrium

stroke volume: amount of blood ejected from the ventricle per heartbeat

summation gallop: the abnormal sound created during tachycardia by the presence of an S₃ and S₄

systemic vascular resistance: resistance to left ventricle ejection of blood from the ventricles into the pulmonary artery and aorta

systolic click: abnormal systolic sound created by the opening of a calcified aortic or pulmonic valve during ventricular contraction

telemetry: the process of continuous electrocardiographic monitoring by the transmission of radio waves from a battery-operated transmitter worn by the patient

More than 80 million Americans have one or more types of cardiovascular disease (CVD), including hypertension, coronary artery disease (CAD), heart failure (HF), stroke, and congenital cardiovascular defects (American Heart Association [AHA], 2009). Because of the prevalence of CVD, nurses practicing in any setting across the continuum of care, whether in the home, office, hospital, long-term care facility, or rehabilitation facility, must be able to assess the cardiovascular system. Key components of assessment include a health history, physical assessment, and monitoring of a variety of laboratory and diagnostic test results. This assessment provides the data necessary to identify nursing diagnoses, formulate an individualized plan of care, evaluate the response of the patient to the care provided, and revise the plan as needed.

Anatomic and Physiologic Overview

An understanding of the structure and function of the heart in health and in disease is essential to develop cardiovascular assessment skills.

Anatomy of the Heart

The heart is a hollow, muscular organ located in the center of the thorax, where it occupies the space between the lungs (mediastinum) and rests on the diaphragm. It weighs approximately 300 g (10.6 oz); the weight and size of the heart

are influenced by age, gender, body weight, extent of physical exercise and conditioning, and heart disease. The heart pumps blood to the tissues, supplying them with oxygen and other nutrients.

The heart is composed of three layers (Fig. 26-1). The inner layer, or endocardium, consists of endothelial tissue and lines the inside of the heart and valves. The middle layer, or **myocardium**, is made up of muscle fibers and is responsible for the pumping action. The exterior layer of the heart is called the epicardium.

The heart is encased in a thin, fibrous sac called the pericardium, which is composed of two layers. Adhering to the epicardium is the visceral pericardium. Enveloping the visceral pericardium is the parietal pericardium, a tough fibrous tissue that attaches to the great vessels, diaphragm, sternum, and vertebral column and supports the heart in the mediastinum. The space between these two layers (pericardial space) is normally filled with about 20 mL of fluid, which lubricates the surface of the heart and reduces friction during systole.

Heart Chambers

The pumping action of the heart is accomplished by the rhythmic relaxation and contraction of the muscular walls of its four chambers. During the relaxation phase, called **diastole**, all four chambers relax simultaneously, which allows the ventricles to fill in preparation for contraction. Diastole is commonly referred to as the period of ventricular filling.

Figure 26-1 Structure of the heart. Arrows show course of blood flow through the heart chambers.

Blue arrow → Unoxygenated blood
 Red arrow → Oxygenated blood

Systole refers to the events in the heart during contraction of the two top chambers (atria) and two bottom chambers (ventricles). Unlike diastole, atrial and ventricular systole are not simultaneous events. Atrial systole occurs first, just at the end of diastole, followed by ventricular systole. This synchronization allows the ventricles to completely fill prior to ejection of blood from their chambers.

The right side of the heart, made up of the right atrium and right ventricle, distributes venous blood (deoxygenated blood) to the lungs via the pulmonary artery (pulmonary circulation) for oxygenation. The right atrium receives blood returning from the superior vena cava (head, neck, and upper extremities), inferior vena cava (trunk and lower extremities), and coronary sinus (coronary circulation). The left side of the heart, composed of the left atrium and left ventricle, distributes oxygenated blood to the remainder of the body via the aorta (systemic circulation). The left atrium receives oxygenated blood from the pulmonary circulation via four pulmonary veins. The relationships among the four heart chambers are shown in Figure 26-1.

The varying thicknesses of the atrial and ventricular walls relate to the workload required by each chamber. The myocardial layer of both atria is much thinner than that of the ventricles because there is little resistance as blood flows out of the atria and into the ventricles during diastole. In contrast, the ventricular walls are much thicker than the atrial walls. During ventricular systole, the right and left ventricles must overcome resistance to blood flow from the pulmonary and systemic circulatory systems, respectively. The left ventricle is two-and-a-half times more muscular than the right ventricle. It must overcome high aortic and arterial pressures, whereas the right ventricle contracts against a low-pressure system within the pulmonary arteries and capillaries. Figure 26-2 identifies the pressures in each of these areas.

The heart lies in a rotated position within the chest cavity. The right ventricle lies anteriorly (just beneath

the sternum) and the left ventricle is situated posteriorly. As a result of this close proximity to the chest wall, the pulsation created during normal ventricular contraction, called the **apical impulse** (also called the **point of maximal impulse [PMI]**), is easily detected. In the normal heart, the PMI is located at the intersection of the mid-clavicular line of the left chest wall and the fifth intercostal space.

Heart Valves

The four valves in the heart permit blood to flow in only one direction. The valves, which are composed of thin leaflets of fibrous tissue, open and close in response to the movement of blood and pressure changes within the chambers. There are two types of valves: atrioventricular and semilunar.

Atrioventricular Valves

The atrioventricular valves separate the atria from the ventricles. The tricuspid valve, so named because it is composed of three cusps or leaflets, separates the right atrium from the right ventricle. The mitral or bicuspid (two cusps) valve lies between the left atrium and the left ventricle (see Fig. 26-1).

During diastole, the tricuspid and mitral valves are open, allowing the blood in the atria to flow freely into the relaxed ventricles. As ventricular systole begins, the ventricles contract and blood flows upward into the cusps of the tricuspid and mitral valves, causing them to close. As the pressure against these valves increases, two additional structures, the papillary muscles and the chordae tendineae, maintain valve closure. The papillary muscles, located on the sides of the ventricular walls, are connected to the valve leaflets by thin fibrous bands called chordae tendineae. During ventricular systole, contraction of the papillary muscles causes the chordae tendineae to become taut, keeping the valve leaflets approximated and closed. This action prevents backflow of blood into the atria (regurgitation) as blood is ejected out into the pulmonary artery and aorta.

Semilunar Valves

The two semilunar valves are composed of three leaflets, which are shaped like half-moons. The valve between the right ventricle and the pulmonary artery is called the pulmonary valve. The valve between the left ventricle and the aorta is called the aortic valve. The semilunar valves are closed during diastole. At this point, the pressure in the pulmonary artery and aorta decreases, causing blood to flow back toward the semilunar valves. This action fills the cusps with blood and closes the valves. The semilunar valves are forced open during ventricular systole as blood is ejected from the right and left ventricles into the pulmonary artery and aorta.

Coronary Arteries

The left and right coronary arteries and their branches supply arterial blood to the heart. These arteries originate from the aorta just above the aortic valve leaflets. The heart has high metabolic requirements, extracting approximately 70% to 80% of the oxygen delivered (other organs extract,

Figure 26-2 Great vessel and chamber pressures. Pressures are identified in mm Hg as mean pressure or systolic over diastolic pressure.

on average, 25%). Unlike other arteries, the coronary arteries are perfused during diastole. With a normal heart rate of 60 to 80 bpm there is ample time during diastole for myocardial perfusion. However, as heart rate increases, diastolic time is shortened, which may not allow adequate time for myocardial perfusion. As a result, patients are at risk for **myocardial ischemia** (inadequate oxygen supply) during tachycardias (heart rate greater than 100), especially patients with CAD.

The left coronary artery has three branches. The artery from the point of origin to the first major branch is called the left main coronary artery. Two branches arise from the left main coronary artery: the left anterior descending artery, which courses down the anterior wall of the heart, and the circumflex artery, which circles around to the lateral left wall of the heart.

The right side of the heart is supplied by the right coronary artery, which leads to the inferior wall of the heart. The posterior wall of the heart receives its blood supply by an additional branch from the right coronary artery called the posterior descending artery (see Chapter 28, Fig. 28-2).

Superficial to the coronary arteries are the coronary veins. Venous blood from these veins returns to the heart primarily through the coronary sinus, which is located posteriorly in the right atrium.

Myocardium

The myocardium is the middle, muscular layer of the atrial and ventricular walls. It is composed of specialized cells called myocytes, which form an interconnected network of muscle fibers. These fibers encircle the heart in a figure-of-eight pattern, forming a spiral from the base (top) of the heart to the apex (bottom). During contraction, this muscular configuration facilitates a twisting and compressive movement of the heart that begins in the atria and moves to the ventricles. The sequential and rhythmic pattern of contraction, followed by relaxation of the muscle fibers, maximizes the volume of blood ejected with each contraction. This cyclical pattern of myocardial contraction is controlled by the conduction system.

Function of the Heart

Cardiac Electrophysiology

The **cardiac conduction system** generates and transmits electrical impulses that stimulate contraction of the myocardium. Under normal circumstances, the conduction system first stimulates contraction of the atria and then the ventricles. The synchronization of the atrial and ventricular events allows the ventricles to fill completely before ventricular ejection, thereby maximizing cardiac output. Three physiologic characteristics of two types of specialized electrical cells, the nodal cells and the Purkinje cells, provide this synchronization:

Automaticity: ability to initiate an electrical impulse

Excitability: ability to respond to an electrical impulse

Conductivity: ability to transmit an electrical impulse from one cell to another

Both the **sinoatrial (SA) node** and the **atrioventricular (AV) node** are composed of nodal cells. The SA node,

Figure 26-3 Cardiac conduction system. AV, atrioventricular; SA, sinoatrial.

the primary pacemaker of the heart, is located at the junction of the superior vena cava and the right atrium (Fig. 26-3). The SA node in a normal resting adult heart has an inherent firing rate of 60 to 100 impulses per minute, but the rate changes in response to the metabolic demands of the body.

The electrical impulses initiated by the SA node are conducted along the myocardial cells of the atria via specialized tracts called internodal pathways. The impulses cause electrical stimulation and subsequent contraction of the atria. The impulses are then conducted to the AV node, which is located in the right atrial wall near the tricuspid valve (see Fig. 26-3). The AV node coordinates the incoming electrical impulses from the atria and after a slight delay (allowing the atria time to contract and complete ventricular filling) relays the impulse to the ventricles.

Initially, the impulse is conducted through a bundle of specialized conducting tissue, referred to as the bundle of His, which then divides into the right bundle branch (conducting impulses to the right ventricle) and the left bundle branch (conducting impulses to the left ventricle). To transmit impulses to the left ventricle, the largest chamber of the heart, the left bundle branch divides into the left anterior and left posterior bundle branches. Impulses travel through the bundle branches to reach the terminal point in the conduction system, called the Purkinje fibers. These fibers are composed of Purkinje cells, specialized to rapidly conduct the impulses through the thick walls of the ventricles. This is the point at which the myocardial cells are stimulated, causing ventricular contraction.

The heart rate is determined by the myocardial cells with the fastest inherent firing rate. Under normal circumstances, the SA node has the highest inherent rate (60 to 100 impulses per minute), the AV node has the second-highest inherent rate (40 to 60 impulses per minute), and the ventricular pacemaker sites have the lowest inherent rate (30 to 40 impulses per minute). If the SA node malfunctions, the AV node generally takes over the pacemaker function of the heart at its inherently lower rate.

Should both the SA and the AV nodes fail in their pacemaker function, a pacemaker site in the ventricle will fire at its inherent bradycardic rate of 30 to 40 impulses per minute.

Cardiac Action Potential

The nodal and Purkinje cells (electrical cells) generate and transmit impulses across the heart, stimulating the cardiac myocytes (working cells) to contract. Stimulation of the myocytes occurs due to the exchange of electrically charged particles, called ions, across channels located in the cell membrane. The channels regulate the movement and speed of specific ions, namely, sodium, potassium, and calcium, as they enter and exit the cell. Sodium rapidly enters into the cell through sodium fast channels, in contrast to calcium, which enters the cell through calcium slow channels. In the resting or polarized state, sodium is the primary extracellular ion, whereas potassium is the primary intracellular ion. This difference in ion concentration means that the inside of the cell has a negative charge compared to the positive charge on the outside. This relationship changes during cellular stimulation, when sodium or calcium crosses the cell membrane into the cell and potassium ions exit into the extracellular space. This exchange of ions creates a positively charged intracellular space and a negatively charged extracellular space that characterizes the period known as **depolarization**. Once depolarization is complete, the exchange of ions reverts to its resting state; this period is known as **repolarization**. The repeated cycle of depolarization and repolarization is called the cardiac action potential.

As shown in Figure 26-4, the cardiac action potential has five phases:

- Phase 0: Cellular depolarization is initiated as positive ions influx into the cell. During this phase, the atrial and ventricular myocytes rapidly depolarize as sodium moves into the cells through sodium fast channels. The myocytes have a fast response action potential. In contrast, the cells of the SA and AV node depolarize when calcium enters these cells through calcium slow channels. These cells have a slow response action potential.

Figure 26-4 Cardiac action potential of a fast-response Purkinje fiber. The arrows indicate the approximate time and direction of movement of each ion influencing membrane potential. Ca^{++} movement out of the cell is not well defined but is thought to occur during phase 4.

- Phase 1: Early cellular repolarization begins during this phase as potassium exits the intracellular space.
- Phase 2: This phase is called the plateau phase because the rate of repolarization slows. Calcium ions enter the intracellular space.
- Phase 3: This phase marks the completion of repolarization and return of the cell to its resting state.
- Phase 4: This phase is considered the resting phase before the next depolarization.

Refractory Periods

As reviewed previously, myocardial cells must completely repolarize before they can depolarize again. During this time, the cells are in what is called a refractory period. There are two phases of the refractory period, the effective (or absolute) refractory period and the relative refractory period. During the effective refractory period, the cell is completely unresponsive to any electrical stimulus; it is incapable of initiating an early depolarization. The effective refractory period corresponds with the time in phase 0 to the middle of phase 3 of the action potential. The relative refractory period corresponds with the short time at the end of phase 3. During the relative refractory period, if an electrical stimulus is stronger than normal, the cell may depolarize prematurely. Early depolarizations of the atrium or ventricle cause premature contractions, placing the patient at risk for dysrhythmias. Premature ventricular contractions in certain situations, such as the presence of myocardial ischemia, are of concern because these early ventricular depolarizations can trigger life-threatening dysrhythmias, including ventricular tachycardia or ventricular fibrillation. Several circumstances make the heart more susceptible to early depolarization during the relative refractory period, thus increasing the risk for serious dysrhythmias. These dysrhythmias and others are discussed in detail in Chapter 27.

Cardiac Hemodynamics

An important determinant of blood flow in the cardiovascular system is the principle that fluid flows from a region of higher pressure to one of lower pressure (see Fig. 26-2). The pressures responsible for blood flow in the normal circulation are generated during systole and diastole.

Cardiac Cycle

A cardiac cycle is composed of both systole and diastole. It refers to the events that occur in the heart from one heartbeat to the next. These events cause blood to flow through the heart due to changes in chamber pressures and valvular function during atrial and ventricular diastole and systole. During atrial and ventricular diastole, the heart chambers are relaxed. As a result, the atrioventricular valves are open, whereas the semilunar valves are closed. Pressures in all of the chambers are the lowest during diastole, which facilitates ventricular filling. Venous blood returns to the right atrium from the superior and inferior vena cava, then into the right ventricle. On the left side, oxygenated blood returns from the lungs via the four pulmonary veins into the left atrium and ventricle.

Toward the end of this diastolic period, atrial systole occurs as the atrial muscles contract in response to an electrical impulse initiated by the SA node. Atrial systole increases the pressure inside the atria, ejecting the remaining blood into the ventricles. Atrial systole augments ventricular blood volume by 15% to 25% and is sometimes referred to as the “atrial kick.” At this point, ventricular systole begins in response to propagation of the electrical impulse that began in the SA node some milliseconds earlier.

Beginning with ventricular systole, the pressure inside the ventricles rapidly increases, forcing the atrioventricular valves to close. As a result, blood ceases to flow from the atria into the ventricles, and regurgitation (backflow) of blood into the atria is prevented. The rapid increase of pressure inside the right and left ventricles forces the pulmonary and aortic valves to open, and blood is ejected into the pulmonary artery and aorta, respectively. The exit of blood is at first rapid; then, as the pressure in each ventricle and its corresponding artery equalizes, the flow of blood gradually decreases. At the end of systole, pressure within the right and left ventricles rapidly decreases. As a result, pulmonary arterial and aortic pressures decrease, causing closure of the semilunar valves. These events mark the onset of diastole and the cardiac cycle is repeated.

Chamber pressures can be measured with the use of special monitoring catheters and equipment. This technique is called hemodynamic monitoring. Methods of hemodynamic monitoring are covered in more detail at the end of this chapter.

Cardiac Output

Cardiac output refers to the amount of blood pumped by each ventricle during a given period. The cardiac output in a resting adult is about 5 L/min but varies greatly depending on the metabolic needs of the body. Cardiac output is computed by multiplying the stroke volume by the heart rate. **Stroke volume** is the amount of blood ejected per heartbeat. The average resting stroke volume is about 70 mL, and the heart rate is 60 to 80 bpm. Cardiac output can be affected by changes in either stroke volume or heart rate.

Control of Heart Rate. Cardiac output must be responsive to changes in the metabolic demands of the tissues. For example, during exercise the total cardiac output may increase fourfold, to 20 L/min. This increase is normally accomplished by approximately doubling both the heart rate and the stroke volume. Changes in heart rate are accomplished by reflex controls mediated by the autonomic nervous system, including its sympathetic and parasympathetic divisions.

The parasympathetic impulses, which travel to the heart through the vagus nerve, can slow the cardiac rate, whereas sympathetic impulses increase it. These effects on heart rate result from action on the SA node, to either decrease or increase its inherent rate. The balance between these two reflex control systems normally determines the heart rate. The heart rate is increased by the sympathetic nervous system through an increased level of circulating

catecholamines (secreted by the adrenal gland) and by excess thyroid hormone, which produces a catecholamine-like effect.

In addition, the heart rate is affected by central nervous system and baroreceptor activity. **Baroreceptors** are specialized nerve cells located in the aortic arch and in both right and left internal carotid arteries (at the point of bifurcation from the common carotid arteries). The baroreceptors are sensitive to changes in blood pressure (BP). During significant elevations in BP (**hypertension**), these cells increase their rate of discharge, transmitting impulses to the cerebral medulla. This initiates parasympathetic activity and inhibits sympathetic response, lowering the heart rate and the BP. The opposite is true during **hypotension** (low BP). Hypotension results in less baroreceptor stimulation, which prompts a decrease in parasympathetic inhibitory activity in the SA node, allowing for enhanced sympathetic activity. The resultant vasoconstriction and increased heart rate elevate the BP.

Control of Stroke Volume. Stroke volume is primarily determined by three factors: preload, afterload, and contractility.

Preload refers to the degree of stretch of the ventricular cardiac muscle fibers at the end of diastole. The end of diastole is the period when filling volume in the ventricles is the highest and the degree of stretch on the muscle fibers is the greatest. The volume of blood within the ventricle at the end of diastole determines preload, which directly affects stroke volume. Therefore, preload is commonly referred to as left ventricular end-diastolic pressure (LVEDP). As the volume of blood returning to the heart increases, muscle fiber stretch also increases (increased preload), resulting in stronger contraction and a greater stroke volume. This relationship, called the Frank-Starling (or Starling) law of the heart, is maintained until the physiologic limit of the muscle is reached.

The Frank-Starling law is based on the fact that, within limits, the greater the initial length or stretch of the cardiac muscle cells (sarcomeres), the greater the degree of shortening that occurs. This result is caused by increased interaction between the thick and thin filaments within the cardiac muscle cells. Preload is decreased by a reduction in the volume of blood returning to the ventricles. Diuresis, venodilating agents (eg, nitrates), excessive loss of blood, or dehydration (excessive loss of body fluids from vomiting, diarrhea, or diaphoresis) reduce preload. Preload is increased by increasing the return of circulating blood volume to the ventricles. Controlling the loss of blood or body fluids and replacing fluids (ie, blood transfusions and intravenous [IV] fluid administration) are examples of ways to increase preload.

Afterload, or resistance to ejection of blood from the ventricle, is the second determinant of stroke volume. The resistance of the systemic BP to left ventricular ejection is called **systemic vascular resistance**. The resistance of the pulmonary BP to right ventricular ejection is called **pulmonary vascular resistance**. There is an inverse relationship between afterload and stroke volume. For example, afterload is increased by arterial vasoconstriction, which leads to decreased stroke volume. The opposite is true

with arterial vasodilation: Afterload is reduced because there is less resistance to ejection, and stroke volume increases.

Contractility refers to the force generated by the contracting myocardium. Contractility is enhanced by circulating catecholamines, sympathetic neuronal activity, and certain medications (eg, digoxin [Lanoxin], dopamine [Intropin], or dobutamine [Dobutrex]). Increased contractility results in increased stroke volume. Contractility is depressed by hypoxemia, acidosis, and certain medications (eg, beta-adrenergic blocking agents such as atenolol [Tenormin]).

The heart can achieve an increase in stroke volume (eg, during exercise) if preload is increased (through increased venous return), if contractility is increased (through sympathetic nervous system discharge), and if afterload is decreased (through peripheral vasodilation with decreased aortic pressure).

The percentage of the end-diastolic blood volume that is ejected with each heartbeat is called the **ejection fraction**. The ejection fraction of the normal left ventricle is 55% to 65%. The right ventricular ejection fraction is rarely measured. The ejection fraction is used as a measure of myocardial contractility. An ejection fraction of less than 40% indicates that the patient has decreased left ventricular function and likely requires treatment for heart failure (HF) (refer to Chapter 30 for further discussion).

Gerontologic Considerations

Changes in cardiac structure and function are clearly observable in the aging heart. To understand the changes specifically related to aging, it is helpful to distinguish the normal aging process from changes related to CVD. The anatomic and functional changes in the aging heart are summarized in Table 26-1.

These changes lead to decreased myocardial contractility, increased left ventricular ejection time (prolonged systole), and delayed conduction. Therefore, stressful physical and emotional conditions, especially those that occur suddenly, may have adverse effects on the aged person. The heart cannot respond to such conditions with an adequate rate increase and needs more time to return to a normal resting rate after even a minimal increase in heart rate. In some patients, the added stress may precipitate HF.

Gender Considerations

Structural differences between the hearts of men and women have significant implications. A woman's heart tends to be smaller as compared to a man's heart, and has smaller coronary arteries. Because the coronary arteries of a woman are smaller, they become occluded from atherosclerosis more easily, making procedures such as cardiac catheterization and angioplasty technically more difficult,

Table 26-1 AGE-RELATED CHANGES OF THE CARDIAC SYSTEM

Cardiovascular Structure	Structural Changes	Functional Changes	History and Physical Findings
Atria	↑ Size of left atrium Thickening of the endocardium	↑ Atrial irritability	Irregular heart rhythm from atrial dysrhythmias
Left ventricle	Endocardial fibrosis Myocardial thickening (hypertrophy) Infiltration of fat into myocardium	Left ventricle stiff and less compliant Progressive decline in cardiac output ↑ Risk for ventricular dysrhythmias Prolonged systole	Fatigue ↓ Exercise tolerance Signs and symptoms of HF or ventricular dysrhythmias Point of maximal impulse palpated lateral to the midclavicular line ↓ Intensity S ₁ , S ₂ ; split S ₂ S ₄ may be present Murmurs may be present Thrill may be palpated if significant murmur is present
Valves	Thickening and rigidity of AV valves Calcification of aortic valve	Abnormal blood flow across valves during cardiac cycle	Bradycardia Heart block ECG changes consistent with slowed conduction (↑ PR interval, widened QRS complex)
Conduction system	Connective tissue collects in SA node, AV node, and bundle branches ↓ Number of SA node cells ↓ Number of AV, bundle of His, and right and left bundle branch cells	Slower SA node rate of impulse discharge Slowed conduction across AV node and ventricular conduction system	
Sympathetic nervous system	↓ Response to beta-adrenergic stimulation	↓ Adaptive response to exercise: contractility and heart rate slower to respond to exercise demands Heart rate takes more time to return to baseline	Fatigue Diminished exercise tolerance ↓ Ability to respond to stress
Aorta and arteries	Stiffening of vasculature ↓ Elasticity and widening of aorta Elongation of aorta, displacing the brachiocephalic artery upward	Left ventricular hypertrophy	Progressive increase in systolic BP; slight ↑ in diastolic BP Widening pulse pressure Pulsation visible above right clavicle
Baroreceptor response	↓ Sensitivity of baroreceptors in the carotid artery and aorta to transient episodes of hypertension and hypotension	Baroreceptors unable to regulate heart rate and vascular tone, causing slow response to postural changes in body position	Postural blood pressure changes and reports of feeling dizzy, fainting when moving from lying to sitting or standing position

AV, atrioventricular; BP, blood pressure; ECG, electrocardiographic; HF, heart failure; SA, sinoatrial.

with a higher incidence of postprocedural complications. In addition, the resting rate, stroke volume, and ejection fraction of a woman's heart are higher than those of a man's heart, and the conduction time of an electrical impulse traveling from the SA node through the AV node to the Purkinje fibers is briefer.

For many years, it was believed that the female hormone estrogen had cardioprotective effects. Hormone therapy was routinely prescribed for postmenopausal women in the belief that this pharmacologic therapy would deter the onset and progression of coronary atherosclerosis. This belief was supported by anecdotal evidence that the onset of heart disease in women tends to occur later than in men, at a time when most women had experienced menopause and were largely bereft of estrogen. However, based on results from the multisite, prospective, longitudinal study called the Women's Health Initiative, the AHA no longer recommends the use of hormone therapy as a prevention strategy for women (Mosca, Banka, Benjamin, et al., 2007).

Assessment of the Cardiovascular System

The frequency and extent of the nursing assessment of cardiovascular function are based on several factors, including the severity of the patient's symptoms, the presence of risk factors, the practice setting, and the purpose of the assessment. An acutely ill patient with CVD who is admitted to the emergency department or coronary intensive care unit requires a very different assessment than a person who is being examined for a chronic stable condition. Although the key components of the cardiovascular assessment remain the same, the assessment priorities vary according to the needs of the patient. For example, an emergency department nurse performs a rapid and focused assessment of a patient in which **acute coronary syndrome** (ACS), rupture of an atheromatous plaque in a diseased coronary artery, is suspected. Diagnosis and treatment must be started within minutes of arrival to the emergency department. The physical assessment is ongoing and concentrates on evaluating the patient for ACS complications, such as dysrhythmias and HF, and determining the effectiveness of medical treatment.

Health History

The patient's ability to recognize cardiac symptoms and to know what to do when they occur is essential for effective self-care management. All too often, a patient's new symptoms or those of progressing cardiac dysfunction go unrecognized. This results in prolonged delays in seeking lifesaving treatment. Major barriers to seeking prompt medical care include lack of knowledge about the symptoms of heart disease, attributing symptoms to a benign source, denying symptom significance, and feeling embarrassed about having symptoms (Moser, Kimble, Alberts, et al., 2007). Therefore, during the health history the nurse needs to determine if the patient and involved family members are able to recognize symptoms of an acute cardiac problem, such as ACS

or HF, and seek timely treatment for these symptoms. Responses to this level of inquiry will help the nurse individualize the plan for patient and family education.

Common Symptoms

The signs and symptoms experienced by people with CVD are related to dysrhythmias and conduction problems (see Chapter 27); CAD (see Chapter 28); structural, infectious, and inflammatory disorders of the heart (see Chapter 29); and complications of CVD such as HF and cardiogenic shock (see Chapter 30). These disorders have many signs and symptoms in common; therefore, the nurse must be skillful at recognizing these signs and symptoms so that patients are given timely and often lifesaving care.

The following are the most common signs and symptoms of CVD, with related medical diagnoses in parentheses:

- Chest pain or discomfort (angina pectoris, ACS, dysrhythmias, valvular heart disease)
- Shortness of breath or dyspnea (ACS, cardiogenic shock, HF, valvular heart disease)
- Peripheral edema, weight gain, abdominal distention due to enlarged spleen and liver or ascites (HF)
- Palpitations (tachycardia from a variety of causes, including ACS, caffeine or other stimulants, electrolyte imbalances, stress, valvular heart disease, ventricular aneurysms)
- Vital fatigue, sometimes referred to as vital exhaustion (an early warning symptom of ACS, HF, or valvular heart disease, characterized by feeling unusually tired or fatigued, irritable, and dejected)
- Dizziness, syncope, or changes in level of consciousness (cardiogenic shock, cerebrovascular disorders, dysrhythmias, hypotension, postural hypotension, vasovagal episode)

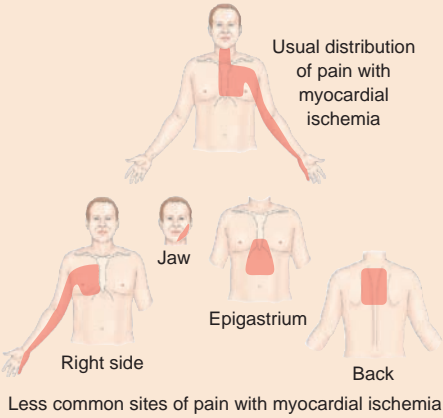

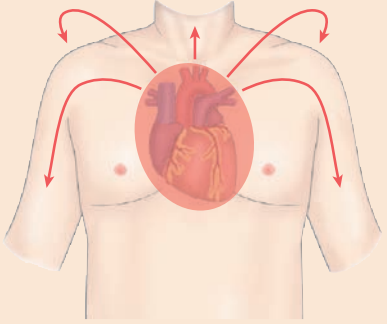

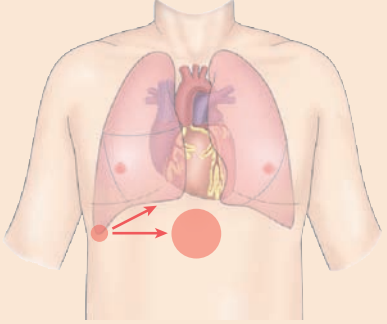

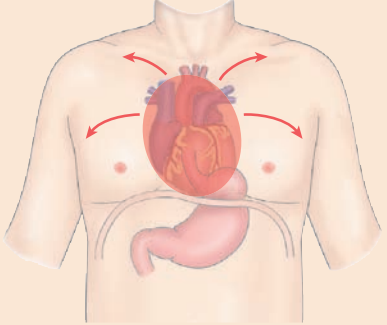

Chest Pain

Chest pain and discomfort are common symptoms that may be caused by a number of cardiac and noncardiac problems. When a patient experiences chest symptoms, the nurse asks questions that aid in differentiating among these sources of chest symptoms. Table 26-2 summarizes the characteristics and patterns of the more common cardiac and noncardiac causes of chest symptoms. During the assessment the patient is asked to identify the quantity of pain using a 0 (no pain) to 10 (worst pain) scale. Next, the nurse asks the patient to describe the character or quality of the pain or discomfort and its location. The nurse needs to determine whether there is radiation to or discomfort in other areas and must assess for associated signs and symptoms such as diaphoresis or nausea. It is important to identify the events that precipitate the onset of symptoms, the duration of the symptoms, and measures that aggravate or relieve the symptoms.

The nurse should keep the following important points in mind when assessing patients reporting chest pain or discomfort:

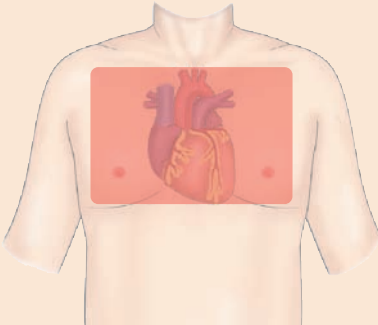

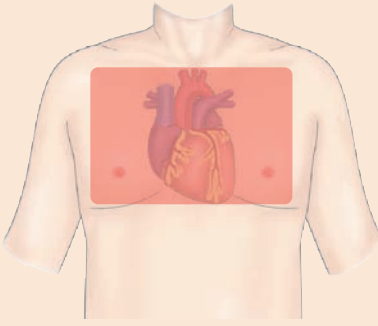

- The location of chest symptoms is not well correlated with the cause of the pain. For example, substernal

Table 26-2 ASSESSING CHEST PAIN

Location	Character	Duration	Precipitating Events and Aggravating Factors	Alleviating Factors
<p>Angina pectoris Acute coronary syndrome (ACS) (unstable angina, myocardial infarction [MI])</p> 	<p>Angina: Uncomfortable pressure, squeezing, or fullness in substernal chest area Can radiate across chest to the medial aspect of one or both arms and hands, jaw, shoulders, upper back, or epigastrum Radiation to arms and hands, described as numbness, tingling, or aching</p> <p>ACS: Same as angina pectoris Pain or discomfort ranges from mild to severe Associated with shortness of breath, diaphoresis, palpitations, fatigue, and nausea or vomiting</p>	<p>Angina: 5–15 min</p> <p>ACS: >15 min</p>	<p>Angina: Physical exertion, emotional upset, eating large meal, or exposure to extremes in temperature</p> <p>ACS: Emotional upset or unusual physical exertion occurring within 24 hr of symptom onset Can occur at rest or while asleep</p>	<p>Angina: Rest, nitroglycerin, oxygen</p> <p>ACS: Morphine, reperfusion of coronary artery with thrombolytic agent or percutaneous coronary intervention</p>
<p>Pericarditis</p> 	<p>Sharp, severe substernal or epigastric pain Can radiate to neck, arms, and back Associated symptoms include fever, malaise, dyspnea, cough, nausea, dizziness, and palpitations</p>	<p>Intermittent</p>	<p>Sudden onset Pain increases with inspiration, swallowing, coughing, and rotation of trunk</p>	<p>Sitting upright, analgesia, anti-inflammatory medications</p>
<p>Pulmonary disorders (pneumonia, pulmonary embolism)</p> 	<p>Sharp, severe substernal or epigastric pain arising from inferior portion of pleura (referred to as pleuritic pain) Patient may be able to localize the pain</p>	<p>≥30 min</p>	<p>Follows an infectious or noninfectious process (MI, cardiac surgery, cancer, immune disorders, uremia) Pleuritic pain increases with inspiration, coughing, movement, and supine positioning Occurs in conjunction with community-acquired or nosocomial lung infections (pneumonia) or deep vein thrombosis (pulmonary embolism)</p>	<p>Treatment of underlying cause</p>
<p>Esophageal disorders (hiatal hernia, reflux esophagitis or spasm)</p> 	<p>Substernal pain described as sharp, burning, or heavy Often mimics angina Can radiate to neck, arm, or shoulders</p>	<p>5–60 min</p>	<p>Recumbency, cold liquids, exercise</p>	<p>Food or antacid Nitroglycerin</p>

Location	Character	Duration	Precipitating Events and Aggravating Factors	Alleviating Factors
<p><i>Anxiety and panic disorders</i></p> 	<p>Pain described as stabbing to dull ache Associated with diaphoresis, palpitations, shortness of breath, tingling of hands or mouth, feeling of unreality, or fear of losing control</p>	<p>Peaks in 10 min</p>	<p>Can occur at any time including during sleep Can be associated with a specific trigger</p>	<p>Removal of stimulus, relaxation, medications to treat anxiety or underlying disorder</p>
<p><i>Musculoskeletal disorders (costochondritis)</i></p> 	<p>Sharp or stabbing pain localized in anterior chest Most often unilateral Can radiate across chest to epigastrium or back</p>	<p>Hours to days</p>	<p>Most often follows respiratory tract infection with significant coughing, vigorous exercise, or posttrauma Some cases are idiopathic Exacerbated by deep inspiration, coughing, sneezing, and movement of upper torso or arms</p>	<p>Rest, ice, or heat Analgesic or anti-inflammatory medications</p>

chest pain can result from a number of causes as outlined in Table 26-2.

- The severity or duration of chest pain or discomfort does not predict the seriousness of its cause. For example, a patient experiencing esophageal spasm may rate chest pain as a “10/10” (eg, the worst pain the patient has ever felt), whereas a patient experiencing a myocardial infarction (MI) may report only mild to moderate chest pressure.
- More than one clinical cardiac condition may occur simultaneously. During an MI, patients may report chest pain from myocardial ischemia, shortness of breath from HF, and palpitations from dysrhythmias. Both HF and dysrhythmias can be complications of an acute MI.

Symptoms of Acute Coronary Syndrome

Nurses and other health care professionals must take a patient’s complaint of CVD-related symptoms seriously until the cause is determined. Because CAD is so prevalent, all patients reporting new or worsening cardiac symptoms, particularly those at risk for CAD or who have a history of CAD, should be evaluated initially for ACS. There are several distinct characteristics of ACS symptoms that need to be kept in mind during assessment of the patient in which ACS is suspected:

- The majority of patients with ACS experience prodromal symptoms sometimes a month or more prior to

developing this acute event. Prodromal symptoms include fatigue, shortness of breath, sleep disturbances, anxiety, or fleeting chest discomfort (aching, pressure) that wax and wane. Because these symptoms are less severe than those experienced during ACS, patients often attribute them to a benign problem such as stress, and fail to seek medical care. Nurses should include questions regarding presence of prodromal symptoms when assessing patients with CVD-related symptoms.

- Approximately 50% of men and women with ACS experience chest symptoms, whereas the remainder may develop a variety of symptoms such as upper back, shoulder, arm, or neck pain; epigastric burning; or shortness of breath.
- At least four symptoms herald the onset of ACS, sometimes referred to as ACS symptom clusters (Ryan, DeVon, Horne, et al., 2007) (Chart 26-1).
- Neuropathies in elderly patients and those with diabetes may prevent these patients from experiencing pain or discomfort associated with myocardial ischemia. Instead, they may report vital fatigue or shortness of breath. In some patients, ACS may be asymptomatic, which is referred to as silent ischemia.
- A 12-lead electrocardiogram (ECG) and serum laboratory analysis of cardiac biomarkers are necessary to determine if the patient with ACS symptoms has

CHART **NURSING RESEARCH PROFILE**
26-1 **Symptom Clusters in Acute Myocardial Infarction**

Ryan, C. J., DeVon, H. A., Horne, R., et al. (2007). Symptom clusters in acute myocardial infarction. *Nursing Research*, 56(2), 72–81.

Purpose

The majority of lay people associate an acute myocardial infarction (MI) with severe debilitating chest pain. Unfortunately, this misinformation leads to significant delays in receiving lifesaving care. People who are in the midst of an acute MI tend to attribute less severe chest pain or other less known symptoms (shortness of breath, upper abdominal pain, or neck, arm, or shoulder discomfort) to benign sources rather than MI. The purpose of this study was to identify symptom clusters that represent an acute MI.

Design

In this secondary data analysis, data sets from nine descriptive, cross-sectional studies were combined to create a sample of 1073 patients from the United States and England who experienced an acute MI. A latent class cluster analysis was used to classify similar symptoms into groups. Variables in this analysis included 12 MI symptoms and demographic characteristics.

Findings

The analysis revealed five different acute MI symptom clusters. Symptom membership in a particular cluster was based on high, moderate, and low probability. The following identify these clusters and their rates of occurrence:

- Chest discomfort; shoulder, arm, or hand pain; weakness ($n = 462$; 43%)
- Chest discomfort; shoulder, arm, or hand pain ($n = 253$; 23%)
- Chest discomfort; shoulder, arm, or hand pain; nausea or vomiting; shortness of breath; sweating; dizziness/lightheadedness; weakness; fatigue ($n = 186$; 17%)
- Shoulder, arm, or hand discomfort; abdominal pain; indigestion ($n = 95$; 8%)
- No symptoms ($n = 75$; 6%)

Nursing Implications

Although secondary analysis has its limitations, these results demonstrate that chest pain is not the only symptom experienced during an acute MI. Acute MI symptoms occur in clusters. In addition, chest pain was not a symptom heralding acute MI in 14% of this sample. Demographic characteristics, such as age, gender, and race, may help to predict what type of symptoms patients will experience. To save lives and reduce morbidity associated with MI, the severe, debilitating chest pain myth needs to be dispelled. Nurses are in a unique position to educate their patients and the public about the various MI symptom clusters and actions to take to manage these symptoms. These interventions will help to ensure that people promptly recognize the seriousness of a variety of MI-related symptoms and access the emergency medical system quickly.

unstable angina, a non-ST-segment elevation MI (NSTEMI), or an ST-segment elevation MI (STEMI) (see Chapter 28).

Past Health, Family, and Social History

In an effort to determine how the patient perceives his or her current health status, the nurse must ask some of the following questions:

- What type of health concerns do you have? Are you able to identify any family history (Chart 26-2) or behaviors (risk factors) that put you at risk for this health condition?
- What are your risk factors for heart disease? What do you do to stay healthy and take care of your heart?
- How is your health? Have you noticed any changes from last year? From 5 years ago?
- Do you have a cardiologist or primary health care provider? How often do you go for checkups?
- Do you use tobacco or consume alcohol?

Patients who do not understand that their behaviors or diagnoses pose a threat to their health may be less motivated to make lifestyle changes or to manage their illness effectively. On the other hand, patients who perceive that their modifiable risk factors for heart disease affect their health and believe that they have the power to modify or change them may be more likely to change these behaviors.

Medications

Nurses collaborate with physicians and pharmacists to obtain a complete list of the patient's medications including dose and frequency. Vitamins, herbals, and other over-the-counter medications are included on this list. During this aspect of the health assessment, the nurse solicits answers to the following questions to ensure that patients are safely and effectively taking their medications.

- Is the patient independent in taking medications?
- Are the medications taken as prescribed?
- Does the patient know what side effects to report to the prescriber?
- Does the patient understand why the medication regimen is important?
- Are doses ever forgotten or skipped, or does the patient ever decide to stop taking a medication?

An aspirin a day is a common nonprescription medication that improves outcomes in patients with CAD. However, if patients are not aware of this benefit, they may be inclined to stop taking aspirin if they think it is a trivial medication. A careful medication history often uncovers common medication errors and causes for nonadherence to the medication regimen.

Nutrition

Dietary modifications, exercise, weight loss, and careful monitoring are important strategies for managing three

CHART
26-2

GENETICS IN NURSING PRACTICE

Cardiovascular Disorders

Several cardiovascular disorders are associated with genetic abnormalities. Some examples are:

- Familial hypercholesterolemia
- Hypertrophic cardiomyopathy
- Long QT syndrome
- Hereditary hemochromatosis
- Elevated homocysteine levels

Nursing Assessments

Family History Assessment

- Assess all patients with cardiovascular symptoms for coronary artery disease (CAD), regardless of age (early-onset CAD occurs).
- Assess family history of sudden death in people who may or may not have been diagnosed with coronary disease (especially of early onset).
- Ask about sudden death in a previously asymptomatic child, adolescent, or adult.
- Ask about other family members with biochemical or neuromuscular conditions (eg, hemochromatosis or muscular dystrophy).
- Assess whether DNA mutation or other genetic testing has been performed on an affected family member.

Patient Assessment

- Assess for signs and symptoms of hyperlipidemias (xanthomas, corneal arcus, abdominal pain of unexplained origin).
- Assess for muscular weakness.

Management Issues Specific to Genetics

- If indicated, refer for further genetic counseling and evaluation so that the family can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetic information and resources (eg, Genetic Alliance Web site, American Heart Association).
- Provide support to families newly diagnosed with genetics-related cardiovascular disease.

Genetics Resources

Genetic Alliance—a directory of support groups for patients and families with genetic conditions, www.geneticalliance.org

Gene Tests—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling, and testing information, www.geneclinics.org

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders, www.rarediseases.org

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions, www.ncbi.nlm.nih.gov/omim/stats/html

major cardiovascular risk factors: hyperlipidemia, hypertension, and diabetes mellitus. Diets that are restricted in sodium, fat, cholesterol, or calories are commonly prescribed. The nurse obtains the following information:

- The patient's current height and weight (to determine body mass index [BMI]), waist measurement (assessment for obesity), BP, and any laboratory test results such as blood glucose, glycosylated hemoglobin (diabetes), total blood cholesterol, high-density and low-density lipoprotein levels, and triglyceride levels (hyperlipidemia)
- How often the patient self-monitors BP, blood glucose, and weight as appropriate to the medical diagnoses
- The patient's level of awareness regarding his or her target goals for each of the risk factors, and any problems achieving or maintaining these goals
- What the patient normally eats and drinks in a typical day and any food preferences (including cultural or ethnic preferences)
- Eating habits (canned or commercially prepared foods versus fresh foods, restaurant cooking versus home cooking, assessing for high-sodium foods, dietary intake of fats)
- Who shops for groceries and prepares meals

Elimination

Typical bowel and bladder habits need to be identified. Nocturia (awakening at night to urinate) is common in

patients with HF. Fluid collected in gravity-dependent tissues (extremities) during the day (ie, edema) redistributes into the circulatory system once the patient is recumbent at night. The increased circulatory volume is excreted by the kidneys (increased urine production).

When straining during defecation, the patient bears down (the Valsalva maneuver), which momentarily increases pressure on the baroreceptors. This triggers a vagal response, causing the heart rate to slow and resulting in syncope in some patients. Straining during urination can produce the same response.

Because many cardiac medications can cause gastrointestinal side effects or bleeding, the nurse asks about bloating, diarrhea, constipation, stomach upset, heartburn, loss of appetite, nausea, and vomiting. Patients taking platelet-inhibiting medications such as aspirin and clopidogrel (Plavix); platelet aggregation inhibitors such as abciximab (ReoPro), eptifibatid (Integrilin), and tirofiban (Aggrastat); and anticoagulants such as low-molecular-weight heparin (ie, dalteparin [Fragmin], enoxaparin [Lovenox]), heparin, or warfarin (Coumadin) are screened for bloody urine or stools.

Activity and Exercise

As the nurse assesses the patient's activity and exercise history, it is important to note that decreases in activity tolerance are typically gradual and may go unnoticed by

the patient. Therefore, the nurse needs to determine whether there has been a change in the activity pattern during the past 6 to 12 months. The patient's subjective response to activity is an essential assessment parameter. New symptoms or a change in the usual anginal symptoms during activity is a significant finding. Fatigue, associated with a low left ventricular ejection fraction (less than 40%) and certain medications (eg, beta-adrenergic blocking agents), can result in activity intolerance. Patients with fatigue may benefit from having their medications adjusted and learning energy conservation techniques.

Additional areas to ask about include possible architectural barriers and challenges in the home, and what the patient does for exercise. If the patient exercises, the nurse asks additional questions: What is the intensity, duration, and frequency of exercise? Has the patient ever participated in a cardiac rehabilitation program? Functional levels are known to improve for almost all patients who participate in a cardiac rehabilitation program, and participation is highly recommended (Leon, Franklin, Costa, et al., 2005; Smith, Allen, Blair, et al., 2006). Patients with disabilities may require an individually tailored exercise program.

Sleep and Rest

Clues to worsening cardiac disease, especially HF, can be revealed by sleep-related events. Determining where and how the patient sleeps or rests is important. Recent changes, such as sleeping upright in a chair instead of in bed, increasing the number of pillows used, awakening short of breath at night (paroxysmal nocturnal dyspnea [PND]), or awakening with angina (nocturnal angina), are all indicative of worsening HF.

Self-Perception and Self-Concept

Self-perception and self-concept are both related to the cognitive and emotional processes that people use to formulate their beliefs and feelings about themselves. Having a chronic cardiac illness, such as HF, or experiencing an acute cardiac event, such as an MI, can alter an individual's self-perception and self-concept. It is important for the nurse to understand that patients' beliefs and feelings about their health are key determinants in adherence to health regimen recommendations and recovery after an acute cardiac event (Astin & Jones, 2006; van der Wal, Jaarsma, Moser, et al., 2007). To reduce or minimize the recurrence of future cardiovascular-related health problems, patients are asked to make difficult lifestyle changes, such as quitting smoking. How well patients adhere to these recommendations is directly related to their health outcomes. Patients who do not understand the health consequences of their disease process and its management are at risk for noncompliance. On the contrary, patients with misperceptions about the consequences of their cardiac illness on their health may fail to return to their usual level of function, including work, despite being physically able. The health history is used to discover how patients perceive their health by asking questions that may include the following:

- What is your cardiac condition?
- How has this illness changed your feelings about your health?

- What do you think caused this illness?
- What consequences do you think this illness will have on your physical activity, work, social relationships, and role in your family?
- How much of an influence do you think you have on controlling this illness?

The patient's responses to these questions can guide the nurse in planning interventions to ensure that the patient is prepared to manage the illness and that adequate services are in place to support the patient's recovery and self-management needs.

Roles and Relationships

Hospital stays for cardiac disorders have shortened, with many invasive diagnostic cardiac procedures, such as cardiac catheterization and percutaneous coronary intervention (PCI), being performed as outpatient procedures.

To assess support systems, the nurse needs to ask: Who is the primary caregiver? With whom does the patient live? Are there adequate services in place to provide a safe home environment? The nurse also assesses for any significant effects the cardiac illness has had on the patient's role in the family. Are there adequate finances and health insurance? The answers to these questions help the nurse develop a plan to meet the patient's home care needs.

Sexuality and Reproduction

Although people recovering from cardiac illnesses or procedures are often concerned about sexual activity, they are unlikely to ask their nurse or other health care provider for information to help them resume their normal sex life. Therefore, the nurse needs to initiate a discussion about sexuality with the patient.

The most commonly cited reasons for changes in sexual activity are fear of another heart attack or sudden death; untoward symptoms such as angina, dyspnea, or palpitations; and problems with impotence or depression. In men, impotence may develop as a side effect of cardiac medications (eg, beta-blockers); some men will stop taking their medication as a result. Other medications may be substituted, so patients should be encouraged to discuss this problem with their health care providers. Often, patients and their partners do not have adequate information about the physical demands related to sexual activity and ways in which these demands can be modified. The physiologic demands are greatest during orgasm, reaching 5 or 6 metabolic equivalents (METs). This level of activity is equivalent to walking 3 to 4 miles per hour on a treadmill. The METs expended before and after orgasm are considerably less, at 3.7 METs. Sharing this information may make the patient and his or her partner more comfortable about resuming sexual activity.

A reproductive history is necessary for women of child-bearing age, particularly those with seriously compromised cardiac function. The reproductive history includes information about previous pregnancies, plans for future pregnancies, oral contraceptive use (especially in women older than 35 years of age who smoke), menopausal status, and use of hormone therapy.

Coping and Stress Tolerance

Anxiety, depression, and stress are known to influence both the development of and recovery from CAD and HF. High levels of anxiety are associated with an increased incidence of CAD and in-hospital complication rates after MI. Patients with a diagnosis of an acute MI and depression have an increased risk of rehospitalization, death, more frequent angina, more physical limitations, and poorer quality of life, compared with patients without depression (Parashar, Rumsfeld & Spertus, 2006). Although the association between depression and CAD is not completely understood, both biologic factors (eg, platelet abnormalities, inflammatory responses) and lifestyle factors may contribute to the development of CAD. Patients who are depressed are less motivated to adhere to recommended lifestyle changes and medical regimens necessary to prevent future cardiac events (Konstam, Moser & De Jong, 2005). Patients with cardiovascular disease should be assessed for depression by asking them if they are feeling sad or blue, if they have lost interest in things they usually enjoy, or if they have thoughts about death or suicide. Other indications of depression include feelings of worthlessness or guilt, problems falling asleep or staying asleep, having difficulty concentrating, restlessness, and recent changes in appetite or weight.

Stress initiates a variety of responses, including increased level of catecholamines and cortisol, and has been strongly linked to cardiovascular events. Therefore, patients need to be assessed for sources of stress; the nurse should ask about recent or ongoing stressors, previous coping styles and effectiveness, and the patient's perception of his or her current mood and coping ability. Consultation with a psychiatric advanced practice nurse, psychologist, psychiatrist, or social worker is indicated for anxious or depressed patients or those patients having difficulty coping with their cardiac illness.

Prevention Strategies

The health history also addresses risk factors for heart disease and measures taken by the patient to prevent disease. The nurse asks the patient about health promotion practices. Certain conditions or behaviors (ie, risk factors) are associated with a greater incidence of coronary artery, peripheral vascular, and cerebrovascular disease (AHA, 2007). Risk factors are classified by the extent to which they can be modified by changing one's lifestyle or modifying personal behaviors.

Once a patient's risk factors are determined, the nurse assesses whether the patient has a plan for making necessary behavioral changes and whether assistance is needed to support these lifestyle changes. For example, tobacco use is one of the most commonly implicated and readily modifiable risk factors for CAD. The first step in treating this health risk is to identify patients who use tobacco products and those who have recently quit. Every encounter that a nurse has with a patient provides an opportunity to assess for tobacco use. If the patient uses tobacco, the next steps are to assess motivation to quit, formulate a smoking cessation plan, and make referrals to community smoking cessation programs. For patients who are obese or who have hyperlipidemia, hypertension, or diabetes, the nurse determines

any problems the patient may be having following the prescribed management plan (ie, diet, exercise, and medications). It may be necessary to clarify the patient's responsibilities, assist with finding additional resources, or make alternative plans for risk factor modification.

Physical Assessment

Physical assessment is conducted to confirm information obtained from the health history, establish the patient's current or baseline condition, and in subsequent assessments, evaluate the patient's response to treatment. Once the initial physical assessment is completed, the frequency of future assessments is determined by the purpose of the encounter and the patient's condition. For example, a focused cardiac assessment may be performed each time the patient is seen in the outpatient setting, whereas patients in the acute care setting may require a more extensive assessment at least every 8 hours. During the physical assessment, the nurse evaluates the cardiovascular system for any deviations from normal with regard to the following (examples of abnormalities are in parentheses):

- The heart as a pump (reduced pulse pressure, deviation of PMI from fifth intercostal space midclavicular line, gallop sounds, murmurs)
- Atrial and ventricular filling volumes and pressures (elevated jugular venous distension [JVD], peripheral edema, ascites, crackles, postural changes in BP)
- Cardiac output (reduced pulse pressure, hypotension, tachycardia, reduced urine output, lethargy, or disorientation)
- Compensatory mechanisms (peripheral vasoconstriction, tachycardia)

General Appearance

This part of the assessment evaluates the patient's level of consciousness (alert, lethargic, stuporous, comatose) and mental status (oriented to person, place, time; coherence). Changes in level of consciousness and mental status may be attributed to inadequate perfusion of the brain from a compromised cardiac output or thromboembolic event (stroke). Patients are observed for signs of distress, which include pain or discomfort, shortness of breath, or anxiety.

The nurse notes the size of the patient (normal, overweight, underweight, or cachectic). The patient's height and weight are measured to calculate BMI (weight in kilograms/square of the height in meters), as well as the waist circumference (refer to Chapter 5). These measures are used to determine if obesity (BMI greater than 30 kg/m²) and abdominal fat (males: waist greater than 40 inches; females: waist greater than 35 inches) are placing the patient at risk for CAD.

Inspection of the Skin

Examination of the skin begins with assessment of the patient's general appearance. It includes all body surfaces, starting with the head and finishing with the lower extremities. Skin color, temperature, and texture are assessed. Table 26-3 summarizes common findings associated with cardiovascular disease.

Table 26-3 COMMON SKIN FINDINGS ASSOCIATED WITH CARDIOVASCULAR DISEASE

Findings	Associated Conditions
Pallor (decreased color of the skin, often noted around the fingernails, lips, and oral mucosa, or in patients with dark skin, the palms of the hands and soles of the feet)	Caused by lack of oxyhemoglobin, it is a result of anemia or decreased arterial perfusion.
Peripheral cyanosis (a bluish tinge, most often of the nails and skin of the nose, lips, earlobes, and extremities)	It suggests decreased blood flow to a particular area, which allows more time for the hemoglobin molecule to become desaturated. This may occur normally in peripheral vasoconstriction associated with a cold environment, in patients with anxiety, or in disease states such as heart failure.
Central cyanosis (a bluish tinge observed in the tongue and buccal mucosa)	It denotes serious cardiac disorders (pulmonary edema and congenital heart disease) in which venous blood passes through the pulmonary circulation without being oxygenated.
Xanthelasma (yellowish, slightly raised plaques in the skin observed along the nasal portion of one or both eyelids)	It may indicate elevated cholesterol levels (hypercholesterolemia).
Ecchymosis (bruise, a purplish-blue color fading to green, yellow, or brown over time)	Patients who are receiving platelet-inhibiting medications or anticoagulant therapy should be carefully observed for unexplained ecchymosis. In these patients, excessive bruising indicates reduced platelet function (platelet-inhibiting medications) or prolonged clotting times (prothrombin, international normalized ratio, or partial thromboplastin time) caused by an anticoagulant dosage that is too high.
Thinning of skin surrounding a pacemaker or implantable cardioverter-defibrillator (ICD)	This could indicate erosion of the device through the skin.
Cool/cold and moist skin	In cardiogenic shock, sympathetic nervous system stimulation causes vasoconstriction, and the skin becomes cold and clammy. During acute coronary syndrome, diaphoresis is common.

Blood Pressure

Systemic arterial BP is the pressure exerted on the walls of the arteries during ventricular systole and diastole. It is affected by factors such as cardiac output; distention of the arteries; and the volume, velocity, and viscosity of the blood. A normal BP in adults is considered a systolic BP less than 120 mm Hg over a diastolic BP less than 80 mm Hg. High blood pressure or hypertension is defined by having a systolic blood pressure that is consistently greater than 140 mm Hg or a diastolic BP greater than 90 mm Hg. Hypotension refers to an abnormally low systolic and diastolic blood pressure that can result in lightheadedness or fainting (see Chapter 32 for additional definitions, measurement, and management).

Pulse Pressure

The difference between the systolic and the diastolic pressures is called the pulse pressure. It is a reflection of stroke volume, ejection velocity, and systemic vascular resistance. Pulse pressure, which normally is 30 to 40 mm Hg, indicates how well the patient maintains cardiac output. The pulse pressure increases in conditions that elevate the stroke volume (anxiety, exercise, bradycardia), reduce systemic vascular resistance (fever), or reduce distensibility of the arteries (atherosclerosis, aging, hypertension). Decreased pulse pressure reflects reduced stroke volume and ejection velocity (shock, HF, hypovolemia, mitral regurgitation) or obstruction to blood flow during systole (mitral or aortic stenosis). A pulse pressure of less than 30 mm Hg signifies a serious reduction in cardiac output and requires further cardiovascular assessment.

Postural Blood Pressure Changes

Postural (orthostatic) hypotension occurs when the BP decreases significantly after the patient assumes an upright posture. It is usually accompanied by dizziness, lightheadedness, or syncope.

Although there are many causes of postural hypotension, the three most common causes in patients with cardiac problems are a reduced volume of fluid or blood in the circulatory system (intravascular volume depletion, dehydration), inadequate vasoconstrictor mechanisms, and insufficient autonomic effect on vascular constriction. Postural changes in BP and an appropriate history help health care providers differentiate among these causes. The following recommendations are important when assessing postural BP changes:

- The patient should be positioned supine and flat (as symptoms permit) for 10 minutes before taking the initial BP and heart rate measurements.
- Supine measurements should be checked before obtaining sitting or standing measurements.
- Postural BP changes should be assessed with the patient sitting on the edge of the bed with feet dangling and, if appropriate, with the patient standing at the side of the bed.
- One to three minutes should elapse after each postural change before measuring BP and heart rate.
- If the patient exhibits any signs or symptoms of distress, he or she is returned to a supine position before completing the test.
- Both heart rate and BP are recorded. The patient's position (eg, supine, sitting, standing) and any signs or symptoms that accompany the postural change are also noted.

Normal postural responses that occur when a person stands up or changes from a lying to a sitting position include (1) a heart rate increase of 5 to 20 bpm above the resting rate (to offset reduced stroke volume and maintain cardiac output); (2) an unchanged systolic pressure, or a slight decrease of up to 10 mm Hg; and (3) a slight increase of 5 mm Hg in diastolic pressure.

A decrease in the amount of blood or fluid in the circulatory system should be suspected after diuretic therapy or bleeding, when a postural change results in an increased heart rate and either a decrease in systolic pressure by 15 mm Hg or a decrease in diastolic pressure by 10 mm Hg. Vital signs alone do not differentiate between a decrease in intravascular volume and inadequate constriction of the blood vessels as a cause of postural hypotension. With intravascular volume depletion, the reflexes that maintain cardiac output (increased heart rate and peripheral vasoconstriction) function correctly; the heart rate increases and the peripheral vessels constrict. However, because of lost volume, the BP falls. With inadequate vasoconstrictor mechanisms, the heart rate again responds appropriately, but because of diminished peripheral vasoconstriction, the BP drops. The following is an example of a postural BP recording showing either intravascular volume depletion or inadequate vasoconstrictor mechanisms:

Supine: BP 120/70 mm Hg, heart rate 70 bpm
 Sitting: BP 100/55 mm Hg, heart rate 90 bpm
 Standing: BP 98/52 mm Hg, heart rate 94 bpm

In autonomic insufficiency, the heart rate cannot increase to completely compensate for the gravitational effects of an upright posture. Peripheral vasoconstriction may be absent or diminished. Autonomic insufficiency does not rule out a concurrent decrease in intravascular volume. The following is an example of autonomic insufficiency as demonstrated by postural BP changes:

Supine: BP 150/90 mm Hg, heart rate 60 bpm
 Sitting: BP 100/60 mm Hg, heart rate 60 bpm

Arterial Pulses

Factors to be evaluated in examining the pulse are rate, rhythm, quality, configuration of the pulse wave, and quality of the arterial vessel.

Pulse Rate

The normal pulse rate varies from a low of 50 bpm in healthy, athletic young adults to rates well in excess of 100 bpm after exercise or during times of excitement. Anxiety frequently raises the pulse rate during the physical examination. If the rate is higher than expected, it is appropriate to reassess it near the end of the physical examination, when the patient may be more relaxed.

Pulse Rhythm

The rhythm of the pulse is as important to assess as the rate. Minor variations in regularity of the pulse are normal. The pulse rate may increase during inhalation and slow during exhalation. This phenomenon, called sinus arrhythmia, occurs most commonly in children and young adults.

For the initial cardiac examination, or if the pulse rhythm is irregular, the heart rate should be counted by auscultating the apical pulse, located at the PMI, for a full minute while simultaneously palpating the radial pulse. Any discrepancy between contractions heard and pulses felt is noted. Disturbances of rhythm (dysrhythmias) often result in a pulse deficit, a difference between the apical pulse and the radial rate. Pulse deficits commonly occur with atrial fibrillation, atrial flutter, premature ventricular

contractions, and varying degrees of heart block (see Chapter 27 for a detailed discussion of these dysrhythmias).

Pulse Quality

The quality, or amplitude, of the pulse can be described as absent, diminished, normal, or bounding. It should be assessed bilaterally. Scales can be used to rate the strength of the pulse. The following is an example of a 0-to-4 scale:

- 0: pulse not palpable or absent
- +1: weak, thready pulse; difficult to palpate; obliterated with pressure
- +2: diminished pulse; cannot be obliterated
- +3: easy to palpate, full pulse; cannot be obliterated
- +4: strong, bounding pulse; may be abnormal

The numerical classification is subjective; therefore, when documenting the pulse quality, it helps to specify a scale range (eg, “left radial +3/+4”).

Pulse Configuration

The configuration (contour) of the pulse conveys important information. In patients with stenosis of the aortic valve, the valve opening is narrowed, reducing the amount of blood ejected into the aorta. The pulse pressure is narrow, and the pulse feels feeble. In aortic insufficiency, the aortic valve does not close completely, allowing blood to flow back from the aorta into the left ventricle. The rise of the pulse wave is abrupt and strong, and its fall is precipitous—a “collapsing” or “water hammer” pulse. The true configuration of the pulse is best appreciated by palpating over the carotid artery rather than the distal radial artery, because the dramatic characteristics of the pulse wave may be distorted when the pulse is transmitted to smaller vessels.

Effect of Vessel Quality on Pulse

The condition of the vessel wall also influences the pulse and is of concern, especially in older patients. Once rate and rhythm have been determined, the nurse assesses the quality of the vessel by palpating along the radial artery and comparing it with normal vessels. Does the vessel wall feel thickened? Is it tortuous?

Palpation of Arterial Pulses

To assess peripheral circulation, the nurse locates and evaluates all arterial pulses. Arterial pulses are palpated at points where the arteries are near the skin surface and are easily compressed against bones or firm musculature. Pulses are detected over the right and left temporal, common carotid, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial arteries (see Fig. 31-9). A reliable assessment of the pulses depends on accurate identification of the location of the artery and careful palpation of the area. Light palpation is essential; firm finger pressure can obliterate the temporal, dorsalis pedis, and posterior tibial pulses and confuse the examiner. In approximately 10% of patients, the dorsalis pedis pulses are not palpable. In such circumstances, both are usually absent and the posterior tibial arteries alone provide adequate blood supply to the feet. Arteries in the extremities are often palpated simultaneously to facilitate comparison of quality.

NURSING ALERT

Do not simultaneously palpate both the temporal and carotid arteries, because it is possible to decrease the blood flow to the brain.

Jugular Venous Pulsations

Right-sided heart function can be estimated by observing the pulsations of the jugular veins of the neck and the central venous pressure (CVP), which reflects right atrial or right ventricular end-diastolic pressure (the pressure immediately preceding the contraction of the right ventricle).

Pulsations of the internal jugular veins are commonly assessed. If they are difficult to see, pulsations of the external jugular veins may be noted. These veins are more superficial and are visible just above the clavicles, adjacent to the sternocleidomastoid muscles. The external jugular veins are frequently distended while the patient lies supine on the examining table or bed. As the patient's head is elevated, distention of the veins normally disappears. The veins normally are not apparent if the patient's head is elevated more than 30 degrees.

Obvious distention of the veins with the patient's head elevated 45 to 90 degrees indicates an abnormal increase in the volume of the venous system. This occurs with right ventricular failure, pulmonary hypertension, and pulmonary stenosis; less commonly with obstruction of blood flow in the superior vena cava; and rarely with acute massive pulmonary embolism.

**Heart Inspection and Palpation**

The heart is examined by inspection, palpation, and auscultation of the chest wall. A systematic approach is used to examine the chest wall in the following six areas. Figure 26-5 identifies these important landmarks:

1. *Aortic area*—second intercostal space to the right of the sternum. To determine the correct intercostal space, the nurse first finds the angle of Louis by locating the bony ridge near the top of the sternum, at the junction of the body and the manubrium. From this angle, the second intercostal space is located by sliding one finger to the left or right of the sternum. Subsequent intercostal spaces are located from this reference point by palpating down the rib cage.
2. *Pulmonic area*—second intercostal space to the left of the sternum
3. *Erb's point*—third intercostal space to the left of the sternum
4. *Tricuspid area*—lower half of the sternum along the left parasternal area
5. *Mitral (apical) area*—left fifth intercostal space at the midclavicular line
6. *Epigastric area*—below the xiphoid process

For most of the examination, the patient lies supine, with the head of the bed slightly elevated. A right-handed examiner stands at the right side of the patient, a left-handed examiner at the left side.

Each area of the precordium is inspected and then palpated. Oblique lighting is used to assist the examiner in

Figure 26-5 Areas of the precordium to be assessed when evaluating heart function. (Numerals identify ribs of adjacent intercostal spaces.)

identifying subtle pulsations. The apical impulse is easier to discern in young patients and adults who have a thin chest wall, compared with patients who are obese or who have chest wall abnormalities.

In many cases, the apical impulse is palpable and is normally felt as a light pulsation, 1 to 2 cm in diameter. It is felt at the onset of the first heart sound and lasts for only half of ventricular systole (see the next section for a discussion of heart sounds). The nurse uses the palm of the hand to locate the apical impulse initially and the fingerpads to assess its size and quality. If the apical impulse cannot be palpated while the patient is supine, the patient is repositioned into the left lateral position as shown in Figure 26-6, to put the heart into closer contact with the chest wall and facilitate palpation of the apical impulse.

Figure 26-6 Locating and palpating the apical impulse (also called the point of maximal impulse [PMI]) in the left lateral position. The apical impulse normally is located at the fifth intercostal space to the left of the sternum at the midclavicular line. The nurse locates the impulse with the palm of the hand and palpates with the fingerpads. © B. Proud in Weber, J. W. & Kelley, J. (2006). *Health assessment in nursing* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.

There are several abnormalities that the nurse may find during palpation of the precordium. Normally, the apical impulse is palpable in only one intercostal space; palpability in two or more adjacent intercostal spaces indicates left ventricular enlargement. An apical impulse below the fifth intercostal space or lateral to the midclavicular line usually denotes left ventricular enlargement from left ventricular failure. If the apical impulse can be palpated in two distinctly separate areas and the pulsation movements are paradoxical (not simultaneous), a ventricular aneurysm may be suspected. A broad and forceful apical impulse is known as a left ventricular heave or lift because it appears to lift the hand from the chest wall during palpation.

A vibration or purring sensation may be felt over areas where abnormal, turbulent blood flow is present. It is best detected by using the palm of the hand. This vibration is called a thrill and is associated with a loud murmur. Depending on the location of the thrill, it may be indicative of serious valvular heart disease, an atrial or ventricular septal defect (abnormal opening), or stenosis of a large artery, such as the carotid artery.

Heart Auscultation

A stethoscope is used to auscultate each of the locations identified in Figure 26-5, with the exception of the epigastric area. The purpose of cardiac auscultation is to determine heart rate and rhythm and evaluate heart sounds. The apical area is auscultated for 1 minute to determine the apical pulse rate and the regularity of the heartbeat. Normal and abnormal heart sounds detected during auscultation are described in the following section.

Normal Heart Sounds

Normal heart sounds, referred to as S_1 and S_2 , are produced by closure of the AV valves and the semilunar valves, respectively. The period between S_1 and S_2 corresponds with ventricular systole (Fig. 26-7). When the heart rate is

within the normal range, systole is much shorter than the period between S_2 and S_1 (diastole). However, as the heart rate increases, diastole shortens.

Normally, S_1 and S_2 are the only sounds heard during the cardiac cycle.

S_1 —First Heart Sound. Tricuspid and mitral valve closure creates the first heart sound (S_1). The word “lub” is used to replicate its sound. S_1 is usually heard the loudest at the apical area. S_1 is easily identifiable and serves as the point of reference for the remainder of the cardiac cycle.

The intensity of S_1 increases during tachycardias or with mitral stenosis. In these circumstances, the AV valves are wide open during ventricular contraction. The accentuated S_1 occurs as the AV valves close with greater force than normal. Similarly, dysrhythmias can vary the intensity of S_1 from beat to beat due to lack of synchronized atrial and ventricular contraction.

S_2 —Second Heart Sound. Closure of the pulmonic and aortic valves produces the second heart sound (S_2), commonly referred to as the “dub” sound. The aortic component of S_2 is heard the loudest over the aortic and pulmonic areas. However, the pulmonic component of S_2 is a softer sound and is heard best over the pulmonic area.

Although these valves close almost simultaneously, the pulmonic valve lags slightly behind the aortic valve. In some individuals, it is possible to distinguish between the closure of the aortic and pulmonic valves. When this situation occurs, the patient is said to have a split S_2 . Normal physiologic splitting of S_2 is accentuated on inspiration and disappears on expiration. During inspiration, there is a decrease in intrathoracic pressure and subsequent increase in venous return to the right atrium and ventricle. The right ventricle takes a little longer to eject this extra volume, which causes the pulmonic valve to close a little later than normal. Splitting of S_2 that remains constant during inspiration and expiration is an abnormal finding. Abnormal

Figure 26-7 Normal heart sounds. The first heart sound (S_1) is produced by closure of the mitral and tricuspid valves (“lub”). The second heart sound (S_2) is produced by closure of the aortic and pulmonic valves (“dub”). Arrows represent the direction of blood flow.

splitting of the second heart sound can be caused by a variety of disease states (valvular heart disease, septal defects, bundle branch blocks). Splitting of S_2 is best heard over the pulmonic area.

Abnormal Heart Sounds

Abnormal sounds develop during systole or diastole when structural or functional heart problems are present. These sounds are called S_3 , or S_4 gallops, opening snaps, systolic clicks, and murmurs. S_3 and S_4 gallop sounds are heard during diastole. These sounds are created by the vibration of the ventricle and surrounding structures as blood meets resistance during ventricular filling. The term *gallop* evolved from the cadence that is produced by the addition of a third or fourth heart sound, similar to the sound of a galloping horse. Gallop sounds are very low-frequency sounds and are heard with the bell of the stethoscope placed very lightly against the chest.

S_3 —Third Heart Sound. An S_3 occurs early in diastole during the period of rapid ventricular filling. It is heard immediately after S_2 . “Lub-dub DUB” (S_3) is used to imitate the sound of the beating heart with this gallop sound. It represents a normal finding in children and adults up to 35 or 40 years of age. In these cases, it is called a physiologic S_3 (Fig. 26-8). On the other hand, in older adults, it is a sign of significant pathophysiology, most commonly due to volume overload of one or both ventricles. It is a significant finding in patients with HF. If the right ventricle is involved, a right-sided S_3 is heard over the tricuspid area with the patient in a supine position. A left-sided S_3 is best heard over the apical area. Having the patient turn to the left lateral position may facilitate auscultation of an S_3 generated by the left ventricle.

S_4 —Fourth Heart Sound. S_4 occurs late in diastole (see Fig. 26-8). An S_4 occurs just before S_1 and is generated during atrial contraction as blood forcefully enters a noncompliant ventricle. This resistance to blood flow is due to ventricular hypertrophy caused by hypertension, CAD, cardiomyopathies, aortic stenosis, and numerous other conditions. “LUB (S_4) lub-dub” is used to imitate this gallop sound. An

S_4 produced in the left ventricle is auscultated over the apical area with the patient in the left lateral position. A right-sided S_4 , although less common, is heard best over the tricuspid area with the patient in supine position. There are times when both S_3 and S_4 are present, creating a quadruple rhythm, which sounds like “LUB lub-dub DUB”. During tachycardia, all four sounds combine into a loud sound, referred to as a **summation gallop**.

Opening Snaps and Systolic Clicks. Normally no sound is produced when valves open. However, diseased valve leaflets create abnormal sounds as they open during diastole or systole. **Opening snaps** are abnormal diastolic sounds heard during opening of an AV valve. For example, mitral stenosis can cause an opening snap, which is an unusually high-pitched sound very early in diastole. This sound is caused by high pressure in the left atrium that abruptly displaces or “snaps” open a rigid valve leaflet. Timing helps to distinguish an opening snap from the other gallop sounds. It occurs too long after S_2 to be mistaken for a split S_2 and too early in diastole to be mistaken for an S_3 . The high-pitched, snapping quality of the sound is another way to differentiate an opening snap from an S_3 . Hearing a murmur or the sound of turbulent blood flow is expected following the opening snap. An opening snap is heard best using the diaphragm of the stethoscope placed medial to the apical area and along the lower left sternal border.

In a similar manner, stenosis of one of the semilunar valves creates a short, high-pitched sound in early systole, immediately after S_1 . This sound, called a **systolic click**, is the result of the opening of a rigid and calcified aortic or pulmonic valve during ventricular contraction. Mid- to late systolic clicks may be heard in patients with mitral or tricuspid valve prolapse, as the malfunctioning valve leaflet is displaced into the atrium during ventricular systole. Murmurs are expected to be heard following these abnormal systolic sounds. These sounds are the loudest in the areas directly over the malfunctioning valve.

Murmurs. Murmurs are created by turbulent flow of blood. The causes of the turbulence may be a critically narrowed valve, a malfunctioning valve that allows regurgitant blood

Chart 26-3 • Characteristics of Heart Murmurs

Heart murmurs are described in terms of location, timing, intensity, pitch, quality, and radiation. These characteristics provide information needed to determine the cause of the murmur and its clinical significance.

Location

Pinpointing the location of the murmur helps to determine the underlying structures that are involved in generating the abnormal sounds. The locations described in Figure 26-5 are used to identify where the loudest sounds are detected. It is helpful to include in the description the exact location from which the sound emanates, such as the location of the intercostal space and other important landmarks (right or left sternal border; midsternal, midclavicular, anterior axillary, or midaxillary lines). For example, a ventricular septal defect can be located at the left sternal border in the third and fourth intercostal spaces.

Timing

A murmur is described in terms of when it occurs during the cardiac cycle (systole or diastole). Murmurs are further differentiated by identifying exactly when during systole or diastole they are heard. A skilled clinician can detect that the murmur is occurring during early, mid-, or late systole or diastole. Some murmurs have sounds that occur in both systole and diastole.

Intensity

A grading system is used to describe the intensity or loudness of a murmur.

Grade 1: very faint and difficult for the inexperienced clinician to hear

Grade 2: quiet, but readily perceived by the experienced clinician

Grade 3: moderately loud

Grade 4: loud and may be associated with a thrill

Grade 5: very loud; heard when stethoscope is partially off the chest; associated with a thrill

Grade 6: extremely loud; detected with the stethoscope off the chest; associated with a thrill

Pitch

Pitch is used to describe the sound frequency, identified as high, medium, or low pitched. High-pitched murmurs are heard best with the stethoscope's diaphragm, whereas low-pitched sounds are detected using the bell of the stethoscope placed lightly on the chest wall.

Quality

Quality is the term used to describe the sound that the murmur resembles. Murmurs can produce a rumbling, blowing, whistling, harsh, or musical sound. For example, murmurs caused by mitral or tricuspid regurgitation have a blowing quality, whereas mitral stenosis generates a rumbling sound.

Radiation

Radiation refers to the transmission of the murmur from the point of maximal intensity to other areas in the upper chest. The examiner determines if radiation is present by listening carefully to areas of the heart adjacent to the point where the murmur is the loudest. If radiation is present, the exact location is described. A murmur associated with aortic stenosis, for example, can radiate into the neck, down the left sternal border, and into the apical area.

flow, a congenital defect of the ventricular wall, a defect between the aorta and the pulmonary artery, or an increased flow of blood through a normal structure (eg, with fever, pregnancy, hyperthyroidism). Murmurs are characterized and consequently described by several characteristics, including their timing in the cardiac cycle, location on the chest wall, intensity, pitch, quality, and pattern of radiation (Chart 26-3).

Friction Rub. A harsh, grating sound that can be heard in both systole and diastole is called a friction rub. It is caused by abrasion of the inflamed pericardial surfaces from pericarditis. Because a friction rub may be confused with a murmur, care should be taken to identify the sound and to distinguish it from murmurs that may be heard in both systole and diastole. A pericardial friction rub can be heard best using the diaphragm of the stethoscope, with the patient sitting up and leaning forward.

Auscultation Procedure

During auscultation, the patient remains supine and the examining room is as quiet as possible. A stethoscope with both diaphragm and bell functions is necessary for accurate auscultation of the heart.

Using the diaphragm of the stethoscope, the examiner starts at the apical area and progresses upward along the left sternal border to the pulmonic and aortic areas. Alternatively, the examiner may begin the examination at the aortic and pulmonic areas and progress downward to the apex

of the heart. Initially, S_1 is identified and evaluated with respect to its intensity and splitting. Next, S_2 is identified, and its intensity and any splitting are noted. After concentrating on S_1 and S_2 , the examiner listens for extra sounds in systole and then in diastole.

Sometimes it helps to ask the following questions: Do I hear snapping or clicking sounds? Do I hear any high-pitched blowing sounds? Is this sound in systole, or diastole, or both? The examiner again proceeds to move the stethoscope to all of the designated areas of the precordium, listening carefully for these sounds. Finally, the patient is turned on the left side and the stethoscope is placed on the apical area, where an S_3 , an S_4 and a mitral murmur are more readily detected.

Once an abnormality is heard, the entire chest surface is reexamined to determine the exact location of the sound and its radiation. The patient may be concerned about the prolonged examination and must be supported and reassured. The auscultatory findings, particularly murmurs, are documented by identifying the following characteristics (see Chart 26-3): location on chest wall, timing, intensity, pitch, quality, and radiation.

Interpretation of Heart Sounds

Interpreting heart sounds requires detailed knowledge of cardiac physiology and pathophysiology. However, all nurses should have adequate knowledge and skill to recognize

normal heart sounds (S_1 , S_2) and the presence of abnormal sounds. When assessment is at this very basic level of practice, abnormal findings are reported for further evaluation and treatment. More advanced skills are required of nurses caring for critically ill patients with CVD or those nurses functioning in advanced practice roles. Nurses in these roles readily identify abnormal heart sounds, recognize the diagnostic significance of their findings, and use their assessment skills to evaluate patients' responses to medical interventions. For example, these highly skilled nurses monitor heart sounds in patients with HF to detect the resolution of an S_3 after treatment with a diuretic.

Inspection of the Extremities

The hands, arms, legs, and feet are observed for skin and vascular changes. The most noteworthy changes include the following:

- Decreased capillary refill time indicates a slower peripheral flow rate from sluggish reperfusion and is often observed in patients with hypotension or HF. Capillary refill time provides the basis for estimating the rate of peripheral blood flow. To test capillary refill, the nurse briefly compresses the nailbed so that it blanches, and then releases the pressure. Normally, reperfusion occurs within 3 seconds, as evidenced by the return of color.
- Vascular changes from decreased arterial circulation include a decrease in quality or loss of pulse, discomfort or pain, paresthesia, numbness, decrease in temperature, pallor, and loss of movement. During the first few hours after invasive cardiac procedures (eg, cardiac catheterization), affected extremities should be assessed frequently for vascular changes.
- Hematoma, or a localized collection of clotted blood in the tissue, may be observed in patients who have undergone invasive cardiac procedures such as cardiac catheterization, PCI, or cardiac electrophysiology testing. Major blood vessels of the arms and legs may be used for catheter insertion. During these procedures, systemic anticoagulation with heparin is necessary, and minor or small hematomas may occur at the catheter puncture site. However, large hematomas are a serious complication that can compromise circulating blood volume and cardiac output. Patients who have undergone these procedures must have their puncture sites frequently observed until hemostasis is adequately achieved.
- Peripheral edema is fluid accumulation in dependent areas of the body (feet and legs, sacrum in the bedridden patient). Pitting edema (a depression over an area of pressure) is assessed by pressing firmly for 5 seconds with the thumb over the dorsum of each foot, behind each medial malleolus, and over the shins. It is graded as absent or as present on a scale from slight ($1+ = 0$ to 2 mm) to very marked ($4+ =$ more than 8 mm). Peripheral edema is observed in patients with HF and in those with peripheral vascular diseases such as deep vein thrombosis or chronic venous insufficiency.
- Clubbing of the fingers and toes implies chronic hemoglobin desaturation, as in congenital heart disease.
- Lower extremity ulcers are observed in patients with arterial or venous insufficiency (see Chapter 31 for a complete description of these conditions).

Assessment of Other Systems

Lungs

The details of respiratory assessment are described in Chapter 21. Findings frequently exhibited by patients with cardiac disorders include the following:

Hemoptysis: Pink, frothy sputum is indicative of acute pulmonary edema.

Cough: A dry, hacking cough from irritation of small airways is common in patients with pulmonary congestion from HF.

Crackles: HF or atelectasis associated with bed rest, splinting from ischemic pain, or the effects of analgesic, sedative, or anesthetic agents often results in the development of crackles. Typically, crackles are first noted at the bases (because of gravity's effect on fluid accumulation and decreased ventilation of basilar tissue), but they may progress to all portions of the lung fields.

Wheezes: Compression of the small airways by interstitial pulmonary edema may cause wheezing. Beta-adrenergic blocking agents (beta-blockers), such as propranolol (Inderal), may cause airway narrowing, especially in patients with underlying pulmonary disease.

Abdomen

For the patient with a cardiovascular disorder, several components of the abdominal examination are relevant:

Abdominal distension: A protuberant abdomen with bulging flanks indicates ascites. Ascites develops in patients with right ventricular or biventricular HF (both right- and left-sided HF). In the failing right heart, abnormally high chamber pressures impede the return of venous blood. As a result, the liver and spleen become engorged with excessive venous blood (hepatosplenomegaly). As pressure in the portal system rises, fluid shifts from the vascular bed into the abdominal cavity. Ascitic fluid, found in the dependent or lowest points in the abdomen, will shift with position changes.

Hepatojugular reflux: This test is performed when right ventricular or biventricular HF is suspected. The patient is positioned so that the jugular venous pulse is visible in the lower part of the neck. While observing the jugular venous pulse, firm pressure is applied over the right upper quadrant of the abdomen for 30 to 60 seconds. An increase of 1 cm or more in jugular venous pressure is indicative of a positive hepatojugular reflux. This positive test aids in confirming the diagnosis of HF.

Bladder distention: Urine output is an important indicator of cardiac function. Reduced urine output may indicate inadequate renal perfusion or a less serious problem such as one caused by urinary retention. When urine output is decreased, the patient must be assessed

for a distended bladder or difficulty voiding. The bladder may be assessed with an ultrasound scanner or the suprapubic area palpated for an oval mass and percussed for dullness, indicative of a full bladder.

Gerontologic Considerations

When performing a cardiovascular examination on an elderly patient, the nurse may note such differences as more readily palpable peripheral pulses because of decreased elasticity of the arteries and a loss of adjacent connective tissue. Palpation of the precordium in the elderly is affected by the changes in the shape of the chest. For example, a cardiac impulse may not be palpable in patients with chronic obstructive pulmonary disease, because these patients usually have an increased anterior–posterior chest diameter. Kyphoscoliosis, a spinal deformity that occurs in many elderly patients, may move the cardiac apex downward so that palpation of the apical impulse is obscured.

Systolic BP increases with age, but diastolic BP usually plateaus after 50 years of age. Isolated systolic hypertension occurs most commonly among the elderly and is associated with significant cardiovascular morbidity and mortality. Orthostatic hypotension may reflect decreased sensitivity of postural reflexes, which must be considered when medication therapy is prescribed.

An S_4 is heard in about 90% of elderly patients and is thought to be due to decreased compliance of the left ventricle. The S_2 is usually split. At least 60% of elderly patients have murmurs, the most common being a soft systolic ejection murmur resulting from sclerotic changes of the aortic leaflets (see Table 26-1).

Diagnostic Evaluation

Laboratory Tests

Laboratory tests may be performed for the following reasons:

- To assist in diagnosing the cause of cardiac-related signs and symptoms
- To determine baseline values before initiating therapeutic interventions
- To screen for modifiable CAD risk factors
- To ensure that therapeutic levels of medications (eg, antiarrhythmic agents and warfarin) are maintained
- To evaluate the patient's response to the therapeutic regimen (eg, effects of diuretics on serum potassium levels)
- To identify abnormalities that affect the prognosis of a patient with CVD

Normal values for laboratory tests may vary depending on the laboratory and the health care institution. This variation is due to the differences in equipment and methods of measurement across organizations.

Cardiac Biomarker Analysis

The diagnosis of MI is made by evaluating the history and physical examination, the 12-lead ECG, and results of laboratory tests that measure serum cardiac biomarkers. Myocardial cells that become necrotic from prolonged ischemia or trauma release specific enzymes (creatine kinase

[CK]), CK isoenzymes (CK-MB), and proteins (myoglobin, troponin T, and troponin I). These substances leak into the interstitial spaces of the myocardium and are carried by the lymphatic system into general circulation. As a result, abnormally high levels of these substances can be detected in serum blood samples. See Chapter 28 for further discussion of cardiac biomarker analysis.

Blood Chemistry, Hematology, and Coagulation Studies

Table 26-4 provides information about some common serum laboratory tests and the implications for patients with CVD. Discussion of lipid, brain (B-type) natriuretic peptide, C-reactive protein, and homocysteine measurements follows.

Lipid Profile

Cholesterol, triglycerides, and lipoproteins are measured to evaluate a person's risk of developing atherosclerotic disease, especially if there is a family history of premature heart disease, or to diagnose a specific lipoprotein abnormality. Cholesterol and triglycerides are transported in the blood by combining with plasma proteins to form lipoproteins. The lipoproteins are referred to as low-density lipoproteins (LDLs) and high-density lipoproteins (HDLs). The risk of CAD increases as the ratio of LDL to HDL or the ratio of total cholesterol (LDL + HDL) to HDL increases. Although cholesterol levels remain relatively constant over 24 hours, the blood specimen for the lipid profile should be obtained after a 12-hour fast.

Cholesterol Levels. Cholesterol (normal level is less than 200 mg/dL) is a lipid required for hormone synthesis and cell membrane formation. It is found in large quantities in brain and nerve tissue. Two major sources of cholesterol are diet (animal products) and the liver, where cholesterol is synthesized. Elevated cholesterol levels are known to increase the risk of CAD. Factors that contribute to variations in cholesterol levels include age, gender, diet, exercise patterns, genetics, menopause, tobacco use, and stress levels.

LDLs (normal level is less than 160 mg/dL) are the primary transporters of cholesterol and triglycerides into the cell. One harmful effect of LDL is the deposition of these substances in the walls of arterial vessels. Elevated LDL levels are associated with a greater incidence of CAD. In people with known CAD or diabetes, the primary goal for lipid management is reduction of LDL levels to less than 70 mg/dL.

HDLs (normal range in men is 35 to 70 mg/dL; in women, 35 to 85 mg/dL) have a protective action. They transport cholesterol away from the tissue and cells of the arterial wall to the liver for excretion. Therefore, there is an inverse relationship between HDL levels and risk of CAD. Factors that lower HDL levels include smoking, diabetes, obesity, and physical inactivity. In patients with CAD, a secondary goal of lipid management is the increase of HDL levels to more than 40 mg/dL.

Triglycerides. Triglycerides (normal range is 100 to 200 mg/dL), composed of free fatty acids and glycerol, are stored in the adipose tissue and are a source of energy. Triglyceride

Table 26-4 COMMON SERUM LABORATORY TESTS AND IMPLICATIONS FOR PATIENTS WITH CARDIOVASCULAR DISEASE (CVD)

Laboratory Test	Implications
Reference Range	
Blood Chemistries	
Sodium (Na ⁺) 135–145 mEq/L	Low or high serum sodium levels do not directly affect cardiac function. <i>Hyponatremia</i> : Decreased sodium levels indicate fluid excess and can be caused by heart failure or administration of thiazide diuretics. <i>Hypernatremia</i> : Increased sodium levels indicate fluid deficits and can result from decreased water intake or loss of water through excessive sweating or diarrhea.
Potassium (K ⁺) 3.5–5.0 mEq/L	Potassium has a major role in cardiac electrophysiologic function. <i>Hypokalemia</i> : Decreased potassium levels due to administration of potassium-excreting diuretics can cause many forms of dysrhythmias, including life-threatening ventricular tachycardia or ventricular fibrillation, and predispose patients taking digitalis preparations to digitalis toxicity. <i>Hyperkalemia</i> : Increased potassium levels can result from an increased intake of potassium (eg, foods high in potassium or potassium supplements), decreased renal excretion of potassium, use of potassium-sparing diuretics (eg, spironolactone), or use of angiotensin-converting enzyme inhibitors (ACE inhibitors) that inhibit aldosterone function. Serious consequences of hyperkalemia include heart block, asystole, and life-threatening ventricular dysrhythmias.
Calcium (Ca ⁺⁺) 8.6–10.2 mg/dL	Calcium is necessary for blood coagulability, neuromuscular activity, and automaticity of the nodal cells (sinus and atrioventricular nodes). <i>Hypocalcemia</i> : Decreased calcium levels slow nodal function and impair myocardial contractility. The latter effect increases the risk for heart failure. <i>Hypercalcemia</i> : Increased calcium levels can occur with the administration of thiazide diuretics because these medications reduce renal excretion of calcium. Hypercalcemia potentiates digitalis toxicity, causes increased myocardial contractility, and increases the risk for varying degrees of heart block and sudden death from ventricular fibrillation.
Magnesium (Mg ⁺⁺) 1.3–2.3 mEq/L	Magnesium is necessary for the absorption of calcium, maintenance of potassium stores, and metabolism of adenosine triphosphate. It plays a major role in protein and carbohydrate synthesis and muscular contraction. <i>Hypomagnesemia</i> : Decreased magnesium levels are due to enhanced renal excretion of magnesium from the use of diuretic or digitalis therapy. Low magnesium levels predispose patients to atrial or ventricular tachycardias. <i>Hypermagnesemia</i> : Increased magnesium levels are commonly caused by the use of cathartics or antacids containing magnesium. Increased magnesium levels depress contractility and excitability of the myocardium, causing heart block and, if severe, asystole.
Blood urea nitrogen (BUN) 10–20 mg/dL	BUN and creatinine are end products of protein metabolism excreted by the kidneys. Elevated BUN reflects reduced renal perfusion from decreased cardiac output or intravascular fluid volume deficit as a result of diuretic therapy or dehydration.
Creatinine 0.7–1.4 mg/dL	Both BUN and creatinine are used to assess renal function, although creatinine is a more sensitive measure. Renal impairment is detected by an increase in both BUN and creatinine. A normal creatinine level and an elevated BUN suggest an intravascular fluid volume deficit.
Glucose Fasting: 60–110 mg/dL	Glucose levels are elevated in stressful situations, when mobilization of endogenous epinephrine results in conversion of liver glycogen to glucose. Serum glucose levels are drawn in a fasting state.
Glycohemoglobin (hemoglobin A _{1c}) Nondiabetic: 4.4–6.4%	Glycohemoglobin (hemoglobin A _{1c}) is monitored in people with diabetes. It reflects the blood glucose levels over 2–3 mo. The glycemic goal is to maintain the hemoglobin A _{1c} below 7% reflecting consistent near-normal blood glucose levels.
Coagulation Studies	
Partial thromboplastin time (PTT) 60–70 sec	Injury to a vessel wall or tissue initiates the formation of a thrombus. This injury activates the coagulation cascade, the complex interactions among phospholipids, calcium, and clotting factors that convert prothrombin to thrombin. The coagulation cascade has two pathways, the intrinsic and extrinsic pathways. Coagulation studies are routinely performed before invasive procedures, such as cardiac catheterization, electrophysiology testing, and cardiac surgery. PTT or aPTT measures the activity of the intrinsic pathway and is used to assess the effects of unfractionated heparin. A therapeutic range is 1.5–2.5 times baseline values. Adjustment of heparin dose is required for aPTT <50 sec (↑ dose) or >100 sec (↓ dose).
Activated partial thromboplastin time (aPTT) 20–39 sec	
Prothrombin time (PT) 9.5–12 sec	PT measures the extrinsic pathway activity and is used to monitor the level of anticoagulation with warfarin (Coumadin).
International normalized ratio (INR) 1.0	The INR, reported with the PT, provides a standard method for reporting PT levels and eliminates the variation of PT results from different laboratories. The INR, rather than the PT alone, is used to monitor the effectiveness of warfarin. The therapeutic range for INR is 2–3.5, although specific ranges vary based on diagnosis.
Hematologic Studies	
Complete blood count (CBC)	The CBC identifies the total number of white and red blood cells and platelets, and measures hemoglobin and hematocrit. The CBC is carefully monitored in patients with cardiovascular disease.
White blood cell (WBC) count 4500–11,000/mm ³	WBC counts are monitored in immunocompromised patients, including patients with heart transplants or in situations where there is concern for infection (eg, after invasive procedures or surgery).
Hematocrit Male: 42–52% Female: 35–47%	The hematocrit represents the percentage of red blood cells found in 100 mL of whole blood. The red blood cells contain hemoglobin, which transports oxygen to the cells. Low hemoglobin and hematocrit levels have serious consequences for patients with cardiovascular disease, such as more frequent angina episodes or acute myocardial infarction.
Hemoglobin Male: 13–18 g/dL Female: 12–16 g/dL	
Platelets 150,000–450,000/mm ³	Platelets are the first line of protection against bleeding. Once activated by blood vessel wall injury or rupture of atherosclerotic plaque, platelets undergo chemical changes that form a thrombus. Several medications inhibit platelet function, including aspirin, clopidogrel (Plavix), and intravenous glycoprotein IIb/IIIa inhibitors (abciximab [ReoPro], eptifibatid [Integrilin], and tirofiban [Aggrastat]). When these medications are administered, it is essential to monitor for thrombocytopenia (low platelet counts).

levels increase after meals and are affected by stress. Diabetes, alcohol use, and obesity can elevate triglyceride levels. These levels have a direct correlation with LDL and an inverse one with HDL.

Brain (B-Type) Natriuretic Peptide

Brain (B-type) natriuretic peptide (BNP) is a neurohormone that helps regulate BP and fluid volume. It is primarily secreted from the ventricles in response to increased preload with resulting elevated ventricular pressure. The level of BNP in the blood increases as the ventricular walls expand from increased pressure, making it a helpful diagnostic, monitoring, and prognostic tool in the setting of HF. Because this serum laboratory test can be quickly obtained, BNP levels are useful for prompt diagnosis of HF in settings such as the emergency department. Elevations in BNP can occur from a number of other conditions such as pulmonary embolus, MI, and ventricular hypertrophy. Therefore, the clinician correlates BNP levels with abnormal physical assessment findings and other diagnostic tests before making a definitive diagnosis of HF. A BNP level greater than 100 pg/mL is suggestive of HF.

C-Reactive Protein

High-sensitivity assay for C-reactive protein (hs-CRP) is a venous blood test that measures levels of CRP, a protein produced by the liver in response to systemic inflammation. Inflammation is thought to play a role in the development and progression of atherosclerosis. Therefore, hs-CRP is used as an adjunct to other tests to predict CVD risk, though its role as an independent risk factor for cardiovascular disease is controversial. People with high levels of hs-CRP (3.0 mg/dL or greater) may be at greatest risk for CVD compared to people with moderate (1.0 to 3.0 mg/dL) or low (less than 1.0 mg/dL) levels of hs-CRP. In addition, an elevated hs-CRP may place patients with ACS at risk for recurrent cardiac events, including unstable angina and acute MI, higher mortality, and increased risk of restenosis of coronary arteries after PCI (Koenig, 2005).

Homocysteine

Determining the homocysteine level enhances the clinician's ability to assess the patient's risk for CVD. Homocysteine, an amino acid, is linked to the development of atherosclerosis because it can damage the endothelial lining of arteries and promote thrombus formation. Therefore, an elevated blood level of homocysteine is thought to indicate a high risk for CAD, stroke, and peripheral vascular disease, although it is not an independent predictor of CAD. Genetic factors and a diet low in folic acid, vitamin B₆, and vitamin B₁₂ are associated with elevated homocysteine levels. A 12-hour fast is necessary before drawing a blood sample for an accurate serum measurement. Test results are interpreted as optimal (less than 12 μ mol/L), borderline (12 to 15 μ mol/L), and high risk (greater than 15 μ mol/L).

Chest X-Ray and Fluoroscopy

A chest x-ray is obtained to determine the size, contour, and position of the heart. It reveals cardiac and pericardial calcifications and demonstrates physiologic alterations in the pulmonary circulation. Although it does not help diag-

nose acute MI, it can help diagnose some complications (eg, HF). Correct placement of pacemakers and pulmonary artery catheters is also confirmed by chest x-ray.

Fluoroscopy is an x-ray imaging technique that allows visualization of the heart on a screen. It shows cardiac and vascular pulsations and unusual cardiac contours. This technique uses a moveable x-ray source, which makes it a useful aid for positioning transvenous pacing electrodes and for guiding the insertion of arterial and venous catheters during cardiac catheterization and other cardiac procedures.

Electrocardiography

The ECG is a graphic representation of the electrical currents of the heart. The ECG is obtained by placing disposable electrodes in standard positions on the skin of the chest wall and extremities (see Chapter 27 for electrode placement). Recordings of the electrical current flowing between two electrodes is made on graph paper or displayed on a monitor. Several different recordings can be obtained by using a variety of electrode combinations, called leads. Simply stated, a lead is a specific view of the electrical activity of heart. The standard ECG is composed of 12 leads or 12 different views, although it is possible to record 15 or 18 leads.

The 12-lead ECG is used to diagnose dysrhythmias, conduction abnormalities, chamber enlargement, and myocardial ischemia, injury, or infarction. It can also suggest cardiac effects of electrolyte disturbances (high or low calcium and potassium levels) and the effects of antiarrhythmic medications. A 15-lead ECG adds three additional chest leads across the right precordium and is used for early diagnosis of right ventricular and left posterior (ventricular) infarction. The 18-lead ECG adds three posterior leads to the 15-lead ECG and is useful for early detection of myocardial ischemia and injury. To enhance interpretation of the ECG, the patient's age, gender, BP, height, weight, symptoms, and medications (especially digitalis and antiarrhythmic agents) are noted on the ECG requisition. The details of electrocardiography are presented in Chapter 27.

Continuous Electrocardiographic Monitoring

Continuous ECG monitoring is the standard of care for patients who are at high risk for dysrhythmias. This form of cardiac monitoring detects abnormalities in heart rate and rhythm. Many systems have the capacity to monitor for changes in ST segments, which are used to identify the presence of myocardial ischemia or injury (see Chapter 28). There are two types of continuous ECG monitoring techniques used in health care settings: hardwire cardiac monitoring, found in emergency departments, critical care units, and progressive care units; and telemetry, found in general nursing care units or outpatient cardiac rehabilitation programs. Hardwire cardiac monitoring and telemetry systems vary in sophistication; however, most systems have the following features in common:

- Monitor more than one lead simultaneously
- Monitor ST segments (ST-segment depression is a marker of myocardial ischemia; ST-segment elevation provides evidence of an evolving MI)
- Provide graded visual and audible alarms (based on priority, asystole merits the highest grade of alarm)
- Interpret and store alarms

- Trend data over time
- Print a copy of rhythms from one or more specific ECG leads over a set time (called a rhythm strip)

NURSING ALERT

Patients placed on continuous ECG monitoring must be informed of its purpose and cautioned that it does not detect shortness of breath, chest pain, or other ACS symptoms. Thus, patients are instructed to report new or worsening symptoms immediately.

Hardwire Cardiac Monitoring

Hardwire cardiac monitoring is used to continuously observe the heart for dysrhythmias and conduction disorders using one or two ECG leads. A real-time ECG is displayed on a bedside monitor and at a central monitoring station. In critical care units, additional components can be added to the bedside monitor to continuously monitor hemodynamic parameters (noninvasive BP, arterial pressures, pulmonary artery pressures) and respiratory parameters (respiratory rate, oxygen saturation).

Telemetry

In addition to hardwire cardiac monitoring, the ECG can be continuously observed by **telemetry**, the transmission of radiowaves from a battery-operated transmitter to a central bank of monitors. The primary benefit of using telemetry is that the system is wireless, which allows patients to ambulate while one or two ECG leads are monitored. The patient has electrodes placed on the chest with a lead cable that connects to the transmitter. The transmitter can be placed in a disposable pouch and worn around the neck, or simply secured to the patient's clothing. Most transmitter batteries are changed every 24 to 48 hours.

Lead Systems

The number of electrodes needed for hardwire cardiac monitoring and telemetry is dictated by the lead system used in the clinical setting. Electrodes need to be securely and accurately placed on the chest wall. Chart 26-4 provides helpful hints on how to apply these electrodes. There are three-, four-, or five-lead systems available for ECG monitoring. With a three-lead system, the nurse has only three lead options, whereas a four-lead system provides six possibilities. Newer monitoring systems have a five-lead system, which provides up to seven different lead selections. The advantage of the latter system is that it can more comprehensively monitor the activity of the anterior wall of the left ventricle (see Fig. 26-9 for electrode placement).

The two ECG leads most often selected for continuous ECG monitoring are leads II and V₁. Lead II provides the best visualization of atrial depolarization (represented by the P wave). Lead V₁ best records ventricular depolarization and is most helpful when monitoring for certain dysrhythmias (eg, premature ventricular contractions, tachycardias, bundle branch blocks) (see Chapter 27).

The EASI monitoring system (Phillips Medical System) uses five electrodes, is capable of printing a 12-lead ECG, and allows that any 3 of 12 leads can be displayed simulta-

Chart 26-4 • Applying Electrodes

The monitoring system requires an adequate electrical signal to analyze the patient's cardiac rhythm. When applying electrodes, the following recommendations should be followed to optimize skin adherence and conduction of the heart's electrical current:

- Débride the skin surface of dead cells with soap and water and dry well (or as recommended by the manufacturer).
- Clip (do not shave) hair from around the electrode site if needed.
- If the patient is diaphoretic (sweaty), apply a small amount of benzoin to the skin, avoiding the area under the center of the electrode.
- Connect the electrodes to the lead wires prior to placing them on the chest (connecting lead wires when electrodes are in place may be uncomfortable for some patients).
- Peel the backing off the electrode and check to make sure the center is moist with electrode gel.
- Locate the appropriate lead placement and apply the electrode to the skin, securing it in place with light pressure.
- Change the electrodes every 24 to 48 hours (or as recommended by the manufacturer), examine the skin for irritation, and apply the electrodes to different locations.
- If the patient is sensitive to the electrodes, use hypoallergenic electrodes.

neously. However, since this system requires that electrodes be placed on the trunk rather than the extremities, it is not considered equivalent to the standard approach. Therefore, it is recommended that the EASI method should not be used for serial comparisons or used in place of a standard 12-lead ECG (Jahrsdoerfer, Giuliano & Stephens, 2005).

Ambulatory Electrocardiography

Ambulatory electrocardiography is a form of continuous ECG monitoring used for diagnostic purposes in the outpatient setting. Electrodes (number varies based on model used) are connected with lead wires to a cable that is inserted into a portable recorder (ie, Holter monitor) that records the ECG onto a digital memory device. The patient wears the Holter monitor for 24 hours to detect dysrhythmias or myocardial ischemia that may occur during waking hours or sleep. The patient keeps a diary, noting the time of any symptoms or performance of unusual activities. Data from the digital memory device are uploaded into a computer for analysis, and rhythms that need further evaluation by a clinician are identified. Ambulatory electrocardiography is used to identify the etiology of symptoms (eg, syncope, palpitations) that may be caused by dysrhythmias, to detect episodes of myocardial ischemia, and to evaluate effectiveness of cardiac medications (eg, antiarrhythmic medications, nitrates) or pacemaker function.

Transtelephonic Monitoring

Another method of evaluating the ECG of a patient at home is by transtelephonic monitoring. The patient attaches

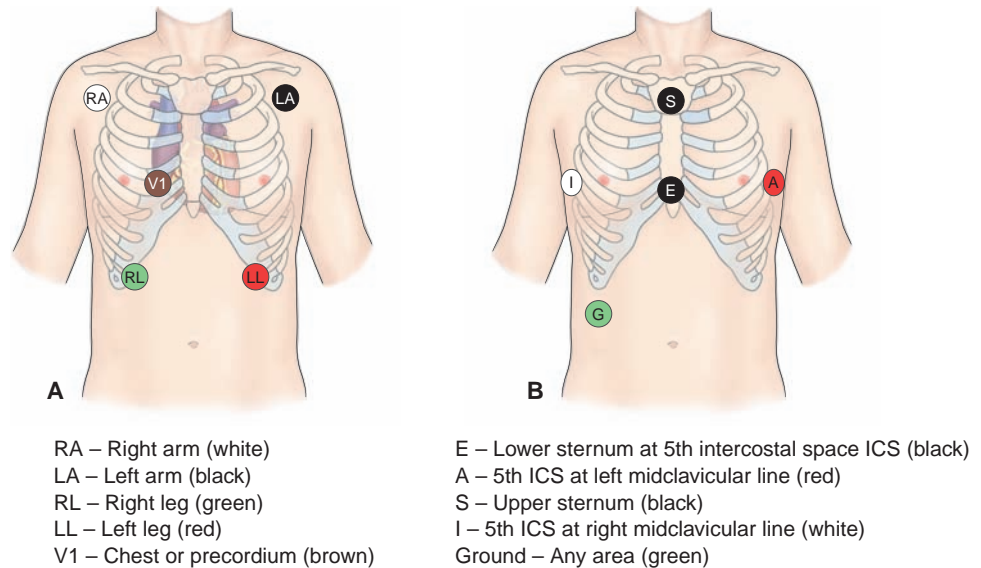

Figure 26-9 Electrode placement used in continuous electrocardiographic monitoring for (A) three-lead system, placement on RA, LA, and LL; four-lead system, placement on RA, LA, RL, and LL; five-lead system, placement on RA, LA, RL, LL, and V1; and (B) EASI-derived 12-lead ECG system.

a specific lead system for transmitting the signals and places a telephone mouthpiece over the transmitter box. The ECG is recorded and evaluated at a remote location, such as a physician's office or community agency. This method is often used for diagnosing dysrhythmias and to evaluate pacemaker function.

Wireless Mobile Cardiac Monitoring Systems

This emerging technology allows health care professionals to monitor and transmit the ECG of patients outside of the hospital or office setting continuously. The wireless method has a number of advantages when compared with Holter and transtelephonic monitoring. It is lightweight and can monitor the patient 24 hours a day 7 days a week. Patients wear a small sensing device that transmits each heartbeat to a small monitor. When a dysrhythmia is detected, the system automatically transmits the patient's ECG to a monitoring center through either the patient's telephone line when at home or through wireless communications systems when outside of the home. This system enhances detection and early treatment of dysrhythmias that might otherwise be diagnosed only after the patient develops serious symptoms.

Cardiac Stress Testing

Normally, the coronary arteries dilate to four times their usual diameter in response to increased metabolic demands for oxygen and nutrients. However, coronary arteries affected by atherosclerosis dilate less, compromising blood flow to the myocardium and causing ischemia. Therefore, abnormalities in cardiovascular function are more likely to be detected during times of increased demand, or "stress." The **cardiac stress test** procedures—the exercise stress test, the pharmacologic stress test, and the mental or emotional stress test—are non-invasive ways to evaluate the response of the cardiovascular system to stress. The stress test helps determine the following: (1) presence of CAD, (2) cause of chest pain, (3) functional capacity of the heart after an MI or heart surgery, (4) effectiveness of antianginal or antiarrhythmic medications, (5)

dysrhythmias that occur during physical exercise, and (6) specific goals for a physical fitness program. Contraindications to stress testing include severe aortic stenosis, acute myocarditis or pericarditis, severe hypertension, suspected left main CAD, HF, and unstable angina. Because complications of stress testing can be life-threatening (MI, cardiac arrest, HF, and severe dysrhythmias), testing facilities must have staff and equipment ready to provide treatment, including advanced cardiac life support.

Stress testing is often combined with echocardiography or radionuclide imaging (discussed later). These techniques are performed during the resting state and immediately after stress testing.

Exercise Stress Testing

Procedure

During an exercise stress test, the patient walks on a treadmill (most common), pedals a stationary bicycle, or uses an arm crank. Exercise intensity progresses according to established protocols. The goal is to increase the heart rate to the "target heart rate," which is 80% to 90% of the maximum predicted heart rate based on the patient's age and gender. During the test, the following are monitored: two or more ECG leads for heart rate, rhythm, and ischemic changes; BP; skin temperature; physical appearance; perceived exertion; and symptoms, including chest pain, dyspnea, dizziness, leg cramping, and fatigue. The test is terminated when the target heart rate is achieved or when the patient experiences chest pain, extreme fatigue, a decrease in BP or pulse rate, serious dysrhythmias or ST-segment changes on the ECG, or other complications. When significant ECG abnormalities occur during the stress test (ST-segment depressions or elevations), the test result is reported as positive and further diagnostic testing such as a cardiac catheterization is required.

Nursing Interventions

In preparation for the exercise stress test, the patient is instructed to fast for 4 hours before the test and to avoid

stimulants such as tobacco and caffeine. Medications may be taken with sips of water. The physician may instruct the patient not to take certain cardiac medications, such as beta-adrenergic blocking agents, before the test. Clothes and sneakers or rubber-soled shoes suitable for exercising are to be worn. The nurse prepares the patient for the stress test by describing how the stress test is performed, the type of monitoring equipment used, the rationale for having an IV catheter inserted, and what symptoms to report. The exercise method is reviewed and patients are asked to put forth their best exercise effort. If the test is to be performed with echocardiography or radionuclide imaging (described in the following section), this information is reviewed as well. After the test, the patient is monitored for 10 to 15 minutes. Once stable, patients may resume their usual activities.

Pharmacologic Stress Testing

Procedure

Patients who are physically disabled or deconditioned will not be able to achieve their target heart rate by exercising on a treadmill or bicycle. Two vasodilating agents, dipyridamole (Persantine) and adenosine (Adenocard), administered IV, are used to mimic the effects of exercise by maximally dilating the coronary arteries. The effects of dipyridamole last about 15 to 30 minutes. The side effects are related to its vasodilating action and include chest discomfort, dizziness, headache, flushing, and nausea. Adenosine has similar side effects, although patients report these symptoms as more severe. Adenosine has an extremely short half-life (less than 10 seconds), so any severe effects subside rapidly. Dipyridamole and adenosine are the agents of choice used in conjunction with radionuclide imaging techniques. Theophylline and other xanthines, such as caffeine, block the effects of dipyridamole and adenosine and must be avoided before these pharmacologic stress tests.

Dobutamine may also be used if the patient cannot exercise. Dobutamine, a synthetic sympathomimetic, increases heart rate, myocardial contractility, and BP, thereby increasing the metabolic demands of the heart. It is the agent of choice when echocardiography is used because of its effects on altering myocardial wall motion (due to enhanced contractility). Dobutamine is also used for patients who have bronchospasm or pulmonary disease and cannot tolerate having doses of theophylline withheld.

Nursing Interventions

In preparation for the pharmacologic stress test, the patient is instructed not to eat or drink anything for at least 4 hours before the test. This includes chocolate, caffeine, caffeine-free coffee, tea, carbonated beverages, or medications that contain caffeine (eg, Anacin, Darvon). If caffeine is ingested before a dipyridamole or adenosine stress test, the test will have to be rescheduled. Patients taking aminophylline, theophylline, or dipyridamole are instructed to stop taking these medications for 24 to 48 hours before the test (if tolerated). The patient is informed about the transient sensations that may occur during infusion of the vasodilating agent, such as flushing or nausea, which will disappear quickly. The patient is instructed to report the

occurrence of any other symptoms during the test to the cardiologist or nurse. The stress test may take about 1 hour, or up to 3 hours if imaging is performed.

Echocardiography

Traditional Echocardiography

Echocardiography is a noninvasive ultrasound test that is used to measure the ejection fraction and examine the size, shape, and motion of cardiac structures. It is particularly useful for diagnosing pericardial effusions; determining chamber size and the etiology of heart murmurs; evaluating the function of heart valves, including prosthetic heart valves; and evaluating ventricular wall motion.

Procedure

Echocardiography involves transmission of high-frequency sound waves into the heart through the chest wall and recording of the return signals. The ultrasound is generated by a handheld transducer applied to the front of the chest. The transducer picks up the echoes, converts them to electrical impulses, and transmits them for display on an oscilloscope and recording on a videotape. An ECG is recorded simultaneously to assist with interpreting the echocardiogram.

Two-dimensional or cross-sectional echocardiography creates a sophisticated, spatially correct image of the heart. Other techniques, such as Doppler and color flow imaging echocardiography, show the direction and velocity of the blood flow through the heart.

Echocardiography may be performed with an exercise or pharmacologic stress test. Images are obtained at rest and then immediately after the target heart rate is reached. Myocardial ischemia from decreased perfusion during stress causes abnormalities in ventricular wall motion and is easily detected by echocardiography. A stress test using echocardiography is considered positive if abnormalities in ventricular wall motion are detected during stress but not during rest. These findings are highly suggestive of CAD and require further evaluation, such as a cardiac catheterization.

Nursing Interventions

Before echocardiography, the nurse informs the patient about the test, explaining that it is painless. Echocardiographic monitoring is performed while a transducer that emits sound waves is moved over the surface of the chest wall. Gel applied to the skin helps transmit the sound waves. Periodically, the patient is asked to turn onto the left side or hold a breath. The test takes about 30 to 45 minutes. If the patient is to undergo an exercise or pharmacologic stress test with echocardiography, information on stress testing is also reviewed with the patient.

Transesophageal Echocardiography

Procedure

A significant limitation of traditional echocardiography is the poor quality of the images produced. Ultrasound loses its clarity as it passes through tissue, lung, and bone. An alternate technique involves threading a small transducer through the mouth and into the esophagus. This technique,

called transesophageal echocardiography (TEE), provides clearer images because ultrasound waves pass through less tissue. A topical anesthetic agent and moderate sedation are used during a TEE because of the discomfort associated with the positioning of the transducer in the esophagus (refer to Chapter 19 for further discussion of moderate sedation). Once the patient is comfortable, the transducer is inserted into the mouth and the patient is asked to swallow several times until it is positioned in the esophagus.

The high-quality imaging obtained during TEE makes this technique an important first-line diagnostic tool for evaluating patients with many types of CVD, including HF, valvular heart disease, dysrhythmias, and many other conditions that place the patient at risk for atrial or ventricular thrombi. Pharmacologic stress testing using dobutamine and TEE can also be performed. It is frequently used during cardiac surgery to continuously monitor the response of the heart to the surgical procedure (eg, valve replacement or coronary artery bypass). Complications are uncommon during TEE, but if they do occur, they are serious. These complications are caused by sedation and impaired swallowing resulting from the topical anesthesia (respiratory depression and aspiration) and by insertion and manipulation of the transducer into the esophagus and stomach (vasovagal response or esophageal perforation). The patient must be assessed before TEE for a history of dysphagia or radiation therapy to the chest, which increases the likelihood of complications.

Nursing Interventions

Prior to the test the nurse provides preprocedure education and ensures that the patient has a clear understanding of what the test entails and why it is being performed, instructs the patient not to eat or drink anything for 6 hours prior to the study, and checks to make sure that informed consent has been obtained. The nurse also inserts an IV line or assesses an existing IV for patency and asks the patient to remove full or partial dentures. During the test, the nurse provides emotional support and monitors level of consciousness, BP, ECG, respiration, and oxygen saturation (SpO₂). During the recovery period, the patient must maintain bed rest with the head of the bed elevated to 45 degrees. Following the moderate sedation policy of the agency, the nurse monitors the patient for dyspnea and assesses vital signs, SpO₂, level of consciousness, and gag reflex as recommended. Food and oral fluids are withheld until the patient is fully alert and the effects of the topical anesthetic agent are reversed, usually 2 hours after the procedure; if gag reflex is intact, the nurse begins feeding with sips of water, then advances to preprocedure diet. The patient is informed that a sore throat may be present for the next 24 hours; he or she is instructed to report the presence of a persistent sore throat, shortness of breath, or difficulty swallowing. If the procedure is performed in an outpatient setting, a family member or friend must be available to transport the patient home from the test site.

Radionuclide Imaging

Radionuclide imaging studies involve the use of radioisotopes to noninvasively evaluate coronary artery perfusion, to detect myocardial ischemia and infarction, and to assess

left ventricular function. **Radioisotopes** are unstable atoms. Thallium 201 (Tl²⁰¹) and technetium 99m (Tc^{99m}) are two radioisotopes used in cardiac nuclear medicine studies that give off small amounts of energy in the form of gamma rays as they decay. When these radioisotopes are injected into the bloodstream, the energy emitted can be detected by a gamma scintillation camera positioned over the body. Planar imaging, used with thallium, provides a one-dimensional view of the heart from three locations. Single photon emission computed tomography (SPECT) provides three-dimensional images. With SPECT, the patient is positioned supine with arms raised above the head, while the camera moves around the patient's chest in a 180- to 360-degree arc to more precisely identify the areas of decreased myocardial perfusion.

Myocardial Perfusion Imaging

Procedure

The radioisotope Tl²⁰¹ crosses into the cells of healthy myocardium and is used to assess myocardial perfusion. It is taken up more slowly and in smaller amounts by myocardial cells that are ischemic from decreased blood flow. However, thallium does not cross into areas of the myocardium that have been scarred by MI.

Thallium is often used with stress testing to assess changes in myocardial perfusion immediately after exercise (or after injection of one of the medications used in stress testing) and at rest. One or two minutes before the end of the stress test, a dose of Tl²⁰¹ is injected into the IV line, allowing the radioisotope to be distributed into the myocardium. Images are taken immediately. Areas that do not show thallium uptake indicate areas of either MI or stress-induced myocardial ischemia. Resting images, taken 3 hours later, help differentiate infarction from ischemia. Infarcted tissue cannot take up thallium regardless of when the scan is taken; the defect remains the same size during exercise or rest. This is called a fixed defect, indicating that there is no perfusion in that area of the myocardium. Ischemic myocardium, on the other hand, recovers in a few hours. If perfusion is restored, thallium crosses into the myocardial cells, and the area of defect on the resting images is either smaller or completely reversed. These reversible defects constitute positive stress test findings. Typically, cardiac catheterization is recommended after a positive test result to determine whether a percutaneous coronary intervention or coronary artery bypass graft surgery is needed.

Another radioisotope used for cardiac imaging is Tc^{99m}. Technetium can be combined with various chemical compounds, giving it an affinity for different types of cells. For example, Tc^{99m} sestamibi (Cardiolite) is distributed to myocardial cells in proportion to its perfusion, making this an excellent tracer for assessing perfusion to the myocardium. The procedure for cardiac imaging using Tc^{99m} sestamibi with stress testing is similar to the procedure for using thallium, but patients receiving Tc^{99m} sestamibi can have their resting images recorded before or after the exercise images.

Nursing Interventions

The patient undergoing nuclear imaging techniques with stress testing should be prepared for the type of stressor to be

used (exercise or drug) and the type of imaging technique (planar or SPECT). The patient may be concerned about receiving a radioactive substance and needs to be reassured that these tracers are safe—the radiation exposure is similar to that of other diagnostic x-ray studies. No postprocedure radiation precautions are necessary.

When providing teaching for a patient undergoing SPECT, the nurse instructs the patient that the arms will need to be positioned over the head for about 20 to 30 minutes. If the patient is physically unable to do this, thallium with planar imaging can be used.

Test of Ventricular Function and Wall Motion

Equilibrium radionuclide angiocardiology (ERNA), also known as multiple-gated acquisition (MUGA) scanning, is a common noninvasive technique that uses a conventional scintillation camera interfaced with a computer to record images of the heart during several hundred heartbeats. The computer processes the data and allows for sequential viewing of the functioning heart. The sequential images are analyzed to evaluate left ventricular function, wall motion, and ejection fraction. MUGA scanning can also be used to assess the differences in left ventricular function during rest and exercise.

The patient is reassured that there is no known radiation danger and is instructed to remain motionless during the scan.

Computed Tomography

Procedure

Computed tomography (CT), also called computerized axial tomographic (CAT) scanning or electron-beam computed tomography (EBCT), uses x-rays to provide cross-sectional images of the chest, including the heart and great vessels. These techniques are used to evaluate cardiac masses and diseases of the aorta and pericardium.

EBCT, also known as the ultrafast CT, is an x-ray scanning technique that results in much faster image acquisition with a higher degree of resolution than traditional x-ray or CT scanning provides. It is used to evaluate bypass graft patency, congenital heart lesions, left and right ventricular muscle mass, chamber volumes, cardiac output, and ejection fraction. For people without previous MI, PCI, or coronary artery bypass surgery, EBCT is used to determine the amount of calcium deposits in the coronary arteries and underlying atherosclerosis. From this scan, a calcium score is derived that predicts the likelihood of cardiac events, such as MI or the need for a revascularization procedure within the next 1 to 2 years.

EBCT is not widely used, but it does show great promise in the early detection of CAD that is not yet clinically significant and that would not be identified by traditional testing methods such as the exercise stress test.

Nursing Interventions

Patient preparation for these tests is the nursing role. The nurse explains to the patient that he or she will be positioned on a table during the scan while the scanner rotates around him or her. The procedure is noninvasive and painless. However, to obtain adequate images, the patient must lie perfectly still during the scanning process. An IV access line is necessary if contrast enhancement is to be used.

Positron Emission Tomography

Positron emission tomography (PET) is a noninvasive scanning method that has been used primarily to study neurologic dysfunction. More recently, and with increasing frequency, PET has been used to diagnose cardiac dysfunction. PET provides more specific information about myocardial perfusion and viability than does TEE or thallium scanning. For cardiac patients, including those without symptoms, PET helps in planning treatment (eg, coronary artery bypass surgery, PCIs). PET also helps evaluate the patency of native and previously grafted vessels and the collateral circulation.

Procedure

During a PET scan, radioisotopes are administered by injection; one compound is used to determine blood flow in the myocardium, and another determines the metabolic function. The PET camera provides detailed three-dimensional images of the distributed compounds. The viability of the myocardium is determined by comparing the extent of glucose metabolism in the myocardium to the degree of blood flow. For example, ischemic but viable tissue will show decreased blood flow and elevated metabolism. For a patient with this finding, revascularization through surgery or angioplasty will probably be indicated to improve heart function. Restrictions of food intake before the test vary among institutions, but because PET evaluates glucose metabolism, the patient's blood glucose level should be within the normal range before testing.

Nursing Interventions

The nurse should instruct the patient to refrain from using tobacco and ingesting caffeine for 4 hours before the PET procedure. The patient should also be reassured that radiation exposure is at safe and acceptable levels, similar to those of other diagnostic x-ray studies.

Magnetic Resonance Angiography

Procedure

Magnetic resonance angiography (MRA) is a noninvasive, painless technique that is used to examine both the physiologic and anatomic properties of the heart. MRA uses a powerful magnetic field and computer-generated pictures to image the heart and great vessels. It is valuable in diagnosing diseases of the aorta, heart muscle, and pericardium, as well as congenital heart lesions. The application of this technique to the evaluation of coronary artery anatomy is limited, however, because the quality of the images obtained during MRA is distorted by respirations, the beating heart, and certain implanted devices (stents and surgical clips). In addition, this technique cannot adequately visualize the small distal coronary arteries as well as conventional angiography that is performed during a cardiac catheterization. Therefore, the latter technique remains the “gold standard” for the diagnosis of CAD.

Nursing Interventions

Because of the magnetic field used during MRA, diagnostic centers where these procedures are performed carefully screen patients for contraindications, including the presence

of a pacemaker, metal plates, prosthetic joints, or other metallic implants that can become dislodged if exposed to MRA. Patients are instructed to remove any jewelry, watches, or other metal items. Transdermal patches that contain a heat-conducting aluminized layer (eg, NicoDerm, Androderm, Transderm Nitro, Transderm Scop, Catapres-TTS) must be removed before MRA to prevent burning of the skin. During an MRA, the patient is positioned supine on a table that is placed into an enclosed imager or tube containing the magnetic field. A patient who is claustrophobic may need to receive a mild sedative before undergoing an MRA. An intermittent clanking or thumping that can be annoying is generated by the magnetic coils, so the patient may be offered a headset to listen to music. The scanner is equipped with a microphone so that the patient can communicate with the staff. The patient is instructed to remain motionless during the scan.

Cardiac Catheterization

Cardiac catheterization is an invasive diagnostic procedure in which radiopaque arterial and venous catheters are introduced into selected blood vessels of the right and left sides of the heart. Catheter advancement is guided by fluoroscopy. Most commonly, the catheters are inserted percutaneously through the blood vessels, or via a cutdown procedure if the patient has poor vascular access. Pressures and oxygen saturation levels in the four heart chambers are measured.

Cardiac catheterization is most frequently used to diagnose CAD, assess coronary artery patency, and determine the extent of atherosclerosis and determine whether revascularization procedures, including PCI or coronary artery bypass surgery, may be of benefit to the patient (see Chapter 28). Cardiac catheterization is also used to diagnose pulmonary arterial hypertension or to treat stenotic heart valves via percutaneous balloon valvuloplasty.

During cardiac catheterization, the patient has one or more IV lines in place for the administration of sedatives, fluids, heparin, and other medications. BP and ECG monitoring is necessary to observe for hemodynamic instability or dysrhythmias. The myocardium can become ischemic and trigger dysrhythmias as catheters are positioned in the coronary arteries or during injection of contrast agents. Resuscitation equipment must be readily available, and staff must be prepared to provide advanced cardiac life support measures as necessary.

Radiopaque contrast agents are used to visualize the coronary arteries. Some contrast agents contain iodine, and the patient is assessed before the procedure for previous reactions to contrast agents or allergies to iodine-containing substances (eg, seafood). If the patient has a suspected or known allergy to the substance, antihistamines or methylprednisolone (Solu-Medrol) may be administered before the procedure. In addition, the following blood tests are performed to identify abnormalities that may complicate recovery: blood urea nitrogen (BUN) and creatinine levels, international normalized ratio (INR) and prothrombin time (PT), activated thromboplastin time (aPTT), hematocrit and hemoglobin values, platelet count, and electrolyte levels.

Patients undergoing cardiac catheterization who have comorbid conditions—including diabetes, HF, preexisting renal disease, hypotension, or dehydration, or who are elderly—are at risk for contrast agent–induced nephropathy

(defined as an increase in the baseline serum creatinine by 25% or more within 2 days of the procedure). Although this form of acute renal failure is usually reversible, temporary dialysis may be necessary. Preventive strategies for high-risk patients include preprocedure and postprocedure hydration with IV infusions of saline or sodium bicarbonate and the antioxidant acetylcysteine (Mucomyst) (Briguori, Airoldi, D'Andrea, et al., 2007).

Diagnostic cardiac catheterization is commonly performed on an outpatient basis and requires 2 to 6 hours of bed rest after the procedure before the patient is allowed to ambulate. Variations in time to ambulation are related to the size of the catheter used during the procedure, the site of catheter insertion (femoral or radial artery), the patient's anticoagulation status, and other variables (eg, advanced age, obesity, bleeding disorder). The use of smaller (4 or 6 Fr) catheters is associated with shorter recovery times. Several options to achieve arterial hemostasis after catheter removal, including manual pressure, mechanical compression devices such as the FemoStop (placed over puncture site for 30 minutes), and percutaneously deployed devices, are used. The latter devices are positioned at the femoral arterial puncture site after completion of the procedure. They deploy a saline-soaked gelatin sponge (QuickSeal), collagen (VasoSeal), sutures (Perclose, Techstar), or a combination of both collagen and sutures (Angio-Seal). Other newer products that expedite arterial hemostasis include external patches (Syvek Patch, Clo-Sur PAD). These products are placed over the puncture site as the catheter is removed and manual pressure is applied for 4 to 10 minutes. Once hemostasis is achieved, the patch is covered with a dressing that remains in place for 24 hours. A number of factors, such as the patient's condition, cost, institutional availability of these devices, and the physician's preference, determine which closure devices are used.

Major benefits of the percutaneously deployed vascular closure devices include reliable, immediate hemostasis and a shorter time on bed rest without a significant increase in bleeding or other complications. However, these devices are not without risk. Bleeding around the closure device, infection, and arterial obstruction due to embolization or local injury to the vessel during placement have all been reported, although they are rare complications (Kalapatapu, Ali, Masroor, et al., 2006).

Patients hospitalized for angina or acute MI who require cardiac catheterization usually return to their hospital rooms for recovery. In some cardiac catheterization laboratories, a PCI (discussed in Chapter 28) may be performed immediately during the catheterization if indicated.

Angiography

Cardiac catheterization is usually performed with angiography, a technique in which a contrast agent is injected into the vascular system to outline the heart and blood vessels. When a specific heart chamber or blood vessel is singled out for study, the procedure is known as selective angiography. Angiography makes use of cineangiograms, a series of rapidly changing films on an intensified fluoroscopic screen that record the passage of the contrast agent through the vascular site or sites. Recording allows for comparison of data over time. Common sites for selective angiography are the aorta, the coronary arteries, and the right and left sides of the heart.

Aortography

An aortogram is a form of angiography that outlines the lumen of the aorta and the major arteries arising from it. In thoracic aortography, a contrast agent is used to study the aortic arch and its major branches. The catheter may be introduced into the aorta using the translumbar or retrograde brachial or femoral artery approach.

Coronary Arteriography

Coronary arteriography involves the introduction of a catheter into the right or left brachial or femoral artery, which is then passed into the ascending aorta and manipulated into the right and left coronary arteries. Angiographic techniques are used to evaluate the degree of atherosclerosis and to determine treatment. They are also used to study suspected congenital anomalies of the coronary arteries.

Right Heart Catheterization

Right heart catheterization usually precedes left heart catheterization. It involves the passage of a catheter from an antecubital or femoral vein into the right atrium, right ventricle, pulmonary artery, and pulmonary arterioles. Pressures and oxygen saturation levels from each of these areas are obtained and recorded.

Although right heart catheterization is considered relatively safe, potential complications include cardiac dysrhythmias, venous spasm, infection of the insertion site, cardiac perforation, and, rarely, cardiac arrest.

Left Heart Catheterization

Left heart catheterization is performed to evaluate the patency of the coronary arteries and the function of the left ventricle and the mitral and aortic valves. Potential complications include dysrhythmias, MI, perforation of the heart or great vessels, and systemic embolization. Left heart catheterization is performed by retrograde catheterization of the left ventricle. In this approach, the physician usually inserts the catheter into the right brachial artery or a femoral artery and advances it into the aorta and left ventricle.

After the procedure, the catheter is carefully withdrawn and arterial hemostasis is achieved using manual pressure or other techniques previously described. If the physician performed an arterial or venous cutdown, the site is sutured and a sterile dressing is applied.

Nursing Interventions

Nursing responsibilities before cardiac catheterization include the following:

- The patient is instructed to fast, usually for 8 to 12 hours, before the procedure. If catheterization is to be performed as an outpatient procedure, a friend, family member, or other responsible person must transport the patient home.
- The patient is informed of the expected duration of the procedure and advised that it will involve lying on a hard table for less than 2 hours.
- The patient is reassured that IV medications are given to maintain comfort.
- The patient is informed about sensations that will be experienced during the catheterization. Knowing

what to expect can help the patient cope with the experience. The nurse explains that an occasional pounding sensation (palpitation) may be felt in the chest because of extra heartbeats that almost always occur, particularly when the catheter tip touches the endocardium. The patient may be asked to cough and to breathe deeply, especially after the injection of contrast agent. Coughing may help disrupt a dysrhythmia and clear the contrast agent from the arteries. Breathing deeply and holding the breath help lower the diaphragm for better visualization of heart structures. The injection of a contrast agent into either side of the heart may produce a flushed feeling throughout the body and a sensation similar to the need to void, which subsides in 1 minute or less.

- The patient is encouraged to express fears and anxieties. The nurse provides teaching and reassurance to reduce apprehension.

Nursing responsibilities after cardiac catheterization may include the following:

- The catheter access site is observed for bleeding or hematoma formation. Peripheral pulses are assessed in the affected extremity (dorsalis pedis and posterior tibial pulses in the lower extremity, radial pulse in the upper extremity) every 15 minutes for 1 hour, and then every 1 to 2 hours until the pulses are stable.
- Temperature, color, and capillary refill of the affected extremity are frequently evaluated, per local nursing standards. The patient is assessed for affected extremity pain, numbness, or tingling sensations that may indicate arterial insufficiency. Any changes are reported promptly.
- Dysrhythmias are carefully screened by observing the cardiac monitor or by assessing the apical and peripheral pulses for changes in rate and rhythm. A vasovagal reaction, consisting of bradycardia, hypotension, and nausea, can be precipitated by a distended bladder or by discomfort from manual pressure that is applied during removal of an arterial or venous catheter. The vasovagal response is reversed by promptly elevating the lower extremities above the level of the heart, infusing a bolus of IV fluid, and administering IV atropine to treat the bradycardia.
- Bed rest is maintained for 2 to 6 hours after the procedure. If manual or mechanical pressure is used, the patient must remain on bed rest for up to 6 hours with the affected leg straight and the head of the bed elevated no greater than 30 degrees. For comfort, the patient may be turned from side to side with the affected extremity straight. If the cardiologist deployed a percutaneous vascular closure device or patch, the nurse checks local nursing care standards and anticipates that the patient will have fewer activity restrictions. The patient may be permitted to ambulate within 2 hours. Analgesic medication is administered as prescribed for discomfort.
- The patient is instructed to report chest pain and bleeding or sudden discomfort from the catheter insertion sites promptly.
- The patient is monitored for contrast agent–induced nephropathy by observing for elevations in serum creatinine levels. Oral and IV hydration is used to increase urinary output and flush the contrast agent from

CHART
26-5

PATIENT EDUCATION

Self-Management After Cardiac Catheterization

After discharge from the hospital for cardiac catheterization, guidelines for self-care include the following:

- For the next 24 hours, do not bend at the waist (to lift anything), strain, or lift heavy objects.
- Avoid tub baths, but shower as desired.
- Talk with your physician about when you may return to work, drive, or resume strenuous activities.
- Call your physician if any of the following occur: bleeding, swelling, new bruising or pain from your procedure puncture site, temperature of 38.6°C (101.5°F) or more.
- If test results show that you have coronary artery disease, talk with your physician about options for treatment, including cardiac rehabilitation programs in your community.

- Talk with your physician and nurse about lifestyle changes to reduce your risk for further or future heart problems, such as quitting smoking, lowering your cholesterol level, initiating dietary changes, beginning an exercise program, or losing weight.
- Your physician may prescribe one or more new medications depending on your risk factors (medications to lower your blood pressure or cholesterol; aspirin or clopidogrel to prevent blood clots). Take all of your medications as instructed. If you feel that any of them are causing side effects, call your physician immediately. Do not stop taking any medications before talking to your doctor.

the urinary tract; accurate intake and output are recorded.

- Patient safety is ensured by instructing the patient to ask for help when getting out of bed the first time after the procedure. The patient is monitored for bleeding from the catheter access site and for orthostatic hypotension, indicated by complaints of dizziness or lightheadedness.

For patients being discharged from the hospital on the same day as the procedure, additional instructions are provided (Chart 26-5).

Electrophysiologic Testing

The electrophysiology study (EPS) is an invasive procedure that plays a major role in the diagnosis and management of serious dysrhythmias. EPS may be indicated for patients with syncope, palpitations, or both, and for survivors of cardiac arrest from ventricular fibrillation (sudden cardiac death). EPS is used to distinguish atrial from ventricular tachycardias when the determination cannot be made from the 12-lead ECG, evaluate how readily a life-threatening dysrhythmia (eg, ventricular tachycardia, ventricular fibrillation) can be induced, evaluate AV node function, evaluate the effectiveness of antiarrhythmic medications in suppressing the dysrhythmia, or determine the need for other therapeutic interventions, such as a pacemaker, implantable cardioverter-defibrillator, or radiofrequency ablation. See Chapter 27 for a detailed discussion of EPS.

Hemodynamic Monitoring

Critically ill patients require continuous assessment of their cardiovascular system to diagnose and manage their complex medical conditions. This type of assessment is achieved by the use of direct pressure monitoring systems, referred to as **hemodynamic monitoring**. Common forms include central venous pressure (CVP), pulmonary artery pressure, and intra-arterial BP monitoring. Patients requiring hemodynamic monitoring are typically cared for in critical care units. Some progressive care units also admit stable patients with CVP or intra-arterial BP monitoring. To perform hemodynamic monitoring, a CVP, pulmonary artery, or arterial catheter is introduced into the appropriate blood vessel

or heart chamber. It is connected to a pressure monitoring system that has several components, including:

- A flush system composed of IV solution (which may include heparin), tubing, stopcocks, and a flush device, which provides continuous and manual flushing of the system
- A pressure bag placed around the flush solution that is maintained at 300 mm Hg of pressure; the pressurized flush system delivers 3 to 5 mL of solution per hour through the catheter to prevent clotting and backflow of blood into the pressure monitoring system
- A transducer to convert the pressure coming from the artery or heart chamber into an electrical signal
- An amplifier or monitor, which increases the size of the electrical signal for display on an oscilloscope

Nurses caring for patients who require hemodynamic monitoring receive training prior to using this sophisticated technology. The following guidelines help ensure safe and effective care:

- The nurse ensures that the system is set up and maintained properly. For example, the pressure monitoring system must be kept patent and free of air bubbles.
- Before the system is used to obtain pressure measurements, the nurse checks that the stopcock of the transducer is positioned at the level of the atrium. This landmark is referred to as the phlebostatic axis (Fig. 26-10). The nurse uses a marker to identify this level on the chest wall, which provides a stable reference point for subsequent pressure readings.
- The nurse establishes the zero reference point in order to ensure that the system is properly functioning at atmospheric pressure. This process is accomplished by placing the stopcock of the transducer at the phlebostatic axis, opening the transducer to air, and activating the zero function key on the bedside monitor. Measurements of CVP, BP, and pulmonary artery pressures can be made with the head of the bed elevated up to 60 degrees, but the system must be repositioned to the phlebostatic axis to ensure an accurate reading.

Complications from use of hemodynamic monitoring systems are uncommon and can include pneumothorax, infection, and air embolism. The nurse observes for signs of pneumothorax during the insertion of catheters using a

Figure 26-10 **A**, The phlebostatic axis is the reference point for the atrium when the patient is positioned supine. It is the intersection of two lines on the chest wall: (1) the midaxillary line drawn between the anterior and posterior surfaces of the chest and (2) the line drawn through the fourth intercostal space. Its location is identified with a skin marker. The stopcock of the transducer used in hemodynamic monitoring is “leveled” at this mark prior to taking pressure measurements. **B**, Measurements can be taken with the head of the bed (HOB) elevated up to 60 degrees. Note the phlebostatic axis changes as the HOB is elevated, so that the stopcock and transducer must be repositioned after each position change.

central venous approach (CVP and pulmonary artery catheters). The longer any of these catheters are left in place (after 72 to 96 hours), the greater the risk of infection. Air emboli can be introduced into the vascular system if the stopcocks attached to the pressure transducers are mishandled during blood drawing, administration of medications, or other procedures that require opening the system to air. Therefore, nurses handling this equipment must demonstrate competence prior to independently caring for a patient requiring hemodynamic monitoring.

Central Venous Pressure Monitoring

CVP is a measurement of the pressure in the vena cava or right atrium. Since the pressure in the vena cava, right atrium, and right ventricle are equal at the end of diastole, the CVP also reflects the filling pressure of the right ventricle (preload). The normal CVP is 2 to 6 mm Hg. It is measured by positioning a catheter in the vena cava or right atrium and connecting it to a pressure monitoring system. The CVP is most valuable when it is monitored over time and correlated with the patient’s clinical status. A CVP greater than 6 mm Hg indicates an elevated right ventricular preload. There are many problems that can cause an elevated CVP, but the most common is due to hypervolemia (excessive fluid circulating in the body) or right-sided HF. In contrast, a low CVP (less than 2 mm Hg) indicates reduced right ventricular preload, which is most often from hypovolemia. Dehydration, excessive blood loss, vomiting or diarrhea, and overdiuresis can result in hypovolemia and a low CVP. This diagnosis can be substantiated when a rapid IV infusion of fluid causes the CVP to increase.

Before insertion of a CVP catheter, the site is prepared by clipping excessive hair, if necessary, and by cleansing with an antiseptic solution. A local anesthetic agent is used. During this sterile procedure, the physician threads a single-lumen or multilumen catheter through the external jugular, antecubital, or femoral vein into the vena cava just above or within the right atrium.

Nursing Interventions

Once the CVP catheter is inserted, it is secured and a dry, sterile dressing is applied. Catheter placement is confirmed

by a chest x-ray, and the site is inspected daily for signs of infection. The dressing and pressure monitoring system are changed according to hospital policy. In general, the dressing is kept dry and air occlusive. Dressing changes are performed using sterile technique. The frequency of CVP measurements is dictated by the patient’s condition and the treatment plan. This catheter can also be used for infusing IV fluids, administering IV medications, and drawing blood specimens.

Pulmonary Artery Pressure Monitoring

Pulmonary artery pressure monitoring is used in critical care for assessing left ventricular function, diagnosing the etiology of shock, and evaluating the patient’s response to medical interventions (eg, fluid administration, vasoactive medications). A pulmonary artery catheter and a pressure monitoring system are used. A variety of catheters are available for cardiac pacing, oximetry, cardiac output measurement, or a combination of functions. Pulmonary artery catheters are balloon-tipped, flow-directed catheters that have distal and proximal lumens (Fig. 26-11). The distal lumen has a port that opens into the pulmonary artery. Once connected by its hub to the pressure monitoring system, it is used to measure continuous pulmonary artery pressures. The proximal lumen has a port that opens into the right atrium. It is used to administer IV medications and fluids or to monitor right atrial pressures (ie, CVP). Each catheter has a balloon inflation hub and valve. A syringe is connected to the hub, which is used to inflate or deflate the balloon with air (1.5-mL capacity). The valve opens and closes the balloon inflation lumen.

A pulmonary artery catheter with specialized capabilities has additional components. For example, the thermodilution catheter has three additional features that enable it to measure cardiac output: a thermistor connector attached to the cardiac output computer of the bedside monitor, a proximal injectate port used for injecting fluids when obtaining the cardiac output, and a thermistor (positioned near the distal port) (see Fig. 26-11).

The pulmonary artery catheter, covered with a sterile sleeve, is inserted into a large vein (subclavian, jugular, or femoral) through a sheath. The sheath is equipped with a side port for infusing IV fluids and medications. The

Figure 26-11 The pulmonary artery catheter used for obtaining pressure measurements and cardiac output. **A**, The pressure monitoring system is connected to the distal lumen hub. **B**, Intravenous solutions are infused through the proximal infusion and injectate lumen hubs. **C**, An air-filled syringe connected to the balloon inflation valve is used for balloon inflation during catheter insertion and pulmonary artery wedge pressure measurements. **D**, To obtain cardiac output, the thermistor connector is inserted into the cardiac output component of the bedside cardiac monitor and 5 to 10 mL of normal saline is injected in 4 seconds into the proximal injectate port. **E**, The thermistor located near the balloon is used to calculate the cardiac output. Redrawn courtesy of Baxter Healthcare Corporation, Edwards Critical Care Division, Santa Ana, California.

catheter is then passed into the vena cava and right atrium. In the right atrium, the balloon tip is inflated, and the catheter is carried rapidly by the flow of blood through the tricuspid valve into the right ventricle, through the pulmonic valve, and into a branch of the pulmonary artery. When the catheter reaches the pulmonary artery, the balloon is deflated and the catheter is secured with sutures (Fig. 26-12). Fluoroscopy may be used during insertion to visualize the progression of the catheter through the right heart chambers to the pulmonary artery. This procedure can be performed in the operating room, in the cardiac catheterization laboratory, or at the bedside in the critical care unit. During insertion of the pulmonary artery catheter, the bedside monitor is observed for pressure and waveform changes, as well as dysrhythmias as the catheter progresses through the right heart to the pulmonary artery.

Once the catheter is in position, the following are measured: right atrial, pulmonary artery systolic, pulmonary artery diastolic, mean pulmonary artery, and pulmonary artery wedge pressures (see Fig. 26-2 for normal chamber pressures). Monitoring of the pulmonary artery diastolic and pulmonary artery wedge pressures is particularly important in critically ill patients because they are used to evaluate left ventricular filling pressures (ie, left ventricular preload).

It is important to note that the pulmonary artery wedge pressure is achieved by inflating the balloon tip, which causes it to float more distally into a smaller portion of the pulmonary artery until it is wedged into position. This is an occlusive maneuver that impedes blood flow through that segment of the pulmonary artery. Therefore, the wedge pressure is measured immediately and the balloon is deflated promptly to restore blood flow.

NURSING ALERT

After measuring the pulmonary artery wedge pressure, the nurse ensures that the balloon is deflated and that the catheter has returned to its normal position. This important intervention is verified by evaluating the pulmonary artery pressure waveform displayed on the bedside monitor.

Nursing Interventions

Catheter site care is essentially the same as for a CVP catheter. Similar to CVP measurement, the transducer must be positioned at the phlebostatic axis to ensure accurate readings (see Fig. 26-10). Serious complications include pulmonary artery rupture, pulmonary thromboembolism, pulmonary infarction, catheter kinking, dysrhythmias, and air embolism.

Intra-Arterial Blood Pressure Monitoring

Intra-arterial BP monitoring is used to obtain direct and continuous BP measurements in critically ill patients who have severe hypertension or hypotension. Arterial catheters are also useful when arterial blood gas measurements and blood samples need to be obtained frequently.

Once an arterial site is selected, usually the radial artery, circulation to the involved extremity is assessed by the Allen test or an ultrasonic Doppler study because placing an arterial catheter can further impede perfusion to an area that has poor circulation. As a result, the tissue distal to the cannulated artery can become ischemic or necrotic. The Allen test is used to evaluate perfusion of the hand and fingers by the radial and ulnar arteries. To perform the Allen test, the hand is elevated and the patient is asked to make a fist for 30 seconds. The nurse compresses the radial and ulnar arteries simultaneously, causing the hand to blanch. After the patient opens the fist, the nurse releases the pressure on the ulnar artery. If blood flow is restored (hand turns pink) within 6 seconds, the circulation to the hand may be adequate enough to tolerate placement of a radial artery catheter. However, an ultrasonic Doppler is the most accurate method for assessing arterial perfusion of the hand.

Nursing Interventions

Site preparation and care are the same as for CVP catheters. The catheter flush solution is the same as for pulmonary artery catheters. A transducer is attached, and pressures are measured in mm Hg. The nurse monitors the patient for complications, which include local obstruction with distal ischemia, external hemorrhage, massive ecchymosis, dissection, air embolism, blood loss, pain, arteriospasm, and infection.

Figure 26-12 Pulmonary artery (PA) catheter and pressure monitoring systems. **A**, Bedside monitor that connects with cables to **(B)** the pressure monitoring systems (includes intravenous [IV] solution in a pressure bag, IV tubing, and two transducers with stopcocks and flush devices). This system connects to **(C)** the proximal infusion port that opens in the right atria and is used to infuse fluids or medications and monitor central venous pressures and **(D)** the distal infusion port. This port opens in the PA and is used to monitor PA pressures. **E**, The thermistor connector is attached to the bedside cardiac monitor to obtain cardiac output. **F**, An air-filled syringe is attached to the balloon inflation valve during catheter insertion and measurement of PA wedge pressure. **G**, PA catheter positioned in the pulmonary artery. Note the sterile sleeve over the PA catheter. The PA catheter is threaded through the sheath until it reaches the desired position in the PA. The side port on the sheath is used to infuse medications or fluids. ECG, electrocardiogram; RA, right atrium.

CRITICAL THINKING EXERCISES

1 During change-of-shift report, the off-going nurse tells you that she heard abnormal sounds while obtaining apical pulses on an elderly female patient, who has had a long history of coronary artery disease and heart failure. She is recovering from a recent myocardial infarction and is being treated now for new-onset atrial fibrillation. Name five types of abnormal heart sounds and explain the pathophysiology

of each sound. Describe the quality of these sounds and their timing in relation to the cardiac cycle. If you suspect a murmur, what six characteristics do you identify to determine the underlying cause? Given this patient's medical history, what do you think caused those abnormal heart sounds?

2 While walking by the central monitoring station you hear an alarm. You notice that this alarm sounded several times within the last 30 minutes. The message "cannot

analyze” is flashing at the central station. Is hearing an alarm from a patient who has an order for continuous ECG monitoring a serious concern? What two common problems might be preventing the monitor from analyzing this patient’s rhythm? What will you do to troubleshoot this situation?

EBP 3 Your patient was transferred today from the coronary intensive care unit after experiencing an ST-segment elevation myocardial infarction. As you are getting him settled in his room, he tells you that he had an asthma attack that was so severe he went to the emergency department. Upon further discussion, you discover that his only symptoms have been increasing episodes of shortness of breath with mild activity and more fatigue than usual. He attributes these symptoms to smoking and being out of shape. What additional information might you need to help explain why he did not experience chest symptoms during his MI? What additional questions might you ask this patient to get a better understanding of his illness perception? What is the strength of the evidence that supports the relationship between ACS symptoms and the symptoms your patient experienced? Why is it important for this patient to have a clear understanding of his diagnosis, symptoms, and health regimen prior to discharge from the hospital?

chapter 27

Management of Patients With Dysrhythmias and Conduction Problems

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Correlate the components of the normal electrocardiogram (ECG) with physiologic events of the heart.
- 2 Define the ECG as a waveform that represents the cardiac electrical event in relation to the lead (placement of electrodes).
- 3 Analyze elements of an ECG rhythm strip: ventricular and atrial rate, ventricular and atrial rhythm, QRS complex and shape, QRS duration, P wave and shape, PR interval, and P:QRS ratio.
- 4 Identify the ECG criteria, causes, and management of several dysrhythmias, including conduction disturbances.
- 5 Use the nursing process as a framework for care of patients with dysrhythmias.
- 6 Compare the different types of pacemakers, their uses, possible complications, and nursing implications.
- 7 Describe the nursing management of patients with implantable cardiac devices.
- 8 Describe the key points of using a defibrillator.
- 9 Describe the purpose of an implantable cardioverter defibrillator, the types available, and the nursing implications.
- 10 Describe invasive methods to diagnose and treat recurrent dysrhythmias and discuss the nursing implications.

GLOSSARY

ablation: purposeful destruction of heart muscle cells, usually in an attempt to control a dysrhythmia
antiarrhythmic medication: a medication that suppresses or prevents a dysrhythmia
automaticity: ability of the cardiac cells to initiate an electrical impulse
cardioversion: electrical current administered in synchrony with the patient's own QRS complex to stop a dysrhythmia
chronotropy: rate of impulse formation
conduction: transmission of electrical impulses from one cell to another
defibrillation: electrical current administered to stop a dysrhythmia, not synchronized with the patient's QRS complex
depolarization: process by which cardiac muscle cells change from a more negatively charged to a more positively charged intracellular state
dromotropy: conduction velocity

GLOSSARY (Continued)

dysrhythmia: disorder of the formation or conduction (or both) of the electrical impulse within the heart, altering the heart rate, heart rhythm, or both and potentially causing altered blood flow (also referred to as arrhythmia)
elective replacement indicator (ERI): a signal produced by a pacemaker when it is interrogated to indicate a near-depleted battery
implantable cardioverter defibrillator (ICD): a device implanted into the chest to treat dysrhythmias
inhibited: in reference to pacemakers, term used to describe the pacemaker withholding an impulse (not firing)
inotropy: force of myocardial contraction
P wave: the part of an electrocardiogram (ECG) that reflects conduction of an electrical impulse through the atrium; atrial depolarization
paroxysmal dysrhythmia: a dysrhythmia that has a sudden onset and/or termination and is usually of short duration
PP interval: the duration between the beginning of one P wave and the beginning of the next P wave; used to calculate atrial rate and rhythm
PR interval: the part of an ECG that reflects conduction of an electrical impulse from the sinoatrial (SA) node through the atrioventricular (AV) node
proarrhythmic: an agent (eg, a medication) that causes or exacerbates a dysrhythmia
QRS complex: the part of an ECG that reflects conduction of an electrical impulse through the ventricles; ventricular depolarization
QT interval: the part of an ECG that reflects the time from ventricular depolarization through repolarization
repolarization: process by which cardiac muscle cells return to a more negatively charged intracellular condition, their resting state
RR interval: the duration between the beginning of one QRS complex and the beginning of the next QRS complex; used to calculate ventricular rate and rhythm
sensitivity: the level that the intracardiac electrical activity must exceed in order to be sensed by a pacemaker
sinus rhythm: electrical activity of the heart initiated by the sinoatrial (SA) node
ST segment: the part of an ECG that reflects the end of the QRS complex to the beginning of the T wave
supraventricular tachycardia (SVT): a rhythm that originates in the conduction system above the ventricles
T wave: the part of an ECG that reflects repolarization of the ventricles
TP interval: the part of an ECG that reflects the time between the end of the T wave and the beginning of the next P wave; used to identify the isoelectric line
triggered: in reference to pacemakers, term used to describe the release of an impulse in response to some stimulus
U wave: the part of an ECG that may reflect Purkinje fiber repolarization; usually it is not seen unless a patient's serum potassium level is low
ventricular tachycardia (VT): a rhythm that originates in the ventricles

Without a regular rate and rhythm, the heart may not perform efficiently as a pump to circulate oxygenated blood and other life-sustaining nutrients to all of the body's tissues and organs (including the heart itself). With an irregular or erratic rhythm, the heart is considered to be dysrhythmic (sometimes called arrhythmic). This is a potentially dangerous condition.

Dysrhythmias

Dysrhythmias are disorders of the formation or conduction (or both) of the electrical impulse within the heart. These disorders can cause disturbances of the heart rate, the heart rhythm, or both. Dysrhythmias may initially be evidenced by the hemodynamic effect they cause (eg, a change in conduction may change the pumping action of the heart and cause decreased blood pressure). Dysrhythmias are diagnosed by analyzing the electrocardiographic (ECG) waveform. Their treatment is based on frequency and severity of symptoms produced. Dysrhythmias are named according to the site of origin of the impulse and the mechanism of formation or conduction involved (Chart 27-1). For example, an impulse that originates in the sinoatrial (SA) node and at a slow rate is called sinus bradycardia.

Normal Electrical Conduction

The electrical impulse that stimulates and paces the cardiac muscle normally originates in the SA node, an area located near the superior vena cava in the right atrium. Usually, the electrical impulse occurs at a rate of 60 to 100 times a minute in the adult. The electrical impulse quickly travels from the sinus node through the atria to the atrioventricular (AV) node (Fig. 27-1); this process is known as **conduction**. The electrical stimulation of the muscle cells of the atria causes them to contract. The structure of the AV node slows the electrical impulse, giving the atria time to contract and fill the ventricles with blood. This part of atrial contraction is frequently referred to as the “atrial kick” and accounts for nearly one third of the volume ejected during ventricular contraction. The electrical impulse then travels very quickly through the bundle of His to the right and left

bundle branches and the Purkinje fibers, located in the ventricular muscle. The electrical stimulation of the muscle cells of the ventricles in turn causes the mechanical contraction of the ventricles (systole). The cells repolarize and the ventricles then relax (diastole). The electrical impulse causes the mechanical contraction of the heart muscle that follows.

The electrical stimulation is called **depolarization**, and the mechanical contraction is called systole. Electrical relaxation is called **repolarization**, and mechanical relaxation is called diastole. The process from sinus node electrical impulse generation through ventricular repolarization completes the electromechanical circuit, and the cycle begins again. See Chapter 26 for a more complete explanation of cardiac function.

Influences on Heart Rate and Contractility

The heart rate is influenced by the autonomic nervous system, which consists of sympathetic and parasympathetic fibers. Sympathetic nerve fibers (also referred to as adrenergic fibers) are attached to the heart and arteries as well as several other areas in the body. Stimulation of the sympathetic system increases heart rate (positive **chronotropy**), conduction through the AV node (positive **dromotropy**), and the force of myocardial contraction (positive **inotropy**). Sympathetic stimulation also constricts peripheral blood vessels, therefore increasing blood pressure. Parasympathetic nerve fibers are also attached to the heart and arteries. Parasympathetic stimulation reduces the heart rate (negative chronotropy), AV conduction (negative dromotropy), and the force of atrial myocardial contraction. The decreased sympathetic stimulation results in dilation of arteries, thereby lowering blood pressure.

Manipulation of the autonomic nervous system may increase or decrease the incidence of dysrhythmias. Increased sympathetic stimulation (eg, caused by exercise, anxiety, fever, or administration of catecholamines, such as dopamine [Intropin], aminophylline, or dobutamine [Dobutrex]) may increase the incidence of dysrhythmias. Decreased sympathetic stimulation (eg, with rest, anxiety-reduction methods such as therapeutic communication or meditation, or administration of beta-adrenergic blocking agents) may decrease the incidence of dysrhythmias.

The Electrocardiogram

The electrical impulse that travels through the heart can be viewed by means of electrocardiography, the end product of which is an ECG. Each phase of the cardiac cycle is reflected by specific waveforms on the screen of a cardiac monitor or on a strip of ECG graph paper.

An ECG is obtained by slightly abrading the skin with a clean dry gauze pad and placing electrodes on the body at specific areas. Electrodes come in various shapes and sizes, but they all have two components: (1) an adhesive substance that attaches to the skin to secure the electrode in place and (2) a substance that reduces the skin's electrical impedance and promotes detection of the electrical current.

The number and placement of the electrodes depend on the type of ECG needed. Most continuous monitors use two to five electrodes, usually placed on the limbs and the chest. These electrodes create an imaginary line, called a lead,

Figure 27-1 Relationship of ECG complex, lead system, and electrical impulse. The heart conducts electrical activity, which the ECG measures and shows. The configurations of electrical activity displayed on the ECG vary depending on the lead (or view) of the ECG and on the rhythm of the heart. Therefore, the configuration of a normal rhythm tracing from lead I will differ from the configuration of a normal rhythm tracing from lead II, lead II will differ from lead III, and so on. The same is true for abnormal rhythms and cardiac disorders. To make an accurate assessment of the heart's electrical activity or to identify where, when, and what abnormalities occur, the ECG needs to be evaluated from every lead, not just from lead II. Here the different areas of electrical activity are identified by color. RA, right arm; LA, left arm; SA, sinoatrial; AV, atrioventricular; LL, left leg.

that serves as a reference point from which the electrical activity is viewed. A lead is like an eye of a camera: It has a narrow peripheral field of vision, looking only at the electrical activity directly in front of it. Therefore, the ECG waveforms that appear on the paper or cardiac monitor represent the electrical current in relation to the lead (see Fig. 27-1). A change in the waveform can be caused by a change in the electrical current (where it originates or how it is conducted) or by a change in the lead.

Obtaining an Electrocardiogram

Electrodes are attached to cable wires, which are connected to one of the following:

- An ECG machine placed at the patient's side for an immediate recording (standard 12-lead ECG)

- A cardiac monitor at the patient's bedside for continuous reading; this kind of monitoring, usually called hardwire monitoring, is used in intensive care units
- A small box that the patient carries that continuously transmits the ECG information by radiowaves to a central monitor located elsewhere (called telemetry)
- A small, lightweight tape recorder-like machine (called ambulatory ECG monitoring or a Holter monitor) that the patient wears and that continuously records the ECG on a tape, which is later viewed and analyzed with a scanner

A patient may undergo an electrophysiology (EP) study in which electrodes are placed inside the heart in order to obtain an intracardiac ECG. This is used not only to diagnose the dysrhythmia, but also to determine the most effective

Figure 27-2 ECG electrode placement. The standard left precordial leads are V₁—fourth intercostal space, right sternal border; V₂—fourth intercostal space, left sternal border; V₃—diagonally between V₂ and V₄; V₄—fifth intercostal space, left midclavicular line; V₅—same level as V₄, anterior axillary line; V₆ (not illustrated)—same level as V₄ and V₅, midaxillary line. The right precordial leads, placed across the right side of the chest, are the mirror opposite of the left leads. RA, right arm; LA, left arm; RL, right leg; LL, left leg. Adapted from Molle, E. A., Kronenberger, J., West-Stack, C., et al. (2005). *Lippincott Williams & Wilkins's pocket guide to medical assisting* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

treatment plan. However, because an EP study is invasive, it is performed in the hospital and may require that the patient be admitted. (A more in-depth discussion is found later in this chapter.)

The placement of electrodes for continuous monitoring, telemetry, or Holter monitoring varies with the type of technology, the purpose of monitoring, and the standards of the health care facility. For a standard 12-lead ECG, 10 electrodes (6 on the chest and 4 on the limbs) are placed on the body (Fig. 27-2). To prevent interference from the electrical activity of skeletal muscle, the limb electrodes

are usually placed on areas that are not bony and that do not have significant movement. These limb electrodes provide the first six leads: leads I, II, III, aVR, aVL, and aVF. The six chest electrodes are applied to the chest at very specific areas. The chest electrodes provide the V or precordial leads, V₁ through V₆. To locate the fourth intercostal space and the placement of V₁, the sternal angle and then the sternal notch, which is about 1 or 2 inches below the sternal angle, are located. When the fingers are moved to the patient's immediate right, the second rib can be palpated. The second intercostal space is the indentation felt just below the second rib.

Locating the specific intercostal space is critical for correct chest electrode placement. Errors in diagnosis can occur if electrodes are incorrectly placed. Sometimes, when the patient is in the hospital and needs to be monitored closely for ECG changes, the chest electrodes are left in place to ensure the same placement for follow-up ECGs.

A standard 12-lead ECG reflects the electrical activity primarily in the left ventricle. Placement of additional electrodes for other leads may be needed to obtain more complete information. For example, in patients with suspected right-sided heart damage, right-sided precordial leads are required to evaluate the right ventricle (see Fig. 27-2).

Interpreting the Electrocardiogram

The ECG waveform reflects the function of the heart's conduction system, which normally initiates and conducts the electrical activity, in relation to the lead. The ECG offers important information about the electrical activity of the heart. ECG waveforms are printed on graph paper that is divided by light and dark vertical and horizontal lines at standard intervals (Fig. 27-3). Time and rate are measured on the horizontal axis of the graph, and amplitude or voltage is measured on the vertical axis. When an ECG waveform moves toward the top of the paper, it is called a positive deflection. When it moves toward the bottom of the paper, it is called a negative deflection. When an ECG is reviewed, each waveform should be examined and compared with the others.

Waves, Complexes, and Intervals

The ECG is composed of waveforms (including the P wave, the QRS complex, the T wave, and possibly a U wave) and of segments and intervals (including the PR interval, the ST segment, and the QT interval) (see Fig. 27-3).

The **P wave** represents the electrical impulse starting in the sinus node and spreading through the atria. Therefore, the P wave represents atrial depolarization. It is normally 2.5 mm or less in height and 0.11 seconds or less in duration.

The **QRS complex** represents ventricular depolarization. Not all QRS complexes have all three waveforms. The Q wave is the first negative deflection after the P wave. The Q wave is normally less than 0.04 seconds in duration and less than 25% of the R-wave amplitude. The R wave is the first positive deflection after the P wave, and the S wave is the first negative deflection after the R wave. When a wave is less than 5 mm in height, small letters (q, r, s) are used; when a wave is taller than 5 mm, capital letters (Q, R, S) are used to label the waves. The QRS complex is normally less than 0.12 seconds in duration.

The **T wave** represents ventricular repolarization (when the cells regain a negative charge; also called the resting

Figure 27-3 ECG graph and commonly measured components. Each small box represents 0.04 seconds on the horizontal axis and 1 mm or 0.1 millivolt on the vertical axis. The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex; the QRS complex is measured from the beginning of the Q wave to the end of the S wave; the QT interval is measured from the beginning of the Q wave to the end of the T wave; and the TP interval is measured from the end of the T wave to the beginning of the next P wave.

state). It follows the QRS complex and is usually the same direction as the QRS complex. Atrial repolarization also occurs but is not visible on the ECG because it occurs at the same time as the QRS.

The **U wave** is thought to represent repolarization of the Purkinje fibers, but it sometimes is seen in patients with hypokalemia (low potassium levels), hypertension, or heart disease. If present, the U wave follows the T wave and is usually smaller than the P wave. If tall, it may be mistaken for an extra P wave.

The **PR interval** is measured from the beginning of the P wave to the beginning of the QRS complex and represents the time needed for sinus node stimulation, atrial depolarization, and conduction through the AV node before ventricular depolarization. In adults, the PR interval normally ranges from 0.12 to 0.20 seconds in duration.

The **ST segment**, which represents early ventricular repolarization, lasts from the end of the QRS complex to the beginning of the T wave. The beginning of the ST segment is usually identified by a change in the thickness or angle of the terminal portion of the QRS complex. The end of the ST segment may be more difficult to identify because it merges into the T wave. The ST segment is normally isoelectric (see discussion of TP interval). It is analyzed to identify whether it is above or below the isoelectric line, which may be, among other signs and symptoms, a sign of cardiac ischemia (see Chapter 28).

The **QT interval**, which represents the total time for ventricular depolarization and repolarization, is measured from the beginning of the QRS complex to the end of the T wave. The QT interval varies with heart rate, gender, and age, and the measured interval needs to be corrected for these variables through specific calculations. Several ECG interpretation books contain charts for these calculations. The QT interval is usually 0.32 to 0.40 seconds in duration if the heart rate is 65 to 95 bpm (beats per minute). If the

QT interval becomes prolonged, the patient may be at risk for a lethal ventricular dysrhythmia called torsades de pointes.

The **TP interval** is measured from the end of the T wave to the beginning of the next P wave, an isoelectric period (see Fig. 27-3). When no electrical activity is detected, the line on the graph remains flat; this is called the isoelectric line. The ST segment is compared with the TP interval to detect changes from the line on the graph during the isoelectric period.

The **PP interval** is measured from the beginning of one P wave to the beginning of the next. The PP interval is used to determine atrial rhythm and atrial rate. The **RR interval** is measured from one QRS complex to the next QRS complex. The RR interval is used to determine ventricular rate and rhythm (Fig. 27-4).

Determining Heart Rate From the Electrocardiogram

Heart rate can be obtained from the ECG strip by several methods. A 1-minute strip contains 300 large boxes and 1500 small boxes. Therefore, an easy and accurate method of determining heart rate with a regular rhythm is to count the number of small boxes within an RR interval and divide 1500 by that number. If, for example, there are 10 small boxes between two R waves, the heart rate is $1500/10$, or 150; if there are 25 small boxes, the heart rate is $1500/25$, or 60 (see Fig. 27-4A).

An alternative but less accurate method for estimating heart rate, which is usually used when the rhythm is irregular, is to count the number of RR intervals in 6 seconds and multiply that number by 10. The top of the ECG paper is usually marked at 3-second intervals, which is 15 large boxes horizontally (see Fig. 27-4B). The RR intervals are counted, rather than QRS complexes, because a computed heart rate based on the latter might be inaccurately high.

Figure 27-4 **A**, Ventricular and atrial heart rate determination with a regular rhythm: 1500 divided by the number of small boxes between two P waves (atrial rate) or between two R waves (ventricular rate). In this example, there are 25 small boxes between both the R waves and the P waves, so the heart rate is 60 beats per minute. **B**, Heart rate determination if the rhythm is irregular. There are approximately seven RR intervals in 6 seconds, so there are about 70 RR intervals in 60 seconds ($7 \times 10 = 70$). The ventricular heart rate is 70 beats per minute.

The same methods may be used for determining atrial rate, using the PP interval instead of the RR interval.

Determining Heart Rhythm From the Electrocardiogram

The rhythm is often identified at the same time the rate is determined. The RR interval is used to determine ventricular rhythm and the PP interval is used to determine atrial rhythm. If the intervals are the same or if the difference between the intervals is less than 0.8 seconds throughout the strip, the rhythm is called regular. If the intervals are different, the rhythm is called irregular.

Analyzing the Electrocardiogram Rhythm Strip

The ECG must be analyzed in a systematic manner to determine the patient's cardiac rhythm and to detect dysrhythmias and conduction disorders, as well as evidence of myocardial ischemia, injury, and infarction. Chart 27-2 is an example of a method that can be used to analyze the patient's rhythm.

Once the rhythm has been analyzed, the findings are compared with and matched to the ECG criteria for dysrhythmias to determine a diagnosis. It is important for the nurse to assess the patient to determine the physiologic effect of the dysrhythmia and to identify possible causes. Treatment of a dysrhythmia is based on clinical evaluation of the patient with identification of the dysrhythmia's etiology and effect, not on its presence alone.

Normal Sinus Rhythm

Normal **sinus rhythm** occurs when the electrical impulse starts at a regular rate and rhythm in the sinus node and travels through the normal conduction pathway. Normal sinus rhythm has the following characteristics (Fig. 27-5):

Ventricular and atrial rate: 60 to 100 in the adult

Ventricular and atrial rhythm: Regular

QRS shape and duration: Usually normal, but may be regularly abnormal

P wave: Normal and consistent shape; always in front of the QRS

PR interval: Consistent interval between 0.12 and 0.20 seconds

P:QRS ratio: 1:1

Types of Dysrhythmias

Dysrhythmias include sinus, atrial, junctional, and ventricular dysrhythmias and their various subcategories.

Sinus Node Dysrhythmias

Sinus Bradycardia. Sinus bradycardia occurs when the sinus node creates an impulse at a slower-than-normal rate.

Chart 27-2 • Interpreting Dysrhythmias: Systematic Analysis of the Electrocardiogram

When examining an ECG rhythm strip to learn more about a patient's dysrhythmia:

1. Determine the ventricular rate.
2. Determine the ventricular rhythm.
3. Determine QRS duration.
4. Determine whether the QRS duration is consistent throughout the strip. If not, identify other duration.
5. Identify QRS shape; if not consistent, then identify other shapes.
6. Identify P waves; is there a P in front of every QRS?
7. Identify P-wave shape; identify whether it is consistent or not.
8. Determine the atrial rate.
9. Determine the atrial rhythm.
10. Determine each PR interval.
11. Determine if the PR intervals are consistent, irregular but with a pattern to the irregularity, or just irregular.
12. Determine how many P waves for each QRS (P:QRS ratio).

In many cases, the nurse may use a checklist and document the findings next to the appropriate ECG criterion.

Figure 27-5 Normal sinus rhythm in lead II.

Causes include lower metabolic needs (eg, sleep, athletic training, hypothyroidism), vagal stimulation (eg, from vomiting, suctioning, severe pain, extreme emotions), medications (eg, calcium channel blockers, amiodarone, beta-blockers), idiopathic sinus node dysfunction, increased intracranial pressure (ICP), and myocardial infarction (MI), especially of the inferior wall. Other possible contributing factors in clinically significant bradycardia include what are referred to as the H's and the T's: hypovolemia, hypoxia, hydrogen ion (acidosis), hypokalemia or hyperkalemia, hypoglycemia, and hypothermia; toxins, tamponade (cardiac), tension pneumothorax, thrombosis (coronary or pulmonary), and trauma (hypovolemia, increased ICP) (American Heart Association [AHA], 2005). Sinus bradycardia has the following characteristics (Fig. 27-6):

Ventricular and atrial rate: Less than 60 in the adult

Ventricular and atrial rhythm: Regular

QRS shape and duration: Usually normal, but may be regularly abnormal

P wave: Normal and consistent shape; always in front of the QRS

PR interval: Consistent interval between 0.12 and 0.20 seconds

P:QRS ratio: 1:1

All characteristics of sinus bradycardia are the same as those of normal sinus rhythm, except for the rate. The patient is assessed to determine the hemodynamic effect and the possible cause of the dysrhythmia. If the decrease in heart rate results from stimulation of the vagus nerve, such as with bearing down during defecation or vomiting, attempts are made to prevent further vagal stimulation. If the bradycardia is caused by a medication such as a beta-blocker,

the medication may be withheld. If the slow heart rate causes significant hemodynamic changes resulting in shortness of breath, acute alteration of mental status, angina, hypotension, ST-segment changes, or premature ventricular complexes, treatment is directed toward increasing the heart rate. If the slow heart rate is due to sinus node dysfunction, which most often occurs in people older than 50 years of age, decreased exercise capacity, fatigue, unexplained confusion, or memory loss may result (Fuster, Walsh & O'Rourke, 2008).

Atropine, 0.5 mg given rapidly as an intravenous (IV) bolus every 3 to 5 minutes to a maximum total dose of 3 mg, is the medication of choice in treating symptomatic sinus bradycardia. It blocks vagal stimulation, thus allowing a normal rate to occur. Rarely, catecholamines and emergency transcutaneous pacing also are implemented.

Sinus Tachycardia. Sinus tachycardia occurs when the sinus node creates an impulse at a faster-than-normal rate. Causes may include the following:

- Physiologic or psychological stress (eg, acute blood loss, anemia, shock, hypervolemia, hypovolemia, heart failure, pain, hypermetabolic states, fever, exercise, anxiety)
- Medications that stimulate the sympathetic response (eg, catecholamines, aminophylline, atropine), stimulants (eg, caffeine, alcohol, nicotine), and illicit drugs (eg, amphetamines, cocaine, Ecstasy)
- Enhanced automaticity of the SA node and/or excessive sympathetic tone with reduced parasympathetic tone, a condition called inappropriate sinus tachycardia (Blomström-Lundqvist, Scheinman, Aliot, et al., 2003)

Figure 27-6 Sinus bradycardia in lead II.

Figure 27-7 Sinus tachycardia in lead II.

- Autonomic dysfunction, which results in a type of sinus tachycardia called postural orthostatic tachycardia syndrome (POTS). Patients with POTS have tachycardia without hypotension within 5 to 10 minutes of standing or with head-upright tilt testing.

Sinus tachycardia has the following characteristics (Fig. 27-7):

Ventricular and atrial rate: Greater than 100 in the adult, but usually less than 120

Ventricular and atrial rhythm: Regular

QRS shape and duration: Usually normal, but may be regularly abnormal

P wave: Normal and consistent shape; always in front of the QRS, but may be buried in the preceding T wave

PR interval: Consistent interval between 0.12 and 0.20 seconds

P:QRS ratio: 1:1

All aspects of sinus tachycardia are the same as those of normal sinus rhythm, except for the rate. Sinus tachycardia does not start or end suddenly (nonparoxysmal). As the heart rate increases, the diastolic filling time decreases, possibly resulting in reduced cardiac output and subsequent symptoms of syncope and low blood pressure. If the rapid rate persists and the heart cannot compensate for the decreased ventricular filling, the patient may develop acute pulmonary edema.

Treatment of sinus tachycardia is usually determined by the severity of symptoms and directed at identifying and abolishing its cause. Beta-blockers and calcium channel blockers (Table 27-1), although rarely used, may be administered to reduce the heart rate quickly. Catheter ablation (discussed later in this chapter) of the SA node may be used in cases of persistent inappropriate sinus tachycardia unresponsive to other treatments. Treatment for POTS may include increased fluid and sodium intake and use of anti-embolism stockings to prevent pooling of blood in the lower extremities.

Sinus Arrhythmia. Sinus arrhythmia occurs when the sinus node creates an impulse at an irregular rhythm; the rate usually increases with inspiration and decreases with expiration. Nonrespiratory causes include heart disease and valvular disease, but these are rare. Sinus arrhythmia has the following characteristics (Fig. 27-8):

Ventricular and atrial rate: 60 to 100 in the adult

Ventricular and atrial rhythm: Irregular

QRS shape and duration: Usually normal, but may be regularly abnormal

P wave: Normal and consistent shape; always in front of the QRS

PR interval: Consistent interval between 0.12 and 0.20 seconds

P:QRS ratio: 1:1

Sinus arrhythmia does not cause any significant hemodynamic effect and usually is not treated.

Atrial Dysrhythmias

Premature Atrial Complex. A premature atrial complex (PAC) is a single ECG complex that occurs when an electrical impulse starts in the atrium before the next normal impulse of the sinus node. The PAC may be caused by caffeine, alcohol, nicotine, stretched atrial myocardium (eg, as in hypervolemia), anxiety, hypokalemia (low potassium level), hypermetabolic states (eg, with pregnancy), or atrial ischemia, injury, or infarction. PACs are often seen with sinus tachycardia. PACs have the following characteristics (Fig. 27-9):

Ventricular and atrial rate: Depends on the underlying rhythm (eg, sinus tachycardia)

Ventricular and atrial rhythm: Irregular due to early P waves, creating a PP interval that is shorter than the others. This is sometimes followed by a longer-than-normal PP interval, but one that is less than twice the normal PP interval. This type of interval is called a noncompensatory pause.

QRS shape and duration: The QRS that follows the early P wave is usually normal, but it may be abnormal (aberrantly conducted PAC). It may even be absent (blocked PAC).

P wave: An early and different P wave may be seen or may be hidden in the T wave; other P waves in the strip are consistent.

PR interval: The early P wave has a shorter-than-normal PR interval, but still between 0.12 and 0.20 seconds.

P:QRS ratio: usually 1:1

PACs are common in normal hearts. The patient may say, “My heart skipped a beat.” A pulse deficit (a difference between the apical and radial pulse rate) may exist.

If PACs are infrequent, no treatment is necessary. If they are frequent (more than six per minute), this may herald a worsening disease state or the onset of more serious dysrhythmias, such as atrial fibrillation. Treatment is directed toward the cause.

Atrial Flutter. Atrial flutter occurs because of a conduction defect in the atrium and causes a rapid, regular atrial rate, usually between 250 and 400 times per minute. Because the

Class*	Action	Drug Names	Side Effects	Nursing Interventions
IA	Moderate depression of depolarization; prolongs repolarization Treats and prevents atrial and ventricular dysrhythmias	quinidine (Quinaglute, Quinidex, Cardioquin) procainamide (Pronestyl, Procan SR) disopyramide (Norpace)	Decreased cardiac contractility Prolonged QRS, QT Proarrhythmic Hypotension with IV administration Diarrhea with quinidine, constipation with disopyramide Cinchonism with quinidine Lupus-like syndrome with procainamide Anticholinergic effects: dry mouth, urinary hesitancy with disopyramide	Observe for HF Monitor BP with IV administration Monitor QRS duration for increase >50% from baseline Monitor for prolonged QT Monitor N-acetyl procainamide (NAPA) laboratory values during procainamide therapy If administered for atrial fibrillation, ensure patient has been pretreated with a medication to control AV conduction
IB	Minimal depression of depolarization; shortened repolarization Treats ventricular dysrhythmias	lidocaine (Xylocaine) mexiletine (Mexitol) tocainide (Tonocard)	CNS changes (eg, confusion, lethargy) Bradycardia GI distress Tremors	Monitor for CNS changes and tremors Discuss with physician decreasing lidocaine dose in elderly patients and patients with cardiac/liver dysfunction
IC	Marked depression of depolarization; little effect on repolarization Treats atrial and ventricular dysrhythmias	flecainide (Tambocor) propafenone (Rythmol)	Proarrhythmic HF Dizziness, visual disturbances, dyspnea	Decreased dose with renal dysfunction, and strict vegetarian diets Avoid use in patients with structural heart disease (eg, coronary artery disease and heart failure)
II	Decreases automaticity and conduction Treats atrial and ventricular dysrhythmias	acebutolol (Sectrol) [†] atenolol (Tenormin) bisoprolol/HCTZ (Ziac, Zebeta) esmolol (Brevibloc) [†] labetalol (Trandate) metoprolol (Lopressor, Toprol-XL) nadolol (Corgard) nebivolol (Bystolic) propranolol (Inderal) [†] sotalol (Betapace; Sorine; also has class III actions) [†]	Bradycardia, AV block Decreased contractility Bronchospasm Nausea Asymptomatic and symptomatic hypotension Masks hypoglycemia and thyrotoxicosis CNS disturbances (eg, confusion, dizziness, fatigue, depression)	Monitor heart rate, PR interval, signs and symptoms of HF, especially in those also taking calcium channel blockers Monitor blood glucose level in patients with type 2 diabetes mellitus Caution the patient about abrupt withdrawal to avoid tachycardia, hypertension, and myocardial ischemia
III	Prolongs repolarization Amiodarone treats and prevents ventricular and atrial dysrhythmias, especially in patients with ventricular dysfunction Dofetilide and ibutilide treat and prevent atrial dysrhythmias	amiodarone (Cordarone) dofetilide (Tikosyn) ibutilide (Corvert)	Pulmonary toxicity (amiodarone) Corneal microdeposits (amiodarone) Photosensitivity (amiodarone) Bradycardia Hypotension, especially with IV administration Polymorphic ventricular dysrhythmias (rare with amiodarone) Nausea and vomiting Potentiates digoxin (amiodarone) See beta-blockers (sotalol)	Make sure patient is sent for baseline pulmonary function tests (amiodarone) Closely monitor patient Assess for contraindications prior to administration Monitor QT duration Continuous ECG monitoring with initiation of dofetilide and ibutilide
IV	Blocks calcium channel Treats and prevents paroxysmal atrial dysrhythmias [‡]	verapamil (Calan, Isoptin) diltiazem (Cardizem, Dilacor, Tiazac, Diltia, Cartia)	Bradycardia, AV blocks Hypotension with IV administration HF, peripheral edema Constipation, dizziness, headache, nausea	Monitor heart rate, PR interval Monitor blood pressure closely with IV administration Monitor for signs and symptoms of HF Do not crush sustained-release medications

*Based on Vaughn-Williams classification.

[†]Beta-blocker with labeled use for dysrhythmias.

[‡]There are other calcium channel blockers, but they are not approved or used for dysrhythmias.

Figure 27-8 Sinus arrhythmia in lead II. Note irregular RR and PP intervals.

atrial rate is faster than the AV node can conduct, not all atrial impulses are conducted into the ventricle, causing a therapeutic block at the AV node. This is an important feature of this dysrhythmia. If all atrial impulses were conducted to the ventricle, the ventricular rate would also be 250 to 400, which could result in ventricular fibrillation, a life-threatening dysrhythmia. Atrial flutter often occurs in patients with chronic obstructive pulmonary disease, valvular disease, and thyrotoxicosis, as well as following open heart surgery and repair of congenital cardiac defects (Fuster, et al., 2008).

Atrial flutter has the following characteristics (Fig. 27-10):
Ventricular and atrial rate: Atrial rate ranges between 250 and 400; ventricular rate usually ranges between 75 and 150

Ventricular and atrial rhythm: The atrial rhythm is regular; the ventricular rhythm is usually regular but may be irregular because of a change in the AV conduction

QRS shape and duration: Usually normal, but may be abnormal or may be absent

P wave: Saw-toothed shape; these waves are referred to as F waves

PR interval: Multiple F waves may make it difficult to determine the PR interval

P:QRS ratio: 2:1, 3:1, or 4:1

Vagal maneuvers or administration of adenosine (Adenocard, Adenoscan), which causes sympathetic block and

slowing of conduction in the AV node, may allow better visualization of flutter waves. Adenosine should be rapidly administered intravenously, followed by a 20-mL saline flush and elevation of the arm with the IV line to promote rapid circulation of the medication.

Atrial flutter can cause serious signs and symptoms, such as chest pain, shortness of breath, and low blood pressure. Electrical cardioversion (discussed later) is often successful in converting the rhythm to sinus rhythm. If the dysrhythmia has lasted longer than 48 hours and a transesophageal echocardiogram has not confirmed the absence of atrial clots, then adequate anticoagulation, using the same criteria as for atrial fibrillation, may be indicated before cardioversion or ablation. Medications used to slow the ventricular response rate include beta-blockers, nondihydropyridine calcium channel blockers, and digitalis, alone or in combination (Fuster, et al., 2008) (see Table 27-1). Catheter ablation rather than antiarrhythmic medications is now the long-term treatment of choice.

Atrial Fibrillation. Atrial fibrillation is an uncoordinated atrial electrical activation that causes a rapid, disorganized, and uncoordinated twitching of atrial musculature. The ventricular rate response is dependent on the ability of the AV node to conduct the atrial impulses, the level of sympathetic and parasympathetic tone, presence of accessory

Figure 27-9 Premature atrial complexes (PACs) in lead II. Note that the pause following the PAC is longer than the normal PP interval but shorter than twice the normal PP interval.

Figure 27-10 Atrial flutter in lead II.

pathways, and effects of any medications (Fuster, Ryden, Cannom, et al., 2006). For example, regular RR intervals in atrial fibrillation may indicate the presence of complete AV block, junctional tachycardia, or ventricular tachycardia. Atrial fibrillation may be transient, starting and stopping suddenly and occurring for a very short time (**paroxysmal dysrhythmia**), or it may be persistent, requiring treatment to terminate the rhythm or to control the ventricular rate. The lack of consistency in describing the pattern of atrial fibrillation has led to use of numerous labels (eg, acute, chronic, paroxysmal, persistent, permanent) and difficulty in comparative assessment of treatments (Fuster, et al., 2006).

Atrial fibrillation usually occurs in people of advanced age with structural heart disease, such as valvular heart disease (most often mitral or tricuspid), inflammatory or infiltrative disease (pericarditis, myocarditis, amyloidosis), coronary artery disease, hypertension, congenital disorder (especially atrial septal defect), and heart failure (diastolic or systolic) (Fuster, et al., 2008). The dysrhythmia also may be found in people with diabetes, obesity, hyperthyroidism, pheochromocytoma, pulmonary hypertension and embolism, obstructive sleep apnea, and acute moderate to heavy ingestion of alcohol (“holiday heart” syndrome), as well as following pulmonary or open heart surgery (Fuster, et al., 2006; Mehra, Benjamin, Shahar, et al., 2006). Atrial fibrillation has been linked to increased risk of stroke and premature death, and it is considered a growing health problem in developed countries (Fuster, et al., 2008). Neurogenic atrial fibrillation that occurs with subarachnoid hemorrhage and nonhemorrhagic stroke is caused by increased vagal or sympathetic stimulation. Sometimes atrial fibrillation occurs

in people with no underlying pathophysiology (called lone atrial fibrillation).

Occurrence of atrial fibrillation after coronary artery bypass, valvular replacements, and heart transplantation may prolong the duration and cost of the hospitalization (Fuster, et al., 2008). Hospital admissions for atrial fibrillation increased by 66% over the past 20 years, and occurrence of the dysrhythmia increases the length and cost of the hospital stay (Fuster, et al., 2006).

Atrial fibrillation has the following characteristics (Fig. 27-11):

Ventricular and atrial rate: Atrial rate is 300 to 600; ventricular rate is usually 120 to 200 in untreated atrial fibrillation

Ventricular and atrial rhythm: Highly irregular

QRS shape and duration: Usually normal, but may be abnormal

P wave: No discernible P waves; irregular undulating waves that vary in amplitude and shape are seen and are referred to as fibrillatory or f waves

PR interval: Cannot be measured

P:QRS ratio: Many:1

A rapid and irregular ventricular response reduces the time for ventricular filling, resulting in a smaller stroke volume. Because atrial fibrillation causes a loss in AV synchrony (the atria and ventricles contract at different times), the atrial kick (the last part of diastole and ventricular filling, which accounts for 25% to 30% of the cardiac output) is also lost. This may lead to irregular palpitations and symptoms of heart failure such as shortness of breath, fatigue, exercise intolerance, and malaise. Patients may be asymptomatic or experience significant hemodynamic collapse (hypotension,

Figure 27-11 Atrial fibrillation in lead II.

chest pain, pulmonary edema, and altered level of consciousness), especially if they also have hypertension, mitral stenosis, hypertrophic cardiomyopathy, or some form of restrictive heart failure. There is usually a pulse deficit, a numeric difference between apical and radial pulse rates. The shorter time in diastole reduces the time available for coronary artery perfusion, thereby increasing the risk of myocardial ischemia with the onset of chest discomfort. The erratic atrial contraction and the atrial myocardial dysfunction promote the formation of thrombi, especially within the atria, increasing the risk of an embolic event.

In addition, a high ventricular rate response during atrial fibrillation can lead to dilated ventricular cardiomyopathy. The rapid ventricular rate can also lead to mitral valve dysfunction, mitral regurgitation, and intraventricular conduction delay. Controlling the ventricular rate may prevent and correct these effects.

The clinical evaluation of atrial fibrillation should include a history and physical examination (to identify pattern of atrial fibrillation, associated symptoms, and any underlying conditions); 12-lead ECG (to identify presence of ventricular hypertrophy, preexcitation from accessory pathways, intraventricular conduction defects, and history of MI); echocardiogram (to assess cardiac chamber size, thickness, and function; to identify potential causes, such as cardiomyopathy or valvular dysfunction; and to identify the presence of a thrombus); and blood tests to assess thyroid, renal, and hepatic function (Fuster, et al., 2008). Additional tests may include a chest x-ray (to evaluate pulmonary vasculature), exercise test (to assess rate control as well as myocardial ischemia), Holter or event monitoring, and an EP study. The physical examination may reveal an irregular pulse, irregular jugular venous pulsations, and irregular S₁ heart sounds.

Treatment of atrial fibrillation depends on the cause, pattern, and duration of the dysrhythmia; the ventricular response rate; and the patient's symptoms, age, and comorbidities. In many patients, atrial fibrillation converts to sinus rhythm within 24 hours and without treatment. Hospitalization may not be necessary. Electrical cardioversion is indicated for patients with atrial fibrillation that is hemodynamically unstable unless they have digitalis toxicity or hypokalemia. Because of the high risk of embolization of atrial thrombi, cardioversion of atrial fibrillation that has lasted longer than 48 hours should be avoided unless the patient has received warfarin (Coumadin) for at least 3 to 4 weeks prior to cardioversion. Alternatively, the absence of a mural thrombus can be confirmed by transesophageal echocardiogram and heparin can be administered immediately prior to cardioversion. Because atrial function may be impaired for several weeks after cardioversion, warfarin is indicated for at least 4 weeks after the procedure. Patients may be given amiodarone (Cordarone), flecainide (Tambocor), ibutilide (Corvert), propafenone (Rythmol), or sotalol (Betapace) prior to cardioversion to prevent relapse of the atrial fibrillation (Fuster, et al., 2006).

Medications that may be administered to achieve cardioversion to sinus rhythm include flecainide, propafenone, or sotalol (Fuster, et al., 2008). Other choices include dofetilide (Tikosyn), amiodarone, and ibutilide. Because of the incidence of torsade de pointes, a ventricular tachycardia,

the use of ibutilide warrants ECG monitoring for at least 4 hours after its administration.

If the QRS is wide and the ventricular rhythm is very fast and irregular, atrial fibrillation with an accessory pathway should be suspected. An accessory pathway is congenital tissue between the atria, His bundle, AV node, Purkinje fibers, or ventricular myocardium. This anomaly is known as Wolff-Parkinson-White or WPW syndrome. Electrical cardioversion is the treatment of choice for atrial fibrillation in the presence of WPW syndrome. Medications that block AV conduction (eg, digoxin [Digitek], diltiazem [Cardizem], and verapamil [Calan]) should be avoided. If the patient is hemodynamically stable, procainamide (Pronestyl), propafenone, flecainide, or ibutilide is recommended to restore sinus rhythm (Fuster, et al., 2008). Other medications that may be used include sotalol, quinidine (Quinaglute), disopyramide (Norpace), or amiodarone. Catheter ablation is performed for long-term management.

To control the heart rate in persistent atrial fibrillation, an IV beta-blocker or a nondihydropyridine calcium channel blocker (diltiazem and verapamil) is recommended (Fuster, et al., 2006). However, people with impaired ventricular function should not receive verapamil, those with bronchospasm should not receive a beta-blocker, and those with AV block should not receive any of these medications. IV digoxin or amiodarone may be used for rate control in patients with heart failure or left ventricular dysfunction but without an accessory pathway. IV procainamide or ibutilide is an alternative for rate control in patients with an accessory pathway. In pregnant women, digoxin, a beta-blocker, or a nondihydropyridine calcium channel blocker may be used for rate control. If medications fail to control the heart rate or cause significant side effects, catheter ablation may be indicated.

Persistent atrial fibrillation can cause sinus node dysfunction and alteration in the atrial musculature and contractile function (atrial remodeling), which may persist for days or weeks following conversion to sinus rhythm (Fuster, et al., 2006). This has implications for the length of recovery time and the duration of anticoagulation therapy needed after conversion.

If maintenance of sinus rhythm is necessary to maintain quality of life, flecainide, propafenone, or sotalol may be prescribed (Fuster, et al., 2006). Patients who have been observed in the hospital while being given a dose of either propafenone or flecainide to convert atrial fibrillation may be given the medication to self-administer outside the hospital if they have a recurrence, an approach called "pill in the pocket" (Fuster, et al., 2008). Several approaches are used to prevent the occurrence of postoperative atrial fibrillation; preoperative administration of a beta-blocker or amiodarone is the most successful (Fuster, et al., 2006). Pacemaker implantation, ablation, or surgery may be indicated for patients who do not respond to medications.

Although control of the rhythm had been the initial treatment of choice, recent studies have found that controlling the heart rate (resting heart rate less than 80) is equal to controlling the rhythm in terms of quality of life, frequency of hospitalization for heart failure, and incidence of stroke (AFFIRM Investigators, 2002; Fuster, et al., 2006). Antithrombotic therapy is indicated for all patients with

Figure 27-12 Junctional rhythm in lead II; note short PR intervals.

atrial fibrillation. The type of therapy should be based on the risks of stroke and bleeding versus its benefits in a particular patient. Warfarin is indicated if the patient with atrial fibrillation is at high risk for stroke (ie, older than 75 years of age or has hypertension, diabetes, heart failure, or history of stroke) (Fuster, et al., 2008). If immediate anticoagulation is necessary, the patient may be placed on heparin until the warfarin level is therapeutic, usually defined as an international normalized ratio (INR) between 2 and 3. If a patient sustains an ischemic stroke or develops a systemic embolization during treatment, the antithrombotic therapy may be increased with the goal of increasing the INR to between 3.0 and 3.5 (Fuster, et al., 2006). Although aspirin may be substituted for warfarin in patients with contraindications to warfarin or those who are at a high risk of bleeding, warfarin is generally preferred (Fuster, et al., 2008). If a patient will be undergoing a procedure that carries a risk of bleeding, anticoagulation therapy may be withheld for up to a week. If more than a week is needed, heparin may be given, although its efficiency is unknown. Patients with atrial fibrillation who have a coronary artery stent implanted should receive clopidogrel (Plavix), an antiplatelet agent, plus warfarin for 1 to 12 months following the procedure (Fuster, et al., 2006).

Junctional Dysrhythmias

Premature Junctional Complex. A premature junctional complex is an impulse that starts in the AV nodal area before the next normal sinus impulse reaches the AV node. Premature junctional complexes are less common than PACs. Causes include digitalis toxicity, heart failure, and coronary artery disease. The ECG criteria for premature junctional complex are the same as for PACs, except for the P wave and the PR interval. The P wave may be absent, may follow the QRS, or may occur before the QRS but with a PR interval of less than 0.12 seconds. This dysrhythmia rarely produces significant symptoms. Treatment for frequent premature junctional complexes is the same as for frequent PACs.

Junctional Rhythm. Junctional or idionodal rhythm occurs when the AV node, instead of the sinus node, becomes the pacemaker of the heart. When the sinus node slows (eg, from increased vagal tone) or when the impulse cannot be conducted through the AV node (eg, because of complete heart block), the AV node automatically discharges an impulse.

Junctional rhythm not caused by complete heart block has the following characteristics (Fig. 27-12):

Ventricular and atrial rate: Ventricular rate 40 to 60; atrial rate also 40 to 60 if P waves are discernible

Ventricular and atrial rhythm: Regular

QRS shape and duration: Usually normal, but may be abnormal

P wave: May be absent, after the QRS complex, or before the QRS; may be inverted, especially in lead II

PR interval: If the P wave is in front of the QRS, the PR interval is less than 0.12 seconds

P:QRS ratio: 1:1 or 0:1

Junctional rhythm may produce signs and symptoms of reduced cardiac output. If this occurs, the treatment is the same as for sinus bradycardia. Emergency pacing may be needed.

Nonparoxysmal Junctional Tachycardia. Junctional tachycardia is caused by enhanced automaticity in the junctional area, resulting in a rhythm similar to junctional rhythm, except at a rate of 70 to 120. Although this rhythm generally does not have any detrimental hemodynamic effect, it may indicate a serious underlying condition, such as digitalis toxicity, myocardial ischemia, hypokalemia, or chronic obstructive pulmonary disease. Because junctional tachycardia is caused by increased automaticity, cardioversion is not an effective treatment; in fact, it causes an increase in the ventricular rate (AHA, 2005).

Atrioventricular Nodal Reentry Tachycardia. Atrioventricular nodal reentry tachycardia (AVNRT) is a common dysrhythmia that occurs when an impulse is conducted to an area in the AV node that causes the impulse to be rerouted back into the same area over and over again at a very fast rate. Each time the impulse is conducted through this area, it is also conducted down into the ventricles, causing a fast ventricular rate. AVNRT that has an abrupt onset and an abrupt cessation with a QRS of normal duration has been termed paroxysmal atrial tachycardia (PAT). AVNRT also occurs when the duration of the QRS complex is 0.12 seconds or greater and a block in the bundle branch is known to be present. This dysrhythmia may last for seconds or several hours. Factors associated with the development of AVNRT include caffeine, nicotine, hypoxemia, and stress. Underlying pathologies include coronary artery disease and cardiomyopathy; however, it occurs more

Figure 27-13 AV nodal reentry tachycardia in lead II.

often in females and not in association with underlying structural heart disease (Blomström-Lundqvist, et al., 2003). AVNRT has the following characteristics (Fig. 27-13):

Ventricular and atrial rate: Atrial rate usually 150 to 250; ventricular rate usually 120 to 200

Ventricular and atrial rhythm: Regular; sudden onset and termination of the tachycardia

QRS shape and duration: Usually normal, but may be abnormal

P wave: Usually very difficult to discern

PR interval: If the P wave is in front of the QRS, the PR interval is less than 0.12 seconds

P:QRS ratio: 1:1, 2:1

The clinical symptoms vary with the rate and duration of the tachycardia and the patient's underlying condition. The tachycardia usually is of short duration, resulting only in palpitations. A fast rate may also reduce cardiac output, resulting in significant signs and symptoms such as restlessness, chest pain, shortness of breath, pallor, hypotension, and loss of consciousness.

Because AVNRT is generally a benign dysrhythmia, the goal of treatment is to alleviate symptoms that affect quality of life. Patients who become significantly symptomatic and require emergency department visits to terminate the rhythm may want to initiate therapy immediately. However, those with minimum symptoms with an AVNRT that terminates spontaneously or with minimal treatment may choose just to be monitored.

The aim of therapy is to break the reentry of the impulse. Catheter ablation is the initial treatment of choice and is used to eliminate the area that permits the rerouting of the impulse that causes the tachycardia. Vagal maneuvers, such as carotid sinus massage (Fig. 27-14), gagging, breath holding, and immersing the face in ice water, may be used to interrupt AVNRT. These techniques increase parasympathetic stimulation, causing slower conduction through the AV node and blocking the reentry of the rerouted impulse. Some patients use some of these methods to terminate the episode on their own. Because of the risk of a cerebral embolic event, carotid sinus massage is contraindicated in patients with carotid bruits. If the vagal maneuvers are ineffective, the patient may then receive a bolus of adenosine to correct the rhythm; this is nearly 100% effective in terminating AVNRT (Fuster, et al., 2008). Patients who are also taking dipyridamole (Persantin) or who are cardiac transplant recipients are more sensitive to adenosine, and they should receive a lower initial dose (Fuster, et al., 2008). Because the effect of adenosine is so short,

AVNRT may recur; the first dose may be followed with a larger dose or with a calcium channel blocker, such as verapamil, followed by one or two additional boluses. Digoxin is not indicated because of its slow onset. If the patient is unstable or does not respond to the medications, cardioversion is the treatment of choice. The unstable patient may be given adenosine while preparations for cardioversion are being made. For recurrent sustained AVNRT, treatment with calcium channel blockers such as verapamil and diltiazem, class 1a antiarrhythmic agents such as procainamide and disopyramide, class 1c antiarrhythmics such as flecainide and propafenone, and class 3 agents such as sotalol and amiodarone may prevent a recurrence. If the rhythm is infrequent and there is no underlying cardiac structural disorder, a single oral dose of flecainide or a combination of diltiazem and propranolol during an episode of tachycardia may be effective.

If P waves cannot be identified, the rhythm may be called **supraventricular tachycardia (SVT)**, or paroxysmal supraventricular tachycardia (PSVT) if it has an abrupt onset, until the underlying rhythm and resulting diagnosis is determined. SVT and PSVT indicate only that the rhythm is not **ventricular tachycardia (VT)**. SVT could be atrial fibrillation, atrial flutter, or AVNRT, among others. Vagal maneuvers and adenosine may be used to convert the rhythm or at least slow conduction in the AV node to allow visualization of the P waves. If the ECG does not assist in the differentiation of the dysrhythmia, invasive electrophysiology testing may be necessary to make the diagnosis.

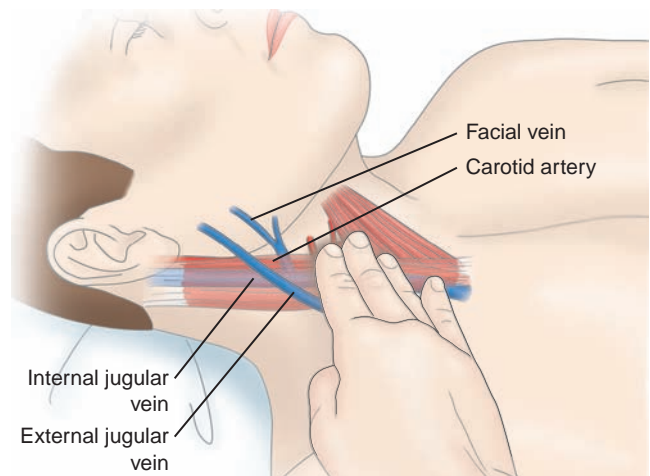

Figure 27-14 Carotid sinus massage.

Figure 27-15 Multifocal premature ventricular complexes (PVCs) in quadrigeminy in lead V₁. Note regular PP interval (P wave within PVC).

Ventricular Dysrhythmias

Premature Ventricular Complex. A premature ventricular complex (PVC) is an impulse that starts in a ventricle and is conducted through the ventricles before the next normal sinus impulse. PVCs can occur in healthy people, especially with intake of caffeine, nicotine, or alcohol. PVCs may be caused by cardiac ischemia or infarction, increased workload on the heart (eg, heart failure, and tachycardia), digitalis toxicity, hypoxia, acidosis, or electrolyte imbalances, especially hypokalemia. The Sleep Heart Health Study found that those people with sleep disordered breathing (eg, obstructive sleep apnea) had a significantly higher prevalence of complex ventricular ectopy and nonsustained ventricular tachycardia during sleep (Mehra, et al., 2006). The implication of the presence of PVCs during and after exercise is not clear and remains controversial (Fuster, et al., 2008).

In a rhythm called bigeminy, every other complex is a PVC. In trigeminy, every third complex is a PVC, and in quadrigeminy, every fourth complex is a PVC. PVCs have the following characteristics (Fig. 27-15):

Ventricular and atrial rate: Depends on the underlying rhythm (eg, sinus rhythm)

Ventricular and atrial rhythm: Irregular due to early QRS, creating one RR interval that is shorter than the others. PP interval may be regular, indicating that the PVC did not depolarize the sinus node.

QRS shape and duration: Duration is 0.12 seconds or longer; shape is bizarre and abnormal

P wave: Visibility of P wave depends on the timing of the PVC; may be absent (hidden in the QRS or T wave) or in front of the QRS. If the P wave follows the QRS, the shape of the P wave may be different.

PR interval: If the P wave is in front of the QRS, the PR interval is less than 0.12 seconds

P:QRS ratio: 0:1; 1:1

The patient may feel nothing or may say that the heart “skipped a beat.” The effect of a PVC depends on its timing in the cardiac cycle and how much blood was in the ventricles when they contracted. Initial treatment is aimed at correcting the cause.

In the absence of disease, PVCs usually are not serious. PVCs that are frequent and persistent may be treated with amiodarone or sotalol. Long-term pharmacotherapy for only PVCs is not indicated. In patients with acute MI, PVCs may warrant more aggressive therapy. Lidocaine (Xylocaine) may be used in the patient with acute MI. Patients with acute MI who did not receive thrombolytics and had more than 10 PVCs per hour and those who did receive thrombolytics and had more than 25 PVCs per hour were found to be at the greatest risk for sudden cardiac death (Fuster, et al., 2008). In the past, PVCs were considered to be indicative of an increased risk for ensuing VT. However, PVCs that (1) are more frequent than six per minute, (2) are multifocal or polymorphic (having different shapes and rhythms), (3) occur two in a row (pair), and (4) occur on the T wave (the vulnerable period of ventricular depolarization) have not been found to be precursors of VT in patients without structural heart disease (Cardiac Arrhythmia Suppression Trial Investigators, 1989). These PVCs are no longer considered as warning or complex PVCs.

Ventricular Tachycardia. VT is defined as three or more PVCs in a row, occurring at a rate exceeding 100 bpm. The causes are similar to those of PVC. Patients with larger MIs and lower ejection fractions are at higher risk of lethal ventricular tachycardia (see Chapter 30). VT is an emergency because the patient is usually (although not always) unresponsive and pulseless. VT has the following characteristics (Fig. 27-16):

Ventricular and atrial rate: Ventricular rate is 100 to 200 bpm; atrial rate depends on the underlying rhythm (eg, sinus rhythm)

Figure 27-16 Ventricular tachycardia in lead V₁.

Ventricular and atrial rhythm: Usually regular; atrial rhythm may also be regular

QRS shape and duration: Duration is 0.12 seconds or more; bizarre, abnormal shape

P wave: Very difficult to detect, so atrial rate and rhythm may be indeterminable

PR interval: Very irregular, if P waves are seen

P:QRS ratio: Difficult to determine, but if P waves are apparent, there are usually more QRS complexes than P waves

The patient's tolerance or lack of tolerance for this rapid rhythm depends on the ventricular rate and severity of ventricular dysfunction. However, hemodynamic stability does not predict mortality risk (Fuster, et al., 2008). Several factors determine the initial treatment, including the following: identifying the rhythm as monomorphic (having a consistent QRS shape and rate) or polymorphic (having varying QRS shapes and rhythms); determining the existence of a prolonged QT interval before the initiation of VT; and ascertaining the patient's heart function (normal or decreased). If the patient is stable, continuing the assessment, especially obtaining a 12-lead ECG, may be the only action necessary.

However, the patient may need antiarrhythmic medications, antitachycardia pacing, or direct cardioversion. IV procainamide is the antiarrhythmic medication of choice for a patient with stable acute MI with VT, whereas IV amiodarone is the medication of choice for a patient with unstable VT or impaired cardiac function. Sotalol may also be used. Although lidocaine has been the medication most commonly used for immediate, short-term therapy, especially for patients with impaired cardiac function, it has no proven short-term or long-term efficacy in cardiac arrest (AHA, 2005). Cardioversion is the treatment of choice for monophasic VT in a symptomatic patient. Defibrillation is the treatment of choice for pulseless VT. Any type of VT in a patient who is unconscious and without a pulse is treated in the same manner as ventricular fibrillation: immediate **defibrillation** is the action of choice. For long-term management, patients with an ejection fraction less than 35% should be considered for an implantable cardioverter defibrillator. Those with an ejection fraction greater than 35% may be managed with amiodarone. A small percentage of patients with VT have structurally normal hearts and respond well to medications and ablation, and they have an excellent prognosis (Fuster, et al., 2008). If the ventricular rate is above 200, then presence of an accessory pathway

should be suspected. If the ventricular rhythm is irregular, atrial fibrillation should be suspected and treated appropriately (Fuster, et al., 2006).

Torsade de pointes is a polymorphic VT preceded by a prolonged QT interval. Common causes include central nervous system disease; certain medications; or low levels of potassium, calcium, or magnesium. Congenital QT prolongation is another cause. Because this rhythm is likely to cause the patient to deteriorate and become pulseless, immediate treatment is required: correction of any electrolyte imbalance, administration of isoproterenol (Isuprel) IV, or initiation of ventricular pacing. Magnesium has frequently been used to treat torsades, but its use has not been proved effective (AHA, 2005).

Ventricular Fibrillation. The most common dysrhythmia in patients with cardiac arrest is ventricular fibrillation, which is a rapid, disorganized ventricular rhythm that causes ineffective quivering of the ventricles. No atrial activity is seen on the ECG. The most common cause of ventricular fibrillation is coronary artery disease and resulting acute MI. Other causes include untreated or unsuccessfully treated VT, cardiomyopathy, valvular heart disease, several **proarrhythmic** medications, acid-base and electrolyte abnormalities, and electrical shock. Another cause is Brugada syndrome, in which the patient (frequently of Asian descent) has a structurally normal heart, few or no risk factors for coronary artery disease, and a family history of sudden cardiac death. Ventricular fibrillation has the following characteristics (Fig. 27-17):

Ventricular rate: Greater than 300 per minute

Ventricular rhythm: Extremely irregular, without a specific pattern

QRS shape and duration: Irregular, undulating waves without recognizable QRS complexes

Ventricular fibrillation is always characterized by the absence of an audible heartbeat, a palpable pulse, and respirations. Because there is no coordinated cardiac activity, cardiac arrest and death are imminent if the dysrhythmia is not corrected. Early defibrillation is critical to survival, with administration of immediate bystander cardiopulmonary resuscitation (CPR) until defibrillation is available. The chance of survival decreases by 7% to 10% for every minute in delay of defibrillation (AHA, 2005). If the arrest was not witnessed or there was more than a 4-minute

Figure 27-17 Ventricular fibrillation in lead II.

Figure 27-18 Idioventricular rhythm in lead V₁.

delay in emergency services response, five cycles of CPR may be given prior to defibrillation (AHA, 2005). After the initial defibrillation, five additional cycles of CPR (about 2 minutes of continuous chest compressions in the intubated patient), beginning with chest compression and alternating with a rhythm check and defibrillation, are used to convert ventricular fibrillation to an electrical rhythm that produces a pulse. Cardiocerebral resuscitation for cardiac arrest with continuous chest compressions, interrupted only with defibrillation, and its de-emphasis on the use of positive-pressure ventilation continues to be explored as a better method for improving survival (Fuster, et al., 2008). Epinephrine should be administered as soon as possible after the second rhythm check (immediately before or after the second defibrillation) and then every 3 to 5 minutes. One dose of vasopressin (Pitressin) may be administered instead of epinephrine if the cardiac arrest persists. Other antiarrhythmic medications (amiodarone, lidocaine, or possibly magnesium) should be administered as soon as possible after the third rhythm check (immediately before or after the third defibrillation).

For refractory ventricular fibrillation, amiodarone may be the medication of choice. However, once the patient is intubated, CPR should be given continuously, not in cycles, and the rhythm check and medication administration occur every 2 minutes. In addition, underlying and contributing factors are identified and eliminated throughout the event (AHA, 2005).

Current AHA guidelines recommend inducing mild hypothermia in unconscious adults who experience cardiac arrest (including cardiac arrest due to ventricular fibrillation) and who receive CPR within 10 minutes. Hypothermia is defined as a core body temperature of 32°C to 34°C (89.6°F to 93.2°F). Induction should be started as soon as possible after circulation is restored, preferably within 60 minutes, and maintained for 12 to 24 hours. It is usually initiated by applying ice packs to the axilla and groin as well as administering iced saline gastric lavage until a cooling machine is obtained.

The nurse caring for a patient with hypothermia (passive or induced) needs to monitor for appropriate level of cooling, sedation, and neuromuscular paralysis to prevent seizures, myoclonus, and shivering. The nurse also needs to monitor for complications of hypothermia, which include electrolyte imbalance (especially due to the diuresis caused by hypothermia), hypotension, pneumonia, sepsis, hyperglycemia, dysrhythmias, and coagulopathy, especially if the

temperature drops below the intended goal. Because of these numerous nursing interventions, patients receive care in intensive care units. Each patient should be assigned three nurses during the induction process and two nurses during the hypothermia state (Bader, Rovzar, Baumgartner, et al., 2007).

Idioventricular Rhythm. Idioventricular rhythm, also called ventricular escape rhythm, occurs when the impulse starts in the conduction system below the AV node. When the sinus node fails to create an impulse (eg, from increased vagal tone) or when the impulse is created but cannot be conducted through the AV node (eg, due to complete AV block), the Purkinje fibers automatically discharge an impulse. When idioventricular rhythm is not caused by AV block, it has the following characteristics (Fig. 27-18):

Ventricular rate: 20 and 40; if the rate exceeds 40, the rhythm is known as accelerated idioventricular rhythm (AIVR)

Ventricular rhythm: Regular

QRS shape and duration: Bizarre, abnormal shape; duration is 0.12 seconds or more

Idioventricular rhythm commonly causes the patient to lose consciousness and experience other signs and symptoms of reduced cardiac output. In such cases, the treatment is the same as for asystole and pulseless electrical activity (PEA) if the patient is in cardiac arrest or for bradycardia if the patient is not in cardiac arrest. Interventions include identifying the underlying cause; administering IV epinephrine, atropine, and vasopressor medications; and initiating emergency transcutaneous pacing. In some cases, idioventricular rhythm may cause no symptoms of reduced cardiac output. However, bed rest is prescribed so as not to increase the cardiac workload.

Ventricular Asystole. Commonly called flatline, ventricular asystole (Fig. 27-19) is characterized by absent QRS complexes confirmed in two different leads, although P waves may be apparent for a short duration. There is no heartbeat, no palpable pulse, and no respiration. Without immediate treatment, ventricular asystole is fatal.

Ventricular asystole is treated the same as PEA, focusing on high-quality CPR with minimal interruptions and identifying underlying and contributing factors. The guidelines for advanced cardiovascular life support (ACLS) (AHA, 2005) state that the key to successful treatment is rapid assessment to identify a possible cause, which may be hypoxia,

Figure 27-19 Asystole. Always check two different leads to confirm rhythm.

acidosis, severe electrolyte imbalance, drug overdose, hypovolemia, cardiac tamponade, tension pneumothorax, coronary or pulmonary thrombosis, trauma, or hypothermia. After the initiation of CPR, intubation and establishment of IV access are the next recommended actions, with no or minimal interruptions in chest compressions. After 2 minutes or five cycles of CPR, a bolus of IV epinephrine is administered and repeated at 3- to 5-minute intervals. One dose of vasopressin may be administered for the first or second dose of epinephrine. A bolus of IV atropine may also be administered as soon as possible after the rhythm check (AHA, 2005). Because of the poor prognosis associated with asystole, if the patient does not respond to these actions and others aimed at correcting underlying causes, resuscitation efforts are usually ended (“the code is called”) unless special circumstances (eg, hypothermia, transportation to a hospital is required) exist.

Conduction Abnormalities

When assessing the rhythm strip, the underlying rhythm is first identified (eg, sinus rhythm, sinus arrhythmia). Then the PR interval is assessed for the possibility of an AV block. AV blocks occur when the conduction of the impulse through the AV nodal or His bundle area is decreased or stopped. These blocks can be caused by medications (eg, digitalis, calcium channel blockers, beta-blockers), Lyme disease, myocardial ischemia and infarction, valvular disorders, cardiomyopathy, endocarditis, or myocarditis. If the AV block is caused by increased vagal tone (eg, long-term athletic training, sleep, coughing, suctioning, pressure above the eyes or on large vessels, anal stimulation), it is commonly accompanied by sinus bradycardia. AV block may be

temporary and resolve on its own, or it may be permanent and require permanent pacing.

The clinical signs and symptoms of a heart block vary with the resulting ventricular rate and the severity of any underlying disease processes. Whereas first-degree AV block rarely causes any hemodynamic effect, the other blocks may result in decreased heart rate, causing a decrease in perfusion to vital organs, such as the brain, heart, kidneys, lungs, and skin. A patient with third-degree AV block caused by digitalis toxicity may be stable; another patient with the same rhythm caused by acute MI may be unstable. Health care providers must always keep in mind the need to treat the patient, not the rhythm. The treatment is based on the hemodynamic effect of the rhythm.

First-Degree Atrioventricular Block. First-degree AV block occurs when all the atrial impulses are conducted through the AV node into the ventricles at a rate slower than normal. This conduction disorder has the following characteristics (Fig. 27-20):

Ventricular and atrial rate: Depends on the underlying rhythm

Ventricular and atrial rhythm: Depends on the underlying rhythm

QRS shape and duration: Usually normal, but may be abnormal

P wave: In front of the QRS complex; shows sinus rhythm, regular shape

PR interval: Greater than 0.20 seconds; PR interval measurement is constant

P:QRS ratio: 1:1

Figure 27-20 Sinus rhythm with first-degree AV block in lead II. Note that PR is constant but greater than 0.20 seconds.

Figure 27-21 Sinus rhythm with second-degree AV block, type I in lead II. Note progressively longer PR durations until there is a nonconducted P wave, indicated by the asterisk.

Second-Degree Atrioventricular Block, Type I (Wenckebach). Second-degree AV block, type I, occurs when there is a repeating pattern in which all but one of a series of atrial impulses are conducted through the AV node into the ventricles (eg, every four of five atrial impulses are conducted). Each atrial impulse takes a longer time for conduction than the one before, until one impulse is fully blocked. Because the AV node is not depolarized by the blocked atrial impulse, the AV node has time to fully repolarize, so that the next atrial impulse can be conducted within the shortest amount of time. Second-degree AV block, type I, has the following characteristics (Fig. 27-21):

Ventricular and atrial rate: Depends on the underlying rhythm

Ventricular and atrial rhythm: The PP interval is regular if the patient has an underlying normal sinus rhythm; the RR interval characteristically reflects a pattern of change. Starting from the RR that is the longest, the RR interval gradually shortens until there is another long RR interval.

QRS shape and duration: Usually normal but may be abnormal

P wave: In front of the QRS complex; shape depends on underlying rhythm

PR interval: PR interval becomes longer with each succeeding ECG complex until there is a P wave not followed by a QRS. The changes in the PR interval are repeated between each “dropped” QRS, creating a pattern in the irregular PR interval measurements.

P:QRS ratio: 3:2, 4:3, 5:4, and so forth

Second-Degree Atrioventricular Block, Type II. Second-degree AV block, type II, occurs when only some of the atrial impulses are conducted through the AV node into the ventricles. Second-degree AV block, type II, has the following characteristics (Fig. 27-22):

Ventricular and atrial rate: Depends on the underlying rhythm

Ventricular and atrial rhythm: The PP interval is regular if the patient has an underlying normal sinus rhythm.

Figure 27-22 Sinus rhythm with second-degree AV block, type II in lead V₁; note constant PR interval and presence of more P waves than QRS complexes.

Figure 27-23 Sinus rhythm with third-degree AV block and idioventricular rhythm in lead V₁; note irregular PR intervals.

The RR interval is usually regular but may be irregular, depending on the P:QRS ratio.

QRS shape and duration: Usually abnormal but may be normal

P wave: In front of the QRS complex; shape depends on underlying rhythm

PR interval: PR interval is constant for those P waves just before QRS complexes

P:QRS ratio: 2:1, 3:1, 4:1, 5:1, and so forth

Third-Degree Atrioventricular Block. Third-degree AV block occurs when no atrial impulse is conducted through the AV node into the ventricles. In third-degree AV block, two impulses stimulate the heart: one stimulates the ventricles (eg, junctional or ventricular escape rhythm), represented by the QRS complex, and one stimulates the atria (eg, sinus rhythm or atrial fibrillation), represented by the P wave. P waves may be seen, but the atrial electrical activity is not conducted down into the ventricles to cause the QRS complex, the ventricular electrical activity. Having two impulses stimulate the heart results in a condition called AV dissociation, which may also occur during VT. Complete block (third-degree AV block) has the following characteristics (Fig. 27-23):

Ventricular and atrial rate: Depends on the escape rhythm and underlying atrial rhythm

Ventricular and atrial rhythm: The PP interval is regular and the RR interval is regular, but the PP interval is not equal to the RR interval

QRS shape and duration: Depends on the escape rhythm; with junctional rhythm, QRS shape and duration are usually normal; with idioventricular rhythm, QRS shape and duration are usually abnormal

P wave: Depends on underlying rhythm

PR interval: Very irregular

P:QRS ratio: More P waves than QRS complexes

Medical Management of Conduction Abnormalities. Based on the cause of the AV block and the stability of the patient, treatment is directed toward increasing the heart rate to maintain a normal cardiac output. If the patient is stable and has no symptoms, no treatment may be indicated other than decreasing or eliminating the cause (eg, withholding the medication or treatment). If the causal medication is necessary for treating other conditions and no effective alternative is available, pacemaker implantation may be indicated.

The initial treatment of choice is an IV bolus of atropine, although it is not effective in second-degree AV block, type II, or third-degree AV block. If the patient does not respond to atropine, has advanced AV block, or has had an acute MI, temporary transcutaneous pacing may be started. If the patient has no pulse, treatment is the same as for ventricular asystole. A permanent pacemaker may be necessary if the block persists.

NURSING PROCESS

THE PATIENT WITH A DYSRHYTHMIA

Assessment

Major areas of assessment include possible causes of the dysrhythmia, contributing factors, and the dysrhythmia's effect on the heart's ability to pump an adequate blood volume. When cardiac output is reduced, the amount of oxygen reaching the tissues and vital organs is diminished.

This diminished oxygenation produces the signs and symptoms associated with dysrhythmias. If these signs and symptoms are severe or if they occur frequently, the patient may experience significant distress and disruption of daily life.

A health history is obtained to identify any previous occurrences of decreased cardiac output, such as syncope (fainting), lightheadedness, dizziness, fatigue, chest discomfort, and palpitations. Coexisting conditions that could be possible causes of the dysrhythmia (eg, heart disease, chronic obstructive pulmonary disease) may also be identified. All medications, prescribed and over-the-counter (including herbs and nutritional supplements), as well as the route of administration, are reviewed. If a patient is taking an antiarrhythmic medication, assessment for side effects, adverse reactions, and potential contraindications is necessary. For example, some medications (eg, digoxin) can cause dysrhythmias. Laboratory results are reviewed to assess levels of medications as well as factors that could contribute to the dysrhythmia (eg, anemia). A thorough psychosocial assessment is performed to identify the possible effects of the dysrhythmia, the patient's perception and understanding of the dysrhythmia and its treatment, and whether anxiety is a significant contributing factor.

The nurse conducts a physical assessment to confirm the data obtained from the history and to observe for signs of

diminished cardiac output during the dysrhythmic event, especially changes in level of consciousness. The nurse assesses the patient's skin, which may be pale and cool. Signs of fluid retention, such as neck vein distention and crackles and wheezes auscultated in the lungs, may be detected. The rate and rhythm of apical and peripheral pulses are also assessed, and any pulse deficit is noted. The nurse auscultates for extra heart sounds (especially S₃ and S₄) and for heart murmurs, measures blood pressure, and determines pulse pressures. A declining pulse pressure indicates reduced cardiac output. Just one assessment may not disclose significant changes in cardiac output; therefore, the nurse compares multiple assessment findings over time, especially those that occur with and without the dysrhythmia.

Diagnosis

Nursing Diagnoses

Based on assessment data, major nursing diagnoses of the patient may include:

- Decreased cardiac output
- Anxiety related to fear of the unknown
- Deficient knowledge about the dysrhythmia and its treatment

Collaborative Problems/Potential Complications

Potential complications that may develop include the following:

- Cardiac arrest (see Chapter 30)
- Heart failure (see Chapter 30)
- Thromboembolic event, especially with atrial fibrillation (see Chapter 30)

Planning and Goals

The major goals for the patient may include eliminating or decreasing the occurrence of the dysrhythmia (by decreasing contributory factors) to maintain cardiac output, minimizing anxiety, and acquiring knowledge about the dysrhythmia, tests used to diagnose the problem, and its treatment.

Nursing Interventions

Monitoring and Managing the Dysrhythmia

The nurse regularly evaluates the patient's blood pressure, pulse rate and rhythm, rate and depth of respirations, and breath sounds to determine the dysrhythmia's hemodynamic effect. The nurse also asks the patient about episodes of lightheadedness, dizziness, or fainting as part of the ongoing assessment. If a patient with a dysrhythmia is hospitalized, the nurse may obtain a 12-lead ECG, continuously monitor the patient, and analyze rhythm strips to track the dysrhythmia.

Control of the occurrence or the effect of the dysrhythmia, or both, is often achieved with **antiarrhythmic medications**. The nurse assesses and observes for the benefits and adverse effects of each medication. The nurse, in collaboration with the physician, also manages medication administration carefully so that a constant serum level of the medication is maintained. The nurse may also conduct a 6-minute walk test as prescribed, which is used to identify the patient's ventricular rate in response to exercise. The patient is asked to walk for 6 minutes, covering as much distance as possible. The nurse

monitors the patient for symptoms. At the end, the nurse records the distance covered and the preexercise and post-exercise heart rate as well as the patient's response.

The nurse assesses for factors that contribute to the dysrhythmia (eg, oxygen deficits, acid-base and electrolyte imbalances, caffeine, or nonadherence to the medication regimen). The nurse also monitors for ECG changes (eg, widening of the QRS, prolongation of the QT interval, increased heart rate) that increase the risk of a dysrhythmic event.

Minimizing Anxiety

When the patient experiences episodes of dysrhythmia, the nurse stays with the patient and provides assurance of safety and security while maintaining a calm and reassuring attitude. This assists in reducing anxiety (reducing the sympathetic response) and fosters a trusting relationship with the patient. The nurse seeks the patient's view of the events and discusses the emotional response to the dysrhythmia, encouraging verbalization of feelings and fears, providing supportive or empathetic statements, and assisting the patient to recognize feelings of anxiety, anger, or sadness. The nurse emphasizes successes with the patient to promote a sense of self-management of the dysrhythmia. For example, if a patient is experiencing episodes of dysrhythmia and a medication is administered that begins to reduce the incidence of the dysrhythmia, the nurse communicates that information to the patient. In addition, the nurse can help the patient develop a system to identify possible causative, influencing, and alleviating factors (eg, keeping a diary). The nursing goal is to maximize the patient's control and to make the episode less threatening.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. When teaching patients about dysrhythmias, the nurse first assesses the patient's understanding, clarifies misinformation, and then shares needed information in terms that are understandable and in a manner that is not frightening or threatening. The nurse clearly explains treatment options to the patient and family. If necessary, the nurse explains the importance of maintaining therapeutic serum levels of antiarrhythmic medications so that the patient understands why medications should be taken regularly each day and the importance of regular blood testing. If the medication has the potential to alter the heart rate, the patient should be taught how to take his or her pulse before each dose and to notify the health care provider if the pulse is abnormal. In addition, the relationship between a dysrhythmia and cardiac output is explained so that the patient recognizes symptoms of the dysrhythmia and the rationale for the treatment regimen. The patient and family need to know what measures to take to decrease the risk of recurrence of the dysrhythmia. If the patient has a potentially lethal dysrhythmia, it is also important to establish with the patient and family a plan of action to take in case of an emergency and, if appropriate, to encourage a family member to obtain CPR training.

The patient and family should also be taught about potential risks of the dysrhythmia and their signs and symptoms. For example, the patient with chronic atrial fibrillation should be taught about the possibility of an embolic event.

CONTINUING CARE. A referral for home care usually is not necessary for the patient with a dysrhythmia unless the patient is hemodynamically unstable and has significant symptoms of decreased cardiac output. Home care may be warranted if the patient has significant comorbidities, socioeconomic issues, or limited self-management skills that could increase the risk of nonadherence to the therapeutic regimen.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Maintains cardiac output
 - a. Demonstrates heart rate, blood pressure, respiratory rate, and level of consciousness within normal ranges
 - b. Demonstrates no or decreased episodes of dysrhythmia
2. Experiences reduced anxiety
 - a. Expresses a positive attitude about living with the dysrhythmia
 - b. Expresses confidence in ability to take appropriate actions in an emergency
3. Expresses understanding of the dysrhythmia and its treatment
 - a. Explains the dysrhythmia and its effects
 - b. Describes the medication regimen and its rationale
 - c. Explains the need to maintain a therapeutic serum level of the medication
 - d. Describes a plan to eliminate or limit factors that contribute to the dysrhythmia
 - e. States actions to take in the event of an emergency

Adjunctive Modalities and Management

Dysrhythmia treatments depend on whether the disorder is acute or chronic as well as on the cause of the dysrhythmia and its actual or potential hemodynamic effects.

Acute dysrhythmias may be treated with medications or with external electrical therapy (emergency defibrillation, cardioversion, or pacing). Many antiarrhythmic medications are used to treat atrial and ventricular tachydysrhythmias (see Table 27-1). The choice of medication depends on the specific dysrhythmia and its duration, the presence of structural heart disease, (eg, heart failure), and the patient's response to previous treatment. The nurse is responsible for monitoring and documenting the patient's responses to the medication and for ensuring that the patient has the knowledge and ability to manage the medication regimen.

If medications alone are ineffective in eliminating or decreasing the dysrhythmia, certain adjunctive mechanical therapies are available. The most common therapies are elective cardioversion and defibrillation for acute tachydysrhythmia, and implantable devices (pacemakers for bradycardias and internal cardioresuscitators for chronic tachydysrhythmias). Surgical treatments, although less common, are also

Figure 27-24 Standard paddle placement for defibrillation.

available. The nurse is responsible for assessing the patient's understanding of and response to mechanical therapy, as well as the patient's self-management abilities. The nurse explains that the purpose of the device is to help the patient lead a life that is as active and productive as possible.

Cardioversion and Defibrillation

Cardioversion and defibrillation are used to treat tachydysrhythmias by delivering an electrical current that depolarizes a critical mass of myocardial cells. When the cells repolarize, the sinus node is usually able to recapture its role as the heart's pacemaker. One major difference between cardioversion and defibrillation is the timing of the delivery of electrical current. In cardioversion, the delivery of the electrical current is synchronized with the patient's electrical events; in defibrillation, the delivery of the current is immediate and unsynchronized.

The electrical current may be delivered externally through the skin with the use of paddles or with conductor pads. The paddles or pads may be placed on the front of the chest (Fig. 27-24) (standard placement), or one may be placed on the front of the chest and the other, using an adapter with a long handle if using paddles, placed under the patient's back just left of the spine (anteroposterior placement) (Fig. 27-25).

Defibrillator multifunction conductor pads (Fig. 27-26) contain a conductive medium and are connected to the defibrillator to allow for hands-off defibrillation. This method reduces the risk of touching the patient during the procedure and increases electrical safety. Automatic external

Figure 27-25 Anteroposterior paddle placement for defibrillation.

Figure 27-26 Multifunction pads for defibrillation.

defibrillators (AEDs), which are now found in public areas such as airports and grocery stores, use this type of delivery for the electrical current.

NURSING ALERT

When using paddles, the appropriate conductant is applied between the paddles and the patient's skin. Any other type of conductant, such as ultrasound gel, should not be substituted.

Whether using pads or paddles, the nurse must observe two safety measures. First, good contact must be maintained between the pads or paddles and the patient's skin (with a conductive medium between them) to prevent electrical current from leaking through the air (arcing) when the defibrillator is discharged. Second, no one is to be in contact with the patient or with anything that is touching the patient when the defibrillator is discharged, to minimize the chance that electrical current is conducted to anyone other than the patient.

When assisting with external defibrillation or cardioversion, the nurse should remember these key points:

- Use multifunction conductor pads or paddles with a conducting medium between the paddles and the skin (the conducting medium is available as a sheet, gel, or paste). Do not use gels or pastes with poor electrical conductivity (eg, ultrasound gel) (AHA, 2005).
- Place paddles or pads so that they do not touch the patient's clothing or bed linen and are not near medication patches or direct oxygen flow.
- During cardioversion, ensure that the monitor leads are attached to the patient and that the defibrillator is in the synchronized mode ("in sync"). If defibrillating, ensure that the defibrillator is *not* in the synchronized mode (most machines default to the "not-sync" mode).
- If using paddles, exert 20 to 25 pounds of pressure to ensure good skin contact.
- If using a manual discharge device, do not charge the device until ready to shock; then keep thumbs and fingers off the discharge buttons until paddles or pads are on the chest and ready to deliver the electrical charge.
- Before pressing the discharge button, call "Clear!" three times: As "Clear" is called the first time, ensure that you are not touching the patient, bed, or equipment; as "Clear" is called the second time, ensure that

no one is touching the bed, the patient, or equipment, including the endotracheal tube or adjuncts; and as "Clear" is called the third time, perform a final visual check to ensure that you and everyone else are clear of the patient and anything touching the patient.

- Record the delivered energy.
- After the defibrillation, immediately resume CPR, starting with chest compressions.
- After five cycles (about 2 minutes) of CPR, check the cardiac rhythm and deliver another shock if indicated. Administer a vasoactive or antiarrhythmic medication as soon as possible after the rhythm check.
- After the event is complete, inspect the skin under the pads or paddles for burns; if any are detected, consult with the physician or a wound care nurse about treatment.

Electrical Cardioversion

Electrical **cardioversion** involves the delivery of a "timed" electrical current to terminate a tachydysrhythmia. In cardioversion, the defibrillator is set to synchronize with the ECG on a cardiac monitor so that the electrical impulse discharges during ventricular depolarization (QRS complex). The synchronization prevents the discharge from occurring during the vulnerable period of repolarization (T wave), which could result in VT or ventricular fibrillation. The ECG monitor connected to the external defibrillator usually displays a mark or line that indicates sensing of a QRS complex. Sometimes the lead and the electrodes must be changed for the monitor to recognize the patient's QRS complex. When the synchronizer is on, no electrical current is delivered if the defibrillator does not discern a QRS complex. Therefore, it is important to ensure that the patient is connected to the monitor and to select a lead (not "paddles") that has the most appropriate sensing of the QRS. Because there may be a short delay until recognition of the QRS, the discharge buttons of an external manual defibrillator must be held down until the shock has been delivered. In most monitors, the synchronization mode must be reactivated if the initial cardioversion was ineffective and another cardioversion is needed (ie, the device defaults to unsynchronized defibrillation mode).

If the cardioversion is elective and the dysrhythmia has lasted longer than 48 hours, anticoagulation for a few weeks before cardioversion may be indicated. Digoxin is usually withheld for 48 hours before cardioversion to ensure the resumption of sinus rhythm with normal conduction. The patient is instructed not to eat or drink for at least 4 hours before the procedure. Gel-covered paddles or conductor pads are positioned front and back (anteroposteriorly) for cardioversion. Before cardioversion, the patient receives moderate sedation IV as well as an analgesic medication or anesthesia. Respiration is then supported with supplemental oxygen delivered by a bag-mask-valve device with suction equipment readily available. Although patients rarely require intubation, equipment is nearby in case it is needed. The amount of voltage used varies from 50 to 360 J, depending on the defibrillator's technology, the type and duration of the dysrhythmia, and the size and hemodynamic status of the patient. If ventricular fibrillation occurs after cardioversion, the defibrillator is used to defibrillate the patient (synchronization mode is *not* used).

Indications of a successful response are conversion to sinus rhythm, adequate peripheral pulses, and adequate blood pressure. Because of the sedation, airway patency must be maintained and the patient's state of consciousness assessed. Vital signs and oxygen saturation are monitored and recorded until the patient is stable and recovered from sedation and analgesic medications or anesthesia. ECG monitoring is required during and after cardioversion.

Defibrillation

Defibrillation is used in emergency situations as the treatment of choice for ventricular fibrillation and pulseless VT, the most common cause of abrupt loss of cardiac function and sudden cardiac death. Defibrillation is not used for patients who are conscious or have a pulse. The sooner defibrillation is used, the better the survival rate: If it is used within 1 minute of the onset of VT or fibrillation, the survival rate is 90%; if it is delayed for 12 minutes, the survival rate is only 2% to 5%. Several studies have demonstrated that early defibrillation performed by lay people in a community setting can increase the survival rate. If immediate CPR is provided and defibrillation is performed within 5 minutes, more adults in ventricular fibrillation may survive with intact neurologic function (AHA, 2005). A large multisite study found that the availability of AEDs in public places and their use shortened the interval from collapse to rhythm recognition and defibrillation, which significantly increased the number of survivors (Hazinski, Idris, Kerber, et al., 2005). However, only a minority of prehospital arrests occur in public places, and prediction of the exact locations of future arrests is difficult. Therefore, although AEDs are clinically effective, money spent on AED equipment and training may be better spent on prevention interventions (Pell, Walker & Cobber, 2007).

Defibrillation depolarizes a critical mass of myocardial cells all at once; when they repolarize, the sinus node usually recaptures its role as the pacemaker. The electrical voltage required to defibrillate the heart is usually greater than that required for cardioversion and may cause more myocardial damage. Defibrillators are classified as monophasic or biphasic. Monophasic defibrillators deliver current in only one direction and require increased energy loads. Newer biphasic defibrillators deliver the electrical charge to the positive paddle, which then reverses back to the originating paddle. This system allows for lower, possibly nonprogressive energy levels (eg, 150 J with each defibrillation) with potentially less myocardial damage. If defibrillation was unsuccessful, CPR is immediately initiated and other advanced life support treatments are begun.

Epinephrine or vasopressin is administered after defibrillation to make it easier to convert the dysrhythmia to a normal rhythm with the next defibrillation. These medications may also increase cerebral and coronary artery blood flow. Antiarrhythmic medications such as amiodarone, lidocaine, or magnesium are administered if ventricular dysrhythmia persists (see Table 27-1). This treatment with continuous CPR, medication administration, and defibrillation continues until a stable rhythm resumes or until it is determined that the patient cannot be revived.

Pacemaker Therapy

A pacemaker is an electronic device that provides electrical stimuli to the heart muscle. Pacemakers are usually used when a patient has a permanent or temporary slower-than-normal impulse formation, or a symptomatic AV or ventricular conduction disturbance. They may also be used to control some tachydysrhythmias that do not respond to medication. Biventricular (both ventricles) pacing, also called resynchronization therapy, may be used to treat advanced heart failure that does not respond to medication. Pacemaker technology also may be used in an implantable cardioverter defibrillator (eg, in patients with coronary artery disease and a reduced ejection fraction). (See Chapter 30 for further discussion of heart failure.)

Pacemakers can be permanent or temporary. Temporary pacemakers are used to support patients until they improve or receive a permanent pacemaker (eg, after acute MI or during open heart surgery). Temporary pacemakers are used only in hospital settings.

Pacemaker Design and Types

Pacemakers consist of two components: an electronic pulse generator and pacemaker electrodes, which are located on leads or wires. The generator contains the circuitry and batteries that determine the rate (measured in beats per minute) and the strength or output (measured in milliamperes [mA]) of the electrical stimulus delivered to the heart. The generator also has circuitry that can detect the intracardiac electrical activity to cause an appropriate response; this component of pacing is called **sensitivity** and is measured in millivolts (mV). Sensitivity is set at the level that the intracardiac electrical activity must exceed to be sensed by the device. Leads, which carry the impulse created by the generator to the heart, can be threaded by fluoroscopy through a major vein into the heart, usually the right atrium and ventricle (endocardial leads), or they can be lightly sutured onto the outside of the heart and brought through the chest wall during open heart surgery (epicardial wires). The epicardial wires are always temporary and are removed by a gentle tug a few days after surgery. The endocardial leads may be temporarily placed with catheters through a vein (usually the femoral, subclavian, or internal jugular vein [transvenous wires]), usually guided by fluoroscopy. The leads may also be part of a specialized pulmonary artery catheter (see Chapter 30). However, obtaining a pulmonary artery wedge pressure may cause the leads to move out of pacing position. The endocardial and epicardial wires are connected to a temporary generator, which is about the size of a small paperback book. The energy source for a temporary generator is a common household battery. Monitoring for pacemaker malfunctioning and battery failure is a nursing responsibility.

The endocardial leads also may be placed permanently, passed into the heart through the subclavian, axillary, or cephalic vein, and connected to a permanent generator. Most current leads have a fixation mechanism (eg, a screw) at the end of the lead that allows precise positioning and avoidance of dislodgement. The permanent generator, which often weighs less than 1 oz and is the size of a thick credit card, is usually implanted in a subcutaneous pocket created in the pectoral region, below the clavicle, or behind the breast, especially in young women (Fig. 27-27). This

Figure 27-27 Implanted transvenous pacing lead (with electrode) and pacemaker generator.

procedure usually takes about 1 hour, and it is performed in a cardiac catheterization laboratory using a local anesthetic and moderate sedation. Close monitoring of the respiratory status is needed until the patient is fully awake.

Permanent pacemaker generators are insulated to protect against body moisture and warmth and have filters that protect them from electrical interference from most household devices, motors, and appliances. Several different energy sources for permanent generators have been used and others have been investigated, but lithium cell units are most often used today. They last approximately 6 to 12 years, depending on the type of pacemaker, how it is programmed, and how often it is used. Most pacemakers have an **elective replacement indicator (ERI)**, a signal that indicates when the battery is approaching depletion. The pacemaker continues to function for several months after the appearance of ERI to ensure that there is adequate time for a battery replacement. Although some batteries are rechargeable, most are not. Because the battery is permanently sealed in the pacemaker, the entire generator must be replaced. To replace a failing generator, the leads are disconnected, the old generator is removed, and a new generator is reconnected to the existing leads and reimplanted in the already existing subcutaneous pocket. Sometimes the leads are also replaced. Battery replacement is usually performed using a local anesthetic. Hospitalization is necessary for implantation or battery replacement; the patient usually can be discharged the next day.

If a patient suddenly develops a bradycardia, is symptomatic but has a pulse, and is unresponsive to atropine, emergency pacing may be started with transcutaneous pacing, which most defibrillators are now equipped to perform. AEDs are not yet able to do transcutaneous pacing. Large pacing ECG electrodes (sometimes the same conductive pads used for cardioversion and defibrillation) are placed on

Figure 27-28 Transcutaneous pacemaker with electrode pads connected to the anterior and posterior chest walls.

the patient's chest and back. The electrodes are connected to the defibrillator, which is the temporary pacemaker generator (Fig. 27-28). Because the impulse must travel through the patient's skin and tissue before reaching the heart, transcutaneous pacing can cause significant discomfort and is intended to be used only in emergencies. This type of pacing necessitates hospitalization. If the patient is alert, sedation and analgesia may be administered. Transcutaneous pacing is not indicated for pulseless bradycardia.

Pacemaker Generator Functions

Because of the sophistication and wide use of pacemakers, a universal code has been adopted to provide a means of safe communication about their function. The coding is referred to as the NASPE-BPEG code because it is sanctioned by the North American Society of Pacing and Electrophysiology (now called the Heart Rhythm Society) and the British Pacing and Electrophysiology Group. The complete code consists of five letters and was revised in 2002 (Bernstein, Daubert, Fletcher, et al., 2002). The fourth and fifth letters are used only with permanent pacemakers.

- The first letter of the code identifies the chamber or chambers being paced (ie, the chamber containing a pacing electrode). The letter characters for this code are A (atrium), V (ventricle), or D (dual, meaning both A and V).
- The second letter identifies the chamber or chambers being sensed by the pacemaker generator. Information from the electrode within the chamber is sent to the generator for interpretation and action by the generator. The letter characters are A (atrium), V (ventricle), D (dual), and O (indicating that the sensing function is turned off).
- The third letter of the code describes the type of response that will be made by the pacemaker to what is sensed. The letter characters used to describe this response are I (**inhibited**), T (**triggered**), D (dual, inhibited and triggered), and O (none). Inhibited response means that the response of the pacemaker is controlled by the activity of the patient's heart; that is, when the patient's heart beats the pacemaker does not

Figure 27-29 Pacing with appropriate sensing (on-demand pacing) in lead V_1 . Arrows denote pacing spike. Asterisk denotes intrinsic (patient's own) beats; therefore, no pacing. F denotes a fusion beat, which is a combination of an intrinsic beat and a paced beat occurring at the same time.

function, but when the heart does not beat, the pacemaker does function. In contrast, triggered response means that the pacemaker responds (paces the heart) when it senses intrinsic heart activity.

- The fourth letter of the code is related to a permanent generator's ability to vary the heart rate. This ability is available in most current pacemakers. The possible letters are O, indicating no rate responsiveness, or R, indicating that the generator has rate modulation (ie, the pacemaker has the ability to automatically adjust the pacing rate from moment to moment based on parameters such as QT interval, physical activity, acid-base changes, body temperature, rate and depth of respirations, or oxygen saturation). A pacemaker with rate-responsive ability is capable of improving cardiac output during times of increased cardiac demand, such as exercise, and decreasing the incidence of atrial fibrillation (Fuster, et al., 2008).
- The fifth letter of the code has two different indications: (1) that the permanent generator has multisite pacing capability with the letters A (atrium), V (ventricle), D (dual), and O (none); or (2) that the pacemaker has an antitachycardia function.

Commonly, only the first three letters are used for a pacing code. An example of a NASPE-BPEG code is DVI:

D: Both the atrium and the ventricle have a pacing electrode in place.

V: The pacemaker is sensing the activity of the ventricle only.

I: The pacemaker's stimulating effect is inhibited by ventricular activity—in other words, it does not create an impulse when the pacemaker senses that the patient's ventricle is active.

The pacemaker paces the atrium and then the ventricle when no ventricular activity is sensed for a period of time (the time is individually programmed into the pacemaker for each patient).

The type of generator and its selected settings depend on the patient's dysrhythmia, underlying cardiac function, and age. A straight vertical line usually can be seen on the ECG when pacing is initiated. The line that represents pacing is called a pacemaker spike. The appropriate ECG complex should immediately follow the pacing spike; therefore, a P wave should follow an atrial pacing spike and a QRS complex should follow a ventricular pacing spike. Because the impulse starts in a different place than the patient's normal rhythm, the QRS complex or P wave that responds to pacing looks different from the patient's normal ECG complex. *Capture* is a term used to denote that the appropriate complex followed the pacing spike.

Pacemakers are generally set to sense and respond to intrinsic activity, which is called on-demand pacing (Fig. 27-29). If the pacemaker is set to pace but not to sense, it is called a fixed or asynchronous pacemaker (Fig. 27-30); this is written in pacing code as AOO or VOO. The pacemaker paces at a constant rate, independent of the patient's intrinsic rhythm. Because AOO pacing stimulates only the atrium, it may be used in a patient who has undergone open

Figure 27-30 Fixed pacing or total loss of sensing pacing in lead V_1 ; arrows denote pacing spikes.

heart surgery and develops sinus bradycardia. AOO pacing ensures synchrony between atrial stimulation and ventricular stimulation (and therefore contraction), as long as the patient has no conduction disturbances in the AV node. VOO pacing is rare because of the risk that the pacemaker may deliver an impulse during the vulnerable repolarization phase, leading to VT. The occurrence of this type of pacing may indicate battery failure.

VVI (V, paces the ventricle; V, senses ventricular activity; I, paces only if the ventricles do not depolarize) pacing causes loss of AV synchrony and atrial kick, which may cause a decrease in cardiac output and an increase in atrial distention and venous congestion. This can lead to pacemaker syndrome, causing symptoms such as chest discomfort, shortness of breath, fatigue, activity intolerance, and postural hypotension. In addition, atrial pacing and dual-chamber (right atrial and right ventricular) pacing have been found to reduce the incidence of atrial fibrillation; however, research has not yet shown that this reduction decreases the incidence of heart failure or mortality (Olshansky, Day, Moore, et al., 2007; Sweeney, Bank, Nsah, et al., 2007). Long-term right ventricular pacing and dual-chamber pacing allows AV synchrony but also induces left from right ventricular conduction and, therefore, ventricular dysfunction (Fuster, et al., 2008).

Synchronized biventricular pacing, also called cardiac resynchronized therapy (CRT), has been found to modify the intraventricular, interventricular, and atrial-ventricular conduction defects identified with symptomatic moderate to severe (New York Heart Association Functional Class III and IV) left ventricular dysfunction and heart failure. The generator for biventricular pacing has three leads: one for the right atrium; one for the right ventricle, as with most standard pacemaker generators; and one for the left ventricle, usually placed in the left lateral wall. This therapy improves cardiac function, resulting in decreased heart failure symptoms and an improved quality of life (Trupp, 2004). Biventricular pacing may be used with an implantable cardioverter defibrillator.

Complications of Pacemaker Use

Complications associated with pacemakers relate to their presence within the body and improper functioning. The following complications may arise from a pacemaker:

- Local infection at the entry site of the leads for temporary pacing, or at the subcutaneous site for permanent generator placement. Prophylactic antibiotics and antibiotic irrigation of the subcutaneous pocket prior to generator placement has decreased the rate of infection to less than 2% (Fuster, et al., 2008).
- Pneumothorax. However, the current procedure and use of safe sheaths reduce this risk.
- Bleeding and hematoma at the lead entry sites for temporary pacing or at the subcutaneous site for permanent generator placement. This usually can be managed with cold compresses and discontinuation of antiplatelet and antithrombotic medications.
- Hemothorax from puncture of the subclavian vein or internal mammary artery.
- Ventricular ectopy and tachycardia from irritation of the ventricular wall by the endocardial electrode.

- Movement or dislocation of the lead placed transvenously (perforation of the myocardium).
- Phrenic nerve, diaphragmatic (hiccuping may be a sign), or skeletal muscle stimulation if the lead is dislocated or if the delivered energy (mA) is set high. The occurrence of this complication is avoided by testing during device implantation.
- Cardiac perforation resulting in pericardial effusion and rarely, cardiac tamponade, which may occur at the time of implantation or months later. This condition can be recognized by the change in QRS complex morphology, diaphragmatic stimulation, or hemodynamic instability.
- Twiddler syndrome may occur when the patient manipulates the generator, causing lead dislodgement or fracture of the lead.
- Pacemaker syndrome (hemodynamic instability caused by ventricular pacing and the loss of AV synchrony). This causes mild symptoms in more than 20% of ventricularly paced patients and severe symptoms in 5% to 7% of these patients (Fuster, et al., 2008).

In the initial hours after a temporary or permanent pacemaker is inserted, the most common complication is dislodgement of the pacing electrode. Minimizing patient activity can help prevent this complication. If a temporary electrode is in place, the extremity through which the catheter has been advanced is immobilized. With a permanent pacemaker, the patient is instructed initially to restrict activity on the side of the implantation.

The ECG is monitored very carefully to detect pacemaker malfunction. Improper pacemaker function, which can arise from failure in one or more components of the pacing system, is outlined in Table 27-2. The following data should be noted on the patient's record: model of pacemaker, type of generator, date and time of insertion, location of pulse generator, stimulation threshold, and pacer settings (eg, rate, energy output [mA], sensitivity [mV], and duration of interval between atrial and ventricular impulses [AV delay]). This information is important for identifying normal pacemaker function and diagnosing pacemaker malfunction.

A patient experiencing pacemaker malfunction may develop bradycardia as well as signs and symptoms of decreased cardiac output. The degree to which these symptoms become apparent depends on the severity of the malfunction, the patient's level of dependency on the pacemaker, and the patient's underlying condition. Pacemaker malfunction is diagnosed by analyzing the ECG. Manipulating the electrodes, changing the generator's settings, or replacing the pacemaker generator or leads (or both) may be necessary.

Inhibition of permanent pacemakers or reversion to asynchronous fixed rate pacing can occur with exposure to strong electromagnetic fields (electromagnetic interference [EMI]). However, recent pacemaker technology allows patients to safely use most household electronic appliances and devices (eg, microwave ovens, electric tools). Gas-powered engines should be turned off before working on them. Objects that contain magnets (eg, the earpiece of a phone; large stereo speakers; mattresses, jewelry, and wraps) should not be near the generator for longer than a few seconds. Patients are advised to place digital cellular phones at least 6 to 12 inches away from (or on the side opposite of)

Table 27-2 ASSESSING PACEMAKER MALFUNCTION

Problem	Possible Cause	Intervention
Loss of capture—complex does <i>not</i> follow pacing spike	Inadequate stimulus Lead dislodgement Lead wire fracture Catheter malposition Battery depletion Electronic insulation break Medication change Myocardial ischemia	Check security of all connections; increase milliamperage. Reposition extremity; turn patient to left side. Change battery. Change generator.
Undersensing—pacing spike occurs at preset interval despite patient's intrinsic rhythm	Sensitivity too high Electrical interference (eg, by a magnet) Faulty generator	Decrease sensitivity. Eliminate interference. Replace generator.
Oversensing—loss of pacing artifact; pacing does not occur at preset interval despite lack of intrinsic rhythm	Sensitivity too low Electrical interference Battery depletion Change in medication	Increase sensitivity. Eliminate interference. Change battery.
Loss of pacing—total absence of pacing spikes	Oversensing Battery depletion Loose or disconnected wires Perforation	Change battery. Check security of all connections. Apply magnet over permanent generator. Obtain 12-lead ECG and portable chest x-ray. Assess for murmur. Contact physician.
Change in pacing QRS shape	Septal perforation	Obtain 12-lead ECG and portable chest x-ray. Assess for murmur. Contact physician.
Rhythmic diaphragmatic or chest wall twitching or hiccuping	Output too high Myocardial wall perforation	Decrease milliamperage. Turn pacer off. Contact physician at once. Monitor closely for decreased cardiac output.

the pacemaker generator and not to carry them in a shirt pocket. Large electromagnetic fields, such as those produced by magnetic resonance imaging, radio and television transmitter towers and lines, transmission power lines (not the distribution lines that bring electricity into a home), and electrical substations may cause EMI. Patients should be cautioned to avoid such situations or to simply move farther away from the area if they experience dizziness or a feeling of rapid or irregular heartbeats (palpitations). Welding and the use of a chain saw should be avoided. If such tools are used, precautionary steps such as limiting the welding current to a 60- to 130-ampere range or using electric rather than gasoline-powered chain saws are advised.

In addition, the metal of the pacemaker generator may trigger store and library antitheft devices as well as airport and building security alarms; however, these alarm systems generally do not interfere with the pacemaker function. Patients should walk through them quickly and avoid standing in or near these devices. The handheld screening devices used in airports may interfere with the pacemaker. Patients should be advised to ask security personnel to perform a hand search instead of using the handheld screening device. Patients also should be instructed to wear or carry medical identification to alert personnel to the presence of the pacemaker.

Pacemaker Surveillance

Pacemaker clinics have been established to monitor patients and to test pulse generators for impending pacemaker battery failure. A computerized device is held over the generator to “interrogate” it with painless radio signals; it detects the generator’s settings, battery status and the presence of ERI, pacing threshold, sensing function, lead integrity, pacing data (eg, number of pacing events), and other stored information. Several factors, such as lead fracture, muscle inhibition, and insulation disruption, also may be assessed

depending on the type of pacemaker and the equipment available. If indicated, the pacemaker is turned off for a few seconds, using a magnet or a programmer, while the ECG is recorded to assess the patient’s underlying cardiac rhythm. Transtelephonic transmission of the generator’s information is another follow-up method. Special equipment is used to transmit information about the patient’s pacemaker over the telephone to a receiving system at a pacemaker clinic. The information is converted into tones; equipment at the clinic converts these tones to an electronic signal and records them on an ECG strip. The pacemaker rate and other data concerning pacemaker function are obtained and evaluated by a cardiologist. This simplifies the diagnosis of a failing generator, reassures the patient, and improves management when the patient is physically remote from pacemaker testing facilities. The frequency of the pacemaker checks varies with the patient’s age and underlying condition, the degree of pacemaker dependency, the age and type of the device, the results from previous pacemaker checks, and physician preference. A typical follow-up schedule is every 2 weeks during the first month, every 4 to 8 weeks for 3 years, and every 4 weeks thereafter.

Implantable Cardioverter Defibrillator

The implantable cardioverter defibrillator (ICD) is an electronic device that detects and terminates life-threatening episodes of tachycardia or fibrillation, especially those that are ventricular in origin. Patients at high risk of VT or ventricular fibrillation are those who have survived sudden cardiac death syndrome, usually caused by ventricular fibrillation, or have experienced spontaneous, symptomatic VT (syncope secondary to VT) not due to a reversible cause. Other people at risk of sudden cardiac death include those with dilated cardiomyopathy, hypertrophic cardiomyopathy, arrhythmogenic right ventricular dysfunction, and idiopathic

Figure 27-31 The implantable cardioverter defibrillator (ICD) consists of a generator and a sensing/pacing/defibrillating electrode.

prolonged QT syndrome. In addition, patients with moderate to severe left ventricular dysfunction (ejection fraction of 40% or less), with or without nonsustained VT, with ischemic heart disease or nonischemic dilated cardiomyopathy, and a QRS duration of more than 150 milliseconds are at high risk for cardiac arrest; therefore, prophylactic implantation may be indicated (Fuster, et al., 2008). ICDs may also be implanted in patients with symptomatic, recurrent, medication-refractory atrial fibrillation.

An ICD has a generator about the size of a book of matches and at least a right ventricular lead that can sense intrinsic electrical activity and deliver an electrical impulse. The implantation procedure, postimplantation care, and length of hospitalization are much like those for insertion of a pacemaker (Fig. 27-31). ICDs are designed to respond to two criteria: a rate that exceeds a predetermined level and a change in the isoelectric line segments. When a dysrhythmia occurs, rate sensors require a set duration of time to sense the dysrhythmia. Then the device automatically charges, and, after a second “look” confirms the dysrhythmia, it delivers the programmed charge through the lead to the heart. The time from dysrhythmia detection to electrical discharge depends on the charging time, which depends on the programmed energy level (Fuster, et al., 2008). However, in an ICD that has the capability of providing atrial therapies, the device can be programmed to be activated by the patient, giving the patient time to activate the charge at a time and place of his or her choosing. The life of the lithium battery is about 9 years but varies depending on use of the ICD. ICD surveillance is similar to that of the pacemaker; however, it includes stored endocardial electrocardiograms and information about the number and frequency of shocks that have been delivered.

Antiarrhythmic medication usually is administered with this technology to minimize the occurrence of the tachy-dysrhythmia and to reduce the frequency of ICD discharge.

Several types of devices are available and may be programmed for multiple treatments (Fuster, et al., 2008). ICD, the generic name, is used as the abbreviation for these various devices. Each device offers a different delivery sequence, but all are capable of delivering high-energy (high-intensity) defibrillation to treat a tachycardia (atrial or ventricular). The device may deliver up to six shocks if necessary.

Some ICDs can respond with (1) antitachycardia pacing, in which the device delivers electrical impulses at a fast rate in an attempt to disrupt the tachycardia, (2) low-energy (low-intensity) cardioversion, or (3) defibrillation; others may use all three techniques (Fuster, et al., 2008). Antitachycardia pacing is used to terminate tachycardias caused by a conduction disturbance called reentry, which is repetitive restimulation of the heart by the same impulse. An impulse or a series of impulses is delivered to the heart by the device at a fast rate to collide with and stop the heart’s reentry conduction impulses and therefore to stop the tachycardia. Some ICDs also have pacemaker capability if the patient develops bradycardia, which sometimes occurs after treatment of the tachycardia. Usually the mode is VVI (V, paces the ventricle; V, senses ventricular activity; I, paces only if the ventricles do not depolarize). Some ICDs also treat atrial fibrillation (Fuster, et al., 2008).

Which device is used and how it is programmed depend on the patient’s dysrhythmia(s). The device may be programmed differently for different dysrhythmias (eg, ventricular fibrillation, ventricular tachycardia with a fast ventricular rate, and ventricular tachycardia with a slow ventricular rate). As with pacemakers, there is a NASPE-BPEG code for communicating the functions of the ICDs (Berstein, et al., 2002). The first letter represents the chamber or chambers shocked (O, none; A, atrium; V, ventricle; D, both atrium and ventricle). The second letter represents the chamber that can be antitachycardia paced (O, A, V, D, meaning the same as the first letter). The third letter indicates the method used by the generator to detect a tachycardia (E, electrogram; H, hemodynamics). The last letter represents the chambers that have antibradycardia pacing (O, A, V, D, meaning the same as the first and second letters of the ICD code).

One significant issue with ICDs is cost. Although ICDs reduce the number of sudden cardiac deaths, they are costly and should be used by people for whom the benefits are the most substantial. A large research trial showed that the cost-effectiveness of ICDs improved over time, especially for people who were 65 years of age or older with QRS duration of 0.12 seconds or longer (Zwanziger, Hall, Dick, et al., 2006).

Complications of ICD implantation are similar to those associated with pacemaker insertion. The primary complication is surgery-related infection; its risk increases with battery or lead replacement (Fuster, et al., 2008). A few complications are associated with the technical aspects of the equipment, like those of pacemakers, such as premature battery depletion and dislodged or fractured leads. Inappropriate delivery of ICD therapy, usually due to oversensing or atrial and sinus tachycardias with a rapid ventricular rate response, is the most frequent complication. This requires reprogramming of the device.

A

B

Figure 27-32 A, Ventricular pacing with intermittent loss of capture (a pacing spike not followed by a QRS complex). B, Ventricular pacing with loss of sensing (a pacing spike occurring at an inappropriate time). ↑, pacing spike; *, loss of capture; P, pacemaker-induced QRS complex; I, patient's intrinsic QRS complex; F, fusion (a QRS complex formed by a merging of the patient's intrinsic QRS complex and the pacemaker-induced QRS complex). Both in lead V₁.

Nursing Management of the Patient With an Implantable Cardiac Device

After a permanent electronic device (pacemaker or ICD) is inserted, the patient's heart rate and rhythm are monitored by ECG. The device's settings are noted and compared with the ECG recordings to assess the device's function. For example, pacemaker malfunction is detected by examining the pacemaker spike and its relationship to the surrounding ECG complexes (Fig. 27-32). In addition, cardiac output and hemodynamic stability are assessed to identify the patient's response to pacing and the adequacy of pacing. The appearance or increasing frequency of dysrhythmia is observed and reported to the physician. If the patient has an ICD implanted and develops VT or ventricular fibrillation, the ECG should be recorded to note the time between the onset of the dysrhythmia and the onset of the device's shock or antitachycardia pacing.

The incision site where the generator was implanted is observed for bleeding, hematoma formation, or infection, which may be evidenced by swelling, unusual tenderness, drainage, and increased warmth. The patient may complain of continuous throbbing or pain. These symptoms are reported to the physician.

A chest x-ray is usually taken after the procedure and prior to discharge to document the position of leads in addition to ensuring that the procedure did not cause a pneumothorax. It is necessary to assess the function of the device throughout its lifetime and especially after changes in the patient's medication regimen. For example, antiarrhythmics, beta-blockers, and diuretics may increase the pacing threshold, whereas corticosteroids and alpha adrenergics

may decrease the pacing threshold; the opposite effect occurs when the patient is taken off these medications.

The patient is also assessed for anxiety, depression, or anger, which may be symptoms of ineffective coping with the implantation. In addition, the level of knowledge and learning needs of the patient and family and the history of adherence to the therapeutic regimen should be identified. It is especially important to include the family when providing education and support.

In the perioperative and postoperative phases, the nurse carefully observes the patient's responses to the device and provides the patient and family with further teaching as needed (Chart 27-3). The nurse also assists the patient and family in addressing concerns and in making decisions about self-care and lifestyle changes necessitated by the dysrhythmia and resulting device implantation.

Preventing Infection

The nurse changes the dressing as needed and inspects the insertion site for redness, swelling, soreness, or any unusual drainage. Any change in wound appearance, an increase in the patient's temperature, or an increase in the patient's white blood cell count should be reported to the physician.

Promoting Effective Coping

The patient treated with an electronic device experiences not only lifestyle and physical changes but also emotional changes. At different times during the healing process, the patient may feel angry, depressed, fearful, anxious, or a combination of these emotions. Although each patient uses individual coping strategies (eg, humor, prayer, communication

CHART
27-3

HOME CARE CHECKLIST

The Patient With an Implantable Cardiac Device

At the completion of home care instructions, the patient and significant other will be able to:	PATIENT	CAREGIVER
Avoid infection at the insertion site of the device.		
• Leave the incision uncovered and observe it daily for redness, increased swelling, and heat.	✓	✓
• Take temperature at same time each day; report any increase.	✓	✓
• Avoid wearing tight restrictive clothing that may cause friction over the insertion site.	✓	
• Initially avoid soaking in the tub and lotion, creams, or powders in the area of the device.	✓	
Adhere to activity restrictions.		
• Restrict movement of arm until incision heals; do not raise arm above head for 2 weeks.	✓	✓
• Avoid heavy lifting for a few weeks.	✓	✓
• Discuss safety of activities (eg, driving) with physician.	✓	✓
• Avoid contact sports.	✓	
• Recognize that, although it may take up to 2 to 3 weeks to resume normal activities, physical activity does not usually have to be curtailed, with the exception of contact sports.	✓	✓
Electromagnetic interference: Understand the importance of the following:		
• Avoid large magnetic fields such as those created by magnetic resonance imaging, large motors, arc welding, electrical substations, and so forth. Magnetic fields may deactivate the device, negating its effect on a dysrhythmia.	✓	
• At security gates at airports, government buildings, or other secured areas, show identification card and request a hand (not handheld device) search. Obtain and carry a physician's letter about this requirement.	✓	
• Some electrical and small motor devices, as well as products that contain magnets (eg, cellular phones), may interfere with the functioning of the cardiac device if the electrical device is placed very close to it. Avoid leaning directly over large electrical devices or motors, or ensure contact is of brief duration; place cellular phone on opposite side of cardiac device.	✓	
• Household appliances (eg, microwave ovens) should not cause any concern.	✓	✓
Promote safety.		
• Describe what to do if symptoms occur and notify physician if any discharges seem unusual.	✓	✓
• Maintain a log that records discharges of an ICD. Record events that precipitate the sensation of shock. This provides important data for the physician to use in readjusting the medical regimen.	✓	✓
• Encourage family members to attend a CPR class.		✓
• Call 911 for emergency assistance if feeling of dizziness occurs.	✓	✓
• Wear medical identification (eg, Medic-Alert) that includes physician information.	✓	
• Avoid frightening family or friends with unexpected shocks from an ICD, which will not harm them. Inform family and friends that in the event they are in contact with the patient when a shock is delivered, they may also feel the shock. It is especially important to warn sexual partners that this may occur.	✓	✓
• Carry medical identification with physician's name, type and model number of the device, manufacturer's name, and hospital where device was inserted.	✓	✓
Follow-up care.		
• Discuss psychological responses to the device implantation, such as changes in self-image, depression due to loss of mobility secondary to driving restrictions, fear of shocks, increased anxiety, concerns that sexual activity may trigger the device, and changes in partner relationship.	✓	✓
• Adhere to appointments that are scheduled to monitor the electronic performance of the cardiac device. This is especially important during the first month after implantation and near the end of the battery life. Remember to take a log of ICD discharges to review with physician.	✓	✓
• For patients with pacemakers, check pulse daily. Report <i>immediately</i> any sudden slowing or increasing of the pulse rate. This may indicate pacemaker malfunction.	✓	✓
• Attend a cardiac device support group within the area.	✓	
• Hospitalization may be necessary periodically to change battery or replace pacemaker unit.	✓	✓

with a significant other) to manage emotional distress, some strategies may work better than others. Signs that may indicate ineffective coping include social isolation, increased or prolonged irritability or depression, and difficulty in relationships.

To promote effective coping strategies, the nurse must recognize the patient's as well as the family's perceptions of the situation and their resulting emotional state and assist them to explore their reactions and feelings. Because of the unpredictable and possibly painful ICD discharge, patients with ICDs are most vulnerable to feelings of helplessness, leading to depression. The nurse can help the patient identify positive methods to deal with the actual or perceived limitations and manage any lifestyle changes needed. The nurse may help the patient identify changes (eg, loss of ability to participate in contact sports), the emotional responses to the change (eg, anger), and how the patient responds to that emotion (eg, quickly becomes angry when talking with spouse). The nurse reassures the patient that the responses are normal and helps the patient identify realistic goals (eg, develop interest in another activity) and develop a plan to attain these goals. The patient and family should be encouraged to talk about their experiences and emotions with each other and the health care team. The nurse may refer the patient and family to a hospital, community, or online support group. The nurse may also encourage the use of spiritual resources. The nurse also may teach the patient easy-to-use stress reduction techniques (eg, deep-breathing exercises) to facilitate coping. Instructing the patient about the ICD may help the patient to cope with changes that occur as a result of device implantation (see Chart 27-3).

Promoting Home and Community-Based Care

After device insertion, the patient's hospital stay may be 1 day or less, and follow-up in an outpatient clinic or office is common. The patient's anxiety and feelings of vulnerability may interfere with the ability to learn information provided. The nurse needs to include caregivers in the teaching and provide printed materials for use by the patient and caregiver. The nurse establishes priorities for learning with the patient and caregiver. Teaching may include the importance of periodic device monitoring, promoting safety, surgical site care, and avoiding EMI (see Chart 27-3). In addition, the educational plan should include information about activities that are safe and those that may be dangerous. The nurse discusses with the patient and family what they are to do when a shock is delivered. The nurse may facilitate CPR training for the family.

Electrophysiologic Studies

An EP study is an invasive procedure used to evaluate and treat various dysrhythmias that have caused cardiac arrest or significant symptoms. It also is indicated for patients with symptoms that suggest a dysrhythmia that has gone undetected and undiagnosed by other methods. Because an EP study is invasive, it is performed in the hospital and may require that the patient be admitted. An EP study is used to do the following:

- Identify the impulse formation and propagation through the cardiac electrical conduction system
- Assess the function or dysfunction of the SA and AV nodal areas
- Identify the location (called mapping) and mechanism of dysrhythmogenic (the ability to cause dysrhythmias) foci
- Assess the effectiveness of antiarrhythmic medications and devices for the patient with a dysrhythmia
- Treat certain dysrhythmias through the destruction of the causative cells (**ablation**)

An EP procedure is a type of cardiac catheterization that is performed in a specially equipped cardiac catheterization laboratory by an electrophysiologist, who is a cardiologist with specialized training, assisted by other EP laboratory personnel. The patient is conscious but lightly sedated. Usually a catheter with multiple electrodes is inserted through a small incision in the femoral vein, threaded through the inferior vena cava, and advanced into the heart; however, depending on the type of study and the information needed, a second catheter may be inserted into the femoral artery. The electrodes are positioned within the heart at specific locations—for instance, in the right atrium near the sinus node, in the coronary sinus, near the tricuspid valve, and at the apex of the right ventricle. The number and placement of electrodes depend on the type of study being conducted. These electrodes allow the electrical signal to be recorded from within the heart (intracardiogram).

The electrodes also allow the clinician to introduce a pacing stimulus to the intracardiac area at a precisely timed interval and rate, thereby stimulating the area (programmed stimulation). An area of the heart may be paced at a rate much faster than the normal rate of **automaticity**, the rate at which impulses are spontaneously formed (eg, in the sinus node). This allows the pacemaker to become an artificial focus of automaticity and to assume control (overdrive suppression). Then the pacemaker is stopped suddenly, and the time it takes for the sinus node to resume control is assessed. A prolonged time indicates dysfunction of the sinus node.

One of the main purposes of programmed stimulation is to assess the ability of the area surrounding the electrode to cause a reentry dysrhythmia. One or a series of premature impulses is delivered to an area in an attempt to cause the tachydysrhythmia. Because the precise location of the suspected area and the specific timing of the pacing needed are unknown, the electrophysiologist uses several different techniques to cause the dysrhythmia during the study. If the dysrhythmia can be reproduced by programmed stimulation, it is called inducible. Once a dysrhythmia is induced, a treatment plan is determined and implemented. If, on the follow-up EP study, the tachydysrhythmia cannot be induced, then the treatment is determined to be effective. Different medications may be administered and combined with electrical devices (pacemaker, ICD) to determine the most effective treatment to suppress the dysrhythmia.

Patient care, patient teaching, and associated complications of an EP study are similar to those associated with cardiac catheterization (see Chapter 26). The study is usually about 2 hours in length; however, if the electrophysiologist conducts not only a diagnostic procedure but also treatment, the study can take up to 6 hours. During the procedure, patients benefit from a calm, reassuring approach.

Patients who are to undergo an EP study may be anxious about the procedure and its outcome. A detailed discussion

involving the patient, the family, and the electrophysiologist usually occurs to ensure that the patient can give informed consent and to reduce the patient's anxiety about the procedure. Before the procedure, the patient should receive instructions about the procedure and its usual duration, the environment where the procedure is performed, and what to expect. Although an EP study is not painful, it does cause discomfort and can be tiring. It may also cause feelings that were experienced when the dysrhythmia occurred in the past. In addition, patients are taught what will be expected of them (eg, lying very still during the procedure, reporting symptoms or concerns).

The patient should also know that the dysrhythmia may occur during the procedure. It often stops on its own; if it does not, treatment is given to restore the patient's normal rhythm. The dysrhythmia may have to be terminated using cardioversion or defibrillation, but this is performed under more controlled circumstances than if performed in an emergency.

Postprocedural care is similar to that for cardiac catheterization, including restriction of activity to promote hemostasis at the insertion site. To identify any complications and to ensure healing, the patient's vital signs and the appearance of the insertion site are assessed frequently. Because an artery is not always used, there is a lower incidence of vascular complications than with other catheterization procedures. Cardiac arrest may occur, but the incidence is low (less than 1%) (Fuster, et al., 2008).

Cardiac Conduction Surgery

Atrial tachycardias and ventricular tachycardias that do not respond to medications and are not suitable for antitachycardia pacing may be treated by methods that include a maze procedure and ablation. Hospitalization is required for both procedures.

Maze Procedure

The maze procedure is an open heart surgical procedure for refractory atrial fibrillation. Small transmural incisions are made throughout the atria. The resulting formation of scar tissue prevents reentry conduction of the electrical impulse. Because the procedure requires significant time and cardiopulmonary bypass, its use is reserved only for those patients undergoing cardiac surgery for other reason (eg, coronary artery bypass) (Fuster, et al., 2008). In addition, some patients need a permanent pacemaker after the surgery.

Catheter Ablation Therapy

Catheter ablation destroys specific cells that are the cause or central conduction route of a tachydysrhythmia. It is performed with or after an EP study. Usual indications for ablation are AVNRT, a recurrent atrial dysrhythmia (especially atrial fibrillation), or VT unresponsive to previous therapy (or for which the therapy produced significant side effects).

Figure 27-33 Wolff-Parkinson-White syndrome. **A**, Sinus rhythm. Note the short PR interval, slurred initial upstroke of the QRS complex (delta wave, at the arrow), and prolonged QRS duration, upper lead II, lower lead V₁. **B**, Rhythm strip of same patient following ablation, upper lead V₁, lower lead II. ECG strips courtesy of Linda Ardini and Catherine Berkmeier, Inova Fairfax Hospital, Falls Church, VA.

Ablation is also indicated to eliminate accessory AV pathways or bypass tracts that exist in the hearts of patients with preexcitation syndromes such as WPW syndrome. During normal embryonic development, all connections between the atria and ventricles disappear, except for that between the AV node and the bundle of His. In some people, embryonic connections of normal heart muscle between the atria and ventricles remain, providing an accessory pathway or a tract through which the electrical impulse can bypass the AV node. These pathways can be located in several different areas. If the patient develops atrial fibrillation, the impulse may be conducted into the ventricle at a rate of 300 times per minute or more, which can lead to ventricular fibrillation and sudden cardiac death. Preexcitation syndromes are identified by specific ECG findings. For example, in WPW syndrome there is a shortened PR interval, slurring (called a delta wave) of the initial QRS deflection, and prolonged QRS duration (Fig. 27-33).

Ablation is most often accomplished by using radiofrequency, which involves placing a special catheter at or near the origin of the dysrhythmia. High-frequency, low-energy sound waves are passed through the catheter, causing thermal injury and cellular changes that result in localized destruction and scarring. The tissue damage is more specific to the dysrhythmic tissue, with less trauma to the surrounding cardiac tissue than occurs with cryoablation (extreme cold) or electrical ablation. Although cryoablation has less risk of causing AV block and has been found to be less painful to the patient, the procedure takes longer and has lower acute and long-term efficacy rates (Fuster, et al., 2008).

During the ablation procedure, defibrillation pads, an automatic blood pressure cuff, and a pulse oximeter are used and an indwelling urinary catheter is inserted. The patient is usually given moderate sedation. An EP study is performed to induce the dysrhythmia. The ablation catheter is placed at the origin of the dysrhythmia, and the ablation procedure is performed. Multiple ablations may be necessary. Successful ablation is achieved when the dysrhythmia can no longer be induced. The patient is monitored for another 30 to 60 minutes and then retested to ensure that the dysrhythmia does not recur.

Postprocedural care on a step-down unit is similar to that for an EP study, except that the patient is monitored more closely, depending on the time needed for recovery from sedation. Major risks of catheter ablation include pericardial tamponade, phrenic nerve injury, stroke, pulmonary vein stenosis, and atrioesophageal fistulas (Fuster, et al., 2008).

CRITICAL THINKING EXERCISES

EBP 1 You are caring for a 69-year-old woman who had an acute MI and received thrombolytic therapy. You notice that her pulse is irregular and your analysis of the ECG strip indicates that she has sinus rhythm and frequent PVCs. What are some of the possible causes of this dysrhythmia? Identify some of the key factors that would need to be included in your assessment to assist in identification of the cause of the dysrhythmia. What nursing interventions are needed? What is the evidence base that

supports these nursing interventions? Discuss the strength of the evidence and the criteria used to evaluate the strength of the evidence.
