The liver and spleen are often moderately enlarged for a few days after onset; other than jaundice, there are few other physical signs. Hepatitis A antigen may be found in the stool 7 to 10 days before illness and for 2 to 3 weeks after symptoms appear. HAV antibodies are detectable in the serum, but usually not until symptoms appear. Analysis of subclasses of immunoglobulins can help determine whether the antibody represents acute or past infection.

Prevention

A number of strategies exist to prevent transmission of HAV. Patients and their families are encouraged to follow general precautions that can prevent transmission of the virus. Scrupulous handwashing, safe water supplies, and proper control of sewage disposal are just a few of these prevention strategies.

Effective (95% to 100% after two to three doses) and safe HAV vaccines include Havrix and Vaqta (Goldman &

Ausiello, 2008; Rodes, et al., 2007). It is recommended that the two-dose vaccine be given to adults 18 years of age or older, with the second dose given 6 to 12 months after the first. Protection against hepatitis A develops within several weeks after the first dose of the vaccine. Children and adolescents 2 to 18 years of age receive three doses; the second dose is given 1 month after the first, and the third dose is given 6 to 12 months later. Hepatitis A routine immunization of young children has proved effective in reducing disease incidence and maintaining very low incidence levels among vaccine recipients and across all age groups in many settings (Goldman & Ausiello, 2008; Rodes, et al., 2007). Hepatitis A vaccine is recommended for people traveling to locations where sanitation and hygiene are unsatisfactory. Vaccination is also recommended for those from high-risk groups, such as homosexual men, IV or injection drug users, staff of day care centers, and health care personnel (Hauser, et al., 2006; Rodes, et al., 2007; Wolfe, 2006). The vaccine has also been used to interrupt community-wide outbreaks. As with other vaccinations, precautions must be taken to ensure prevention, detection, and treatment of hypersensitivity reactions to the vaccine.

For people who have not been previously vaccinated, hepatitis A can be prevented by intramuscular administration of globulin during the incubation period, if given within 2 weeks of exposure. This bolsters the person's antibody production and provides 6 to 8 weeks of passive immunity. Immune globulin may suppress overt symptoms of the disease; the resulting subclinical case of hepatitis A would produce immunity to subsequent episodes of the virus.

Immune globulin is also recommended for household members and sexual contacts of people with hepatitis A. Susceptible people in the same household as the patient are usually also infected by the time the diagnosis is made and should receive immune globulin. Institutional contacts of patients with hepatitis A should also receive postexposure prophylaxis with immune globulin. Prophylaxis is not necessary for casual contacts of an infected person, such as classmates, coworkers, or hospital employees (Rodes, et al., 2007). Although they are rare, systemic reactions to immune globulin do occur. Caution is required when anyone who has previously had angioedema, hives, or other allergic reactions is treated with any human immune globulin. Epinephrine should be available in case of systemic, anaphylactic reaction.

Preexposure prophylaxis is recommended for those traveling to developing countries or settings with poor or uncertain sanitation conditions who do not have sufficient time to acquire protection by administration of hepatitis A vaccine (Rodes, et al., 2007). Community interventions for preventing hepatitis A are outlined in Chart 39-7.

Medical Management

Bed rest during the acute stage and a diet that is both acceptable to the patient and nutritious are part of the treatment and nursing care. During the period of anorexia, the patient should receive frequent small feedings, supplemented if necessary by IV fluids with glucose. Because the patient often has an aversion to food, gentle persistence and creativity may be required to stimulate appetite. Optimal

CHART
39-7**HEALTH PROMOTION**
Prevention of Hepatitis

- Encourage proper community and home sanitation.
- Encourage conscientious individual hygiene.
- Instruct patients regarding safe practices for preparing and dispensing food.
- Support effective health supervision of schools, dormitories, extended care facilities, barracks, and camps.
- Promote community health education programs.
- Facilitate mandatory reporting of viral hepatitis to local health departments.
- Recommend vaccination for all children 1 year of age and older.
- Recommend vaccination for travelers to developing countries, illegal drug users (injection and noninjection drug users), men who have sex with men, and people with chronic liver disease, and recipients (eg, hemophiliacs) of pooled plasma products.
- Promote vaccination to interrupt community-wide outbreaks.

food and fluid levels are necessary to counteract weight loss and to speed recovery. Even before the icteric phase, however, many patients recover their appetites (Chart 39-8).

The patient's sense of well-being and laboratory test results are generally appropriate guides to bed rest and restriction of physical activity. Gradual but progressive ambulation seems to hasten recovery, provided the patient rests after activity and does not participate in activities to the point of fatigue.

Nursing Management

Management usually occurs in the home unless symptoms are severe. Therefore, the nurse assists the patient and family in coping with the temporary disability and fatigue that are common in hepatitis and instructs them to seek additional health care if the symptoms persist or worsen. The patient and family also need specific guidelines about diet, rest, follow-up blood work, and the importance of avoiding alcohol, as well as sanitation and hygiene measures (particularly handwashing) to prevent spread of the disease to other family members.

Chart 39-8 • Dietary Management of Viral or Drug-Related Hepatitis

- Recommend small, frequent meals.
- Provide intake of 2000 to 3000 kcal/d during acute illness.
- Although early studies indicate that a high-protein, high-calorie diet may be beneficial, advise patient not to force food and to restrict fat intake.
- Carefully monitor fluid balance.
- If anorexia and nausea and vomiting persist, enteral feedings may be necessary.
- Instruct patient to abstain from alcohol during acute illness and for at least 6 mo after recovery.
- Advise patient to avoid substances (medications, herbs, illicit drugs, and toxins) that may affect liver function.

Specific teaching to patients and families about reducing the risk of contracting hepatitis A includes good personal hygiene, stressing careful handwashing (after bowel movements and before eating) and environmental sanitation (safe food and water supply, effective sewage disposal).

NURSING ALERT

A combined hepatitis A and B vaccine (Twinrix) is available for vaccination of people 18 years of age and older with indications for both hepatitis A and B vaccination. Vaccination consists of three doses, given on the same schedule as that used for single-antigen hepatitis B vaccine.

Hepatitis B Virus

Unlike HAV, the hepatitis B virus (HBV) is transmitted primarily through blood (percutaneous and permucosal routes). HBV can be found in blood, saliva, semen, and vaginal secretions and can be transmitted through mucous membranes and breaks in the skin. HBV is also transferred from carrier mothers to their infants, especially in areas with a high incidence (eg, Southeast Asia). The infection usually is not transmitted via the umbilical vein but from the mother at the time of birth and during close contact afterward.

HBV has a long incubation period. It replicates in the liver and remains in the serum for relatively long periods, allowing transmission of the virus. Risk factors for HBV infection are summarized in Chart 39-9. Screening of blood donors has greatly reduced the occurrence of hepatitis B after blood transfusion.

Most people (more than 90%) who contract HBV infection develop antibodies and recover spontaneously in 6 months. The mortality rate from hepatitis B has been reported to be as high as 10%. Another 10% of patients who have hepatitis B progress to a carrier state or develop chronic hepatitis with persistent HBV infection and hepatocellular

CHART
39-9**Risk Factors for Hepatitis B**

- Frequent exposure to blood, blood products, or other body fluids
- Health care workers: hemodialysis staff, oncology and chemotherapy nurses, personnel at risk for needlesticks, operating room staff, respiratory therapists, surgeons, dentists
- Hemodialysis
- Male homosexual and bisexual activity
- IV/injection drug use
- Close contact with carrier of HBV
- Travel to or residence in area with uncertain sanitary conditions
- Multiple sexual partners
- Recent history of sexually transmitted disease
- Receipt of blood or blood products (eg, clotting factor concentrate)

injury and inflammation. It remains a major worldwide cause of cirrhosis and hepatocellular carcinoma.

The elderly patient who contracts hepatitis B has a serious risk of severe liver cell necrosis or fulminant hepatic failure, particularly if other illnesses are present. Because the patient is seriously ill and the prognosis is poor, efforts should be undertaken to eliminate other factors (eg, medications, alcohol) that may affect liver function.

The immune system is altered in the aged. A less responsive immune system may be responsible for the increased incidence and severity of hepatitis B among elderly people and the increased incidence of liver abscesses secondary to decreased phagocytosis by the Kupffer cells. With the advent of hepatitis B vaccine as the standard for prevention, the incidence of hepatic diseases may decrease in the future.

Clinical Manifestations

Clinically, the disease closely resembles hepatitis A, but the incubation period is much longer (1 to 6 months). Signs and symptoms of hepatitis B may be insidious and variable. Fever and respiratory symptoms are rare; some patients have arthralgias and rashes. The patient may have loss of appetite, dyspepsia, abdominal pain, generalized aching, malaise, and weakness. Jaundice may or may not be evident. If jaundice occurs, light-colored stools and dark urine accompany it. The liver may be tender and enlarged to 12 to 14 cm vertically. The spleen is enlarged and palpable in a few patients; the posterior cervical lymph nodes may also be enlarged. Subclinical episodes also occur frequently.

Assessment and Diagnostic Findings

HBV is a DNA virus composed of the following antigenic particles:

- HBcAg—hepatitis B core antigen (antigenic material in an inner core)
- HBsAg—hepatitis B surface antigen (antigenic material on the viral surface, a marker of active replication and infection)
- HBeAg—an independent protein circulating in the blood
- HBxAg—gene product of X gene of HBV DNA

Each antigen elicits its specific antibody and is a marker for different stages of the disease process:

- anti-HBc—antibody to core antigen of HBV; persists during the acute phase of illness; may indicate continuing HBV in the liver
- anti-HBs—antibody to surface determinants on HBV; detected during late convalescence; usually indicates recovery and development of immunity
- anti-HBe—antibody to hepatitis B e-antigen; usually signifies reduced infectivity
- anti-HBxAg—antibody to the hepatitis B x-antigen; may indicate ongoing replication of HBV

HBsAg appears in the circulation in 80% to 90% of infected patients 1 to 10 weeks after exposure to HBV and 2 to 8 weeks before the onset of symptoms or an increase in transferase levels. Patients with HBsAg that persists for 6 months or longer after acute infection are considered to be HBsAg carriers (Rodes, et al., 2007). HBeAg is the next antigen of HBV to appear in the serum. It usually appears within 1 week of the appearance of HBsAg but before

changes in aminotransferase levels; it disappears from the serum within 2 weeks. HBV DNA, detected by polymerase chain reaction testing, appears in the serum at about the same time as HBeAg. HBcAg is not always detected in the serum in HBV infection.

About 15% of American adults are positive for anti-HBs, which indicates that they have had hepatitis B. Anti-HBs may be positive in as many as two thirds of IV or injection drug users. Prevacination screening for anti-HBs is not recommended except for high-risk adults who may have already been exposed to the disease.

Prevention

Preventing Transmission

Continued screening of blood donors for the presence of hepatitis B antigens further decreases the risk of transmission by blood transfusion. The use of disposable syringes, needles, and lancets and the introduction of needleless IV administration systems have reduced the risk of spreading this infection from one patient to another or to health care personnel during the collection of blood samples or the administration of parenteral therapy. Good personal hygiene is fundamental to infection control. In the clinical laboratory, work areas should be disinfected daily. Gloves are worn when handling all blood and body fluids, as well as HBsAg-positive specimens, or when there is potential exposure to blood (eg, blood drawing) or to patients' secretions. Eating and smoking are prohibited in the laboratory and in other areas exposed to secretions, blood, or blood products. Patient education regarding the nature of the disease, its infectiousness, and prognosis is a critical factor in preventing transmission and protecting contacts.

Active Immunization: Hepatitis B Vaccine

Active immunization is recommended for people who are at high risk for hepatitis B (eg, health care personnel, hemodialysis patients). In addition, people with hepatitis C and other chronic liver diseases should receive the vaccine. A yeast-recombinant hepatitis B vaccine (Recombivax HB) is used to provide active immunity and has shown rates of protection greater than 90% in healthy people (Rodes, et al., 2007). Although antibody levels may become low or undetectable, immunologic memory may remain intact for at least 5 to 10 years. Measurable levels of antibodies may not be essential for protection. In general, in those with normal immune systems, booster doses are not required, and no data support the use of booster doses of hepatitis B vaccine among immunocompetent people who have responded to the vaccination series. However, booster doses are recommended for people who are immunocompromised (Rodes, et al., 2007). Additional information is required to determine if booster injections are needed for adults 15 years or more after initial vaccination as well as those at high risk for HBV infection.

A hepatitis B vaccine prepared from plasma of humans chronically infected with HBV is used only rarely in patients who are immunodeficient or allergic to recombinant yeast-derived vaccines.

Both forms of the hepatitis B vaccine are administered intramuscularly in three doses; the second and third doses

are given 1 and 6 months, respectively, after the first dose. The third dose is very important in producing prolonged immunity. Hepatitis B vaccination should be administered to adults in the deltoid muscle. Antibody response may be measured by anti-HBs levels 1 to 3 months after completion of the basic course of vaccine, but this testing is not routine and is not currently recommended. People who do not respond may benefit from one to three additional doses (Rodes, et al., 2007).

People who are at high risk, including nurses and other health care personnel exposed to blood or blood products, should receive active immunization. Health care workers who have had frequent contact with blood are screened for anti-HBs to determine whether immunity is already present from previous exposure. The vaccine produces active immunity to HBV in 90% of healthy people (Rodes, et al., 2007). It does not provide protection to those already exposed to HBV, and it provides no protection against other types of viral hepatitis. Side effects of immunization are infrequent; soreness and redness at the injection site are the most common complaints.

Because hepatitis B infection is frequently transmitted sexually, hepatitis B vaccination is recommended for all unvaccinated people being evaluated for a sexually transmitted disease (STD). It is also recommended for those with a history of an STD, people with multiple sex partners, people who have sex with IV or injection drug users, and sexually active men who have sex with other men (Goldman & Ausiello, 2008).

Universal childhood vaccination for hepatitis B prevention has been instituted in the United States, and universal vaccination of all infants is encouraged. Catch-up vaccination is recommended for all children and prepubertal adolescents up to the age of 19 years who have not been previously immunized (Feldman, et al., 2006). Development of chronic carrier states has not been reported in adult responders to the vaccine.

Passive Immunity: Hepatitis B Immune Globulin

Hepatitis B immune globulin (HBIG) provides passive immunity to hepatitis B and is indicated for people exposed to HBV who have never had hepatitis B and have never received hepatitis B vaccine. Specific indications for postexposure vaccine with HBIG include (1) inadvertent exposure to HBsAg-positive blood through percutaneous (needlestick) or transmucosal (splashes in contact with mucous membrane) routes, (2) sexual contact with people positive for HBsAg, and (3) perinatal exposure (infants born to HBV-infected mothers should receive HBIG within 12 hours after delivery). HBIG is prepared from plasma selected for high titers of anti-HBs. Prompt immunization with HBIG (within hours to a few days after exposure to hepatitis B) increases the likelihood of protection. Both active and passive immunization are recommended for people who have been exposed to hepatitis B through sexual contact or through the percutaneous or transmucosal routes. If HBIG and hepatitis B vaccine are administered at the same time, separate sites and separate syringes should be used. There has been no evidence that human immunodeficiency virus (HIV) infection can be transmitted by HBIG (Wolfe, 2006).

Medical Management

The goals of treatment are to minimize infectivity and liver inflammation and decrease symptoms. Of all the agents that have been used to treat chronic type B viral hepatitis, alpha-interferon as the single modality of therapy that offers the most promise. A regimen of 5 million units daily or 10 million units three times weekly for 16 to 24 weeks results in remission of disease in approximately one third of patients (Wolfe, 2006). A prolonged course of treatment may also have additional benefits and is currently under study. Interferon must be administered by injection and has significant side effects, including fever, chills, anorexia, nausea, myalgias, and fatigue. Delayed side effects are more serious and may necessitate dosage reduction or discontinuation. These include bone marrow suppression, thyroid dysfunction, alopecia, and bacterial infections. Several recombinant forms of alpha-interferon are also available, including the pegylated form (Pegasys), with once-weekly dosing (Wolfe, 2006).

Two antiviral agents, lamivudine (Epivir) and adefovir (Hepsera), oral nucleoside analogs, have been approved for use in chronic hepatitis B in the United States. Studies have revealed improved seroconversion rates, loss of detectable virus, improved liver function, and reduced progression to cirrhosis with lamivudine. It can be used for patients with decompensated cirrhosis who are awaiting liver transplantation (Rodes, et al., 2007). Adefovir may be effective in people who are resistant to lamivudine.

Bed rest may be recommended, regardless of other treatment, until the symptoms of hepatitis have subsided. Activities are restricted until the hepatic enlargement and levels of serum bilirubin and liver enzymes have decreased. Gradually increased activity is then allowed.

Adequate nutrition should be maintained. Proteins are restricted if symptoms indicate that the liver's ability to metabolize protein byproducts is impaired. Measures to control the dyspeptic symptoms and general malaise include the use of antacids and antiemetics, but all medications should be avoided if vomiting occurs. If vomiting persists, the patient may require hospitalization and fluid therapy. Because of the mode of transmission, the patient is evaluated for other bloodborne diseases (eg, HIV infection).

Nursing Management

Convalescence may be prolonged, with complete symptomatic recovery sometimes requiring 3 to 4 months or longer. During this stage, gradual resumption of physical activity is encouraged after the jaundice has resolved.

The nurse identifies psychosocial issues and concerns, particularly the effects of separation from family and friends if the patient is hospitalized during the acute and infective stages. Even if not hospitalized, the patient will be unable to work and must avoid sexual contact. Planning is required to minimize social isolation. Planning that includes the family helps to reduce their fears and anxieties about the spread of the disease.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Because of the prolonged period of convalescence, the patient and family must be prepared for home care. Provision

for adequate rest and nutrition must be ensured. The nurse informs family members and friends who have had intimate contact with the patient about the risks of contracting hepatitis B and makes arrangements for them to receive hepatitis B vaccine or hepatitis B immune globulin as prescribed. Those at risk must be made aware of the early signs of hepatitis B and of ways to reduce risk by avoiding all modes of transmission. Patients with all forms of hepatitis should avoid drinking alcohol and eating raw shellfish.

Continuing Care

Follow-up visits by a home care nurse may be needed to assess the patient's progress and answer family members' questions about disease transmission. During a home visit, the nurse assesses the patient's physical and psychological status and confirms that the patient and family understand the importance of adequate rest and nutrition. The nurse also reinforces previous instructions. Because of the risk of transmission through sexual intercourse, strategies to prevent exchange of body fluids are recommended, such as abstinence or the use of condoms. The nurse emphasizes the importance of keeping follow-up appointments and participating in other health promotion activities and recommended health screenings.

Hepatitis C Virus

A significant proportion of cases of viral hepatitis are neither hepatitis A, hepatitis B, nor hepatitis D, and are classified as hepatitis C. Whereas blood transfusions and sexual contact once accounted for most cases of hepatitis C in the United States, other parenteral means, such as sharing of contaminated needles by IV or injection drug users and unintentional needlesticks and other injuries in health care workers now account for a significant number of cases. Approximately 35,000 new cases of hepatitis C are reported in the United States each year. About 4 million people (1.8% of the U.S. population) have been infected with the hepatitis C virus (HCV), making it the most common chronic bloodborne infection nationally. A fourfold increase in the number of adults diagnosed with HCV infection is projected from 1990 to 2015. The highest prevalence of hepatitis C is in adults 40 to 59 years of age, and in this age group its prevalence is highest among African Americans. There are 10,000 to 12,000 deaths each year in the United States due to hepatitis C, and it has been suggested that deaths from this cause are underestimated. HCV is the underlying cause of about one third of cases of hepatocellular carcinoma, and it is the most common reason for liver transplantation (Wolfe, 2006).

People who are at particular risk for hepatitis C include IV or injection drug users, sexually active people with multiple partners, patients receiving frequent transfusions, those who require large volumes of blood, and health care personnel (Chart 39-10). The incubation period is variable and may range from 15 to 160 days. The clinical course of acute hepatitis C is similar to that of hepatitis B; symptoms are usually mild. However, a chronic carrier state occurs frequently, and there is an increased risk of chronic liver dis-

CHART
39-10

Risk Factors for Hepatitis C

- Recipient of blood products or organ transplant before 1992 or clotting factor concentrates before 1987
- Health care and public safety workers after needlestick injuries or mucosal exposure to blood
- Children born to women infected with hepatitis C virus
- Past/current illicit IV/injection drug use
- Past treatment with chronic hemodialysis
- Multiple sex partners, history of sexually transmitted disease, unprotected sex

ease, including cirrhosis or liver cancer, after hepatitis C. Small amounts of alcohol taken regularly appear to cause progression of the disease. Therefore, alcohol and medications that may affect the liver should be avoided.

There is no benefit from rest, diet, or vitamin supplements. Studies have demonstrated that a combination of two antiviral agents, interferon (Intron-A) and ribavirin (Rebetol), is effective in producing improvement in patients with hepatitis C and in treating relapses. Some patients experience complete remission with combination therapy (Hauser, et al., 2006). Hemolytic anemia, the most frequent side effect, may be severe enough to require discontinuation of treatment. Ribavirin must be used with caution in women of childbearing age. The molecule polyethylene glycol moiety (PEG) is added to the interferon to keep it in the body longer without reducing its efficacy; this extends the dosing interval to once a week. Pegylated interferon (Pegasys) is now available, and some studies have shown it to have a somewhat improved virologic response rate compared with interferon (Hauser, et al., 2006; Wolfe, 2006).

Screening of blood has reduced the incidence of hepatitis C associated with blood transfusion, and public health programs are helping to reduce the number of cases associated with shared needles in IV or injection drug use.

Hepatitis D Virus

Hepatitis D virus (delta agent) infection occurs in some cases of hepatitis B. Because the virus requires hepatitis B surface antigen for its replication, only people with hepatitis B are at risk for hepatitis D. Anti-delta antibodies in the presence of HBsAg on testing confirm the diagnosis. Hepatitis D is common among IV or injection drug users, hemodialysis patients, and recipients of multiple blood transfusions. Sexual contact with those with hepatitis B is considered to be an important mode of transmission of hepatitis B and D. The incubation period varies between 30 and 150 days (Goldman & Ausiello, 2008).

The symptoms of hepatitis D are similar to those of hepatitis B, except that patients are more likely to develop fulminant hepatitis and to progress to chronic active hepatitis and cirrhosis. Treatment is similar to that of other forms of hepatitis; interferon as a specific treatment for hepatitis D is under investigation.

Hepatitis E Virus

It is believed that hepatitis E virus (HEV) is transmitted by the fecal–oral route, principally through contaminated water in areas with poor sanitation. The incubation period is variable, estimated to range between 15 and 65 days. In general, hepatitis E resembles hepatitis A. It has a self-limited course with an abrupt onset. Jaundice is almost always present. Chronic forms do not develop.

Avoiding contact with the virus through good hygiene, including handwashing, is the major method of prevention of hepatitis E. The effectiveness of immune globulin in protecting against hepatitis E virus is uncertain.

Hepatitis G Virus and GB Virus-C

It has long been believed that there is another non-A–E agent causing hepatitis in humans. The incubation period for posttransfusion hepatitis is 14 to 145 days, too long for hepatitis B or C. In the United States, about 5% of chronic liver disease remains cryptogenic (ie, does not appear to be autoimmune or viral in origin), and 50% of these patients have received blood transfusions before developing disease. Therefore, another form of hepatitis, called hepatitis G virus (HGV) or GB virus-C (GBV-C) has been described; these are thought to be two different isolates of the same virus. Autoantibodies are absent.

The clinical significance of this virus remains uncertain. Risk factors are similar to those for hepatitis C. There is no clear relationship between HGV/GBV-C infection and progressive liver disease. Persistent infection does occur but does not affect the clinical course.

NONVIRAL HEPATITIS

Certain chemicals have toxic effects on the liver and produce acute liver cell necrosis or toxic hepatitis when inhaled, injected parenterally, or are taken by mouth. The chemicals most commonly implicated in this disease are carbon tetrachloride, phosphorus, chloroform, and gold compounds. These substances are true hepatotoxins. Many medications can induce hepatitis but are only sensitizing rather than toxic. Drug-induced hepatitis is similar to acute viral hepatitis, but parenchymal destruction tends to be more extensive. Medications that can lead to hepatitis include isoniazid (Nydrazid), halothane (Fluothane), acetaminophen, methyl dopa (Aldomet), and certain antibiotics, antimetabolites, and anesthetic agents.

Toxic Hepatitis

At the onset of disease, toxic hepatitis resembles viral hepatitis. Obtaining a history of exposure to hepatotoxic chemicals, medications, botanical agents, or other toxic agents assists in early treatment and removal of the causative agent. Anorexia, nausea, and vomiting are the usual symptoms; jaundice and hepatomegaly are noted on physical assessment. Symptoms are more intense for the more severely toxic patient.

Recovery from acute toxic hepatitis is rapid if the hepatotoxin is identified early and removed or if exposure to the agent has been limited. Recovery is unlikely if there is a prolonged period between exposure and onset of symptoms. There are no effective antidotes. The fever rises; the patient becomes toxic and prostrated. Vomiting may be persistent, with the emesis containing blood. Clotting abnormalities may be severe, and hemorrhages may appear under the skin. The severe GI symptoms may lead to vascular collapse. Delirium, coma, and seizures develop, and within a few days the patient may die of fulminant hepatic failure (discussed later) unless he or she receives a liver transplant.

Short of liver transplantation, few treatment options are available. Therapy is directed toward restoring and maintaining fluid and electrolyte balance, blood replacement, and comfort and supportive measures. A few patients recover from acute toxic hepatitis only to develop chronic liver disease. If the liver heals, there may be scarring, followed by postnecrotic cirrhosis.

Drug-Induced Hepatitis

Drug-induced liver disease is the most common cause of acute liver failure, accounting for more than 50% of all cases in the United States (Wolfe, 2006). Manifestations of sensitivity to a medication may occur on the first day of its use or not until several months later. Usually, the onset is abrupt, with chills, fever, rash, pruritus, arthralgia, anorexia, and nausea. Later, there may be jaundice, dark urine, and an enlarged and tender liver. After the offending medication is withdrawn, symptoms may gradually subside. However, reactions can be severe, or even fatal, even if the medication is stopped. If fever, rash, or pruritus occurs from any medication, its use should be stopped immediately.

Although any medication can affect liver function, use of acetaminophen (found in many over-the-counter medications used to treat fever and pain) has been identified as the leading cause of acute liver failure (Wolfe, 2006). Other mechanisms commonly associated with liver injury include many anesthetic agents, medications used to treat rheumatic and musculoskeletal disease, antidepressants, psychotropic medications, anticonvulsants, and antituberculosis agents.

A short course of high-dose corticosteroids may be used in patients with severe hypersensitivity reactions, although its efficacy is uncertain. Liver transplantation is an option for drug-induced hepatitis, but outcomes may not be as successful as with other causes of liver failure.

FULMINANT HEPATIC FAILURE

Fulminant hepatic failure is the clinical syndrome of sudden and severely impaired liver function in a previously healthy person. According to the original and generally accepted definition, fulminant hepatic failure develops within 8 weeks after the first symptoms of jaundice (Hauser, et al., 2006). Patterns of the progression from jaundice to encephalopathy have been identified and have led to proposals of time-based classifications. However, no agreement as

to these classifications has been reached. Three categories are frequently cited: hyperacute, acute, and subacute liver failure. In hyperacute liver failure, the duration of jaundice before the onset of encephalopathy is 0 to 7 days; in acute liver failure, it is 8 to 28 days; and in subacute liver failure, it is 28 to 72 days. The prognosis for fulminant hepatic failure is much worse than for chronic liver failure. However, in fulminant failure, the hepatic lesion is potentially reversible, and survival rates are approximately 20% to 50%, depending greatly on the cause of liver failure. Those who do not survive die of massive hepatocellular injury and necrosis (Wolfe, 2006).

Viral hepatitis is a common cause of fulminant hepatic failure; other causes include toxic medications (eg, acetaminophen) and chemicals (eg, carbon tetrachloride), metabolic disturbances (eg, Wilson's disease, a hereditary syndrome with deposition of copper in the liver), and structural changes (eg, Budd-Chiari syndrome, an obstruction to outflow in major hepatic veins).

Jaundice and profound anorexia may be the initial reasons the patient seeks health care. Fulminant hepatic failure is often accompanied by coagulation defects, renal failure and electrolyte disturbances, cardiovascular abnormalities, infection, hypoglycemia, encephalopathy, and cerebral edema.

The key to optimized treatment is rapid recognition of acute liver failure and intensive intervention. Supporting the patient in the ICU and assessing the indications for and feasibility of liver transplantation are hallmarks of management of this population. The use of antidotes for certain conditions may be indicated such as *N*-acetylcysteine for acetaminophen toxicity and penicillin for mushroom poisoning. Treatment modalities may include plasma exchanges (plasmapheresis) to correct coagulopathy and to stabilize the patient awaiting liver transplantation and prostaglandin therapy to enhance hepatic blood flow; however, more clinical trials are needed to determine the effects or outcomes of these treatments. Hepatocytes within synthetic fiber columns have been tested as liver support systems (liver assist devices) to provide a bridge to transplantation.

Research into interventions for acute liver failure has begun to focus on techniques that combine the efficacy of a whole liver with the convenience and biocompatibility of hemodialysis. The acronyms ELAD (*extracorporeal liver assist devices*) and BAL (*bioartificial liver*) have been used to describe these hybrid devices. These short-term devices, which remain experimental, may help patients survive until transplantation is possible. The BAL device exposes separated plasma to a cartridge containing porcine liver cells after the plasma has flowed through a charcoal column that removes substances toxic to hepatocytes. The ELAD exposes whole blood to cartridges containing human hepatoblastoma cells, resulting in removal of toxic substances. In the near future, similar extracorporeal circuits using **xenografts** may be studied as a bridge to liver transplantation. These approaches appear promising and have had success in animal studies. In human clinical application, the use of various BAL systems has resulted in improved neurologic and biochemical parameters. Adding albumin to the dialysate is effective in removing protein-bound toxins and is potentially useful in unstable patients with fulminant liver failure (Rodes, et al., 2007). To fully determine the

clinical applicability of such systems on outcomes and survival rates, controlled, randomized clinical trials in large patient groups are required.

In patients who have fulminant liver failure with stage 4 encephalopathy, there is a high risk of cerebral edema, a life-threatening complication. The cause is not fully understood, although disruption of the blood-brain barrier and plasma leakage into the cerebrospinal fluid may be one cause. An increase in the intracellular osmolarity within cerebral astrocyte cells, possibly related to increased sodium and glutamine in these cells, may be another (Rodes, et al., 2007). These patients require intracranial pressure monitoring. Measures to promote adequate cerebral perfusion include careful fluid balance and hemodynamic assessments, a quiet environment, and diuresis with mannitol (Osmitol), an osmotic diuretic.

Use of barbiturate anesthesia or pharmacologic paralysis and sedation is indicated to prevent surges in intracranial pressure related to agitation. Other support measures include monitoring for and treating hypoglycemia, coagulopathies, and infection. Despite these treatment modalities, the mortality rate remains high. Consequently, liver transplantation (discussed later) has become the treatment of choice for fulminant hepatic failure.

HEPATIC CIRRHOSIS

Cirrhosis is a chronic disease characterized by replacement of normal liver tissue with diffuse fibrosis that disrupts the structure and function of the liver. There are three types of cirrhosis or scarring of the liver:

- **Alcoholic cirrhosis**, in which the scar tissue characteristically surrounds the portal areas. This is most frequently caused by chronic alcoholism and is the most common type of cirrhosis.
- **Postnecrotic cirrhosis**, in which there are broad bands of scar tissue. This is a late result of a previous bout of acute viral hepatitis.
- **Biliary cirrhosis**, in which scarring occurs in the liver around the bile ducts. This type of cirrhosis usually results from chronic biliary obstruction and infection (cholangitis); it is much less common than the other two types.

The portion of the liver chiefly involved in cirrhosis consists of the portal and the periportal spaces, where the bile canaliculi of each lobule communicate to form the liver bile ducts. These areas become the sites of inflammation, and the bile ducts become occluded with inspissated (thickened) bile and pus. The liver attempts to form new bile channels; hence, there is an overgrowth of tissue made up largely of disconnected, newly formed bile ducts and surrounded by scar tissue.

Pathophysiology

Although several factors have been implicated in the etiology of cirrhosis, alcohol consumption is considered the major causative factor. Cirrhosis occurs with greatest frequency among people with alcoholism. Although nutritional deficiency with reduced protein intake contributes to liver

destruction in cirrhosis, excessive alcohol intake is the major causative factor in fatty liver and its consequences. However, cirrhosis has also occurred in people who do not consume alcohol and in those who consume a normal diet and have a high alcohol intake.

Some people appear to be more susceptible than others to this disease, whether or not they have alcoholism or are malnourished. Other factors may play a role, including exposure to certain chemicals (carbon tetrachloride, chlorinated naphthalene, arsenic, or phosphorus) or infectious schistosomiasis. Twice as many men as women are affected, although, for unknown reasons, women are at greater risk for development of alcohol-induced liver disease. Most patients are between 40 and 60 years of age. Each year more than 27,000 people die of chronic liver diseases and cirrhosis in the United States (Rodes, et al., 2007).

Alcoholic cirrhosis is characterized by episodes of necrosis involving the liver cells, which sometimes occur repeatedly throughout the course of the disease. The destroyed liver cells are gradually replaced by scar tissue. Eventually, the amount of scar tissue exceeds that of the functioning liver tissue. Islands of residual normal tissue and regenerating liver tissue may project from the constricted areas, giving the cirrhotic liver its characteristic hobnail appearance. The disease usually has an insidious onset and a protracted course, occasionally proceeding over a period of 30 or more years.

The prognoses for different forms of cirrhosis caused by various liver diseases have been investigated in several studies. Of the many prognostic indicators, the Child-Pugh classification seems most useful in predicting the outcome of patients with liver disease (Table 39-5). It is also used in choosing management approaches.

Clinical Manifestations

Signs and symptoms of cirrhosis increase in severity as the disease progresses. Their severity is used to categorize the disorder as compensated or decompensated cirrhosis (Chart 39-11). Compensated cirrhosis, with its less severe, often vague symptoms, may be discovered secondarily at a routine physical examination. The hallmarks of decompensated cirrhosis result from failure of the liver to synthesize proteins, clotting factors, and other substances and manifestations of portal hypertension (see earlier sections of this chapter for

CHART 39-11 Assessing for Cirrhosis

Be alert for the following signs and symptoms:

Compensated

- Intermittent mild fever
- Vascular spiders
- Palmar erythema (reddened palms)
- Unexplained epistaxis
- Ankle edema
- Vague morning indigestion
- Flatulent dyspepsia
- Abdominal pain
- Firm, enlarged liver
- Splenomegaly

Decompensated

- Ascites
- Jaundice
- Weakness
- Muscle wasting
- Weight loss
- Continuous mild fever
- Clubbing of fingers
- Purpura (due to decreased platelet count)
- Spontaneous bruising
- Epistaxis
- Hypotension
- Sparse body hair
- White nails
- Gonadal atrophy

clinical manifestations and management of portal hypertension, ascites, varices, and hepatic encephalopathy).

Liver Enlargement

Early in the course of cirrhosis, the liver tends to be large, and the cells are loaded with fat. The liver is firm and has a sharp edge that is noticeable on palpation. Abdominal pain may be present because of recent, rapid enlargement of the liver, which produces tension on the fibrous covering of the liver (Glisson's capsule). Later in the disease, the liver decreases in size as scar tissue contracts the liver tissue. The liver edge, if palpable, is nodular.

Portal Obstruction and Ascites

Portal obstruction and ascites, late manifestations of cirrhosis, are caused partly by chronic failure of liver function and partly by obstruction of the portal circulation. Almost all of the blood from the digestive organs is collected in the portal veins and carried to the liver. Because a cirrhotic liver does not allow free blood passage, blood backs up into the spleen and the GI tract, and these organs become the seat of chronic passive congestion; that is, they are stagnant with blood and therefore cannot function properly. Indigestion and altered bowel function result. Fluid rich in protein may accumulate in the peritoneal cavity, producing ascites. This can be detected through percussion for shifting dullness or a fluid wave (see Fig. 39-5).

Table 39-5 MODIFIED CHILD-PUGH CLASSIFICATION OF THE SEVERITY OF LIVER DISEASE*

Parameter	Points Assigned		
	1	2	3
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	≤ 2	2–3	> 3
Albumin (g/dL)	> 3.5	2.8–3.5	< 2.8
Prothrombin time (seconds over control)	1–3	4–6	> 6
Encephalopathy	None	Grade 1–2	Grade 3–4

*Total score of 1–6, grade A; 7–9, grade B; 10–15, grade C. Schiff, E. R., Somell, M. F. & Maddrey, W. C. (Eds.) (2006). *Schiff's diseases of the liver* (10th ed.). Philadelphia: Lippincott Williams & Wilkins.

Infection and Peritonitis

Bacterial peritonitis may develop in patients with cirrhosis and ascites in the absence of an intra-abdominal source of infection or an abscess. This condition is referred to as spontaneous bacterial peritonitis (SBP). Bacteremia due to translocation of intestinal flora is believed to be the most likely route of infection. Clinical signs may be absent, necessitating paracentesis for diagnosis. Antibiotic therapy is effective in the treatment and prevention of recurrent episodes of SBP. The most severe complication of SBP is hepatorenal syndrome, a form of renal failure unresponsive to administration of fluid or diuretics. This type of renal failure is characterized by a lack of pathologic changes in the kidney; there is no evidence of dehydration or obstruction of the urinary tract or any other renal disorder.

Gastrointestinal Varices

The obstruction to blood flow through the liver caused by fibrotic changes also results in the formation of collateral blood vessels in the GI system and shunting of blood from the portal vessels into blood vessels with lower pressures. As a result, the patient with cirrhosis often has prominent, distended abdominal blood vessels, which are visible on abdominal inspection (*caput medusae*) and distended blood vessels throughout the GI tract. The esophagus, stomach, and lower rectum are common sites of collateral blood vessels. These distended blood vessels form varices or hemorrhoids, depending on their location (see Fig. 39-6).

Because these vessels were not intended to carry the high pressure and volume of blood imposed by cirrhosis, they may rupture and bleed. Therefore, assessment must include observation for occult and frank bleeding from the GI tract.

Edema

Another late symptom of cirrhosis is edema, which is attributed to chronic liver failure. A reduced plasma albumin concentration predisposes the patient to the formation of edema. Although edema is generalized, it often affects the lower extremities, the upper extremities, and the presacral area. Facial edema is not typical. Overproduction of aldosterone occurs, causing sodium and water retention and potassium excretion.

Vitamin Deficiency and Anemia

Because of inadequate formation, use, and storage of certain vitamins (notably vitamins A, C, and K), signs of deficiency are common, particularly hemorrhagic phenomena associated with vitamin K deficiency. Chronic gastritis and impaired GI function, together with inadequate dietary intake and impaired liver function, account for the anemia that is often associated with cirrhosis. The patient's anemia, poor nutritional status, and poor state of health result in severe fatigue, which interferes with the ability to carry out routine activities of daily living (ADLs).

Mental Deterioration

Additional clinical manifestations include deterioration of mental and cognitive function with impending hepatic encephalopathy and hepatic coma, as previously described. Neurologic assessment is indicated, including assessment of

the patient's general behavior, cognitive abilities, orientation to time and place, and speech patterns.

Assessment and Diagnostic Findings

The extent of liver disease and the type of treatment are determined after review of the laboratory findings. The functions of the liver are complex, and many diagnostic tests provide information about liver function (see Table 39-1). The patient needs to know why these tests are being performed and how to cooperate.

In severe parenchymal liver dysfunction, the serum albumin level tends to decrease, and the serum globulin level rises. Enzyme tests indicate liver cell damage: serum alkaline phosphatase, AST, ALT, and GGT levels increase, and the serum cholinesterase level may decrease. Bilirubin tests are performed to measure bile excretion or retention; increased levels of bilirubin can occur with cirrhosis and other liver disorders. Prothrombin time is prolonged.

Ultrasound scanning is used to measure the difference in density of parenchymal cells and scar tissue. CT, MRI, and radioisotope liver scans give information about liver size and hepatic blood flow and obstruction. Diagnosis is confirmed by liver biopsy. Arterial blood gas analysis may reveal a ventilation-perfusion imbalance and hypoxia.

Medical Management

The management of the patient with cirrhosis is usually based on the presenting symptoms. For example, antacids or histamine-2 (H_2) antagonists are prescribed to decrease gastric distress and minimize the possibility of GI bleeding. Vitamins and nutritional supplements promote healing of damaged liver cells and improve the patient's general nutritional status. Potassium-sparing diuretics such as spironolactone or triamterene (Dyrenium) may be indicated to decrease ascites, if present; these diuretics are preferred because they minimize the fluid and electrolyte changes commonly seen with other agents. An adequate diet and avoidance of alcohol are essential. Although the fibrosis of the cirrhotic liver cannot be reversed, its progression may be halted or slowed by such measures.

Preliminary studies indicate that colchicine, an anti-inflammatory agent used to treat the symptoms of gout, may increase survival time in patients with mild to moderate cirrhosis. Many medications have been shown to possess antifibrotic activity for the treatment of cirrhosis. Some of these medications include angiotensin system inhibitors, statins, diuretics, immunosuppressants, and glitazones. These medications have reasonable safety profiles, but their long-term safety and efficacy in patients with cirrhosis has yet to be demonstrated (Schuppan & Afdhal, 2008).

Many patients who have end-stage liver disease (ESLD) with cirrhosis use the herb milk thistle (*Silybum marianum*) to treat jaundice and other symptoms. This herb has been used for centuries because of its healing and regenerative properties for liver disease. Silymarin from milk thistle has anti-inflammatory and antioxidant properties that may have beneficial effects, especially in hepatitis. The natural compound, SAM-e (s-adenosylmethionine), may improve outcomes in liver disease by improving liver function, possibly through enhancing antioxidant function. Primary

biliary cirrhosis has been treated with ursodeoxycholic acid (Actigall, URSO) to improve liver function.

Nursing Management

Nursing management for the patient with cirrhosis of the liver is described in detail in the Plan of Nursing Care for the Patient with Impaired Liver Function (Chart 39-12). Nursing interventions are directed toward promoting patient's rest, improving nutritional status, providing skin care, reducing risk of injury, and monitoring and managing potential complications.

Promoting Rest

The patient with cirrhosis requires rest and other supportive measures to permit the liver to reestablish its functional ability. If the patient is hospitalized, weight and fluid intake and output are measured and recorded daily. The nurse adjusts the patient's position in bed for maximal respiratory efficiency, which is especially important if ascites is marked, because it interferes with adequate thoracic excursion. Oxygen therapy may be required in liver failure to oxygenate the damaged cells and prevent further cell destruction.

Rest reduces the demands on the liver and increases the liver's blood supply. Because the patient is susceptible to the hazards of immobility, efforts to prevent respiratory, circulatory, and vascular disturbances are initiated. These measures may help prevent such problems as pneumonia, thrombophlebitis, and pressure ulcers. After nutritional status improves and strength increases, the nurse encourages the patient to increase activity gradually. Activity and mild exercise, as well as rest, are planned.

Improving Nutritional Status

The patient with cirrhosis without ascites, edema, or signs of impending hepatic coma should receive a nutritious, high-protein diet, if tolerated, supplemented by vitamins of the B complex, as well as A, C, and K. The nurse encourages the patient to eat. If ascites is present, small, frequent meals may be better tolerated than three large meals because of the abdominal pressure exerted by ascites. Patient preferences are considered. Patients with prolonged or severe anorexia and those who are vomiting or eating poorly for any reason may receive nutrients by the enteral or parenteral route.

Patients with fatty stools (steatorrhea) should receive water-soluble forms of fat-soluble vitamins A, D, and E (Aquasol A, D, and E). Folic acid and iron are prescribed to prevent anemia. If the patient shows signs of impending or advancing coma, the amount of protein in the diet is decreased temporarily. Protein is restricted if encephalopathy develops. Incorporating vegetable protein to meet protein needs may decrease the risk for encephalopathy. Sodium restriction is also indicated to prevent ascites.

Providing Skin Care

Providing careful skin care is important because of subcutaneous edema, the patient's immobility, jaundice, and increased susceptibility to skin breakdown and infection. Frequent changes in position are necessary to prevent pressure ulcers. Irritating soaps and the use of adhesive tape are avoided to prevent trauma to the skin. Lotion may be

soothing to irritated skin; the nurse takes measures to minimize scratching by the patient.

Reducing Risk of Injury

The nurse protects the patient with cirrhosis from falls and other injuries. The side rails should be in place and padded with blankets or other materials in case the patient becomes agitated or restless. To minimize agitation, the nurse orients the patient to time and place and explains all procedures. The nurse instructs the patient to ask for assistance to get out of bed. The nurse carefully evaluates any injury because of the possibility of internal bleeding.

Because of the risk for bleeding from abnormal clotting, the patient should use an electric razor rather than a safety razor. A soft-bristled toothbrush helps minimize bleeding gums, and pressure applied to all venipuncture sites helps minimize bleeding.

Monitoring and Managing Potential Complications

A major role of the nurse is monitoring of the patient with cirrhosis for complications.

Bleeding and Hemorrhage

The patient is at increased risk for bleeding and hemorrhage because of decreased production of prothrombin and decreased ability of the diseased liver to synthesize the necessary substances for blood coagulation. This was discussed earlier in the section on esophageal varices.

Hepatic Encephalopathy

As previously described, hepatic encephalopathy and coma, complications of cirrhosis, may manifest as deteriorating mental status and dementia or as physical signs such as abnormal voluntary and involuntary movements. Hepatic encephalopathy was discussed earlier in the chapter in detail and in Chart 39-12.

Monitoring is an essential nursing function to identify early deterioration in mental status. The nurse monitors the patient's mental status closely and reports changes so that treatment of encephalopathy can be initiated promptly. An extensive neurologic evaluation is key to identify progression through the four stages of encephalopathy.

Each advancing stage demands more intensive nursing interventions aimed at providing for patient safety and prevention and early identification of life-threatening complications such as respiratory failure and cerebral edema, which would necessitate interventions in an ICU. Because electrolyte disturbances can contribute to encephalopathy, serum electrolyte levels are carefully monitored and corrected if abnormal. Oxygen is administered if oxygen desaturation occurs. The nurse monitors for fever or abdominal pain, which may signal the onset of bacterial peritonitis or other infection (see earlier discussion of hepatic encephalopathy).

Fluid Volume Excess

Patients with advanced chronic liver disease develop cardiovascular abnormalities. These occur due to an increased cardiac output and decreased peripheral vascular resistance, possibly resulting from the release of vasodilators.

CHART
39-12
PLAN OF NURSING CARE
The Patient With Impaired Liver Function
NURSING DIAGNOSIS: Activity intolerance related to fatigue, lethargy, and malaise

GOAL: Patient reports decrease in fatigue and reports increased ability to participate in activities

Nursing Interventions

1. Assess level of activity tolerance and degree of fatigue, lethargy, and malaise when performing routine activities of daily living.
2. Assist with activities and hygiene when fatigued.
3. Encourage rest when fatigued or when abdominal pain or discomfort occurs.
4. Assist with selection and pacing of desired activities and exercise.
5. Provide diet high in carbohydrates with protein intake consistent with liver function.
6. Administer supplemental vitamins (A, B complex, C, and K).

Rationale

1. Provides baseline for further assessment and criteria for assessment of effectiveness of interventions.
2. Promotes exercise and hygiene within patient's level of tolerance.
3. Conserves energy and protects the liver.
4. Stimulates patient's interest in selected activities.
5. Provides calories for energy and protein for healing.
6. Provides additional nutrients.

Expected Outcomes

- Exhibits increased interest in activities and events.
- Participates in activities and gradually increases exercise within physical limits.
- Reports increased strength and well-being.
- Reports absence of abdominal pain and discomfort.
- Plans activities to allow ample periods of rest.
- Takes vitamins as prescribed.

NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements, related to abdominal distention and discomfort and anorexia

GOAL: Positive nitrogen balance, no further loss of muscle mass; meets nutritional requirements

Nursing Interventions

1. Assess dietary intake and nutritional status through diet history and diary, daily weight measurements, and laboratory data.
2. Provide diet high in carbohydrates with protein intake consistent with liver function.
3. Assist patient in identifying low-sodium foods.
4. Elevate the head of the bed during meals.
5. Provide oral hygiene before meals and pleasant environment for meals at meal time.
6. Offer smaller, more frequent meals (6 per day).
7. Encourage patient to eat meals and supplementary feedings.
8. Provide attractive meals and an aesthetically pleasing setting at meal time.
9. Eliminate alcohol.
10. Apply an ice collar for nausea.
11. Administer medications prescribed for nausea, vomiting, diarrhea, or constipation.
12. Encourage increased fluid intake and exercise if the patient reports constipation.

Rationale

1. Identifies deficits in nutritional intake and adequacy of nutritional state.
2. Provides calories for energy, sparing protein for healing.
3. Reduces edema and ascites formation.
4. Reduces discomfort from abdominal distention and decreases sense of fullness produced by pressure of abdominal contents and ascites on the stomach.
5. Promotes positive environment and increased appetite; reduces unpleasant taste.
6. Decreases feeling of fullness, bloating.
7. Encouragement is essential for the patient with anorexia and gastrointestinal discomfort.
8. Promotes appetite and sense of well-being.
9. Eliminates "empty calories" and further damage from alcohol.
10. May reduce incidence of nausea.
11. Reduces gastrointestinal symptoms and discomforts that decrease the appetite and interest in food.
12. Promotes normal bowel pattern and reduces abdominal discomfort and distention.

Expected Outcomes

- Exhibits improved nutritional status by increased weight (without fluid retention) and improved laboratory data.
- States rationale for dietary modifications.
- Identifies foods high in carbohydrates and within protein requirements (moderate to high protein in cirrhosis and hepatitis, low protein in hepatic failure).
- Reports improved appetite.
- Participates in oral hygiene measures.
- Reports increased appetite; identifies rationale for smaller, frequent meals.
- Demonstrates intake of high-calorie diet; adheres to protein restriction.
- Identifies foods and fluids that are nutritious and permitted on diet.
- Gains weight without increased edema or ascites formation.
- Reports increased appetite and well-being.
- Excludes alcohol from diet.
- Takes medications for gastrointestinal disorders as prescribed.
- Reports normal gastrointestinal function with regular bowel function.

Continued

CHART
39-12

PLAN OF NURSING CARE
The Patient With Impaired Liver Function (Continued)

NURSING DIAGNOSIS: Impaired skin integrity related to pruritus from jaundice and edema
GOAL: Decrease potential for pressure ulcer development; breaks in skin integrity

Nursing Interventions

1. Assess degree of discomfort related to pruritus and edema.
2. Note and record degree of jaundice and extent of edema.
3. Keep patient's fingernails short and smooth.
4. Provide frequent skin care; avoid use of soaps and alcohol-based lotions.
5. Massage every 2 h with emollients; turn every 2 h.
6. Initiate use of alternating-pressure mattress or low air loss bed.
7. Recommend avoiding use of harsh detergents.
8. Assess skin integrity every 4–8 h. Instruct patient and family in this activity.
9. Restrict sodium as prescribed.
10. Perform range of motion exercises every 4 h; elevate edematous extremities whenever possible.

Rationale

1. Assists in determining appropriate interventions.
2. Provides baseline for detecting changes and evaluating effectiveness of interventions.
3. Prevents skin excoriation and infection from scratching.
4. Removes waste products from skin while preventing dryness of skin.
5. Promotes mobilization of edema.
6. Minimizes prolonged pressure on bony prominences susceptible to breakdown.
7. May decrease skin irritation and need for scratching.
8. Edematous skin and tissue have compromised nutrient supply and are vulnerable to pressure and trauma.
9. Minimizes edema formation.
10. Promotes mobilization of edema.

Expected Outcomes

- Exhibits intact skin without redness, excoriation, or breakdown.
- Reports relief from pruritus.
- Exhibits no skin excoriation from scratching.
- Uses nondrying soaps and lotions. States rationale for use of nondrying soaps and lotions.
- Turns self periodically. Exhibits reduced edema of dependent parts of the body.
- Exhibits no areas of skin breakdown.
- Exhibits decreased edema; normal skin turgor.

NURSING DIAGNOSIS: High risk for injury related to altered clotting mechanisms and altered level of consciousness
GOAL: Reduced risk of injury

Nursing Interventions

1. Assess level of consciousness and cognitive level.
2. Provide safe environment (pad side rails, remove obstacles in room, prevent falls).
3. Provide frequent surveillance to orient patient and avoid use of restraints.
4. Replace sharp objects (razors) with safer items.
5. Observe each stool for color, consistency, and amount.
6. Be alert for symptoms of anxiety, epigastric fullness, weakness, and restlessness.
7. Test each stool and emesis for occult blood.
8. Observe for hemorrhagic manifestations: ecchymosis, epistaxis, petechiae, and bleeding gums.
9. Record vital signs at frequent intervals, depending on patient acuity (every 1–4 h).

Rationale

1. Assists in determining patient's ability to protect self and comply with required self-protective actions; may detect deterioration of hepatic function.
2. Minimizes falls and injury if falls occur.
3. Protects patient from harm while stimulating and orienting patient; use of restraints may disturb patient further.
4. Avoids cuts and bleeding.
5. Permits detection of bleeding in gastrointestinal tract.
6. May indicate early signs of bleeding and shock.
7. Detects early evidence of bleeding.
8. Indicates altered clotting mechanisms.
9. Provides baseline and evidence of hypovolemia, and hemorrhagic shock.

Expected Outcomes

- Is oriented to time, place, and person.
- Exhibits no hallucinations, and demonstrates no efforts to get up unassisted or to leave hospital.
- Exhibits no ecchymoses (bruises), cuts, or hematoma.
- Uses electric razor rather than sharp-edged razor.
- Exhibits absence of frank bleeding from gastrointestinal tract.
- Exhibits absence of restlessness, epigastric fullness, and other indicators of hemorrhage and shock.
- Exhibits negative results of test for occult gastrointestinal bleeding.
- Is free of ecchymotic areas or hematoma formation.
- Exhibits normal vital signs.
- Maintains rest and remains quiet if active bleeding occurs.
- Identifies rationale for blood transfusions and measures to treat bleeding.
- Uses measures to prevent trauma (eg, uses soft toothbrush, blows nose gently, avoids bumps and falls, avoids straining during defecation).
- Experiences no side effects of medications.

<p>NURSING DIAGNOSIS: Disturbed thought processes and potential for mental deterioration related to abnormal liver function and increased serum ammonia level</p> <p>GOAL: Improved mental status; safety maintained; ability to cope with cognitive and behavioral changes</p>		
Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Restrict dietary protein as prescribed for transient period. 2. Give frequent, small feedings of carbohydrates. 3. Protect from infection. 4. Keep environment warm and draft-free. 5. Pad the side rails of the bed. 6. Limit visitors. 7. Provide careful nursing surveillance to ensure patient's safety. 8. Avoid opioids and barbiturates. 9. Awaken at intervals (every 2–4 h) to assess cognitive status. 10. Identify subtle changes in behavior or sleep–wake pattern (consistent staff caring for the patient enhances this assessment as they become familiar with patient's baseline). 11. Assess handwriting or drawing skill daily as indication of cognitive ability. 12. Encourage patient and family to participate in therapeutic strategies to enhance coping with episodes of mental deterioration. 13. Encourage patient and family to discuss feeling of fear, powerlessness or emotional distress related to patient's mental deterioration. 	<ol style="list-style-type: none"> 1. Reduces source of ammonia (protein foods). 2. Promotes consumption of adequate carbohydrates for energy requirements and spares protein from breakdown for energy. 3. Minimizes risk for further increase in metabolic requirements. 4. Minimizes shivering, which would increase metabolic requirements. 5. Provides protection for the patient should hepatic coma and seizure activity occur. 6. Minimizes patient's activity and metabolic requirements. 7. Provides close monitoring of new symptoms and minimizes trauma to the confused patient. 8. Prevents masking of symptoms of hepatic coma and prevents drug overdose secondary to reduced ability of the damaged liver to metabolize opioids and barbiturates. Prevents respiratory depression. 9. Provides stimulation to the patient and opportunity for observing the patient's level of consciousness. 10/11. These changes may herald worsening of encephalopathy which requires rapid intervention including medication. 12. Promoting activities such as listening to music, relaxation techniques or preillness coping strategies can reduce anxiety. 13. Actively listening demonstrates caring and concern. 	<ul style="list-style-type: none"> • Adheres to protein restriction. • Demonstrates an interest in events and activities in environment. • Demonstrates normal attention span. • Follows and participates in conversation appropriately. • Is oriented to person, place, and time. • Remains in bed when indicated. • Reports no urinary or fecal incontinence. • Experiences no seizures. • No neurological or respiratory depression. • Develops no cognitive impairments but if they develop they are quickly identified and treated enhancing the potential of recovery. • Patient and family describe adequate feelings of coping and lowered anxiety. They demonstrate ability to listen and to make decisions as able. • Patient and family communicate their feelings and their needs in a secure and caring environment.

PLAN OF NURSING CARE

The Patient With Impaired Liver Function (Continued)

NURSING DIAGNOSIS: Risk for imbalanced body temperature: hyperthermia related to inflammatory process of cirrhosis or hepatitis

GOAL: Maintenance of normal body temperature, free from infection

Nursing Interventions

1. Record temperature regularly (every 4 h).
2. Encourage fluid intake.
3. Apply cool sponges or ice bag for elevated temperature.
4. Administer antibiotics as prescribed.
5. Avoid exposure to infections.
6. Keep patient at rest while temperature is elevated.
7. Assess for abdominal pain, tenderness.
8. Use sterile technique for all invasive procedures.

Rationale

1. Provides baseline to detect fever and to evaluate interventions.
2. Corrects fluid loss from perspiration and fever and increases patient's level of comfort.
3. Promotes reduction of fever and increases patient's comfort.
4. Ensures appropriate serum concentration of antibiotics to treat infection.
5. Minimizes risk of further infection and further increases in body temperature and metabolic rate.
6. Reduces metabolic rate.
7. May occur with bacterial peritonitis.
8. Many evidence-based practice guidelines (for example central venous catheter care) recommend the use of sterile technique to prevent nosocomial infections.

Expected Outcomes

- Exhibits normal temperature and reports absence of chills or sweating.
- Demonstrates adequate intake of fluids.
- Exhibits no evidence of local or systemic infection.
- Develops no nosocomial infections related to invasive procedures/lines.

NURSING DIAGNOSIS: Ineffective breathing pattern related to ascites and restriction of thoracic excursion secondary to ascites, abdominal distention, and fluid in the thoracic cavity

GOAL: Improved respiratory status

Nursing Interventions

1. Elevate head of bed to at least 30 degrees.
2. Conserve patient's strength by providing rest periods and assisting with activities.
3. Change position every 2 h.
4. Assist with paracentesis or thoracentesis.
 - a. Explain procedure and its purpose to patient.
 - b. Have patient void before paracentesis.
 - c. Support and maintain position during procedure.
 - d. Record both the amount and the character of fluid aspirated.
 - e. Observe for evidence of coughing, increasing dyspnea, or pulse rate.

Rationale

1. Reduces abdominal pressure on the diaphragm and permits fuller thoracic excursion and lung expansion.
2. Reduces metabolic and oxygen requirements.
3. Promotes expansion and oxygenation of all areas of the lungs.
4. Paracentesis and thoracentesis (performed to remove fluid from the abdominal and thoracic cavities, respectively) may be frightening to the patient.
 - a. Helps obtain patient's cooperation with procedures.
 - b. Prevents inadvertent bladder injury.
 - c. Prevents inadvertent organ or tissue injury.
 - d. Provides record of fluid removed and indication of severity of limitation of lung expansion by fluid.
 - e. Indicates irritation of the pleural space and evidence of pneumothorax or hemothorax.

Expected Outcomes

- Experiences improved respiratory status.
- Reports decreased shortness of breath.
- Reports increased strength and sense of well-being.
- Exhibits normal respiratory rate (12–18/min) with no adventitious sounds.
- Exhibits full thoracic excursion without shallow respirations.
- Exhibits normal arterial blood gases.
- Exhibits adequate oxygen saturation by pulse oximetry.
- Experiences absence of confusion or cyanosis.

 CHART
39-12

PLAN OF NURSING CARE
The Patient With Impaired Liver Function (Continued)
COLLABORATIVE PROBLEM: Gastrointestinal bleeding and hemorrhage

GOAL: Absence of episodes of gastrointestinal bleeding and hemorrhage

Nursing Interventions

1. Assess patient for evidence of gastrointestinal bleeding or hemorrhage. If bleeding does occur:
 - a. Monitor vital signs (blood pressure, pulse, respiratory rate) every 4 h or more frequently, depending on acuity.
 - b. Assess skin temperature, level of consciousness every 4 h or more frequently, depending on acuity.
 - c. Monitor gastrointestinal secretions and output (emesis, stool for occult or obvious bleeding). Test emesis for blood once per shift and with any color change. Hematest each stool.
 - d. Monitor hematocrit and hemoglobin for trends and changes.
2. Avoid activities that increase intra-abdominal pressure (straining, turning).
 - a. Avoid coughing/sneezing.
 - b. Assist patient to turn.
 - c. Keep all needed items within easy reach.
 - d. Use measures to prevent constipation such as adequate fluid intake; stool softeners.
 - e. Ensure small meals.
3. Have equipment (Blakemore tube, medications, IV fluids) available if indicated.
4. Assist with procedures and therapy needed to treat gastrointestinal bleeding and hemorrhage.
5. Monitor respiratory status every hour and minimize risk of respiratory complications if balloon tamponade is needed.
6. Prepare patient physically and psychologically for other treatment modalities if needed.
7. Monitor patient for recurrence of bleeding and hemorrhage.
8. Keep family informed of patient's status.
9. Once recovered from bleeding episode, provide patient and family with information regarding signs and symptoms of gastrointestinal bleeding.

Rationale

1. Allows early detection of signs and symptoms of bleeding and hemorrhage.
2. Minimizes increases in intra-abdominal pressure that could lead to rupture and bleeding of esophageal or gastric varices.
3. Equipment, medications, and supplies will be readily available if patient experiences bleeding from ruptured esophageal or gastric varices.
4. Gastrointestinal bleeding and hemorrhage require emergency measures (eg, insertion of Blakemore tube, administration of fluids and medications).
5. The patient is at high risk for respiratory complications, including asphyxiation if gastric balloon of tamponade tube ruptures or migrates upward.
6. The patient who experiences hemorrhage is very anxious and fearful; minimizing anxiety assists in control of hemorrhage.
7. Risk of rebleeding is high with all treatment modalities used to halt gastrointestinal bleeding.
8. Family members are likely to be anxious about the patient's status; providing information will reduce their anxiety level and promote more effective coping.
9. Risk of rebleeding is high. Subtle signs may be more quickly identified.

Expected Outcomes

- Experiences no episodes of bleeding and hemorrhage.
- Vital signs are within acceptable range for patient.
- No evidence of bleeding from gastrointestinal tract.
- Hematocrit and hemoglobin levels within acceptable limits.
- Turns and moves without straining and increasing intra-abdominal pressure.
- No straining with bowel movements.
- No further bleeding episodes if aggressive treatment of bleeding and hemorrhage was needed.
- Patient and family state rationale for treatments.
- Patient and family identify supports available to them.
- Patient and family describe signs and symptoms of a recurrent bleeding episode and identify needed action.

Continued

CHART
39-12

PLAN OF NURSING CARE

*The Patient With Impaired Liver Function (Continued)***COLLABORATIVE PROBLEM:** Hepatic encephalopathy**GOAL:** Absence of changes in cognitive status and of injury**Nursing Interventions**

1. Assess cognitive status every 4–8 h:
 - a. Assess patient's orientation to person, place, and time.
 - b. Monitor patient's level of activity, restlessness, and agitation. Assess for presence of flapping hand tremors (asterixis).
 - c. Obtain and record daily sample of patient's handwriting or ability to construct a simple figure (eg, star).
 - d. Assess neurologic signs (deep tendon reflexes, ability to follow instructions).
2. Monitor medications to prevent administration of those that may precipitate hepatic encephalopathy (sedatives, hypnotics, analgesics).
3. Monitor laboratory data, especially serum ammonia level.
4. Notify physician of even subtle changes in patient's neurologic assessment, cognitive function, sleep pattern, or mood.
5. Limit sources of protein from diet if indicated.
6. Administer medications prescribed to reduce serum ammonia level (eg, lactulose, antibiotics, glucose, benzodiazepine antagonist [Flumazenil] if indicated).
7. Assess respiratory status and initiate measures to prevent complications.
8. Protect patient's skin and tissue from pressure and breakdown.
9. Provide support and active listening for patient and family as patient's mental status deteriorates.

Rationale

1. Data will provide baseline of patient's cognitive status and enable detection of changes.
2. Medications are a common precipitating factor in development of hepatic encephalopathy in patients at risk.
3. Increases in serum ammonia level are associated with hepatic encephalopathy and coma.
4. Allows early initiation of treatment of hepatic encephalopathy and prevention of hepatic coma.
5. Reduces breakdown and conversion of protein to ammonia.
6. Reduces serum ammonia level.
7. The patient who develops hepatic coma is at risk for respiratory complications (ie, pneumonia, atelectasis, infection).
8. The patient in coma is at risk for skin breakdown and pressure ulcer formation.
9. The patient with hepatic encephalopathy can experience episodes of mental deterioration due to liver failure. This can produce feelings of fear and anxiety.

Expected Outcomes

- Remains awake, alert, and aware of surroundings.
- Is oriented to time, place, and person.
- Exhibits no restlessness or agitation.
- Record of handwriting demonstrates no deterioration in cognitive function.
- States rationale for treatment used to prevent or treat hepatic encephalopathy.
- Demonstrates stable serum ammonia level within acceptable limits.
- Consumes adequate caloric intake and adheres to protein restriction.
- Takes medications as prescribed.
- Breath sounds are normal without adventitious sounds.
- Skin and tissue intact without evidence of pressure or breaks in integrity.
- Verbalizes understanding of need for treatments and procedures to promote recovery.

A hyperdynamic circulatory state develops in patients with cirrhosis, and plasma volume increases. This increase in circulating plasma volume is probably multifactorial, but some studies have implicated excess production of nitrous oxide, like that seen in sepsis, as one causative factor (Rodes, et al., 2007). The greater the degree of hepatic decompensation, the more severe the hyperdynamic state. Close assessment of cardiovascular and respiratory status is of key importance for the care of patients with this disorder. Pulmonary compromise, which is always a potential complication of ESLD because of plasma volume excess, makes prevention of pul-

monary complications an important role for the nurse. Administering diuretics, implementing fluid restrictions, and enhancing patient positioning can optimize pulmonary function. Fluid retention may be noted in the development of ascites, lower extremity swelling, and dyspnea. Monitoring of intake and output, daily weight changes, changes in abdominal girth, and edema formation is part of nursing assessment in the hospital or in the home setting. Patients are also monitored for nocturia and, later, for oliguria, because these states indicate increasing severity of liver dysfunction (Rodes, et al., 2007).

Promoting Home and Community-Based Care

Teaching Patients Self-Care

During the hospital stay, the nurse and other health care providers prepare the patient with cirrhosis for discharge, focusing on dietary instruction. Of greatest importance is the exclusion of alcohol from the diet. The patient may need referral to Alcoholics Anonymous, psychiatric care, or counseling or may benefit from support from a spiritual advisor. The patient should also avoid the consumption of raw shellfish.

Sodium restriction will continue for a considerable time, if not permanently. The patient will require written instructions, teaching, reinforcement, and support from the staff as well as family members.

Successful treatment depends on convincing the patient of the need to adhere completely to the therapeutic plan. This includes rest, lifestyle changes, adequate dietary intake, and the elimination of alcohol. The nurse also instructs the patient and family about symptoms of impending encephalopathy, possible bleeding tendencies, and susceptibility to infection.

Recovery is neither rapid nor easy; there are frequent setbacks and apparent lack of improvement. Many patients find it difficult to refrain from using alcohol for comfort or escape. The nurse has a significant role in offering support and encouragement to the patient and in providing positive feedback when the patient experiences success.

Continuing Care

Referral for home care may assist the patient in dealing with the transition from hospital to home. The use of alcohol may have been an important part of normal home and social life in the past. The home care nurse assesses the patient's progress at home and the manner in which the patient and family are coping with the elimination of alcohol and the dietary restrictions. The nurse also reinforces previous teaching and answers questions that may not have occurred to the patient or family until the patient is back home and trying to establish new patterns of eating, drinking, and lifestyle.

CANCER OF THE LIVER

Hepatic tumors may be malignant or benign. Benign liver tumors were uncommon until oral contraceptives were in widespread use. Now benign liver tumors occur most frequently in women in their reproductive years who are taking oral contraceptives.

Primary Liver Tumors

Few cancers originate in the liver. Primary liver tumors usually are associated with chronic liver disease, hepatitis B and C infections, and cirrhosis. Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer, with more than half a million cases diagnosed each year on a worldwide basis. HCC is the third leading cause of cancer-related mortality worldwide. It is rare in the United States

and Northern Europe, accounting for less than 5 cases per 100,000 inhabitants (Rodes, et al., 2007). Other types of primary liver cancer include cholangiocellular carcinoma and combined hepatocellular and cholangiocellular carcinoma. HCC is usually nonresectable because of rapid growth and metastasis. If found early, resection of primary liver cancer may be possible, but early detection is unlikely.

Cirrhosis, chronic infection with hepatitis B and C, and exposure to certain chemical toxins (eg, vinyl chloride, arsenic) have been implicated as causes of HCC. Cigarette smoking has also been identified as a risk factor, especially when combined with alcohol use. Some evidence suggests that aflatoxin, a metabolite of the fungus *Aspergillus flavus*, may be a risk factor for HCC. This is especially true in areas where HCC is endemic (ie, Asia and Africa). Aflatoxin and other similar toxic molds can contaminate food such as ground nuts and grains and may act as co-carcinogens with hepatitis B. The risk of contamination is greatest when these foods are stored unrefrigerated in tropical or subtropical climates.

Liver Metastases

Metastases from other primary sites, particularly the digestive system, breast, and lung, are found in the liver 2.5 times more frequently than tumors due to primary liver cancers (Rodes, et al., 2007). Malignant tumors are likely to reach the liver eventually, by way of the portal system or lymphatic channels, or by direct extension from an abdominal tumor. Moreover, the liver apparently is an ideal place for these malignant cells to thrive. Often the first evidence of cancer in an abdominal organ is the appearance of liver metastases; unless exploratory surgery or an autopsy is performed, the primary tumor may never be identified.

Clinical Manifestations

The early manifestations of malignancy of the liver include pain—a continuous dull ache in the right upper quadrant, epigastrium, or back. Weight loss, loss of strength, anorexia, and anemia may also occur. The liver may be enlarged and irregular on palpation. Jaundice is present only if the larger bile ducts are occluded by the pressure of malignant nodules in the hilum of the liver. Ascites develops if such nodules obstruct the portal veins or if tumor tissue is seeded in the peritoneal cavity.

Assessment and Diagnostic Findings

The diagnosis of liver cancer is based on clinical signs and symptoms, the history and physical examination, and the results of laboratory and x-ray studies. Increased serum levels of bilirubin, alkaline phosphatase, AST, GGT, and lactic dehydrogenase may occur. Leukocytosis (increased white blood cells), erythrocytosis (increased red blood cells), hypercalcemia, hypoglycemia, and hypocholesterolemia may also be seen on laboratory assessment.

The serum level of alpha-fetoprotein (AFP), which serves as a tumor marker, is elevated in 30% to 40% of patients with primary liver cancer. The level of carcinoembryonic antigen (CEA), a marker of advanced cancer of the digestive tract, may be elevated. These two markers together

are useful to distinguish between metastatic liver disease and primary liver cancer.

Many patients have metastases from the primary liver tumor to other sites by the time the diagnosis is made; metastases occur primarily to the lung but may also occur to regional lymph nodes, adrenals, bone, kidneys, heart, pancreas, or stomach.

X-rays, liver scans, CT scans, ultrasound studies, MRI, arteriography, and laparoscopy may be part of the diagnostic workup and may be performed to determine the extent of the cancer. Positive emission tomograms (PET) scans are used to evaluate a wide range of metastatic tumors of the liver.

Confirmation of a tumor's histology can be made by biopsy under imaging guidance (CT scan or ultrasound) or laparoscopically. Local or systemic dissemination of the tumor by needle biopsy or fine-needle biopsy can occur but is rare. Some clinicians believe that these procedures should not be performed if the tumor is thought to be resectable; rather, primary HCC diagnosis should be confirmed by frozen section at the time of laparotomy in those patients with resectable lesions detected by imaging studies.

Medical Management

Although surgical resection of the liver tumor is possible in some patients, the underlying cirrhosis is so prevalent in cancer of the liver that it increases the risks associated with surgery. Radiation therapy and chemotherapy have been used to treat cancer of the liver with varying degrees of success. Although these therapies may prolong survival and improve quality of life by reducing pain and discomfort, their major effect is palliative.

Radiation Therapy

The use of external beam radiation for the treatment of liver tumors has been limited by the radiosensitivity of normal hepatocytes and the risk of destruction of normal liver parenchyma. More effective methods of delivering radiation to tumors of the liver include (1) IV or intra-arterial injection of antibodies tagged with radioactive isotopes that specifically attack tumor-associated antigens and (2) percutaneous placement of a high-intensity source for interstitial radiation therapy (delivery of radiation directly to the tumor cells). Internal radiotherapy can result in reduction in tumor size, but its effect on survival is yet to be determined.

Chemotherapy

Typically, studies of patients with advanced cases of liver cancer have shown that the use of systemic chemotherapeutic agents leads to poor outcomes. There is no evidence to support a standard systemic chemotherapy and, in the United States, there is no approved systemic treatment for HCC (Wolfe, 2006). However, systemic chemotherapy may be used to treat metastatic liver lesions. Embolization of tumor vessels with chemotherapy (a process known as transarterial chemoembolization [TACE]) produces anoxic necrosis with high concentrations of trapped chemotherapeutic agents. This therapy has begun to show some promising results. An implantable pump has been used to deliver a high concentration of chemotherapy by constant infusion to the liver through the hepatic artery in cases of metastatic dis-

ease. This method has shown a moderate response rate, (Rodes, et al., 2007).

Percutaneous Biliary Drainage

Percutaneous biliary or transhepatic drainage is used to bypass biliary ducts obstructed by liver, pancreatic, or bile duct tumors in patients who have inoperable tumors or are considered poor surgical risks. Under fluoroscopy, a catheter is inserted through the abdominal wall and past the obstruction into the duodenum. Such procedures are used to reestablish biliary drainage, relieve pressure and pain from the buildup of bile behind the obstruction, and decrease pruritus and jaundice. As a result, the patient is made more comfortable and quality of life and survival are improved.

For several days after its insertion, the catheter is opened to external drainage. The bile is observed closely for amount, color, and presence of blood and debris. Complications of percutaneous biliary drainage include sepsis, leakage of bile, hemorrhage, and reobstruction of the biliary system by debris in the catheter or by encroaching tumor. Therefore, the patient is observed for fever and chills, bile drainage around the catheter, changes in vital signs, and evidence of biliary obstruction, including increased pain or pressure, pruritus, and recurrence of jaundice.

Other Nonsurgical Treatments

Laser hyperthermia has been used to treat hepatic metastases. Heat has been directed to tumors through several methods to cause necrosis of the tumor cells while sparing normal tissue. In radiofrequency thermal ablation, a needle electrode is inserted into the liver tumor under imaging guidance. Radiofrequency energy passes through to the noninsulated needle tip, causing heat and tumor cell death from coagulation necrosis.

Immunotherapy is another treatment modality under investigation. In this therapy, lymphocytes with antitumor reactivity are administered to the patient with hepatic cancer. Tumor regression has been demonstrated in patients with metastatic cancer for whom standard treatment has failed.

Transcatheter arterial embolization interrupts the arterial blood flow to small tumors by injecting small particulate embolic or chemotherapeutic agents (as previously described) into the artery supplying the tumor. As a result, ischemia and necrosis of the tumor occur.

For multiple small lesions, ultrasound-guided injection of alcohol promotes dehydration of tumor cells and tumor necrosis (Rodes, et al., 2007; Wolfe, 2006).

Surgical Management

Surgical resection is the treatment of choice when HCC is confined to one lobe of the liver and the function of the remaining liver is considered adequate for postoperative recovery. In the case of metastasis, hepatic resection can be performed if the primary site can be completely excised and the metastasis is limited. However, metastases to the liver are rarely limited or solitary. Capitalizing on the regenerative capacity of the liver cells, some surgeons have successfully removed 90% of the liver. However, the presence of cirrhosis limits the ability of the liver to regenerate. Staging of liver tumors aids in predicting the likelihood of surgical cure.

In preparation for surgery, the patient's nutritional, fluid, and general physical status are assessed, and efforts are undertaken to ensure the best physical condition possible. Extensive diagnostic studies may be performed. Specific studies may include liver scan, liver biopsy, cholangiography, selective hepatic angiography, percutaneous needle biopsy, peritoneoscopy, laparoscopy, ultrasound, CT scan, PET scan, MRI, and blood tests, particularly determinations of serum alkaline phosphatase, AST, and GGT and its isoenzymes.

Lobectomy

Removal of a lobe of the liver is the most common surgical procedure for excising a liver tumor. If it is necessary to restrict blood flow from the hepatic artery and portal vein for longer than 15 minutes, it is likely that hypothermia will be used. For a right-liver lobectomy or an extended right lobectomy (including the medial left lobe), a thoracoabdominal incision is used. An extensive abdominal incision is made for a left lobectomy.

Local Ablation

In patients who are not candidates for resection or transplantation, ablation of HCC may be accomplished by chemicals such as ethanol or by physical means such as radiofrequency ablation or microwave coagulation. These techniques may be performed under ultrasound or CT guidance laparoscopically or percutaneously. Radiofrequency ablation is becoming a standard mode of treatment; a tumor up to 5 cm in size can be destroyed in one session. The most common complications following ablation are local pain or bleeding. Serious complications are rare (Wolfe, 2006).

Immunotherapy with interferon has been under study as an adjuvant after liver resection or ablation of HCC. When patients have developed HCC related to hepatitis B or C, interferon may prevent recurrence of the lesion (Clavien, 2007; Rodes, et al., 2007).

Liver Transplantation

Removing the liver and replacing it with a healthy donor organ is another way to treat liver cancer. Studies have shown decreased recurrence rates of the primary liver malignancy after transplantation, with improvement in 5-year survival rates to consistently greater than 70% (Rodes, et al., 2007; Wolfe, 2006). Metastasis and recurrence may be enhanced by the immunosuppressive therapy that is needed to prevent rejection of the transplanted liver. In patients with small (less than 5 cm), single lesions, liver transplantation has been shown to be beneficial, but its use is limited by organ shortages. The increasing use of living donor transplantation may improve this situation and decrease the waiting time and tumor proliferation that is characteristic of patients with liver cancer (see later discussion).

Nursing Management

For the surgical patient, support, explanation, and encouragement are provided to help the patient prepare psychologically for the surgery. After surgery, potential problems related to cardiopulmonary involvement may include vascular complications and respiratory and liver dysfunction. Metabolic abnormalities require careful attention. A con-

stant infusion of 10% glucose may be required in the first 48 hours to prevent a precipitous fall in the blood glucose level that results from decreased gluconeogenesis. Because extensive blood loss may occur as well, the patient receives infusions of blood and IV fluids. The patient requires constant, close monitoring and care for the first 2 or 3 days, similar to postsurgical abdominal and thoracic nursing care.

If the patient is to receive chemotherapy or radiation therapy in an effort to relieve symptoms, he or she may be discharged home while still receiving one or both of these therapies. The patient may also go home with a biliary drainage system or hepatic artery catheter in place. In most cases, the hepatic artery catheter has been inserted surgically and has a prefilled infusion pump that delivers a continuous chemotherapeutic dose until completed. An hepatic artery port may also be inserted to provide access for intermittent chemotherapy infusion. This port dwells under the skin, but, because it provides direct arterial access, it is not used for continuous infusion therapy in the home environment; the access line is discontinued once the chemotherapeutic agent has infused. The patient and family require teaching about care of the biliary catheter and the effects and side effects of hepatic artery chemotherapy. This teaching is necessary because of participation of the patient and family in patient care in the home setting.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The nurse instructs the patient to recognize and report the potential complications and side effects of the chemotherapy and the desirable and undesirable effects of the specific chemotherapy regimen. The nurse also emphasizes the importance of follow-up visits to assess the patient and the tumor's response to chemotherapy and radiation therapy. In addition, if the patient is receiving chemotherapy on an outpatient basis, the nurse explains the patient's and family's role in managing the chemotherapy infusion and in assessing the infusion or insertion site. The nurse encourages the patient to resume routine activities as soon as possible, while cautioning about activities that may damage the infusion pump or site.

The family of as well as the patient at home with a biliary drainage system in place typically fear that the catheter will become dislodged. Reassurance and instruction can help reduce their fear that the catheter will fall out easily. The patient and family also require instruction on catheter care. The family and the patient need to learn how to keep the catheter site clean and dry and how to assess the catheter and its insertion site. Irrigation of the catheter with sterile normal saline solution or water may be prescribed to keep the catheter patent and free of debris. The patient and caregivers are taught proper technique to avoid introducing bacteria into the biliary system or catheter during irrigation. They are instructed not to aspirate or draw back on the syringe during irrigation, to prevent entry of irritating duodenal contents into the biliary tree or catheter. The patient and caregivers are also instructed about the signs of complications and are encouraged to notify the nurse or physician if problems or questions arise.

Patients with implantable ports are instructed about the chemotherapy regimen, types of medications, effects and side effects that may occur, and appropriate management strategies if problems occur. If a hepatic artery port is inserted for intermittent chemotherapy, patients and their families are provided the same educational content. Such a port has an internal one-way valve; therefore, it is not aspirated for a blood return before the infusion is initiated. The patient is instructed to assess the port site between infusions and to note and report any sign of infection or inflammation.

Continuing Care

In many cases, referral for home care enables the patient with liver cancer to be at home in a familiar environment with family and friends. Because of the poor prognosis associated with liver cancer, the home care nurse serves a vital role in assisting the patient and family to cope with the symptoms that may occur and the prognosis. The home care nurse assesses the patient's physical and psychological status, adequacy of pain relief, nutritional status, and presence of symptoms indicating complications of treatment or progression of disease. During home visits, the nurse assesses the function of the chemotherapy pump, the infusion site, and the biliary drainage system, if indicated. The nurse collaborates with the other members of the health care team, the patient, and the family to ensure effective pain management and to manage potential problems, which include weakness, pruritus, inadequate dietary intake, jaundice, and symptoms associated with metastasis to other sites. The home care nurse also assists the patient and family in making decisions about hospice care and assists with initiation of referrals. The patient is encouraged to discuss preferences for end-of-life care with family members and health care providers (see Chapter 17).

Liver Transplantation

Liver transplantation is used to treat life-threatening ESLD for which no other form of treatment is available. The transplantation procedure involves total removal of the diseased liver and replacement with a healthy liver in the same anatomic location (**orthotopic liver transplantation [OLT]**). Removal of the liver creates a space for the new liver and permits anatomic reconstruction of the hepatic vasculature and biliary tract as close to normal as possible.

The success of liver transplantation depends on successful immunosuppression. Immunosuppressants currently used include cyclosporine (Neoral), tacrolimus (Prograf), corticosteroids, azathioprine (Imuran), mycophenolate mofetil (CellCept), OKT3 (a monoclonal antibody), sirolimus (formerly known as rapamycin [Rapamune]), anti-thymocyte globulin (Thymoglobulin), basiliximab (Simulect), and dalcizumab (Zenapax). There is no one, accepted, optimal immunosuppressive regimen. Most centers have developed their own therapeutic practices, largely based on experience. Few large-scale trials have been undertaken and even if they reach established endpoints, many experts agree that newer agents will be developed, making findings less useful (Rodes, et al., 2007).

Despite the success of immunosuppression in reducing the incidence of rejection of transplanted organs, liver transplantation is not routine and may be accompanied by complications related to the lengthy surgical procedure, immunosuppressive therapy, infection, and the technical difficulties encountered in reconstructing the blood vessels and biliary tract. Long-standing systemic problems resulting from the primary liver disease may complicate the preoperative and postoperative course. Previous surgery of the abdomen, including procedures to treat complications of advanced liver disease (ie, shunt procedures used to treat portal hypertension and esophageal varices) increase the complexity of the transplantation procedure.

The indications for liver transplantation are not as limited today as they were when the procedure was first introduced because of advances in immunosuppressive therapy, improvements in biliary tract reconstruction, and, in some cases, the use of venovenous bypass. General indications for liver transplantation include irreversible advanced chronic liver disease, fulminant hepatic failure, metabolic liver diseases, and some hepatic malignancies. Examples of disorders that are indications for liver transplantation include hepatocellular liver diseases (eg, viral hepatitis, drug-induced or alcohol-induced liver disease, Wilson's disease) and cholestatic diseases (primary biliary cirrhosis, sclerosing cholangitis, and biliary atresia).

The patient being considered for liver transplantation frequently has many systemic problems that influence preoperative and postoperative care. Because transplantation is more difficult if the patient has developed severe GI bleeding and hepatic coma, efforts are made to perform the procedure before the disease progresses to this stage. The patient must undergo a thorough evaluation of hepatic reserve and general health. Part of this evaluation includes classification of the degree of medical need, an objective determination known as the Model of End-Stage Liver Disease (MELD) classification, which stratifies the level of illness of those awaiting a liver transplant. The MELD score is derived from a complex formula incorporating bilirubin levels, prothrombin time (reported as international normalized ratio [INR]), creatinine, and the cause of the liver disease (ie, cholestatic, alcoholic, or other). This system has replaced the Child-Pugh classification and other related scoring systems for prioritizing patients on the liver transplantation list (Rodes, et al., 2007; Wolfe, 2006). Although the Child-Pugh score classifies the severity of liver disease and stratifies patients into levels for varied treatment regimens, the MELD score is an indicator of short-term mortality for those with ESLD. Organs are allocated using the MELD score in an effort to provide transplants to the most severely ill patients.

Because liver transplantation is now an established therapeutic modality, rather than an experimental procedure, the number of liver transplantation centers is increasing. Patients requiring transplantation are often referred from distant hospitals to these centers. To prepare the patient and family for liver transplantation, nurses in all settings must understand the processes and procedures of liver transplantation.

Many ethical issues arise concerning liver transplantation, particularly concerning the allocation of organs. The

way in which some persons contracted liver disease (eg, alcohol use; hepatitis) leads others to question allocation of organs to them, and some believe that preference should be given to people who need liver transplants but do not have a history of socially unacceptable behavior. Even more controversy exists when a patient requires a second transplant operation because of a return to alcohol or drug use or failure to follow immunosuppressive regimens (Chart 39-13). These are difficult issues with no easy solutions. Transplant recipients must go through a rigorous selection and preparation process that includes counseling and education to aid them in making critical choices for their improved health. Nurses and other health care providers need to be aware of and confront their own biases and work toward improved understanding and acceptance.

Surgical Procedure

During the procedure, the donor liver is freed from other structures, the bile is flushed from the gallbladder to prevent damage to the walls of the biliary tract, and the liver is perfused with a preservative and cooled. Before the donor liver is placed in the recipient, it is flushed with cold lactated Ringer's solution to remove potassium and air bubbles. The presence of portal hypertension increases the difficulty of the procedure.

To minimize this problem, many centers use venovenous bypass, which decompresses the venous system below the diaphragm by temporarily shunting blood to the superior vena cava via the axillary vein (Bayless & Diehl, 2005).

Anastomoses (connections) of the blood vessels and bile duct are performed between the donor liver and the recipient liver. There are two types of biliary anastomoses. Biliary reconstruction is performed with an end-to-end anastomosis of the donor and recipient common bile ducts; a stented T-tube may be inserted for external drainage of bile. In patients with biliary disease such as primary sclerosing cholangitis or if the recipient's bile duct is not suitable for anastomosis for other reasons, a biliary-enteric end-to-side anastomosis with a 40 to 50 cm Roux-en-Y loop of jejunum is created for biliary drainage (known as a Roux-en-Y procedure) (Fig. 39-15A); in this case, bile drainage is internal, and a T-tube is not inserted (Rodes, et al., 2007). Figure 39-15B and C illustrates the final appearance of the grafted liver and final closure and drain placement.

Several additional techniques have been developed to expand the donor pool for liver transplantation. In a split liver transplant, a single organ is used to provide grafts for two individuals with ESLD, with the smaller patient receiving the smaller left lobe. This procedure has resulted in a higher complication rate and lower survival rate than traditional liver transplantation. Auxiliary liver transplantation has been used in adults with fulminant hepatic failure until the patient's own liver recovers function. This procedure incorporates removal of a segment of diseased liver and implantation of a reduced-size graft. Living donor transplantation is being increasingly performed from adult to adult using full right lobes, although it is controversial because it is a major surgical procedure for the donor, and some donor deaths have occurred. The results thus far have indicated that this procedure is most successful when donor and recipient are appropriately selected using careful screening criteria (Rodes, et al., 2007).

Liver transplantation is a long surgical procedure, partly because the patient with liver failure often has portal hypertension, requiring ligation of many venous collateral vessels. Blood loss during the surgical procedure may be extensive. If the patient has adhesions from previous abdominal surgery, lysis of adhesions is often necessary. If a shunt procedure was performed previously, it must be surgically reversed to permit adequate portal venous blood supply to the new liver. During the lengthy surgery, it is important to provide regular updates to the family about the progress of the operation and the patient's status.

Complications

The postoperative complication rate is high, primarily because of technical complications or infection. Immediate postoperative complications may include bleeding, infection, and rejection. Disruption, infection, obstruction of the biliary anastomosis, and impaired biliary drainage may occur. Vascular thrombosis and stenosis are other potential complications.

Bleeding

Bleeding is common in the postoperative period and may result from coagulopathy, portal hypertension, and fibrinolysis caused by ischemic injury to the donor liver. Hypotension

Ethics and Related Issues

What Ethical Principles Apply When a Candidate for a Second Liver Transplantation Continues His Drug Use?

Situation

A 34-year-old man received a liver transplant a year ago for end-stage liver disease due to hepatitis C (with a history of IV or injection use) and alcoholic liver disease. He experienced a difficult postoperative course with many complications. His liver function has now deteriorated to the point that he is listed to receive a second organ. He is in the hospital, where he is quite ill and in pain. Although he denies further use of alcohol and drug use following his first liver transplant, several bottles of opioids and sedatives are found in his bedside table.

What ethical implications exist in this case? What actions should be taken by the transplant team? What should the nurse document concerning this situation? What factors should be considered when deciding how to proceed in this case?

Dilemma

This patient has already received one liver transplant, and he will not survive unless he receives another one. He is on the list for a second transplant. Because of the limited availability of livers for transplantation and the fact that there is a strong likelihood of his continued use of drugs, questions have been raised about the appropriateness of a second transplant.

Discussion

1. What ethical principles are involved in this situation?
2. What are the competing issues in this case that must be considered in this man's case?
3. How does the nurse respond if the patient asks about the likelihood of his receiving a second liver transplant?

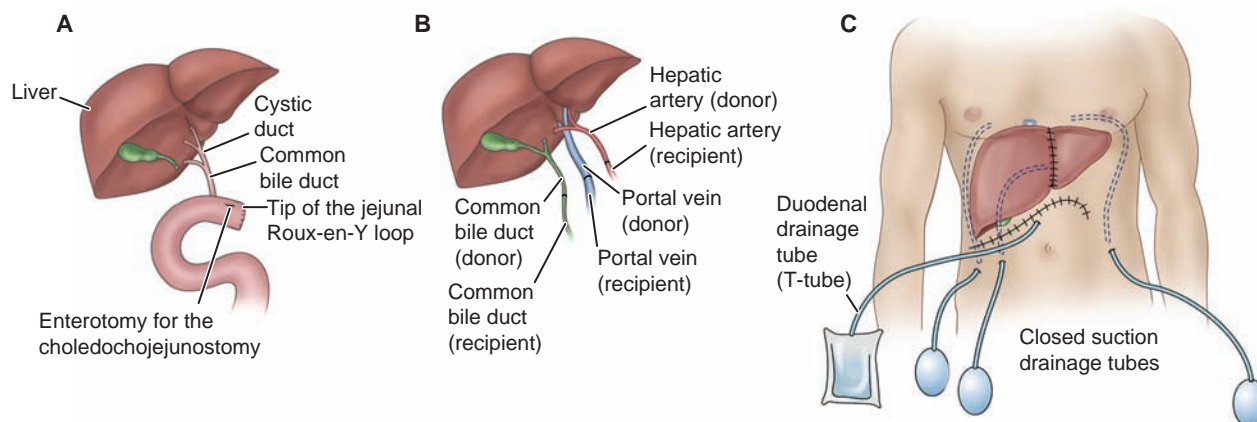

Figure 39-15 **A**, Some transplant recipients have diseases or conditions that cause their bile ducts to be unusable for anastomosis to the donor liver bile duct. In this case, a loop of jejunum is used as a bridge from the donor liver bile duct to the recipient's small bowel for biliary continuity and drainage. This procedure is termed a Roux-en-Y hepaticojejunostomy. **B**, Final appearance of implanted liver graft with an end-to-end biliary anastomosis. **C**, Final closure and drain placement after liver transplantation with an end-to-end biliary anastomosis and T-tube placement.

may occur in this phase, secondary to blood loss. Administration of platelets, fresh-frozen plasma, or other blood products may be necessary. Hypertension is more common, although its cause is uncertain. Blood pressure elevation that is significant or sustained is treated.

Infection

Infection is the leading cause of death after liver transplantation. Pulmonary and fungal infections are common; susceptibility to infection is increased by the immunosuppressive therapy that is needed to prevent rejection (Rodes, et al., 2007). Therefore, precautions must be taken to prevent healthcare-associated infections. The nurse uses strict asepsis when manipulating central venous catheters, arterial lines, and urine, bile, and other drainage systems; obtaining specimens; and changing dressings. Meticulous hand hygiene is crucial. In the ICU, the nurse uses evidence-based practice guidelines in the care of the postoperative liver transplant patient. Some of these care guidelines include prevention of sepsis and its rapid treatment, prevention of ventilator-associated pneumonia (VAP), and prevention of catheter-related bloodstream infections (American Thoracic Society, 2005).

Rejection

Rejection is a primary concern. A transplanted liver is perceived by the immune system as a foreign antigen. This triggers an immune response, leading to the activation of T lymphocytes that attack and destroy the transplanted liver. Immunosuppressive agents are used as long-term therapy to prevent this response and rejection of the transplanted liver. These agents inhibit the activation of immunocompetent T lymphocytes to prevent the production of effector T cells.

Although the 1- and 5-year survival rates have increased dramatically with the use of new immunosuppressive therapies, these advances are not without major side effects. A major side effect of cyclosporine, which was widely used in

transplantation, is nephrotoxicity; this problem seems to be dose related. Cyclosporine-related side effects have caused many centers to use tacrolimus as first-line therapy because of its efficacy and lower side-effect profile.

Corticosteroids, azathioprine, mycophenolate mofetil, sirolimus (formerly known as rapamycin) anti-thymocyte globulin, basiliximab, daclizumab, and muromonab-CD3 (OKT3) are also used in various regimens of immunosuppression. These agents may be used as the initial therapy to prevent rejection or used later to treat rejection. Liver biopsy and ultrasound may be required to evaluate suspected episodes of rejection.

Retransplantation is usually attempted if the transplanted liver fails, but the success rate of retransplantation does not approach that of initial transplantation.

Nursing Management

The patient considering transplantation, together with the family, must make difficult choices about treatment, use of financial resources, and relocation to another area to be closer to the medical center. They must also be aware of the risks and benefits of the procedure and its consequences. In addition, they must also cope with the patient's long-standing health problems and any social and family problems associated with behaviors that may have caused the patient's liver failure. As a result, considerable emotional stress occurs while the patient and family consider liver transplantation and wait for an available liver (Chart 39-14). The nurse must be aware of these issues and attuned to the emotional and psychological status of the patient and family. Referral to a psychiatric liaison nurse, psychologist, psychiatrist, or spiritual advisor may help them cope with the stressors associated with ESKD and liver transplantation.

If the patient and family are considering undergoing a live donor liver transplant, they are subject to additional stressors. Both the patient and the potential donor must undergo a thorough and exhaustive physical and psychological workup to ensure that all involved parties are physically and emotionally prepared. Often, but not always, the donor

CHART

Waiting for a Liver Transplant

Brown, J., Sorrell, J. H., McClaren, J., et al. (2006). Waiting for a liver transplant. *Qualitative Health Research*, 16(1), 119–136.

Purpose

Potential transplant recipients who are waiting for donor livers suffer a high rate of illness and death. In addition, they must cope with the fact that many livers become available for transplant only after the death of a suitable donor. Little definitive information is known about what patients experience as they wait for a liver transplant. This study examined patients' experiences while they wait for a transplant.

Design

Researchers used a phenomenological approach to examine the experience of patients with end-stage liver disease (ESLD) waiting for a transplant. They conducted nine interviews with six patients with ESLD during their wait for a liver transplant. Interviews with six participants were open ended, with three participants having follow-up interviews. The interviews focused on what it was like for patients with ESLD to be on the waiting list for a liver transplant and their experiences during the period of waiting. Researchers performed a qualitative analysis of transcriptions of the interviews to extract statements and ultimately themes that described the experience of waiting for a liver transplant. They identified and verified themes through review of the literature, member checks, and peer review of the data analysis process.

Findings

Eight themes that described the experience of waiting for a liver transplant emerged from the data analysis: transformation; doctors, teams, and trust; transition from elation to de-

spair; loss; questioning the process; searching; coping; and the paradox of time. Patients characterized transformation as experiencing acute episodes of illness and possible death. The theme of doctors, teams, and trust was one of feeling that one became part of the team but dependent on others for the outcome. The transition from elation to despair was experienced as a roller coaster effect over time, ranging from elation that one was put on the list for a transplant to despair because of the length of time, uncertainty of the wait, and the realization that usually someone had to die for a liver to become available. Loss included all the physical, psychological, and emotional changes that occurred during the course of illness and waiting for a transplant. Questioning the process reflected the ambivalence and doubt that were experienced by people as they questioned the wisdom of having a transplant. Searching referred to patients' developing theories about their experiences and the personal search for meaning given their predicament. Coping referred to strategies patients used to grapple with their situation; strategies included denial and patience. Lastly, the paradox of time referred to patients' views of life before and after transplantation and the effect of waiting on their perception of time.

Nursing Implications

The impact on patients of being placed on a wait list for liver transplant needs to be considered by those providing care. The lack of control and the losses experienced by patients waiting for a liver transplant need to be acknowledged and addressed during care by allowing patients to have as much control over their lives as possible. Providing patients with an opportunity to verbalize their fears and concerns about their situation and their future may be helpful in reducing some of the patients' sense of uncertainty and sense of ambivalence about waiting and their uncertain future.

is a close family member. Coercion must be excluded as influencing the decision to donate a portion of one's liver to another. The potential donor must be aware of the risks associated with the procedure.

If the patient and family believe that liver transplantation may be appropriate, the nurse, surgeon, hepatologist, and other health care team members provide the patient and family with full explanations about the procedure, the chances of success, and the risks, including the side effects of long-term immunosuppression. The need for close follow-up and lifelong compliance with the therapeutic regimen, including immunosuppression, is emphasized to the patient and family.

Preoperative Nursing Interventions

Once the patient has been accepted as a candidate, he or she is placed on a waiting list at the transplant center, and patient information is entered into the United Network for Organ Sharing (UNOS) computer system. The UNOS system uses the MELD score to determine organ allocation priorities so that the patient with the highest MELD score will receive the first available organ. Candidates may be matched with appropriate organs as they become available.

MELD scores provide the necessary information regarding medical need.

Except in the case of segmental liver transplantation from a living donor, a liver becomes available for transplantation only with the death of another person, usually someone who had been healthy except for severe brain injury and brain death. Therefore, the patient and family undergo a stressful waiting period, and the nurse is often their major source of support. The patient must be accessible at all times in case an appropriate liver becomes available. During this time, liver function may deteriorate further, and the patient may experience other complications from the primary liver disease. Because of the shortage of donor organs, many patients die awaiting transplantation.

Malnutrition, massive ascites, and fluid and electrolyte disturbances are treated before surgery to increase the likelihood of a successful outcome. If the patient's liver dysfunction has a very rapid onset, as in fulminant hepatic failure, there is little time or opportunity for the patient to consider and weigh options and their consequences; often this patient is in a coma, and the decision to proceed with transplantation is made by the family.

The nurse coordinator is an integral member of the transplant team and plays an important role in preparing the patient for liver transplantation. The nurse serves as an advocate for the patient and family and assumes the important role of liaison between the patient and the other members of the transplant team. The nurse also serves as a resource to other nurses and health care team members involved in evaluating and caring for the patient.

Postoperative Nursing Interventions

The patient is maintained in an environment as free from bacteria, viruses, and fungi as possible, because immunosuppressive medications reduce the body's natural defenses. In the immediate postoperative period, cardiovascular, pulmonary, renal, neurologic, and metabolic functions are monitored continuously. Mean arterial and pulmonary artery pressures are also monitored continuously. Cardiac output, central venous pressure, pulmonary capillary wedge pressure, arterial and mixed venous blood gases, oxygen saturation, oxygen demand and delivery, urine output, heart rate, and blood pressure are used to evaluate the patient's hemodynamic status and intravascular fluid volume. Liver function tests, electrolyte levels, the coagulation profile, chest x-ray, electrocardiogram, and fluid output (including urine, bile from the T-tube, and drainage from Jackson-Pratt tubes) are monitored closely. Because the liver is responsible for the storage of glycogen and the synthesis of protein and clotting factors, these substances need to be monitored and replaced in the immediate postoperative period.

There is a high risk of atelectasis and an altered ventilation-perfusion ratio caused by insult to the diaphragm during the surgical procedure, prolonged anesthesia, immobility, and postoperative pain. The patient will have an endotracheal tube in place and will require mechanical ventilation during the initial postoperative period. Suctioning is performed as required, and sterile humidification is provided. Evidence-based practice guidelines are implemented to prevent the development of VAP in the postoperative liver transplant recipient (American Thoracic Society, 2005). Actions such as keeping the head of the bed elevated at least 30 degrees and performing frequent oral suctioning and cleansing are effective in preventing VAP.

As the patient's condition stabilizes, efforts are made to promote recovery from the trauma of this complex surgery. After removal of the endotracheal tube, the nurse encourages the patient to use an incentive spirometer to decrease the risk of atelectasis. Following extubation, the patient is assisted to get out of bed, to ambulate as tolerated, and to participate in self-care to prevent the complications associated with immobility. Close monitoring for signs and symptoms of liver dysfunction and rejection continue throughout the hospital stay. Plans are made for close follow-up after discharge as well. Teaching is initiated during the preoperative period and continues after surgery.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Teaching the patient and family about long-term measures to promote health is crucial for the success of transplanta-

tion and is an important role of the nurse. The patient and family must understand why they need to adhere closely to the therapeutic regimen, with special emphasis on the methods of administration, rationale, and side effects of the prescribed immunosuppressive agents. The nurse provides written as well as verbal instructions about how and when to take the medications. To avoid running out of medication or skipping a dose, the patient must make sure that an adequate supply of medication is available. Instructions are also provided about the signs and symptoms that indicate problems necessitating consultation with the transplant team. The patient with a T-tube in place must be taught how to manage the tube, drainage, and skin care.

Continuing Care

The nurse emphasizes the importance of follow-up blood tests and appointments with the transplant team. Trough blood levels of immunosuppressive agents are obtained, along with other blood tests that assess the function of the liver and kidneys. During the first months, the patient is likely to require blood tests two or three times a week. As the patient's condition stabilizes, blood studies and visits to the transplant team are less frequent. The importance of routine ophthalmologic examinations is emphasized because of the increased incidence of cataracts and glaucoma associated with the long-term corticosteroid therapy used with transplantation. Regular oral hygiene and follow-up dental care, with administration of prophylactic antibiotics before dental examinations and treatments, are recommended because of the immunosuppression.

The nurse reminds the patient that preventing rejection and infection is essential and increases the chances for survival and a more normal life than before transplantation. Many patients have lived successful and productive lives after receiving a liver transplant. In fact, pregnancy can be considered 1 year after transplantation. Although successful outcomes have been reported, these pregnancies are considered high risk for both mother and infant. Transplant recipients should be advised about birth control. The 1-year waiting period allows time to establish good health, stable liver function, and lower maintenance levels of immunosuppressive therapy (Rodes, et al., 2007).

Liver Abscesses

Two categories of liver abscess have been identified: amebic and pyogenic. Amebic liver abscesses are most commonly caused by *Entamoeba histolytica*. Most amebic liver abscesses occur in the developing countries of the tropics and subtropics because of poor sanitation and hygiene. Pyogenic liver abscesses are much less common, but they are more common in developed countries than the amebic type.

Pathophysiology

Whenever an infection develops anywhere along the biliary or GI tract, infecting organisms may reach the liver through the biliary system, portal venous system, or hepatic arterial or lymphatic system. Most bacteria are destroyed promptly, but occasionally some gain a foothold. The bacterial toxins destroy the neighboring liver cells, and the

resulting necrotic tissue serves as a protective wall for the organisms.

Meanwhile, leukocytes migrate into the infected area. The result is an abscess cavity full of a liquid containing living and dead leukocytes, liquefied liver cells, and bacteria. Pyogenic abscesses of this type may be either single or multiple and small. Examples of causes of pyogenic liver abscess include cholangitis (usually related to benign or malignant obstruction of the biliary tree) and abdominal trauma.

Clinical Manifestations

The clinical picture is one of sepsis with few or no localizing signs. Fever with chills and diaphoresis, malaise, anorexia, nausea, vomiting, and weight loss may occur. The patient may complain of dull abdominal pain and tenderness in the right upper quadrant of the abdomen. Hepatomegaly, jaundice, anemia, and pleural effusion may develop. Sepsis and shock may be severe and life-threatening. In the past, the mortality rate was 100% because of the vague clinical symptoms, inadequate diagnostic tools, and inadequate surgical drainage of the abscess. With the aid of ultrasound, CT, MRI, and liver scans, early diagnosis and surgical drainage of abscesses have greatly reduced the mortality rate.

Assessment and Diagnostic Findings

Although blood cultures are obtained, the organism may not be identified. Aspiration of the liver abscess, guided by ultrasound, CT, or MRI, may be performed to assist in diagnosis and to obtain cultures of the organism. Percutaneous drainage of pyogenic abscesses is carried out to evacuate the abscess material and promote healing. A catheter may be left in place for continuous drainage; the patient must be instructed about its management.

Medical Management

Treatment includes IV antibiotic therapy; the specific antibiotic used in treatment depends on the organism identified. Continuous supportive care is indicated because of the serious condition of the patient. Open surgical drainage may be required if antibiotic therapy and percutaneous drainage are ineffective.

Nursing Management

Although the manifestations of liver abscess vary with the type of abscess, most patients appear acutely ill. Others appear to be chronically ill and debilitated. The nursing management depends on the patient's physical status and the medical management that is indicated. For patients who undergo evacuation and drainage of an abscess, monitoring of the drainage and skin care are imperative. Strategies must be implemented to contain the drainage and to protect the patient from other sources of infection. Vital signs are monitored to detect changes in the patient's physical status. Deterioration in vital signs or the onset of new symptoms such as increasing pain, which may indicate rupture or extension of the abscess, is reported promptly. The nurse administers IV antibiotic therapy as prescribed. The white blood cell count and other laboratory test results are monitored closely for changes consistent with worsening infection. The nurse prepares the patient for discharge by providing instruction about symptom management, signs and symptoms that should be

reported to the physician, management of drainage, and the importance of taking antibiotics as prescribed.

CRITICAL THINKING EXERCISES

1 A 56-year-old professor and consultant has just received unexpected notice that she must travel to Nicaragua for a conference in 2 days. What prophylactic measures to reduce her risk of contracting hepatitis A are available before she leaves for her trip? What signs and symptoms are important for her to watch for and to report to her health care provider? What modifications, if any, should be implemented for her close household contacts? If this woman had 6 months to prepare for her trip, how would the answers to these questions be different?

2 A 36-year-old African man came to the United States from Botswana 3 years ago to live with relatives. He is being treated for end-stage liver disease (ESLD) with cirrhosis related to hepatitis B and is undergoing evaluation for liver transplantation. The sequelae of ESLD that he is experiencing include encephalopathy and ascites. What would you anticipate this patient's treatment regimen to include? What medications would be most appropriate for him? What would you include in your cultural assessment when you develop a preoperative teaching plan for this patient? What alternative therapies might be used preoperatively? Once the patient receives a liver transplant, what medications would you expect to be prescribed for him in addition to an immunosuppressant regimen?

3 A 68-year-old man is admitted to the hospital with a diagnosis of bleeding esophageal varices. Describe the monitoring you would initiate. What possible management strategies to prevent bleeding and to treat active bleeding of the esophageal varices would you anticipate? What are the nursing implications for each of these strategies? How would medical management and nursing care be modified if the patient had chronic obstructive pulmonary disease in addition to esophageal varices? How would you explain treatment strategies to the patient and his family if one or more of them had hearing impairment?

4 A 26-year-old man is transferred to your transplant center with the diagnosis of end-stage liver disease with a severe coagulopathy and encephalopathy. He presents with extreme jaundice, multiple bruises, and severe confusion and agitation. In addition, he is trying to climb out of bed and strike family members and hospital personnel. The cause of his liver failure is hepatitis C from intravenous (IV) or injection drug use along with alcohol abuse. The referring institution had indicated that the man had not used drugs or alcohol for more than 6 months. On obtaining a detailed history from the patient's mother and sister, the nurse and physician learn that his family had seen him use IV or injection drugs only 2 weeks prior to admission. What are the nursing priorities in the care of this patient? What measures would you institute to ensure patient safety? What medications are

likely to be used to improve the patient's mental status? Is the patient an appropriate candidate for a liver transplant? If the patient does not receive a liver transplant, what is the likely outcome?

EBP 5 A 19-year-old college student with fulminant liver failure is hospitalized with hepatic coma related to an acetaminophen overdose. She is in the intensive care unit, intubated and on a ventilator. A pulmonary artery catheter has been placed as well as an arterial line and indwelling urinary catheter. She has also had a device placed to monitor and treat intracranial hypertension. What factors place her at high risk for infection? What particular types of infection are most likely? What evidence-based practice guidelines are you most likely to institute to prevent sepsis in this patient? What criteria will you use to determine the strength of the evidence? On receiving a liver transplant, what other risk factors for infection will she have?

chapter 40

Assessment and Management of Patients With Biliary Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Compare approaches to management of cholelithiasis.
- 2 Use the nursing process as a framework for care of patients with cholelithiasis and those undergoing laparoscopic or open cholecystectomy.
- 3 Differentiate between acute and chronic pancreatitis.
- 4 Describe nursing management of patients with acute pancreatitis.
- 5 Describe the nutritional and metabolic effects of surgical treatment of tumors of the pancreas.

GLOSSARY

amylase: pancreatic enzyme; aids in the digestion of carbohydrates

cholecystectomy: removal of the gallbladder

cholecystitis: inflammation of the gallbladder

cholecystojejunostomy: anastomosis of the jejunum to the gallbladder to divert bile flow

cholecystokinin-pancreozymin (CCK-PZ): hormone; major stimulus for digestive enzyme secretion; stimulates contraction of the gallbladder

cholecystostomy: opening and drainage of the gallbladder

choledochojejunostomy: anastomosis of common duct to jejunum

choledocholithiasis: stones in the common duct

choledocholithotomy: incision of common bile duct for removal of stones

choledochostomy: opening into the common duct

cholelithiasis: calculi in the gallbladder

GLOSSARY (Continued)

dissolution therapy: use of medications to break up/dissolve gallstones

endocrine: secreting internally; hormonal secretion of a ductless gland

endoscopic retrograde cholangiopancreatography (ERCP): an endoscopic procedure using fiberoptic technology to visualize the biliary system

exocrine: secreting externally; hormonal secretion from excretory ducts

laparoscopic cholecystectomy: removal of gallbladder through an endoscopic procedure

lipase: pancreatic enzyme; aids in the digestion of fats

lithotripsy: disintegration of gallstones by shock waves

pancreaticojejunostomy: joining of the pancreatic duct to the jejunum by side-to-side anastomosis; allows drainage of the pancreatic secretions into the jejunum

pancreatitis: inflammation of the pancreas; may be acute or chronic

secretin: hormone responsible for stimulating secretion of pancreatic juice; also used as an aid in diagnosing pancreatic exocrine disease and in obtaining desquamated pancreatic cells for cytologic examination

steatorrhea: frothy, foul-smelling stools with a high fat content; results from impaired digestion of proteins and fats due to a lack of pancreatic juice in the intestine

trypsin: pancreatic enzyme; aids in digestion of proteins

wound-ostomy-continence (WOC) nurse: nurse specially educated in appropriate skin, wound, ostomy, and continence care; often referred to as wound-care specialist or enterostomal therapist

Zollinger-Ellison tumor: hypersecretion of gastric acid that produces peptic ulcers as a result of a non-beta-cell tumor of the pancreatic islets

Disorders of the biliary tract and pancreas are common and include gallbladder stones and pancreatic dysfunction. An understanding of the structure and function of the biliary tract and pancreas is essential, along with an understanding of how biliary tract disorders are closely linked with liver disease. Patients with acute or chronic biliary tract or pancreatic disease require care from nurses who are knowledgeable about the diagnostic procedures and interventions that are used in the management of gallbladder and pancreatic disorders.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The Gallbladder

The gallbladder, a pear-shaped, hollow, saclike organ, 7.5 to 10 cm (3 to 4 in) long, lies in a shallow depression on the inferior surface of the liver, to which it is attached by loose connective tissue. The capacity of the gallbladder is 30 to 50 mL of bile. Its wall is composed largely of smooth muscle. The gallbladder is connected to the common bile duct by the cystic duct (Fig. 40-1).

The gallbladder functions as a storage depot for bile. Between meals, when the sphincter of Oddi is closed, bile produced by the hepatocytes enters the gallbladder. During storage, a large portion of the water in bile is absorbed through the walls of the gallbladder, so that bile in the gallbladder is five to 10 times more concentrated than that originally secreted by the liver. When food enters the duodenum, the gallbladder contracts and the sphincter of Oddi (located at the junction of the common bile duct with the duodenum) relaxes. Relaxation of this sphincter allows the bile to enter the intestine. This response is mediated by secretion of the hormone **cholecystokinin-pancreozymin (CCK-PZ)** from the intestinal wall. Bile is composed of water and electrolytes (sodium, potassium, calcium, chloride, and bicarbonate) along with significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. The bile salts, together with cholesterol, assist in emulsification

Figure 40-1 The liver, biliary system, and pancreas.

of fats in the distal ileum. They are then reabsorbed into the portal blood for return to the liver, after which they are once again excreted into the bile. This pathway from hepatocytes to bile to intestine and back to the hepatocytes is called the enterohepatic circulation. Because of this circulation, only a small fraction of the bile salts that enter the intestine are excreted in the feces. This decreases the need for active synthesis of bile salts by the liver cells.

Approximately half of the bilirubin, a pigment derived from the breakdown of red blood cells, is a component of bile. It is converted by the intestinal flora into urobilinogen, a highly soluble substance. Urobilinogen is either excreted in the feces or returned to the portal circulation, where it is reexcreted into the bile. About 5% is normally absorbed into the general circulation and then excreted by the kidneys (Porth & Matfin, 2009).

If the flow of bile is impeded (eg, by gallstones in the bile ducts), bilirubin does not enter the intestine. As a result, blood levels of bilirubin increase. This causes increased renal excretion of urobilinogen, which results from conversion of bilirubin in the small intestine, and decreased excretion in the stool. These changes produce many of the signs and symptoms seen in gallbladder disorders.

The Pancreas

The pancreas, located in the upper abdomen, has **endocrine** as well as **exocrine** functions (see Fig. 40-1). The exocrine functions include secretion of pancreatic enzymes into the gastrointestinal (GI) tract through the pancreatic duct. The endocrine functions include secretion of insulin, glucagon, and somatostatin directly into the bloodstream.

The Exocrine Pancreas

The secretions of the exocrine portion of the pancreas are collected in the pancreatic duct, which joins the common bile duct and enters the duodenum at the ampulla of Vater. Surrounding the ampulla is the sphincter of Oddi, which partially controls the rate at which secretions from the pancreas and the gallbladder enter the duodenum.

The secretions of the exocrine pancreas are digestive enzymes high in protein content and an electrolyte-rich fluid. The secretions, which are very alkaline because of their high concentration of sodium bicarbonate, are capable of neutralizing the highly acid gastric juice that enters the duodenum. The enzyme secretions include **amylase**, which aids in the digestion of carbohydrates; **trypsin**, which aids in the digestion of proteins; and **lipase**, which aids in the digestion of fats. Other enzymes that promote the breakdown of more complex foodstuffs are also secreted.

Hormones originating in the GI tract stimulate the secretion of these exocrine pancreatic juices. The hormone **secretin** is the major stimulus for increased bicarbonate secretion from the pancreas, and the major stimulus for digestive enzyme secretion is the hormone CCK-PZ. The vagus nerve also influences exocrine pancreatic secretion.

The Endocrine Pancreas

The islets of Langerhans, the endocrine part of the pancreas, are collections of cells embedded in the pancreatic tissue. They are composed of alpha, beta, and delta cells. The hormone produced by the beta cells is called insulin;

the alpha cells secrete glucagon, and the delta cells secrete somatostatin.

Insulin

A major action of insulin is to lower blood glucose by permitting entry of glucose into the cells of the liver, muscle, and other tissues, where it is either stored as glycogen or used for energy. Insulin also promotes the storage of fat in adipose tissue and the synthesis of proteins in various body tissues. In the absence of insulin, glucose cannot enter the cells and is excreted in the urine. This condition, called diabetes mellitus, can be diagnosed by high levels of glucose in the blood. In diabetes mellitus, stored fats and protein are used for energy instead of glucose, causing loss of body mass. (Diabetes mellitus is discussed in detail in Chapter 41.) The level of glucose in the blood normally regulates the rate of insulin secretion from the pancreas.

Glucagon

The effect of glucagon (opposite to that of insulin) is chiefly to raise the blood glucose by converting glycogen to glucose in the liver. Glucagon is secreted by the pancreas in response to a decrease in the level of blood glucose.

Somatostatin

Somatostatin exerts a hypoglycemic effect by interfering with release of growth hormone from the pituitary and glucagon from the pancreas, both of which tend to raise blood glucose levels.

Endocrine Control of Carbohydrate Metabolism

Glucose required for energy is derived by metabolism of ingested carbohydrates and also from proteins by the process of gluconeogenesis. Glucose can be stored temporarily in the form of glycogen in the liver, muscles, and other tissues. The endocrine system controls the level of blood glucose by regulating the rate at which glucose is synthesized, stored, and moved to and from the bloodstream. Through the action of hormones, blood glucose is normally maintained at less than 100 mg/dL (5.5 mmol/L). Insulin is the primary hormone that lowers the blood glucose level. Hormones that raise the blood glucose level are glucagon, epinephrine, adrenocorticosteroids, growth hormone, and thyroid hormone.

The endocrine and exocrine functions of the pancreas are interrelated. The major exocrine function is to facilitate digestion through secretion of enzymes into the proximal duodenum. Secretin and CCK-PZ are hormones from the GI tract that aid in the digestion of food substances by controlling the secretions of the pancreas. Neural factors also influence pancreatic enzyme secretion. Considerable dysfunction of the pancreas must occur before enzyme secretion decreases and protein and fat digestion becomes impaired. Pancreatic enzyme secretion is normally 1500 to 2500 mL/day.

Gerontologic Considerations

There is little change in the size of the pancreas with age. However, there is an increase in fibrous material and some fatty deposition in the normal pancreas in people older than

70 years of age. Some localized arteriosclerotic changes occur with age. There is also a decreased rate of pancreatic secretion (decreased lipase, amylase, and trypsin) and decreased bicarbonate output in older people. Some impairment of normal fat absorption occurs with increasing age, possibly because of delayed gastric emptying and pancreatic insufficiency. Decreased calcium absorption may also occur. These changes require care in interpreting diagnostic test results in the normal elderly patient and in providing dietary counseling.

DISORDERS OF THE GALLBLADDER

Several disorders affect the biliary system and interfere with normal drainage of bile into the duodenum. These disorders include inflammation of the biliary system and carcinoma that obstructs the biliary tree. Gallbladder disease with gallstones is the most common disorder of the biliary system. Although not all occurrences of gallbladder inflammation (**cholecystitis**) are related to gallstones (**cholelithiasis**), more than 90% of patients with acute cholecystitis have gallstones. However, most of the 15 million Americans with gallstones have no pain and are unaware of the presence of stones.

Cholecystitis

Cholecystitis, acute inflammation of the gallbladder, causes pain, tenderness, and rigidity of the upper right abdomen that may radiate to the midsternal area or right shoulder and is associated with nausea, vomiting, and the usual signs of an acute inflammation. An empyema of the gallbladder develops if the gallbladder becomes filled with purulent fluid (pus).

Calculous cholecystitis is the cause of more than 90% of cases of acute cholecystitis (Feldman, Friedman & Brandt, 2006). In calculous cholecystitis, a gallbladder stone obstructs bile outflow. Bile remaining in the gallbladder initiates a chemical reaction; autolysis and edema occur; and the blood vessels in the gallbladder are compressed, compromising its vascular supply. Gangrene of the gallbladder with perforation may result. Bacteria play a minor role in acute cholecystitis; however, secondary infection of bile occurs in approximately 50% of cases. The organisms involved are generally enteric (normally live in the GI tract) and include *Escherichia coli*, *Klebsiella* species, and *Streptococcus*. Bacterial contamination is not believed to stimulate the actual onset of acute cholecystitis (Feldman, et al., 2006).

Acalculous cholecystitis describes acute gallbladder inflammation in the absence of obstruction by gallstones. Acalculous cholecystitis occurs after major surgical procedures, severe trauma, or burns. Other factors associated with this type of cholecystitis include torsion, cystic duct obstruction, primary bacterial infections of the gallbladder, and multiple blood transfusions. It is speculated that acalculous cholecystitis is caused by alterations in fluids and electrolytes and alterations in regional blood flow in the visceral circulation. Bile stasis (lack of gallbladder contraction) and increased viscosity of the bile are also thought to play a role.

Figure 40-2 Examples of cholesterol gallstones (*left*) made up of a coalescence of multiple small stones and pigment gallstones (*right*) composed of calcium bilirubinate. From Rubin, E. & Farber, J. L. (2005). *Pathology* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

The occurrence of acalculous cholecystitis with major surgical procedures or trauma makes its diagnosis difficult.

Cholelithiasis

Calculi, or gallstones, usually form in the gallbladder from the solid constituents of bile; they vary greatly in size, shape, and composition (Fig. 40-2). They are uncommon in children and young adults but become more prevalent with increasing age, affecting 30% to 40% of people by the age of 80 years.

Pathophysiology

There are two major types of gallstones: those composed predominantly of pigment and those composed primarily of cholesterol. Pigment stones probably form when unconjugated pigments in the bile precipitate to form stones; these stones account for about 10% to 25% of cases in the United States (Feldman, et al., 2006). The risk of developing such stones is increased in patients with cirrhosis, hemolysis, and infections of the biliary tract. Pigment stones cannot be dissolved and must be removed surgically.

Cholesterol stones account for most of the remaining 75% of cases of gallbladder disease in the United States. Cholesterol, a normal constituent of bile, is insoluble in water. Its solubility depends on bile acids and lecithin (phospholipids) in bile. In gallstone-prone patients, there is decreased bile acid synthesis and increased cholesterol synthesis in the liver, resulting in bile supersaturated with cholesterol, which precipitates out of the bile to form stones. The cholesterol-saturated bile predisposes to the for-

mation of gallstones and acts as an irritant that produces inflammatory changes in the gallbladder.

Two to three times more women than men develop cholesterol stones and gallbladder disease; affected women are usually older than 40 years of age, multiparous, and obese. Stone formation is more frequent in people who use oral contraceptives, estrogens, or clofibrate; these medications are known to increase biliary cholesterol saturation. The incidence of stone formation increases with age as a result of increased hepatic secretion of cholesterol and decreased bile acid synthesis. In addition, there is an increased risk because of malabsorption of bile salts in patients with GI disease or T-tube fistula and in those who have undergone ileal resection or bypass. The incidence is also greater in people with diabetes (Chart 40-1).

CHART
40-1

Risk Factors for Cholelithiasis

- Obesity
- Women, especially those who have had multiple pregnancies or who are of Native American or U.S. Southwestern Hispanic ethnicity
- Frequent changes in weight
- Rapid weight loss (leads to rapid development of gallstones and high risk of symptomatic disease)
- Treatment with high-dose estrogen (eg, in prostate cancer)
- Low-dose estrogen therapy—a small increase in the risk of gallstones
- Ileal resection or disease
- Cystic fibrosis
- Diabetes mellitus

Clinical Manifestations

Gallstones may be silent, producing no pain and only mild GI symptoms. Such stones may be detected incidentally during surgery or evaluation for unrelated problems.

The patient with gallbladder disease resulting from gallstones may develop two types of symptoms: those due to disease of the gallbladder itself and those due to obstruction of the bile passages by a gallstone. The symptoms may be acute or chronic. Epigastric distress, such as fullness, abdominal distention, and vague pain in the right upper quadrant of the abdomen, may occur. This distress may follow a meal rich in fried or fatty foods.

Pain and Biliary Colic

If a gallstone obstructs the cystic duct, the gallbladder becomes distended, inflamed, and eventually infected (acute cholecystitis). The patient develops a fever and may have a palpable abdominal mass. The patient may have biliary colic with excruciating upper right abdominal pain that radiates to the back or right shoulder. Biliary colic is usually associated with nausea and vomiting, and it is noticeable several hours after a heavy meal. The patient moves about restlessly, unable to find a comfortable position. In some patients, the pain is constant rather than colicky.

Such a bout of biliary colic is caused by contraction of the gallbladder, which cannot release bile because of obstruction by the stone. When distended, the fundus of the gallbladder comes in contact with the abdominal wall in the region of the right ninth and tenth costal cartilages. This produces marked tenderness in the right upper quadrant on deep inspiration and prevents full inspiratory excursion.

The pain of acute cholecystitis may be so severe that analgesics are required. The use of morphine has traditionally been avoided because of concern that it could cause spasm of the sphincter of Oddi, and meperidine (Demerol) has been used instead. This is controversial, because morphine is the preferred analgesic agent for management of acute pain, and some metabolites of meperidine are toxic to the central nervous system (CNS). Furthermore, all opioids stimulate the sphincter of Oddi to some degree (Porth & Matfin, 2009).

If the gallstone is dislodged and no longer obstructs the cystic duct, the gallbladder drains and the inflammatory

process subsides after a relatively short time. If the gallstone continues to obstruct the duct, abscess, necrosis, and perforation with generalized peritonitis may result.

Jaundice

Jaundice occurs in a few patients with gallbladder disease, usually with obstruction of the common bile duct. The bile, which is no longer carried to the duodenum, is absorbed by the blood and gives the skin and mucous membranes a yellow color. This is frequently accompanied by marked pruritus (itching) of the skin.

Changes in Urine and Stool Color

The excretion of the bile pigments by the kidneys gives the urine a very dark color. The feces, no longer colored with bile pigments, are grayish, like putty, or clay-colored.

Vitamin Deficiency

Obstruction of bile flow interferes with absorption of the fat-soluble vitamins A, D, E, and K. Patients may exhibit deficiencies of these vitamins if biliary obstruction has been prolonged. For example, a patient may have bleeding caused by vitamin K deficiency (vitamin K is necessary for normal blood clotting).

Assessment and Diagnostic Findings

Table 40-1 identifies various procedures and their diagnostic uses.

Abdominal X-Ray

If gallbladder disease is suspected, an abdominal x-ray may be obtained to exclude other causes of symptoms. However, only 15% to 20% of gallstones are calcified sufficiently to be visible on such x-ray studies.

Ultrasonography

Ultrasonography has replaced cholecystography (discussed later) as the diagnostic procedure of choice because it is rapid and accurate and can be used in patients with liver dysfunction and jaundice. It does not expose patients to ionizing radiation. The procedure is most accurate if the patient fasts overnight so that the gallbladder is distended. Ultrasonography can detect calculi in the gallbladder or a dilated common bile duct with 95% accuracy.

Table 40-1 STUDIES USED IN THE DIAGNOSIS OF BILIARY TRACT AND PANCREATIC DISEASE

Studies	Diagnostic Uses
Cholecystogram, cholangiogram	To visualize gallbladder and bile duct
Celiac axis arteriography	To visualize liver and pancreas
Laparoscopy	To visualize anterior surface of liver, gallbladder, and mesentery through a trocar
Ultrasonography	To show size of abdominal organs and presence of masses
Helical computed tomography (CT scans) and magnetic resonance imaging (MRI)	To detect neoplasms; diagnose cysts, pseudocysts, abscess, and hematomas
Endoscopic retrograde cholangiopancreatography (ERCP)	To visualize biliary structures and pancreas via endoscopy
Endoscopic ultrasound (EUS)	To identify small tumors and to facilitate fine-needle aspiration biopsy of tumors or lymph nodes for diagnosis
Serum alkaline phosphatase	In absence of bone disease, to measure biliary tract obstruction
Gamma-glutamyl (GGT), gamma-glutamyl trans-peptidase (GGTP), lactate dehydrogenase (LDH)	Markers for biliary stasis; also elevated in alcohol abuse
Cholesterol levels	Elevated in biliary obstruction; decreased in parenchymal liver disease

Radionuclide Imaging or Cholescintigraphy

Cholescintigraphy is used successfully in the diagnosis of acute cholecystitis or blockage of a bile duct. In this procedure, a radioactive agent is administered intravenously. It is taken up by the hepatocytes and excreted rapidly through the biliary tract. The biliary tract is then scanned, and images of the gallbladder and biliary tract are obtained. This test is more expensive than ultrasonography, takes longer to perform, exposes the patient to radiation, and cannot detect gallstones. It is often used when ultrasonography is not conclusive.

Cholecystography

Although cholecystography has been replaced by ultrasonography as the test of choice, it is still used if ultrasound equipment is not available or if the ultrasound results are inconclusive. Oral cholangiography may be performed to detect gallstones and to assess the ability of the gallbladder to fill, concentrate its contents, contract, and empty. If the patient is not allergic to iodine or seafood, an iodide-containing contrast agent that is excreted by the liver and concentrated in the gallbladder is administered 10 to 12 hours before the x-ray study. The normal gallbladder fills with this radiopaque substance. If gallstones are present, they appear as shadows on the x-ray film.

Oral cholecystography is likely to continue to be used as part of the evaluation of the few patients who have been treated with gallstone **dissolution therapy** or lithotripsy.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) permits direct visualization of structures that previously could be seen only during laparotomy. The examination of the hepatobiliary system is carried out via a side-viewing flexible fiberoptic endoscope inserted through the esophagus to the descending duodenum (Fig. 40-3). Multiple position changes are required to pass the endoscope during the procedure, beginning in the left semiprone position.

Fluoroscopy and multiple x-rays are used during ERCP to evaluate the presence and location of ductal stones. Careful insertion of a catheter through the endoscope into the common bile duct is the most important step in sphincterotomy (division of the muscles of the biliary sphincter) for gallstone extraction via this technique (see later discussion).

Nursing Implications

The procedure requires a cooperative patient to permit insertion of the endoscope without damage to the GI tract structures, including the biliary tree. Before the procedure, the patient is given an explanation of the procedure and his or her role in it. The patient takes nothing by mouth for several hours before the procedure. Moderate sedation is used, and the sedated patient must be monitored closely. It may be necessary to administer medications, such as glucagon or anticholinergics, to make cannulation easier by decreasing duodenal peristalsis. The nurse observes closely for signs of respiratory and central nervous system depression, hypotension, oversedation, and vomiting (if glucagon is administered). During ERCP, the nurse monitors intravenous (IV) fluids, administers medications, and positions the patient.

Figure 40-3 Endoscopic retrograde cholangiopancreatography (ERCP). A fiberoptic duodenoscope, with side-viewing apparatus, is inserted into the duodenum. The ampulla of Vater is catheterized, and the biliary tree is injected with contrast agent. The pancreatic ductal system is also assessed, if indicated. This procedure is of special value in visualizing neoplasms of the ampulla area and extracting a biopsy specimen.

After the procedure, the nurse monitors the patient's condition, observing vital signs and monitoring for signs of perforation or infection. The nurse also monitors the patient for side effects of any medications received during the procedure and for return of the gag and cough reflexes after the use of local anesthetics.

Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography involves the injection of dye directly into the biliary tract. Because of the relatively large concentration of dye that is introduced into the biliary system, including the hepatic ducts within the liver, the entire length of the common bile duct, the cystic duct, and the gallbladder is outlined clearly.

This procedure can be carried out even in the presence of liver dysfunction and jaundice. It is useful for (1) distinguishing jaundice caused by liver disease (hepatocellular jaundice) from that caused by biliary obstruction, (2) investigating the GI symptoms of a patient whose gallbladder has been removed, (3) locating stones within the bile ducts, and (4) diagnosing cancer involving the biliary system.

This sterile procedure is performed under moderate sedation on a patient who has been fasting; the patient receives local anesthesia and moderate sedation. Coagulation parameters and platelet count should be normal to minimize the risk of bleeding. Broad-spectrum antibiotics are administered during the procedure because of the high prevalence of bacterial colonization from obstructed biliary systems. After infiltration with a local anesthetic agent has occurred,

a flexible needle is inserted into the liver from the right side in the midclavicular line immediately beneath the right costal margin. Successful entry of a duct is noted when bile is aspirated or on injection of a contrast agent. Ultrasound can be used to guide puncture of the duct. Bile is aspirated and samples are sent for bacteriology and cytology. A water-soluble contrast agent is injected to fill the biliary system. The fluoroscopy table is tilted and the patient is repositioned to allow x-rays to be taken in multiple projections. Delayed x-ray views can identify abnormalities of more distant ducts and determine the length of a stricture or multiple strictures. Before the needle is removed, as much dye and bile as possible are aspirated to forestall subsequent leakage into the needle tract and eventually into the peritoneal cavity, thus minimizing the risk of bile peritonitis.

NURSING ALERT

Although the complication rate after this procedure is low, the nurse must closely observe the patient for symptoms of bleeding, peritonitis, and septicemia. The nurse assesses the patient for pain and indications of these complications and reports them promptly to the physician. Antibiotic agents are often prescribed to minimize the risk of sepsis and septic shock.

Medical Management

The major objectives of medical therapy are to reduce the incidence of acute episodes of gallbladder pain and cholecystitis by supportive and dietary management and, if possible, to remove the cause of cholecystitis by pharmacologic therapy, endoscopic procedures, or surgical intervention. Although nonsurgical approaches eliminate risks associated with surgery, these approaches are associated with persistent symptoms or recurrent stone formation. Most of the nonsurgical approaches, including lithotripsy and dissolution of gallstones, provide only temporary solutions to gallstone problems and are infrequently used in the United States. In some instances, other treatment approaches may be indicated; these are described later.

Removal of the gallbladder (**cholecystectomy**) through traditional surgical approaches was the standard treatment for more than 100 years. It has largely been replaced by **laparoscopic cholecystectomy** (removal of the gallbladder through a small incision through the umbilicus). As a result, surgical risks have decreased, along with the length of hospital stay and the long recovery period required after standard surgical cholecystectomy. In relatively rare instances, a standard surgical procedure may be necessary.

Nutritional and Supportive Therapy

Approximately 80% of the patients with acute gallbladder inflammation achieve remission with rest, IV fluids, nasogastric suction, analgesia, and antibiotic agents. Unless the patient's condition deteriorates, surgical intervention is delayed just until the acute symptoms subside (usually within a few days). At this time, the patient should undergo a laparoscopic cholecystectomy (Goldman & Ausiello, 2008).

The diet required immediately after an episode is usually limited to low-fat liquids. These can include powdered

supplements high in protein and carbohydrate stirred into skim milk. Cooked fruits, rice or tapioca, lean meats, mashed potatoes, non-gas-forming vegetables, bread, coffee, or tea may be added as tolerated. The patient should avoid eggs, cream, pork, fried foods, cheese, rich dressings, gas-forming vegetables, and alcohol. It is important to remind the patient that fatty foods may induce an episode of cholecystitis. Dietary management may be the major mode of therapy in patients who have had only dietary intolerance to fatty foods and vague GI symptoms (Dudek, 2006).

Pharmacologic Therapy

Ursodeoxycholic acid (UDCA [URSO, Actigall]) and chenodeoxycholic acid (chenodiol or CDCA [Chenix]) have been used to dissolve small, radiolucent gallstones composed primarily of cholesterol. UDCA has fewer side effects than chenodiol and can be administered in smaller doses to achieve the same effect. It acts by inhibiting the synthesis and secretion of cholesterol, thereby desaturating bile. Treatment with UDCA can reduce the size of existing stones, dissolve small stones, and prevent new stones from forming. Six to 12 months of therapy are required in many patients to dissolve stones, and monitoring of the patient for recurrence of symptoms or the occurrence of side effects (eg, GI symptoms, pruritus, headache) is required during this time. The effective dose of medication depends on body weight. This method of treatment is generally indicated for patients who refuse surgery or for whom surgery is considered too risky.

Patients with significant, frequent symptoms; cystic duct occlusion; or pigment stones are not candidates for therapy with UDCA. Laparoscopic or open cholecystectomy is more appropriate for symptomatic patients with acceptable operative risk.

Nonsurgical Removal of Gallstones

Dissolving Gallstones

Several methods have been used to dissolve gallstones by infusion of a solvent (mono-octanoin or methyl tertiary butyl ether [MTBE]) into the gallbladder. The solvent can be infused through the following routes: through a tube or catheter inserted percutaneously directly into the gallbladder; through a tube or drain inserted through a T-tube tract to dissolve stones not removed at the time of surgery; endoscopically with ERCP; or via a transnasal biliary catheter.

In the latter procedure, the catheter is introduced through the mouth and inserted into the common bile duct. The upper end of the tube is then rerouted from the mouth to the nose and left in place. This enables the patient to eat and drink normally while passage of stones is monitored or chemical solvents are infused to dissolve the stones. This method of dissolution of stones is not widely used.

Stone Removal by Instrumentation

Several nonsurgical methods are used to remove stones that were not removed at the time of cholecystectomy or have become lodged in the common bile duct (Fig. 40-4A,B). A catheter and instrument with a basket attached are threaded through the T-tube tract or fistula formed at the time of T-tube insertion; the basket is used to retrieve and remove the stones lodged in the common bile duct.

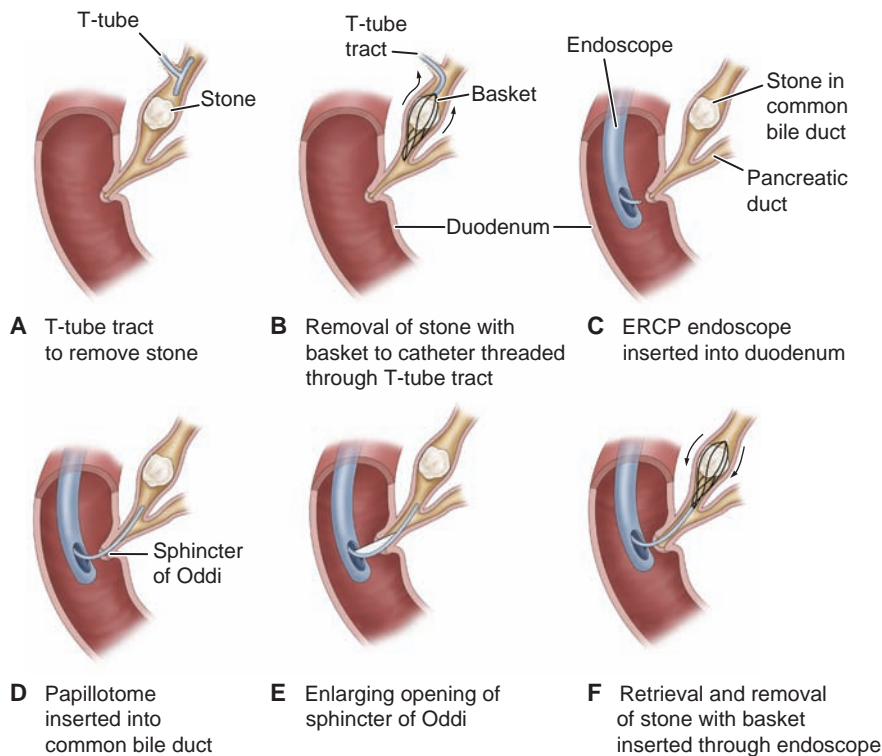

Figure 40-4 Nonsurgical techniques for removing gallstones.

A second procedure involves the use of the ERCP endoscope (Fig. 40-4C). After the endoscope is inserted, a cutting instrument is passed through the endoscope into the ampulla of Vater of the common bile duct. It may be used to cut the submucosal fibers, or papilla, of the sphincter of Oddi, enlarging the opening, which may allow the lodged stones to pass spontaneously into the duodenum. Another instrument with a small basket or balloon at its tip may be inserted through the endoscope to retrieve the stones (Fig. 40-4D–F). The patient is observed closely for bleeding, perforation, and the development of pancreatitis or sepsis.

The ERCP procedure is particularly useful in diagnosis and treatment of patients who have symptoms after biliary tract surgery, patients with intact gallbladders, and patients for whom surgery is particularly hazardous.

Intracorporeal Lithotripsy

Stones in the gallbladder or common bile duct may be fragmented by means of laser pulse technology. A laser pulse is directed under fluoroscopic guidance with the use of devices that can distinguish between stones and tissue. The laser pulse produces rapid expansion and disintegration of plasma on the stone surface, resulting in a mechanical shock wave. Electrohydraulic lithotripsy uses a probe with two electrodes that deliver electric sparks in rapid pulses, creating expansion of the liquid environment surrounding the gallstones. This results in pressure waves that cause stones to fragment. This technique can be used percutaneously with a basket or balloon catheter system or by direct visualization through an endoscope. Repeated procedures may be necessary because of stone size, local anatomy, bleeding, or technical difficulty. A nasobiliary tube can be inserted to allow

for biliary decompression and to prevent stone impaction in the common bile duct. This approach allows time for improvement in the patient's clinical condition until gallstones are cleared endoscopically, percutaneously, or surgically.

Extracorporeal Shock Wave Lithotripsy

Extracorporeal shock wave therapy (lithotripsy or ESWL) has been used for nonsurgical fragmentation of gallstones. **Lithotripsy**, a noninvasive procedure, uses repeated shock waves directed at the gallstones in the gallbladder or common bile duct to fragment the stones. The waves are transmitted to the body through a fluid-filled bag or by immersing the patient in a water bath. After the stones are gradually broken up, the stone fragments can be spontaneously passed from the gallbladder or common bile duct, removed by endoscopy, or dissolved with oral bile acid or solvents. Because the procedure requires no incision and no hospitalization, patients are usually treated as outpatients, but usually several sessions are necessary. This procedure has largely been replaced by laparoscopic cholecystectomy. ESWL is used in some centers for a small percentage of suitable patients (those with common bile duct stones who may not be surgical candidates), sometimes in combination with dissolution therapy.

Surgical Management

Surgical treatment of gallbladder disease and gallstones is carried out to relieve persistent symptoms, to remove the cause of biliary colic, and to treat acute cholecystitis. Surgery may be delayed until the patient's symptoms have subsided, or it may be performed as an emergency procedure, if necessitated by the patient's condition.

Preoperative Measures

Chest x-ray, electrocardiogram (ECG), and liver function tests may be performed in addition to x-ray studies of the gallbladder. Vitamin K may be administered if the prothrombin level is low. Nutritional requirements are considered, and, if the nutritional status is suboptimal, it may be necessary to provide IV glucose with protein supplements to aid wound healing and help prevent liver damage.

Preparation for gallbladder surgery is similar to that for any upper abdominal laparotomy or laparoscopy. Instructions and explanations are given before surgery with regard to turning and deep breathing. Postoperative pneumonia and atelectasis can be avoided by deep-breathing exercises and frequent turning. The patient should be informed that drainage tubes and a nasogastric tube and suction might be required during the immediate postoperative period if an open cholecystectomy is performed.

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy (Fig. 40-5) has dramatically changed the approach to the management of cholecystitis. It has become the new standard for therapy of symptomatic gallstones. Approximately 700,000 patients in the United States require surgery each year for removal of the gallbladder, and 80% to 90% of them are candidates for laparoscopic cholecystectomy (Feldman, et al., 2006). If the common bile duct is thought to be obstructed by a gallstone, an ERCP with sphincterotomy may be performed to explore the duct before laparoscopy.

Before the procedure, the patient is informed that an open abdominal procedure may be necessary, and general

anesthesia is administered. Laparoscopic cholecystectomy is performed through a small incision or puncture made through the abdominal wall at the umbilicus. The abdominal cavity is insufflated with carbon dioxide (pneumoperitoneum) to assist in inserting the laparoscope and to aid in visualizing the abdominal structures. The fiberoptic scope is inserted through the small umbilical incision. Several additional punctures or small incisions are made in the abdominal wall to introduce other surgical instruments into the operative field. A camera attached to the laparoscope permits the surgeon to view the intra-abdominal field and biliary system on a television monitor. After the cystic duct is dissected, the common bile duct can be visualized by ultrasound or cholangiography to evaluate the anatomy and identify stones. The cystic artery is dissected free and clipped. The gallbladder is separated from the hepatic bed and removed from the abdominal cavity after bile and small stones are aspirated. Stone forceps also can be used to remove or crush larger stones.

With the laparoscopic procedure, the patient does not experience the paralytic ileus that occurs with open abdominal surgery and has less postoperative abdominal pain. The patient is often discharged from the hospital on the same day of surgery or within 1 or 2 days and resumes full activity and employment within 1 week after the surgery.

Conversion to a traditional abdominal surgical procedure may be necessary if problems are encountered during the laparoscopic procedure; this occurs in 2.2% of cases in the United States and 3.6% to 8.2% of cases internationally. Conversion to an open procedure occurs if there is inflammation in and around the gallbladder, making safe dissection of the porta hepatis difficult (Feldman, et al., 2006).

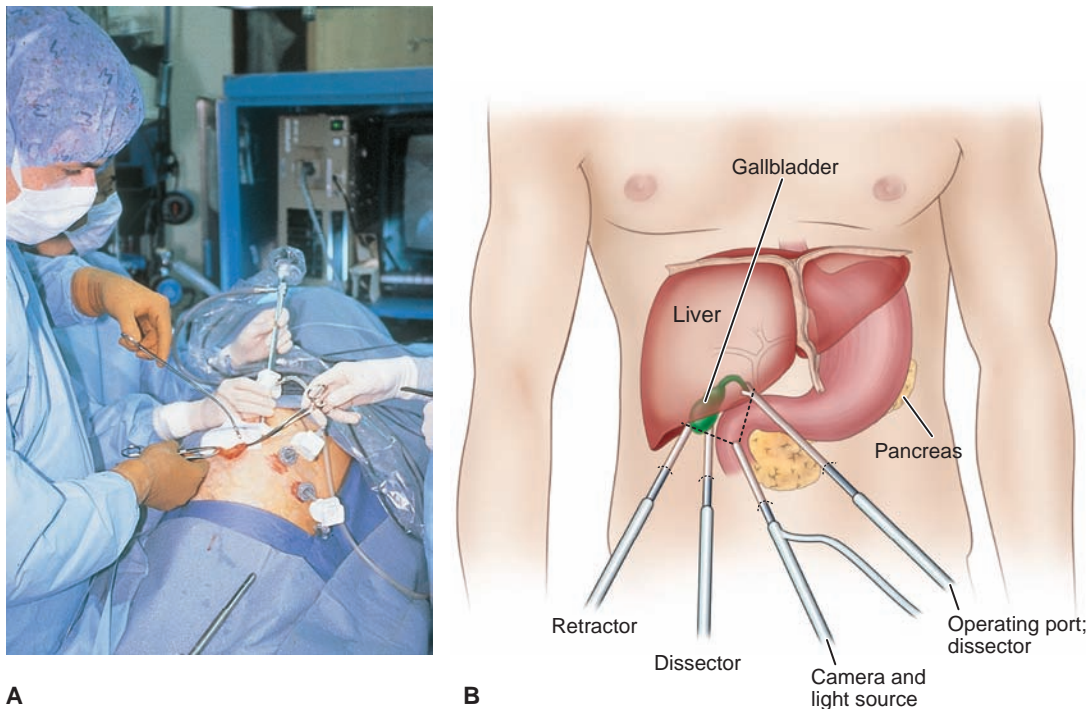

Figure 40-5 A, In laparoscopic cholecystectomy, the surgeon makes four small incisions (less than one half inch each) in the abdomen (B) and inserts a laparoscope with a miniature camera through the umbilical incision. The camera apparatus displays the gallbladder and adjacent tissues on a screen, allowing the surgeon to visualize the sections of the organ for removal.

(The porta hepatis is the fissure of the liver where the portal vein and the hepatic artery enter and the hepatic ducts exit the liver.) Careful screening of patients and identification of those at low risk for complications limit the frequency of conversion to an open abdominal procedure. However, with increasing use of laparoscopic procedures, the number of such conversions may increase.

The most serious complication after laparoscopic cholecystectomy is a bile duct injury, which may be identified and corrected at the time of the procedure. Patients with a postoperative bile leak may not develop symptoms until several days after the procedure, and some have an even more prolonged period before injury to the bile duct becomes apparent (Massoumi, Kiyici & Hertan, 2007). A bile leak may result in fluid collections, which can usually be managed by endoscopic stent placement. Bile peritonitis, a rare complication, may result in serious illness or death.

Because of the short hospital stay with uncomplicated laparoscopic cholecystectomies, it is important to provide written and verbal instructions about managing postoperative pain and reporting signs and symptoms of intra-abdominal complications, including loss of appetite, vomiting, pain, distention of the abdomen, and temperature elevation. Although recovery from laparoscopic cholecystectomy is rapid, patients are drowsy afterward. The patient must have assistance at home during the first 24 to 48 hours. If pain occurs in the right shoulder or scapular area (from migration of the carbon dioxide used to insufflate the abdominal cavity during the procedure), the nurse may recommend a heating pad for 15 to 20 minutes hourly.

Cholecystectomy

In cholecystectomy, the gallbladder is removed through an abdominal incision (usually right subcostal) after the cystic duct and artery are ligated. The procedure is performed for acute and chronic cholecystitis. In some patients, a drain is placed close to the gallbladder bed and brought out through a puncture wound if there is a bile leak. The drain type is chosen based on the physician's preference. A small leak should close spontaneously in a few days, with the drain preventing accumulation of bile. Usually only a small amount of serosanguineous fluid drains in the initial 24 hours after surgery; afterward, the drain is removed. The drain is typically maintained if there is excess oozing or bile leakage. Insertion of a T-tube into the common bile duct during the open procedure is now uncommon; it is used only in the setting of a complication (ie, retained common bile duct stone). Bile duct injury is a serious complication of cholecystectomy, but it occurs less frequently than with the laparoscopic approach, which has largely replaced traditional surgical cholecystectomy.

Mini-Cholecystectomy

Mini-cholecystectomy is a surgical procedure in which the gallbladder is removed through a small incision. If needed, the surgical incision is extended to remove larger gallbladder stones. Drains may or may not be used. The cost savings resulting from the short hospital stay have been identified as a major reason for pursuing this type of procedure. The procedure is controversial because it limits exposure to all the involved biliary structures.

Choledochostomy

Choledochostomy is reserved for the patient with acute cholecystitis who may be too ill to undergo a surgical procedure. It involves making an incision in the common duct, usually for removal of stones (choledochostomy). After the stones have been evacuated, a tube is usually inserted into the duct for drainage of bile until edema subsides. This tube is connected to gravity drainage tubing; the patient is monitored closely, and a laparoscopic cholecystectomy is planned for a future date after acute inflammation has resolved.

Surgical Cholecystostomy

Cholecystostomy is performed when the patient's condition precludes more extensive surgery or when an acute inflammatory reaction is severe. The gallbladder is surgically opened, stones and the bile or the purulent drainage are removed, and a drainage tube is secured with a purse-string suture. The drainage tube is connected to a drainage system to prevent bile from leaking around the tube or escaping into the peritoneal cavity. After recovery from the acute episode, the patient may return for subsequent laparoscopic cholecystectomy. Despite its lower risk, surgical cholecystostomy has a high mortality rate (reported to be as high as 20% to 30%) because of the underlying disease process.

Percutaneous Cholecystostomy

Percutaneous cholecystostomy has been used in the treatment and diagnosis of acute cholecystitis in patients who are poor risks for any surgical procedure or for general anesthesia. These may include patients with sepsis or severe cardiac, renal, pulmonary, or liver failure. Under local anesthesia, a fine needle is inserted through the abdominal wall and liver edge into the gallbladder under the guidance of ultrasound or computed tomography (CT). Bile is aspirated to ensure adequate placement of the needle, and a catheter is inserted into the gallbladder to decompress the biliary tract. Almost immediate relief of pain and resolution of signs and symptoms of sepsis and cholecystitis have been reported with this procedure. Antibiotic agents are administered before, during, and after the procedure.

Gerontologic Considerations

Surgical intervention for disease of the biliary tract is the most common operative procedure performed in the elderly. Cholesterol saturation of bile increases with age because of increased hepatic secretion of cholesterol and decreased bile acid synthesis.

Although the incidence of gallstones increases with age, the elderly patient may not exhibit the typical symptoms of fever, pain, chills, and jaundice. Symptoms of biliary tract disease in the elderly may be accompanied or preceded by those of septic shock, which include oliguria, hypotension, changes in mental status, tachycardia, and tachypnea.

Although surgery in the elderly presents a risk because of preexisting associated diseases, the mortality rate from serious complications of biliary tract disease itself is also high. The risk of death and complications is increased in the elderly patient who undergoes emergency surgery for life-threatening disease of the biliary tract. Despite chronic illness in many elderly patients, elective cholecystectomy is

usually well tolerated and can be carried out with low risk if expert assessment and care are provided before, during, and after the surgical procedure.

Because of recent changes in reimbursement for health care expenses, there has been a decrease in the number of elective surgical procedures performed, including cholecystectomies. As a result, patients requiring the procedure are seen in later stages of disease. At the same time, patients undergoing surgery are increasingly older than 60 years of age and may have complicated acute cholecystitis. The higher risk of complications and shorter hospital stay make it essential that older patients and their family members receive specific information about signs and symptoms of complications and measures to prevent them.

NURSING PROCESS

THE PATIENT UNDERGOING SURGERY FOR GALLBLADDER DISEASE

Assessment

The patient who is to undergo surgical treatment of gallbladder disease is often admitted to the hospital or same-day surgery unit on the morning of surgery. Preadmission testing is often completed a week or longer before admission. At that time, the nurse instructs the patient about the need to avoid smoking, to enhance pulmonary recovery postoperatively, and to avoid respiratory complications. It also is important to instruct the patient to avoid the use of aspirin and other agents (over-the-counter medications and herbal remedies) that can alter coagulation and other biochemical processes.

Assessment should focus on the patient's respiratory status. If a traditional surgical approach is planned, the high abdominal incision required during surgery may interfere with full respiratory excursion. The nurse notes a history of smoking, previous respiratory problems, shallow respirations, a persistent or ineffective cough, and the presence of adventitious breath sounds. Nutritional status is evaluated through a dietary history and a general examination performed at the time of preadmission testing. The nurse also reviews previously obtained laboratory results to obtain information about the patient's nutritional status.

Diagnosis

Nursing Diagnoses

Based on all the assessment data, the major postoperative nursing diagnoses for the patient undergoing surgery for gallbladder disease may include the following:

- Acute pain and discomfort related to surgical incision
- Impaired gas exchange related to the high abdominal surgical incision (if traditional surgical cholecystectomy was performed)
- Impaired skin integrity related to altered biliary drainage after surgical intervention (if a T-tube was inserted because of retained stones in the common bile duct or another drainage device was employed)
- Imbalanced nutrition, less than body requirements, related to inadequate bile secretion

- Deficient knowledge about self-care activities related to incision care, dietary modifications (if needed), medications, and reportable signs or symptoms (eg, fever, bleeding, vomiting)

Collaborative Problems/Potential Complications

Based on assessment data, potential complications may include the following:

- Bleeding
- GI symptoms (may be related to biliary leak or injury to the bowel)

Planning and Goals

The goals for the patient include relief of pain, adequate ventilation, intact skin and improved biliary drainage, optimal nutritional intake, absence of complications, and understanding of self-care routines.

Postoperative Nursing Interventions

After recovery from anesthesia, the patient is placed in the low Fowler's position. Fluids may be administered intravenously, and nasogastric suction (a nasogastric tube was probably inserted immediately before surgery for a nonlaparoscopic procedure) may be instituted to relieve abdominal distention. Water and other fluids are administered within hours after laparoscopic procedures. A soft diet is started after bowel sounds return, which is usually the next day if the laparoscopic approach is used.

Relieving Pain

The location of the subcostal incision in nonlaparoscopic gallbladder surgery often causes the patient to avoid turning and moving, to splint the affected site, and to take shallow breaths to prevent pain. Because full expansion of the lungs and gradually increased activity are necessary to prevent postoperative complications, the nurse administers analgesic agents as prescribed to relieve the pain and to promote well-being in addition to helping the patient turn, cough, breathe deeply, and ambulate as indicated. Use of a pillow or binder over the incision may reduce pain during these maneuvers.

Improving Respiratory Status

Patients undergoing biliary tract surgery are especially prone to pulmonary complications, as are all patients with upper abdominal incisions. Therefore, the nurse reminds the patient to take deep breaths and cough every hour to expand the lungs fully and prevent atelectasis. The early and consistent use of incentive spirometry also helps improve respiratory function. Early ambulation prevents pulmonary complications as well as other complications, such as thrombophlebitis. Pulmonary complications are more likely to occur in elderly patients, obese patients, and those with preexisting pulmonary disease.

Maintaining Skin Integrity and Promoting Biliary Drainage

In patients who have undergone a cholecystostomy or choledochostomy, the drainage tube must be connected immediately to a drainage receptacle. The nurse should fasten the tubing to the dressings or to the patient's gown, with enough leeway for the patient to move without dislodging

or kinking the tube. Because a drainage system remains attached when the patient is ambulating, the drainage bag may be placed in a bathrobe pocket or fastened so that it is below the waist or common duct level. If a Penrose drain is used, the nurse changes the dressings as required.

After these surgical procedures, the patient is observed for indications of infection, leakage of bile into the peritoneal cavity, and obstruction of bile drainage. If bile is not draining properly, an obstruction is probably causing bile to be forced back into the liver and bloodstream. Because jaundice may result, the nurse should assess the color of the sclerae. The nurse should note and report right upper quadrant abdominal pain, nausea and vomiting, bile drainage around any drainage tube, clay-colored stools, and a change in vital signs.

Bile may continue to drain from the drainage tract in considerable quantities for some time, necessitating frequent changes of the outer dressings and protection of the skin from irritation (bile is corrosive to the skin).

To prevent total loss of bile, the physician may want the drainage tube or collection receptacle elevated above the level of the abdomen so that the bile drains externally only if pressure develops in the duct system. Every 24 hours, the nurse measures the bile collected and records the amount, color, and character of the drainage. After several days of drainage, the tube may be clamped for 1 hour before and after each meal to deliver bile to the duodenum to aid in digestion. Within 7 to 14 days, the drainage tube is removed. The patient who goes home with a drainage tube in place requires instruction and reassurance about the function and care of the tube.

In all patients with biliary drainage, the nurse (or the patient, if at home) observes the color of stools daily. Urine and stool specimens may be sent to the laboratory for examination for bile pigments. In this way, it is possible to determine whether the bile pigment is disappearing from the blood and is draining again into the duodenum. Maintaining a careful record of fluid intake and output is important.

Improving Nutritional Status

The nurse encourages the patient to eat a diet that is low in fats and high in carbohydrates and proteins immediately after surgery. At the time of hospital discharge, there are usually no special dietary instructions other than to maintain a nutritious diet and avoid excessive fats. Fat restriction usually is lifted in 4 to 6 weeks, when the biliary ducts dilate to accommodate the volume of bile once held by the gallbladder and when the ampulla of Vater again functions effectively. After this time, when the patient eats fat, adequate bile will be released into the GI tract to emulsify the fats and allow their digestion. This is in contrast to the condition before surgery, when fats may not have been digested completely or adequately and flatulence may have occurred. One purpose of gallbladder surgery is to allow a normal diet.

Monitoring and Managing Potential Complications

Bleeding may occur as a result of inadvertent puncture or injury to a major blood vessel. Postoperatively, the nurse closely monitors vital signs and inspects the surgical incisions and any drains for bleeding. The nurse also assesses the patient for increased tenderness and rigidity of the abdomen. If these signs and symptoms occur, they are reported to the

surgeon. The nurse instructs the patient and family to report any change in the color of stools, because this may indicate complications. GI symptoms, although not common, may occur with manipulation of the intestines during surgery.

After laparoscopic cholecystectomy, the nurse assesses the patient for anorexia, vomiting, pain, abdominal distension, and temperature elevation. These may indicate infection or disruption of the GI tract and should be reported to the surgeon promptly. Because the patient is discharged soon after laparoscopic surgery, the patient and family are instructed verbally and in writing about the importance of reporting these symptoms promptly.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The nurse instructs the patient about the medications that are prescribed (vitamins, anticholinergics, and antispasmodics) and their actions. It also is important to inform the patient and family about symptoms that should be reported to the physician, including jaundice, dark urine, pale-colored stools, pruritus, and signs of inflammation and infection, such as pain or fever.

Some patients report one to three bowel movements a day, which is a result of a continual trickle of bile through the choledochoduodenal junction after cholecystectomy. Usually, such frequency diminishes over a period of a few weeks to several months.

If a patient is discharged from the hospital with a drainage tube still in place, the patient and family need instructions about its management. The nurse instructs them in proper care of the drainage tube and the importance of reporting promptly any changes in the amount or characteristics of drainage. Assistance in securing the appropriate dressings reduces the patient's anxiety about going home with the drain or tube still in place. See Chart 40-2 for additional details.

CONTINUING CARE. With sufficient support at home, most patients recover quickly from a cholecystectomy. However, elderly or frail patients and those who live alone may require a referral for home care. During home visits, the nurse assesses the patient's physical status, especially wound healing, and progress toward recovery. Assessing the patient for adequacy of pain relief and pulmonary exercises is also important. If the patient has a drainage system in place, the nurse assesses it for patency and appropriate management by the patient and family. Assessing for signs of infection and teaching the patient about the signs and symptoms of infection are also important nursing interventions. The patient's understanding of the therapeutic regimen (medications, gradual return to normal activities) is assessed, and previous teaching is reinforced. The nurse emphasizes the importance of keeping follow-up appointments and reminds the patient and family of the importance of participating in health promotion activities and recommended health screening.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Reports decrease in pain
 - a. Splints abdominal incision to decrease pain

CHART
40-2

PATIENT EDUCATION

Managing Self-Care After Laparoscopic Cholecystectomy

Resuming Activity

- Begin light exercise (walking) immediately.
- Take a shower or bath after 1 or 2 days.
- Drive a car after 3 or 4 days.
- Avoid lifting objects exceeding 5 pounds after surgery, usually for 1 week.
- Resume sexual activity when desired.

Caring for the Wound

- Check puncture site daily for signs of infection.
- Wash puncture site with mild soap and water.
- Allow special adhesive strips on the puncture site to fall off. Do not pull them off.

Resuming Eating

- Resume your normal diet.
- If you had fat intolerance before surgery, gradually add fat back into your diet in small increments.

Managing Pain

- You may experience pain or discomfort in your right shoulder from the gas used to inflate your abdominal area during surgery. Sitting upright in bed or a chair, walking, or use of a heating pad may ease the discomfort.
- Take analgesics as needed and as prescribed. Report to surgeon if pain is unrelieved even with analgesic use.

Managing Follow-Up Care

- Make an appointment with your surgeon for 7 to 10 days after discharge.
- Call your surgeon if you experience any signs or symptoms of infection at or around the puncture site: redness, tenderness, swelling, heat, or drainage.
- Call your surgeon if you experience a fever of 37.7°C (100°F) or more for 2 consecutive days.
- Call your surgeon if you develop nausea, vomiting, or abdominal pain.

- b. Avoids foods that cause pain
 - c. Uses postoperative analgesia as prescribed
2. Demonstrates appropriate respiratory function
 - a. Achieves full respiratory excursion, with deep inspiration and expiration
 - b. Coughs effectively, using pillow to splint abdominal incision
 - c. Uses postoperative analgesia as prescribed
 - d. Exercises as prescribed (eg, turns, ambulates)
3. Exhibits normal skin integrity around biliary drainage site (if applicable)
 - a. Is free of fever, abdominal pain, change in vital signs, and presence of bile, foul-smelling drainage, or pus around drainage tube
 - b. Demonstrates correct management of drainage tube (if applicable)
 - c. Identifies signs and symptoms of biliary obstruction to be noted and reported
 - d. Has serum bilirubin level within normal range
4. Obtains relief from dietary intolerance
 - a. Maintains adequate dietary intake and avoids foods that cause gastrointestinal symptoms
 - b. Reports decreased or absent nausea, vomiting, diarrhea, flatulence, and abdominal discomfort
5. Absence of complications
 - a. Has normal vital signs (blood pressure, pulse, respiratory rate and pattern, and temperature)
 - b. Reports absence of bleeding from GI tract and from biliary drainage tube or catheter (if present) and no evidence of bleeding in stool
 - c. Reports return of appetite and no evidence of vomiting, abdominal distention, or pain
 - d. Lists symptoms that should be reported to surgeon promptly and demonstrates an understanding of self-care, including wound care

DISORDERS OF THE PANCREAS

Pancreatitis (inflammation of the pancreas) is a serious disorder. The most basic classification system used to describe or categorize the various stages and forms of pancreatitis divides the disorder into acute and chronic forms. Acute pancreatitis can be a medical emergency associated with a high risk of life-threatening complications and mortality, whereas chronic pancreatitis often goes undetected until 80% to 90% of the exocrine and endocrine tissue is destroyed. Acute pancreatitis does not usually lead to chronic pancreatitis unless complications develop. However, chronic pancreatitis can be characterized by acute episodes.

Although the mechanisms causing pancreatic inflammation are unknown, pancreatitis is commonly described as autodigestion of the pancreas. It is believed that the pancreatic duct becomes temporarily obstructed, accompanied by hypersecretion of the exocrine enzymes of the pancreas. These enzymes enter the bile duct, where they are activated and, together with bile, back up (reflux) into the pancreatic duct, causing pancreatitis.

Acute Pancreatitis

Acute pancreatitis ranges from a mild, self-limited disorder to a severe, rapidly fatal disease that does not respond to any treatment. Approximately 185,000 cases of acute pancreatitis occur in the United States each year, of which 150,000 are the result of cholelithiasis or sustained alcohol abuse (Zinner & Ashley, 2007). Mild acute pancreatitis is characterized by edema and inflammation confined to the pancreas. Minimal organ dysfunction is present, and return to normal function usually occurs within 6 months. Although this is considered the milder form of pancreatitis, the

patient is acutely ill and at risk for hypovolemic shock, fluid and electrolyte disturbances, and sepsis. A more widespread and complete enzymatic digestion of the gland characterizes severe acute pancreatitis. Enzymes damage the local blood vessels, and bleeding and thrombosis can occur. The tissue may become necrotic, with damage extending into the retroperitoneal tissues. Local complications include pancreatic cysts or abscesses and acute fluid collections in or near the pancreas. Patients who develop systemic complications with organ failure, such as pulmonary insufficiency with hypoxia, shock, renal failure, and GI bleeding, are also characterized as having severe acute pancreatitis.

Gerontologic Considerations

Acute pancreatitis affects people of all ages, but the mortality rate associated with acute pancreatitis increases with advancing age. In addition, the pattern of complications changes with age. Younger patients tend to develop local complications; the incidence of multiple organ failure increases with age, possibly as a result of progressive decreases in physiologic function of major organs with increasing age. Close monitoring of major organ function (ie, lungs, kidneys) is essential, and aggressive treatment is necessary to reduce mortality from acute pancreatitis in the elderly.

Pathophysiology

Self-digestion of the pancreas by its own proteolytic enzymes, principally trypsin, causes acute pancreatitis. Eighty percent of patients with acute pancreatitis have biliary tract disease or a history of long-term alcohol abuse. These patients usually have had undiagnosed chronic pancreatitis before their first episode of acute pancreatitis. Gallstones enter the common bile duct and lodge at the ampulla of Vater, obstructing the flow of pancreatic juice or causing a reflux of bile from the common bile duct into the pancreatic duct, thus activating the powerful enzymes within the pancreas. Normally, these remain in an inactive form until the pancreatic secretions reach the lumen of the duodenum. Activation of the enzymes can lead to vasodilation, increased vascular permeability, necrosis, erosion, and hemorrhage (Zinner & Ashley, 2007).

Other less common causes of pancreatitis include bacterial or viral infection, with pancreatitis occasionally developing as a complication of mumps virus. Spasm and edema of the ampulla of Vater, caused by duodenitis, can probably produce pancreatitis. Blunt abdominal trauma, peptic ulcer disease, ischemic vascular disease, hyperlipidemia, hypercalcemia, and the use of corticosteroids, thiazide diuretics, oral contraceptives, and other medications have also been associated with an increased incidence of pancreatitis. Acute pancreatitis may develop after surgery on or near the pancreas or after instrumentation of the pancreatic duct. Acute idiopathic pancreatitis accounts for up to 10% of the cases of acute pancreatitis. Some experts postulate that these cases may be related to occult microlithiasis (small stones in the bile) (Zinner & Ashley, 2007). In addition, there is a small incidence of hereditary pancreatitis.

The overall mortality rate of patients with acute pancreatitis is high (2% to 10%) because of shock, anoxia, hypotension, or fluid and electrolyte imbalances. This mortal-

Chart 40-3 • Criteria for Predicting Severity of Pancreatitis*

Criteria on Admission to Hospital

Age >55 years
WBC >16,000 mm³
Serum glucose >200 mg/dL (>11.1 mmol/L)
Serum LDH >350 IU/L (>350 U/L)
AST >250 U/mL (120 U/L)

Criteria Within 48 Hours of Hospital Admission

Fall in hematocrit >10% (>0.10)
BUN increase >5 mg/dL (>1.7 mmol/L)
Serum calcium <8 mg/dL (<2.0 mmol/L)
Base deficit >4 mEq/L (>4 mmol/L)
Fluid retention or sequestration >6 L
PO₂ <60 mm Hg

Two or fewer signs, 1% mortality; 3 or 4 signs, 15% mortality; 5 or 6 signs, 40% mortality; >6 signs, 100% mortality.

*Note: The more risk factors a patient has, the greater the severity and likelihood of complications or death.

ity rate may also be related to the 10% to 30% of patients with severe acute disease characterized by pancreatic and peripancreatic necrosis (Zinner & Ashley, 2007). Attacks of acute pancreatitis may result in complete recovery, may recur without permanent damage, or may progress to chronic pancreatitis. The patient who is admitted to the hospital with a diagnosis of pancreatitis is acutely ill and needs expert nursing and medical care.

The severity of acute alcoholic pancreatitis and its outcomes can be predicted based on clinical and laboratory data (Chart 40-3).

Clinical Manifestations

Severe abdominal pain is the major symptom of pancreatitis that causes the patient to seek medical care. Abdominal pain and tenderness and back pain result from irritation and edema of the inflamed pancreas. Increased tension on the pancreatic capsule and obstruction of the pancreatic ducts also contribute to the pain. Typically, the pain occurs in the midepigastrium. Pain is frequently acute in onset, occurring 24 to 48 hours after a very heavy meal or alcohol ingestion, and it may be diffuse and difficult to localize. It is generally more severe after meals and is unrelieved by antacids. Pain may be accompanied by abdominal distention; a poorly defined, palpable abdominal mass; decreased peristalsis; and vomiting that fails to relieve the pain or nausea.

The patient appears acutely ill. Abdominal guarding is present. A rigid or boardlike abdomen may develop and is generally an ominous sign, usually indicating peritonitis. Ecchymosis (bruising) in the flank or around the umbilicus may indicate severe pancreatitis. Nausea and vomiting are common in acute pancreatitis. The emesis is usually gastric in origin but may also be bile stained. Fever, jaundice, mental confusion, and agitation may also occur.

Hypotension is typical and reflects hypovolemia and shock caused by the loss of large amounts of protein-rich fluid into the tissues and peritoneal cavity. In addition to

hypotension, the patient may develop tachycardia, cyanosis, and cold, clammy skin. Acute renal failure is common.

Respiratory distress and hypoxia are common, and the patient may develop diffuse pulmonary infiltrates, dyspnea, tachypnea, and abnormal blood gas values. Myocardial depression, hypocalcemia, hyperglycemia, and disseminated intravascular coagulation may also occur with acute pancreatitis.

Assessment and Diagnostic Findings

The diagnosis of acute pancreatitis is based on a history of abdominal pain, the presence of known risk factors, physical examination findings, and diagnostic findings. Serum amylase and lipase levels are used in making the diagnosis of acute pancreatitis, although their elevation can be attributed to many other causes (Feldman, et al., 2006). In most cases, serum amylase and lipase levels are elevated within 24 hours of the onset of the symptoms. Serum amylase usually returns to normal within 48 to 72 hours, but serum lipase levels may remain elevated for a longer period, often days longer than amylase. Urinary amylase levels also become elevated and remain elevated longer than serum amylase levels. The white blood cell count is usually elevated; hypocalcemia is present in many patients and correlates well with the severity of pancreatitis. Transient hyperglycemia and glucosuria and elevated serum bilirubin levels occur in some patients with acute pancreatitis.

X-ray studies of the abdomen and chest may be obtained to differentiate pancreatitis from other disorders that can cause similar symptoms and to detect pleural effusions. Ultrasound and contrast-enhanced CT scans are used to identify an increase in the diameter of the pancreas and to detect pancreatic cysts, abscesses, or pseudocysts.

Hematocrit and hemoglobin levels are used to monitor the patient for bleeding. Peritoneal fluid, obtained through paracentesis or peritoneal lavage, may contain increased levels of pancreatic enzymes. ERCP is rarely used in the diagnostic evaluation of acute pancreatitis, because the patient is acutely ill; however, it may be valuable in the treatment of gallstone pancreatitis.

Medical Management

Management of acute pancreatitis is directed toward relieving symptoms and preventing or treating complications. All oral intake is withheld to inhibit stimulation of the pancreas and its secretion of enzymes. Parenteral nutrition plays an important role in the nutritional support of patients with severe acute pancreatitis, particularly in those who are debilitated and those with a prolonged paralytic ileus (more than 48 to 72 hours) (Zinner & Ashley, 2007). Ongoing research has shown positive outcomes with the use of enteral feedings. The current recommendation is that, whenever possible, the enteral route should be used to meet nutritional needs in patients with pancreatitis. This strategy also has been found to prevent infectious complications, safely and cost effectively (DiMugno & DiMugno, 2007; Zinner & Ashley, 2007). Enteral feedings should be started early in the course of acute pancreatitis. Patients who do not tolerate enteral feeding require parenteral nutrition. Nasogastric suction may be used to relieve nausea and vomiting and to decrease painful abdominal distention and paralytic ileus. Research data do not

support the routine use of nasogastric tubes to remove gastric secretions in an effort to limit pancreatic secretion. Histamine-2 (H_2) antagonists such as cimetidine (Tagamet) and ranitidine (Zantac) may be prescribed to decrease pancreatic activity by inhibiting secretion of gastric acid. Proton pump inhibitors such as pantoprazole (Protonix) may be used for patients who do not tolerate H_2 antagonists or for whom this therapy is ineffective.

Pain Management

Adequate administration of analgesia is essential during the course of acute pancreatitis to provide sufficient pain relief and to minimize restlessness, which may stimulate pancreatic secretion further. Pain relief may require parenteral opioids such as morphine, fentanyl (Sublimaze), or hydromorphone (Dilaudid) (Hauser, Pardi & Poterucha, 2006). The use of morphine was avoided in the past because of concern that it could cause painful spasms of the sphincter of Oddi and worsen pancreatitis; however, all opioids stimulate this sphincter to some degree. There is no clinical evidence to support the use of meperidine for pain relief in pancreatitis, and, in fact, accumulation of its metabolites can cause CNS irritability and possibly seizures. The current recommendation for pain management is the use of opioids, with assessment for their effectiveness and altering therapy if pain is not controlled or increased (Wolfe, Davis, Farraye, et al., 2006). More research is needed to identify the best option for pain management in the patient with acute pancreatitis (Hauser, et al., 2006). Antiemetic agents may be prescribed to prevent vomiting.

Intensive Care

Correction of fluid and blood loss and low albumin levels is necessary to maintain fluid volume and prevent renal failure. The patient is usually acutely ill and is monitored in the intensive care unit, where hemodynamic monitoring and arterial blood gas monitoring are initiated. Antibiotic agents may be prescribed if infection is present. The role of prophylactic antibiotics is controversial and still under study. Insulin may be required if hyperglycemia occurs. Intensive insulin therapy (continuous infusion) in the critically ill patient has undergone much study and has shown promise in terms of positive patient outcomes when compared with intermittent insulin dosing. Glycemic control with normal or near normal blood glucose levels improves patient outcomes.

Respiratory Care

Aggressive respiratory care is indicated because of the high risk of elevation of the diaphragm, pulmonary infiltrates and effusion, and atelectasis. Hypoxemia occurs in a significant number of patients with acute pancreatitis, even with normal x-ray findings. Respiratory care may range from close monitoring of arterial blood gases to use of humidified oxygen to intubation and mechanical ventilation (see Chapter 25 for further discussion).

Biliary Drainage

Placement of biliary drains (for external drainage) and stents (indwelling tubes) in the pancreatic duct through endoscopy has been performed to reestablish drainage of the

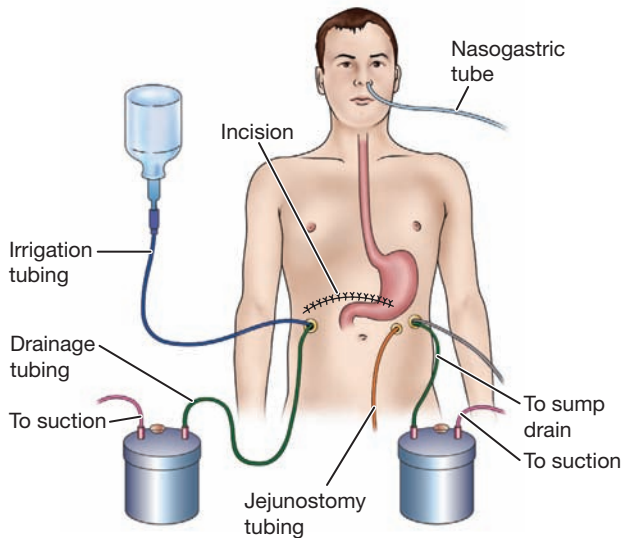

Figure 40-6 Multiple sump tubes are used after pancreatic surgery. Triple-lumen tubes consist of ports that provide tubing for irrigation, air venting, and drainage.

pancreas. This has resulted in decreased pain and increased weight gain.

Surgical Intervention

Although surgery is often risky because the acutely ill patient is a poor surgical risk, it may be performed to assist in the diagnosis of pancreatitis (diagnostic laparotomy), to establish pancreatic drainage, or to resect or débride a necrotic pancreas. The patient who undergoes pancreatic surgery may have multiple drains in place postoperatively, as well as a surgical incision that is left open for irrigation and repacking every 2 to 3 days to remove necrotic debris (Fig. 40-6).

Postacute Management

Antacids may be used after acute pancreatitis begins to resolve. Oral feedings that are low in fat and protein are initiated gradually. Caffeine and alcohol are eliminated from the diet. If the episode of pancreatitis occurred during treatment with thiazide diuretics, corticosteroids, or oral contraceptives, these medications are discontinued. Follow-up may include ultrasound, x-ray studies, or ERCP to determine whether the pancreatitis is resolving and to assess for abscesses and pseudocysts. ERCP may also be used to identify the cause of acute pancreatitis if it is in question and for endoscopic sphincterotomy and removal of gallstones from the common bile duct.

Nursing Management

Relieving Pain and Discomfort

Because the pathologic process responsible for pain is autodigestion of the pancreas, the objectives of therapy are to relieve pain and decrease secretion of pancreatic enzymes. The pain of acute pancreatitis is often very severe, necessitating the liberal use of analgesics. The current recommendation for pain management in this population is parenteral opioids, including morphine, hydromorphone, or fentanyl

via patient-controlled analgesia or bolus (Hauser, et al., 2006; Wolfe, et al., 2006). In critically ill patients, a continuous infusion may be needed. Because most opioids stimulate spasm of the sphincter of Oddi to some degree, consensus has not been reached on the most effective agent. Ensuring patient comfort, regardless of the opioid prescribed, is the most essential aspect of care. The nurse frequently assesses the pain and the effectiveness of the pharmacologic (and nonpharmacologic) interventions. Changes may be needed in the regimen for pain management based on the achievement of pain control. Pain assessment tools (see Chapter 13) are available for the nurse to ensure an accurate rating of pain. Nonpharmacologic interventions such as proper positioning, music, distraction, and imagery may be effective in reducing pain when used along with medications.

In addition, oral feedings are withheld to decrease the secretion of secretin. Parenteral fluids and electrolytes are prescribed to restore and maintain fluid balance. Nasogastric suction may be used to relieve nausea and vomiting or to treat abdominal distention and paralytic ileus. The nurse provides frequent oral hygiene and care to decrease discomfort from the nasogastric tube and relieve dryness of the mouth.

The acutely ill patient is maintained on bed rest to decrease the metabolic rate and reduce the secretion of pancreatic and gastric enzymes. If the patient experiences increasing severity of pain, the nurse reports this to the physician because the patient may be experiencing hemorrhage of the pancreas or the dose of analgesic may be inadequate.

The patient with acute pancreatitis often has a clouded sensorium because of severe pain, fluid and electrolyte disturbances, and hypoxia. Therefore, the nurse provides frequent and repeated but simple explanations about the need for withholding fluids, maintenance of gastric suction, and bed rest.

Improving Breathing Pattern

The nurse maintains the patient in a semi-Fowler's position to decrease pressure on the diaphragm by a distended abdomen and to increase respiratory expansion. Frequent changes of position are necessary to prevent atelectasis and pooling of respiratory secretions. Pulmonary assessment, including monitoring of pulse oximetry or arterial blood gases, is essential to detect changes in respiratory status so that early treatment can be initiated. The nurse instructs the patient in techniques of coughing and deep breathing and in the use of incentive spirometry to improve respiratory function and assists the patient to perform these activities every hour.

Improving Nutritional Status

Oral food or fluid intake is not permitted. However, it is important to assess the patient's nutritional status and to note factors that alter the patient's nutritional requirements (eg, temperature elevation, surgery, drainage). Laboratory test results and daily weights are useful to monitor the nutritional status.

Enteral or parenteral nutrition may be prescribed. In addition to administering enteral or parenteral nutrition, the nurse monitors serum glucose levels every 4 to 6 hours. As the acute symptoms subside, oral feedings are gradually reintroduced.

Between acute attacks, the patient receives a diet that is high in carbohydrates and low in fats and proteins. The patient should avoid heavy meals and alcoholic beverages.

Maintaining Skin Integrity

The patient is at risk for skin breakdown because of poor nutritional status, enforced bed rest, and restlessness, which may result in pressure ulcers and breaks in tissue integrity. In addition, the patient who has undergone surgery may have multiple drains or an open surgical incision and is at risk for skin breakdown and infection. The nurse carefully assesses the wound, drainage sites, and skin for signs of infection, inflammation, and breakdown. The nurse carries out wound care as prescribed and takes precautions to protect intact skin from contact with drainage. Consultation with a **wound-ostomy-contenance (WOC) nurse** (formerly referred to as a wound care specialist or enterostomal therapist) is often helpful in identifying appropriate skin care devices and protocols. It is important to turn the patient every 2 hours; use of specialty beds may be indicated to prevent skin breakdown.

Monitoring and Managing Potential Complications

Fluid and electrolyte disturbances are common complications because of nausea, vomiting, movement of fluid from the vascular compartment to the peritoneal cavity, diaphoresis, fever, and the use of gastric suction. The nurse assesses the patient's fluid and electrolyte status by noting skin turgor and moistness of mucous membranes. The nurse weighs the patient daily and carefully measures fluid intake and output, including urine output, nasogastric secretions, and diarrhea. In addition, it is important to assess for other factors that may affect fluid and electrolyte status, including increased body temperature and wound drainage. The nurse assesses the patient for ascites and measures abdominal girth daily if ascites is suspected.

Fluids are administered intravenously and may be accompanied by infusion of blood or blood products to maintain the blood volume and to prevent or treat hypovolemic shock. It is important to keep emergency medications readily available because of the risk of circulatory collapse and shock. The nurse promptly reports decreased blood pressure and reduced urine output, which indicate hypovolemia and shock or renal failure. Low serum calcium and magnesium levels may occur and require prompt treatment.

Pancreatic necrosis is a major cause of morbidity and mortality in patients with acute pancreatitis because of resulting hemorrhage, septic shock, and multiple organ failure. The patient may undergo diagnostic procedures for confirmation of pancreatic necrosis, for surgical débridement, or for insertion of multiple drains. The patient with pancreatic necrosis is usually critically ill and requires expert medical and nursing management, including hemodynamic monitoring in the intensive care unit.

In addition to carefully monitoring vital signs and other signs and symptoms, the nurse is responsible for administering prescribed fluids, medications, and blood products; assisting with supportive management, such as use of a ventilator; preventing additional complications; and providing physical and psychological care.

Shock and multiple organ failure may occur with acute pancreatitis. Hypovolemic shock may occur as a result of hypovolemia and sequestering of fluid in the peritoneal cavity. Hemorrhagic shock may occur with hemorrhagic pancreatitis. Septic shock may occur with bacterial infection of the pancreas. Cardiac dysfunction may occur as a result of fluid and electrolyte disturbances, acid–base imbalances, and release of toxic substances into the circulation.

The nurse closely monitors the patient for early signs of neurologic, cardiovascular, renal, and respiratory dysfunction. The nurse must be prepared to respond quickly to rapid changes in the patient's status, treatments, and therapies. In addition, it is important to inform the family about the status and progress of the patient and to allow them to spend time with the patient. (Management of shock is discussed in detail in Chapter 15.)

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient who has survived an episode of acute pancreatitis has been acutely ill. A prolonged period is needed to regain strength and return to the previous level of activity. The patient is often still weak and debilitated for weeks or months after an acute episode of pancreatitis. Because of the severity of the acute illness, the patient may not recall many of the explanations and instructions given during the acute phase. Teaching often needs to be repeated and reinforced. The nurse instructs the patient about the factors implicated in the onset of acute pancreatitis and about the need to avoid high-fat foods, heavy meals, and alcohol. It is important to give the patient and family verbal and written instructions about signs and symptoms of acute pancreatitis and possible complications that should be reported promptly to the physician.

If acute pancreatitis is a result of biliary tract disease, such as gallstones and gallbladder disease, additional explanations are needed about required dietary modifications. If the pancreatitis is a result of alcohol abuse, the nurse reinforces the need to avoid all alcohol.

Continuing Care

A referral for home care is often indicated. This enables the nurse to assess the patient's physical and psychological status and adherence to the therapeutic regimen. The nurse also assesses the home situation and reinforces instructions about fluid and nutrition intake and avoidance of alcohol. After the acute attack has subsided, some patients may be inclined to return to their previous drinking habits. The nurse provides specific information about resources and support groups that may be of assistance in avoiding alcohol in the future. Referral to Alcoholics Anonymous or other appropriate support groups is essential. See the accompanying plan of nursing care in Chart 40-4 for the patient with acute pancreatitis.

Chronic Pancreatitis

Chronic pancreatitis is an inflammatory disorder characterized by progressive destruction of the pancreas. As cells are replaced by fibrous tissue with repeated attacks of pancreatitis,

CHART
40-4

PLAN OF NURSING CARE

Care of the Patient With Acute Pancreatitis

NURSING DIAGNOSIS: Acute pain and discomfort related to edema, distention of the pancreas, and peritoneal irritation

GOAL: Relief of pain and discomfort

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> Administer morphine, fentanyl, or hydromorphone frequently, as prescribed, to achieve level of pain acceptable to patient based on patient's level of pain and discomfort. Using a pain scale, assess pain level before and after administration of analgesic. Report unrelieved pain or increasing intensity of pain. Assist the patient to assume positions of comfort; turn and reposition every 2 hours. Use nonpharmacologic interventions for relieving pain (eg, relaxation, focused breathing, diversion). Listen to patient's expression of pain experience. 	<ol style="list-style-type: none"> Morphine, fentanyl, and hydromorphone act by depressing the central nervous system and thereby increasing the patient's pain threshold. Meperidine (Demerol) is avoided because it has failed acute pain studies and it possesses toxic metabolites. Assessment and control of pain are important because restlessness increases body metabolism, which stimulates the secretion of pancreatic and gastric enzymes. Pain may increase pancreatic enzymes and may also indicate pancreatic hemorrhage. Frequent turning relieves pressure and assists in preventing pulmonary and vascular complications. Use of nonpharmacologic methods will enhance the effects of analgesics. Gate control theory suggests that cutaneous stimulation closes the pain pathways. Demonstration of caring can help to decrease anxiety. 	<ul style="list-style-type: none"> Reports relief of pain. Moves and turns without increasing pain and discomfort. Rests comfortably and sleeps for increasing periods. Reports less frequent episodes of pain, discomfort, and cramping. Experiences enhanced pain relief. Reports increased feelings of well-being and security with the health care team.

NURSING DIAGNOSIS: Acute pain and discomfort related to excess stimulation of pancreatic secretions

GOAL: Relief of pain related to stimulation of the pancreas

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> Administer anticholinergic medications as prescribed. Withhold oral intake. Maintain the patient on bed rest. Maintain continuous nasogastric drainage if paralytic ileus or nausea and vomiting, abdominal distention are present. <ol style="list-style-type: none"> Measure gastric secretions at specified intervals. Observe and record color and viscosity of gastric secretions. Ensure that the nasogastric tube is patent to permit free drainage. 	<ol style="list-style-type: none"> Anticholinergic medications reduce gastric and pancreatic secretion. Pancreatic secretion is increased by food and fluid intake. Bed rest decreases body metabolism and thus reduces pancreatic and gastric secretions. Nasogastric suction relieves nausea, vomiting, and abdominal distention. Decompression of the intestines (if intestinal intubation is used) also assists in relieving respiratory distress. 	<ul style="list-style-type: none"> Reports relief of pain, discomfort, and abdominal cramping. Consumes no fluid and food during acute phase. Maintains bed rest. Identifies rationale for fluid and dietary restrictions and use of nasogastric drainage. Cooperates with insertion of nasogastric tube and suction.

NURSING DIAGNOSIS: Discomfort related to nasogastric tube

GOAL: Relief of discomfort associated with nasogastric intubation used to treat ileus, vomiting, distention

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> Use water-soluble lubricant around external nares. Turn patient at intervals; avoid pressure or tension on nasogastric tube. 	<ol style="list-style-type: none"> Prevents irritation of nares. Relieves pressure of tube on esophageal and gastric mucosa. 	<ul style="list-style-type: none"> Exhibits intact skin and tissue of nares at site of nasogastric tube insertion. Reports no pain or irritation of nares or oropharynx.

Continued

CHART
40-4

PLAN OF NURSING CARE
Care of the Patient With Acute Pancreatitis (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 3. Provide oral hygiene and gargling solutions without alcohol. 4. Explain rationale for use of nasogastric drainage 	<ol style="list-style-type: none"> 3. Relieves dryness and irritation of oropharynx. 4. Assists patient to cooperate with the drainage, nasogastric tube, and suction. 	<ul style="list-style-type: none"> • Exhibits moist, clean mucous membranes of mouth and nasopharynx. • States that thirst is relieved by oral hygiene. • Identifies rationale for nasogastric tube and suction.

NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements related to inadequate dietary intake, impaired pancreatic secretions, increased nutritional needs secondary to acute illness, and increased body temperature
GOAL: Improvement in nutritional status

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess current nutritional status and increased metabolic requirements. 2. Monitor serum glucose levels and administer insulin as prescribed. 3. Administer intravenous fluid and electrolytes, enteral or parenteral nutrition as prescribed. 4. Provide high-carbohydrate, low-protein, low-fat diet when tolerated. 5. Instruct patient to eliminate alcohol and refer to Alcoholics Anonymous if indicated. 6. Counsel patient to avoid excessive use of coffee and spicy foods. 7. Monitor daily weights. 	<ol style="list-style-type: none"> 1. Alteration in pancreatic secretions interferes with normal digestive processes. Acute illness, infection, and fever increase metabolic needs. 2. Impairment of endocrine function of the pancreas leads to increased serum glucose levels. 3. Parenteral administration of fluids and electrolytes, and enteral or parenteral nutrients are essential to provide fluids, calories, electrolytes, and nutrients when oral intake is prohibited. 4. These foods increase caloric intake without stimulating pancreatic secretions beyond the ability of the pancreas to respond. 5. Alcohol intake produces further damage to pancreas and precipitates attacks of acute pancreatitis. 6. Coffee and spicy foods increase pancreatic and gastric secretions. 7. This provides a baseline and a means to measure weight gain or weight loss. 	<ul style="list-style-type: none"> • Maintains normal body weight. • Demonstrates no additional weight loss. • Maintains normal serum glucose levels. • Reports decreasing episodes of vomiting and diarrhea. • Reports return of normal stool characteristics and bowel pattern. • Consumes foods high in carbohydrates, low in fat and protein. • Explains rationale for high-carbohydrate, low-fat, low-protein diet. • Eliminates alcohol from diet. • Explains rationale for limiting coffee intake and avoiding spicy foods. • Participates in Alcoholics Anonymous or other counseling approach. • Returns to and maintains desirable weight.

NURSING DIAGNOSIS: Ineffective breathing pattern related to splinting from severe pain, pulmonary infiltrates, pleural effusion, and atelectasis
GOAL: Improvement in respiratory function

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess respiratory status (rate, pattern, breath sounds), pulse oximetry, and arterial blood gases. 2. Maintain semi-Fowler's position. 3. Instruct and encourage patient to take deep breaths and to cough every hour. 4. Assist patient to turn and change position every 2 hours. 	<ol style="list-style-type: none"> 1. Acute pancreatitis produces retroperitoneal edema, elevation of the diaphragm, pleural effusion, and inadequate lung ventilation. Intra-abdominal infection and labored breathing increase the body's metabolic demands, which further decreases pulmonary reserve and leads to respiratory failure. 2. Decreases pressure on diaphragm and allows greater lung expansion. 3. Taking deep breaths and coughing will clear the airways and reduce atelectasis. 4. Changing position frequently assists aeration and drainage of all lobes of the lungs. 	<ul style="list-style-type: none"> • Demonstrates normal respiratory rate and pattern and full lung expansion. • Demonstrates normal breath sounds and absence of adventitious breath sounds. • Demonstrates normal arterial blood gases and pulse oximetry. • Maintains semi-Fowler's position when in bed. • Changes position in bed frequently. • Coughs and takes deep breaths at least every hour. • Demonstrates normal body temperature. • Exhibits no signs or symptoms of respiratory infection or impairment. • Is alert and responsive to environment.

Continued on following page

 CHART
40-4

PLAN OF NURSING CARE
Care of the Patient With Acute Pancreatitis (Continued)

Nursing Interventions	Rationale	Expected Outcomes
5. Reduce the excessive metabolism of the body. <ol style="list-style-type: none"> Administer antibiotics as prescribed. Place patient in an air-conditioned room. Administer nasal oxygen as required for hypoxia. Use a hypothermia blanket if necessary. 	5. Pancreatitis produces a severe peritoneal and retroperitoneal reaction that causes fever, tachycardia, and accelerated respirations. Placing the patient in an air-conditioned room and supporting the patient with oxygen therapy decrease the workload of the respiratory system and the tissue utilization of oxygen. Reduction of fever and pulse rate decreases the metabolic demands on the body.	
COLLABORATIVE PROBLEM: Fluid and electrolyte disturbances, hypovolemia, shock GOAL: Improvement in fluid and electrolyte status, prevention of hypovolemia and shock		
Nursing Interventions	Rationale	Expected Outcomes
1. Assess fluid and electrolyte status (skin turgor, mucous membranes, urine output, vital signs, hemodynamic parameters). 2. Assess sources of fluid and electrolyte loss (vomiting, diarrhea, nasogastric drainage, excessive diaphoresis). 3. Combat shock if present. <ol style="list-style-type: none"> Administer corticosteroids as prescribed if patient does not respond to conventional treatment. Evaluate the amount of urinary output. Attempt to maintain this at 50 mL/h. 4. Administer blood products, fluids, and electrolytes (sodium, potassium, chloride) as prescribed. 5. Administer plasma and blood products as prescribed. 6. Keep a supply of intravenous calcium gluconate readily available. 7. Assess abdomen for ascites formation: <ol style="list-style-type: none"> Measure abdominal girth daily. Weigh patient daily. Palpate abdomen for fluid wave. 8. Monitor for manifestations of multiple organ failure: neurologic, cardiovascular, renal, and respiratory dysfunction.	1. The amount and type of fluid and electrolyte replacement are determined by the status of the blood pressure, the laboratory evaluations of serum electrolyte and blood urea nitrogen levels, the urinary volume, and the assessment of the patient's condition. 2. Electrolyte losses occur from nasogastric suctioning, severe diaphoresis, emesis, and as a result of the patient's being in a fasting state. 3. Extensive acute pancreatitis may cause peripheral vascular collapse and shock. Blood and plasma may be lost into the abdominal cavity, and, therefore, there is a decreased blood and plasma volume. The toxins from the bacteria of a necrotic pancreas may cause shock. 4. Patients with hemorrhagic pancreatitis lose large amounts of blood and plasma, which decreases effective circulation and blood volume. 5. Replacement with blood, plasma or albumin assists in ensuring effective circulating blood volume. 6. Calcium may be prescribed to prevent or treat tetany, which may result from calcium losses into retroperitoneal (peripancreatic) exudate. 7. During acute pancreatitis, plasma may be lost into the abdominal cavity, which diminishes the blood volume. 8. All body systems may fail if pancreatitis is severe and treatment is ineffective.	<ul style="list-style-type: none"> • Exhibits moist mucous membranes and normal skin turgor. • Exhibits normal blood pressure without evidence of postural (orthostatic) hypotension. • Excretes adequate urine volume. • Exhibits normal, not excessive, thirst. • Maintains normal pulse and respiratory rate. • Remains alert and responsive. • Exhibits normal arterial pressures and blood gases. • Exhibits normal electrolyte levels. • Exhibits no signs or symptoms of calcium deficit (eg, tetany, carpopedal spasm). • Exhibits no additional losses of fluids and electrolytes through vomiting, diarrhea, or diaphoresis. • Reports stabilization of weight. • Demonstrates no increase in abdominal girth. • Demonstrates no fluid wave on palpation of the abdomen. • Demonstrates stable organ function without manifestations of failure.

pressure within the pancreas increases. The result is obstruction of the pancreatic and common bile ducts and the duodenum. Additionally, there is atrophy of the epithelium of the ducts, inflammation, and destruction of the secreting cells of the pancreas.

Alcohol consumption in Western societies and malnutrition worldwide are the major causes of chronic pancreatitis. The median age of patients diagnosed with chronic pancreatitis is 37 to 40 years. Frequently, at that age, patients already report a long history of alcohol abuse. Excessive and prolonged consumption of alcohol accounts for approximately 70% to 80% of all cases of chronic pancreatitis (Zinner & Ashley, 2007). The incidence of pancreatitis is 50 times greater in people with alcoholism than in those who do not abuse alcohol. Long-term alcohol consumption causes hypersecretion of protein in pancreatic secretions, resulting in protein plugs and calculi within the pancreatic ducts. Alcohol also has a direct toxic effect on the cells of the pancreas. Damage to these cells is more likely to occur and to be more severe in patients whose diets are poor in protein content and either very high or very low in fat.

Smoking is another factor in the development of chronic pancreatitis. Because heavy drinkers usually smoke, it is difficult to separate the effects of the alcohol abuse and smoking (Lankisch, 2007).

Clinical Manifestations

Chronic pancreatitis is characterized by recurring attacks of severe upper abdominal and back pain, accompanied by vomiting. Attacks are often so painful that opioids, even in large doses, do not provide relief. The risk of opioid dependence is increased in pancreatitis because of the chronic nature and severity of the pain. As the disease progresses, recurring attacks of pain are more severe, more frequent, and of longer duration. Some patients experience continuous severe pain, and others have dull, nagging constant pain. Periods of well-being sometimes follow the episodes of pain (Wolfe, et al., 2006). In fact, in some patients, chronic pancreatitis is painless. The natural history of abdominal pain (character, timing, severity) is variable, and many studies have documented a decrease in pain (“burnout”) over time in a majority of patients (Dominguez-Muñoz & Malfertheiner, 2005).

Weight loss is a major problem in chronic pancreatitis: More than 80% of patients experience significant weight loss, which is usually caused by decreased dietary intake secondary to anorexia or fear that eating will precipitate another attack (Wolfe, et al., 2006). Malabsorption occurs late in the disease, when as little as 10% of pancreatic function remains (Dominguez-Muñoz & Malfertheiner, 2005). As a result, digestion, especially of proteins and fats, is impaired. The stools become frequent, frothy, and foul-smelling because of impaired fat digestion, which results in stools with a high fat content. This is referred to as **steatorrhea**. As the disease progresses, calcification of the gland may occur, and calcium stones may form within the ducts.

Assessment and Diagnostic Findings

ERCP is the most useful study in the diagnosis of chronic pancreatitis. It provides details about the anatomy of the pancreas and the pancreatic and biliary ducts. It is also

helpful in obtaining tissue for analysis and differentiating pancreatitis from other conditions, such as carcinoma. Various imaging procedures, including magnetic resonance imaging (MRI), CT scans, and ultrasound, are used in the diagnostic evaluation of patients with suspected pancreatic disorders. A CT scan or ultrasound study is also helpful to detect pancreatic cysts.

A glucose tolerance test evaluates pancreatic islet cell function and provides necessary information for making decisions about surgical resection of the pancreas. An abnormal glucose tolerance test may indicate the presence of diabetes associated with pancreatitis. Acute exacerbations of chronic pancreatitis may result in increased serum amylase levels. Steatorrhea is best confirmed by laboratory analysis of fecal fat content (Dominguez-Muñoz & Malfertheiner, 2005).

Medical Management

The management of chronic pancreatitis depends on its probable cause in each patient. Treatment is directed toward preventing and managing acute attacks, relieving pain and discomfort, and managing exocrine and endocrine insufficiency of pancreatitis.

Nonsurgical Management

Nonsurgical approaches may be indicated for the patient who refuses surgery, who is a poor surgical risk, or whose disease and symptoms do not warrant surgical intervention. Endoscopy to remove pancreatic duct stones, correct strictures, and drain cysts may be effective in selected patients to manage pain and relieve obstruction (Zinner & Ashley, 2007).

Management of abdominal pain and discomfort is similar to that of acute pancreatitis; however, the focus is usually on the use of nonopioid methods to manage pain. Antioxidants that may relieve pain and improve reported quality of life are being studied (Kirk, White, McKie, et al., 2006). Researchers have proposed that yoga may be an effective nonpharmacologic method for pain reduction and for relief of other coexisting symptoms of chronic pancreatitis (Sareen & Kumari, 2006). Persistent, unrelieved pain is often the most difficult aspect of management (Zinner & Ashley, 2007). The physician, nurse, and dietitian emphasize to the patient and family the importance of avoiding alcohol and foods that have produced abdominal pain and discomfort in the past. The health care team stresses to the patient that no other treatment is likely to relieve pain if the patient continues to consume alcohol.

Diabetes mellitus resulting from dysfunction of the pancreatic islet cells is treated with diet, insulin, or oral antidiabetic agents. The hazard of severe hypoglycemia with alcohol consumption is stressed to the patient and family. Pancreatic enzyme replacement is indicated for the patient with malabsorption and steatorrhea.

Surgical Management

Chronic pancreatitis is not often managed by surgery. However, surgery may be indicated to relieve persistent abdominal pain and discomfort, restore drainage of pancreatic secretions, and reduce the frequency of acute attacks of pancreatitis and hospitalization (Zinner & Ashley, 2007).

The type of surgery performed depends on the anatomic and functional abnormalities of the pancreas, including the location of disease within the pancreas, the presence of diabetes, exocrine insufficiency, biliary stenosis, and pseudocysts of the pancreas. Other considerations for surgery selection include the patient's likelihood for continued use of alcohol and the likelihood that the patient will be able to manage the endocrine or exocrine changes that are expected after surgery.

Pancreaticojejunostomy (also referred to as Roux-en-Y), with a side-to-side anastomosis or joining of the pancreatic duct to the jejunum, allows drainage of the pancreatic secretions into the jejunum. Pain relief occurs within 6 months in more than 85% of the patients who undergo this procedure, but pain returns in a substantial number of patients as the disease progresses (Zinner & Ashley, 2007).

Other surgical procedures may be performed for different degrees and types of underlying disorders. These procedures include revision of the sphincter of the ampulla of Vater, internal drainage of a pancreatic cyst into the stomach (see later discussion), insertion of a stent, and wide resection or removal of the pancreas. A Whipple resection (pancreaticoduodenectomy) can be carried out to relieve the pain of chronic pancreatitis. In an effort to provide permanent pain relief and avoid endocrine and exocrine insufficiency that ensue with major resections of the pancreas, surgeons have designed new procedures that combine limited resection of the head of the pancreas with a pancreaticojejunostomy. These procedures, known as the Beger or Frey operations, remove most of the head of the pancreas except for a shell of pancreatic tissue posteriorly (Bayless & Diehl, 2005; Zinner & Ashley, 2007).

When chronic pancreatitis develops as a result of gallbladder disease, surgery is performed to explore the common duct and remove the stones; usually, the gallbladder is removed at the same time. In addition, an attempt is made to improve the drainage of the common bile duct and the pancreatic duct by dividing the sphincter of Oddi, a muscle that is located at the ampulla of Vater (this surgical procedure is known as a sphincterotomy). A T-tube usually is placed in the common bile duct, requiring a drainage system to collect the bile postoperatively. Nursing care after such surgery is similar to that indicated after other biliary tract surgery.

Approximately two thirds of all patients with chronic pancreatitis can be managed with endoscopic or laparoscopic intervention (Wolfe, et al., 2006). Endoscopic and laparoscopic procedures such as distal pancreatectomy, longitudinal decompression of the pancreatic duct, nerve denervation, and stenting have been performed in patients with jaundice or recurrent inflammation and are being refined. Minimally invasive procedures to treat chronic pancreatitis may prove to be successful adjuncts in the management of this complex disorder (Beger & Bettina, 2007; Wolfe, et al., 2006).

Patients who undergo surgery for chronic pancreatitis may experience weight gain and improved nutritional status; this may result from reduction in pain associated with eating rather than from correction of malabsorption. However, morbidity and mortality after these surgical procedures are high because of the poor physical condition of the patient before surgery and the concomitant presence of

cirrhosis. Even after undergoing these surgical procedures, the patient is likely to continue to have pain and impaired digestion secondary to pancreatitis, unless alcohol is avoided completely.

Pancreatic Cysts

As a result of the local necrosis that occurs at the time of acute pancreatitis, collections of fluid may form close to the pancreas. These fluid collections become walled off by fibrous tissue and are called pancreatic pseudocysts. They are the most common type of pancreatic cyst. Less common cysts occur as a result of congenital anomalies or secondary to chronic pancreatitis or trauma to the pancreas.

Diagnosis of pancreatic cysts and pseudocysts is made by ultrasound, CT scan, and ERCP. ERCP may be used to define the anatomy of the pancreas and evaluate the patency of pancreatic drainage. Pancreatic pseudocysts may be of considerable size. When pancreatic pseudocysts enlarge, they impinge on and displace the adjacent stomach or the colon because of the location of pseudocysts behind the posterior peritoneum. Eventually, through pressure or secondary infection, they produce symptoms and require drainage.

Drainage into the GI tract or through the skin and abdominal wall may be established. In the latter instance, the drainage is likely to be profuse and destructive to tissue because of the enzyme contents. Hence, steps (including application of skin ointment) must be taken to protect the skin near the drainage site from excoriation. A suction apparatus may be used to continuously aspirate digestive secretions from the drainage tract so that skin contact with the digestive enzymes is avoided. Expert nursing attention is required to ensure that the suction tube does not become dislodged and suction is not interrupted. Consultation with a WOC nurse is indicated to identify appropriate strategies for maintaining drainage and protecting the skin.

Cancer of the Pancreas

Pancreatic cancer is the fourth leading cause of cancer death in men in the United States and the fifth leading cause of cancer death in women. It is very rare before the age of 45 years, and the majority of patients present in or beyond the sixth decade of life (Feldman, et al., 2006; Zinner & Ashley, 2007). The incidence of pancreatic cancer increases with age, peaking in the seventh and eighth decades for both men and women (American Cancer Society, 2009). The frequency of pancreatic cancer has decreased slightly over the past 25 years among non-Caucasian men. There is a slight male preponderance, and in the United States, incidence is highest in African American males (Zinner & Ashley, 2007). Cigarette smoking, exposure to industrial chemicals or toxins in the environment, and a diet high in fat, meat, or both are associated with pancreatic cancer, although their roles are not completely clear. The risk of pancreatic cancer increases as the extent of cigarette smoking increases. Diabetes mellitus, chronic pancreatitis, and hereditary pancreatitis are also associated with

pancreatic cancer. The pancreas can also be the site of metastasis from other tumors.

Cancer may develop in the head, body, or tail of the pancreas; clinical manifestations vary depending on the site and whether functioning insulin-secreting pancreatic islet cells are involved. Approximately 70% of pancreatic cancers originate in the head of the pancreas and give rise to a distinctive clinical picture (Zinner & Ashley, 2007). Functioning islet cell tumors, whether benign (adenoma) or malignant (carcinoma), are responsible for the syndrome of hyperinsulinism. The symptoms are typically nonspecific, and patients usually do not seek medical attention until late in the disease. Only about 7% of cases are diagnosed in early stages; 80% to 85% of patients have advanced, unresectable tumor when first detected. As a result, pancreatic carcinoma has only a 5% survival rate at 5 years regardless of the stage of disease at diagnosis or treatment (American Cancer Society, 2009).

Clinical Manifestations

Pain, jaundice, or both are present in more than 80% of patients and, along with weight loss, are considered classic signs of pancreatic carcinoma (Hauser, et al., 2006). However, they often do not appear until the disease is far advanced. Other signs include rapid, profound, and progressive weight loss as well as vague upper or midabdominal pain or discomfort that is unrelated to any GI function and is often difficult to describe. Such discomfort radiates as a boring pain in the midback and is unrelated to posture or activity. It is often progressive and severe, requiring the use of opioids. It is often more severe at night and is accentuated when lying supine. Relief may be obtained by sitting up and leaning forward.

Malignant cells from pancreatic cancer are often shed into the peritoneal cavity, increasing the likelihood of metastasis. The formation of ascites is common. An important sign, if it is present, is the onset of symptoms of insulin deficiency: glucosuria, hyperglycemia, and abnormal glucose tolerance. Therefore, diabetes may be an early sign of carcinoma of the pancreas. Meals often aggravate epigastric pain, which usually occurs before the appearance of jaundice and pruritus.

Assessment and Diagnostic Findings

Spiral (helical) CT is more than 85% to 90% accurate in the diagnosis and staging of pancreatic cancer and is currently the most useful preoperative imaging technique. MRI may also be used. ERCP is also used in the diagnosis of pancreatic carcinoma. Endoscopic ultrasound (EUS) is useful in identifying small tumors and in performing fine-needle aspiration biopsy of the primary tumor or lymph nodes (Hauser, et al., 2006). Cells obtained during ERCP are sent to the laboratory for analysis. GI x-ray findings may demonstrate deformities in adjacent organs caused by the impinging pancreatic mass.

A histologic diagnosis is not usually required in patients who are candidates for surgery. The tissue diagnosis is made at the time of the surgical procedure. Percutaneous fine-needle aspiration biopsy of the pancreas, which is used to diagnose pancreatic tumors, is also used to confirm the diagnosis in patients whose tumors are not resectable so that

a palliative plan of care can be determined. This may eliminate the stress and postoperative pain of ineffective surgery. In this procedure, a needle is inserted through the anterior abdominal wall into the pancreatic mass, guided by CT, ultrasound, ERCP, or other imaging techniques. The aspirated material is examined for malignant cells. Although percutaneous biopsy is a valuable diagnostic tool, it has some potential drawbacks: a false-negative result if small tumors are missed and the risk of seeding of cancer cells along the needle track. Low-dose radiation to the site may be used before the biopsy to reduce this risk.

Percutaneous transhepatic cholangiography is another procedure that may be performed to identify obstructions of the biliary tract by a pancreatic tumor. Several tumor markers (eg, cancer antigen [CA] 19-9, carcinoembryonic antigen [CEA], DU-PAN-2) may be used in the diagnostic workup, but they are nonspecific for pancreatic carcinoma. These tumor markers are useful as indicators of disease progression.

Angiography, CT scans, and laparoscopy may be performed to determine whether the tumor can be removed surgically. Intraoperative ultrasonography has been used to determine whether there is metastatic disease to other organs.

Medical Management

If the tumor is resectable and localized (typically tumors in the head of the pancreas), the surgical procedure to remove it is usually extensive (see later discussion). However, total excision of the lesion often is not possible for two reasons: (1) extensive growth of tumor before diagnosis and (2) probable widespread metastases (especially to the liver, lungs, and bones). More often, treatment is limited to palliative measures.

Although pancreatic tumors may be resistant to standard radiation therapy, the patient may be treated with radiation and chemotherapy (5-fluorouracil [5-FU, Adrucil], leucovorin [Wellcovorin], and gemcitabine [Gemzar]). Currently, gemcitabine is the standard of care for patients with metastatic pancreatic cancer (Feldman, et al., 2006). At present, newer biologic agents, including farnesyl transferase inhibitors and monoclonal antibodies, are under study for the treatment of metastatic pancreatic cancer (Feldman, et al., 2006; Zinner & Ashley, 2007). If the patient undergoes surgery, intraoperative radiation therapy (IORT) may be used to deliver a high dose of radiation to the tumor with minimal injury to other tissues; this may also be helpful in relief of pain. Interstitial implantation of radioactive sources has also been used, although the rate of complications is high. A large biliary stent inserted percutaneously or by endoscopy may be used to relieve jaundice.

Nursing Management

Pain management and attention to nutritional requirements are important nursing measures that improve the level of patient comfort. Skin care and nursing measures are directed toward relief of pain and discomfort associated with jaundice, anorexia, and profound weight loss. Specialty mattresses are beneficial and protect bony prominences from pressure. Pain associated with pancreatic cancer may be severe and may require liberal use of opioids;

patient-controlled analgesia should be considered for the patient with severe, escalating pain.

Because of the poor prognosis and likelihood of short survival, end-of-life preferences are discussed and honored. If appropriate, the nurse refers the patient to hospice care. (See Chapters 16 and 17 for care of the patient with cancer and end-of-life care, respectively.)

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The specific teaching for the patient and family varies with the stage of disease and the treatment choices made by the patient. If the patient elects to receive chemotherapy, the nurse focuses teaching on prevention of side effects and complications of the agents used. If surgery is performed to relieve obstruction and establish biliary drainage, teaching addresses management of the drainage system and monitoring for complications. The nurse instructs the family about changes in the patient's status that should be reported to the physician.

Continuing Care

A referral for home care is indicated to help the patient and family deal with the physical problems and discomforts associated with pancreatic cancer and the psychological impact of the disease. The home care nurse assesses the patient's physical status, fluid and nutritional status, skin integrity, and the adequacy of pain management. The nurse teaches the patient and family strategies to prevent skin breakdown and relieve pain, pruritus, and anorexia. It is important to discuss and arrange palliative care (hospice services) in an effort to relieve patient discomfort, assist with care, and comply with the patient's end-of-life decisions and wishes.

Tumors of the Head of the Pancreas

Sixty percent to 80% of pancreatic tumors occur in the head of the pancreas (Zinner & Ashley, 2007). Tumors in this region of the pancreas obstruct the common bile duct where the duct passes through the head of the pancreas to join the pancreatic duct and empty at the ampulla of Vater into the duodenum. The tumors producing the obstruction may arise from the pancreas, the common bile duct, or the ampulla of Vater.

Clinical Manifestations

The obstructed flow of bile produces jaundice, clay-colored stools, and dark urine. Malabsorption of nutrients and fat-soluble vitamins may result if the tumor obstructs the entry of bile to the GI tract. Abdominal discomfort or pain and pruritus may be noted, along with anorexia, weight loss, and malaise. If these signs and symptoms are present, cancer of the head of the pancreas is suspected.

The jaundice of this disease must be differentiated from that due to a biliary obstruction caused by a gallstone in the common duct. Jaundice caused by a gallstone is usually intermittent and appears typically in obese patients, who are most often women, and who have had previous symptoms of gallbladder disease.

Assessment and Diagnostic Findings

Diagnostic studies may include duodenography, angiography by hepatic or celiac artery catheterization, pancreatic scanning, percutaneous transhepatic cholangiography, ERCP, and percutaneous needle biopsy of the pancreas. Results of a biopsy of the pancreas may aid in the diagnosis.

Medical Management

Before extensive surgery can be performed, a fairly long period of preparation is often necessary, because the patient's nutritional status and physical condition are often quite compromised. Various liver and pancreatic function studies are performed. A diet high in protein along with pancreatic enzymes is often prescribed. Preoperative preparation includes adequate hydration, correction of prothrombin deficiency with vitamin K, and treatment of anemia to minimize postoperative complications. Parenteral nutrition and blood component therapy are frequently required.

A biliary-enteric shunt may be performed to relieve the jaundice and, perhaps, to provide time for a thorough diagnostic evaluation. Total pancreatectomy (removal of the pancreas) may be performed if there is no evidence of direct extension of the tumor to adjacent tissues or regional lymph nodes. A pancreaticoduodenectomy (Whipple's procedure or resection) is used for potentially resectable cancer of the head of the pancreas (Fig. 40-7). This procedure involves removal of the gallbladder, a portion of the stomach, duodenum, proximal jejunum, head of the pancreas, and distal common bile duct. Reconstruction involves anastomosis of the remaining pancreas and stomach to the jejunum (Hauser, et al., 2006). The result is removal of the tumor, allowing flow of bile into the jejunum. If the tumor cannot be excised, the jaundice may be relieved by diverting the bile flow into the jejunum by anastomosing the jejunum to the gallbladder, a procedure known as *cholecystojejunostomy*.

The postoperative management of patients who have undergone a pancreatectomy or a pancreaticoduodenectomy is similar to the management of patients after extensive gastrointestinal or biliary surgery. The patient's physical status is often suboptimal, increasing the risk of postoperative complications. Hemorrhage, vascular collapse, and hepatorenal failure remain the major postoperative complications. The mortality rate associated with these procedures has decreased because of advances in nutritional support and improved surgical techniques. A nasogastric tube with suction and parenteral nutrition allow the GI tract to rest while promoting adequate nutrition.

Nursing Management

Preoperatively and postoperatively, nursing care is directed toward promoting patient comfort, preventing complications, and assisting the patient to return to and maintain as normal and comfortable a life as possible. The nurse closely monitors the patient in the intensive care unit after surgery; in the immediate postoperative period, multiple IV and arterial lines are used for fluid and blood replacement and hemodynamic monitoring, and a mechanical ventilator may be used. It is important to note and report changes in vital

Figure 40-7 Pancreatoduodenectomy (Whipple's procedure or resection). End result of resection of carcinoma of the head of the pancreas or the ampulla of Vater. The common duct is sutured to the side of the jejunum (choledochojejunostomy), and the remaining portion of the pancreas and the end of the stomach are sutured to the side of the jejunum.

signs, arterial blood gases and pressures, pulse oximetry, laboratory values, and urine output. The nurse must also consider the patient's compromised nutritional status and risk of bleeding. Depending on the type of surgical procedure performed, malabsorption syndrome and diabetes mellitus are likely; the nurse must address these issues during acute and long-term patient care.

Although the patient's physiologic status is the focus of the health care team in the immediate postoperative period, the patient's psychological and emotional states must be considered, along with that of the family. The patient has undergone a major high-risk surgery and is critically ill; anxiety and depression may affect recovery. The immediate and long-term outcomes of this extensive surgical resection are uncertain, and the patient and family require emotional support and understanding in the critical and stressful preoperative and postoperative periods.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient who has undergone this extensive surgery requires careful and thorough preparation for self-care at home. The nurse instructs the patient and family about the need for modifications in the diet because of malabsorption and hyperglycemia resulting from the surgery. It is important to instruct the patient and family about the continuing need for pancreatic enzyme replacement, a low-fat diet, and vitamin supplementation.

The nurse teaches the patient and family strategies to relieve pain and discomfort, along with strategies to manage drains, if present, and to care for the surgical incision. The patient and family members may require instruction about use of patient-controlled analgesia, parenteral nutrition, wound care, skin care, and management of drainage. It is important to describe, verbally and in writing, the signs and symptoms of complications and to teach the patient and family about indicators of complications that should be reported promptly.

Discharge of the patient to a long-term care or rehabilitation facility may be warranted after surgery as extensive as pancreatectomy or pancreaticoduodenectomy, particularly if the patient's preoperative status was not optimal. Information about the teaching that has been provided is shared with the long-term care staff so that instructions can be clarified and reinforced. During the recovery or long-term phase of care, the patient and family receive further instructions about self-care in the home.

Continuing Care

A referral for home care may be indicated when the patient returns home. The home care nurse assesses the patient's physical and psychological status and the ability of the patient and family to manage needed care. The home care nurse provides needed physical care and monitors the adequacy of pain management. In addition, it is important to assess the patient's nutritional status and monitor the use of enteral or parenteral nutrition, if used. The nurse discusses the use of hospice services with the patient and family and makes a referral if indicated.

Pancreatic Islet Tumors

The pancreas contains the islets (islands) of Langerhans, small nests of cells that secrete hormones directly into the bloodstream and therefore are part of the endocrine system. The hormone insulin is essential for the metabolism of glucose. Diabetes mellitus (see Chapter 41) is the result of deficient insulin secretion. At least two types of tumors of the pancreatic islet cells are known: those that secrete insulin (insulinoma) and those in which insulin secretion is not increased (nonfunctioning islet cell cancer). Insulinomas produce hypersecretion of insulin and cause an excessive rate of glucose metabolism. The resulting hypoglycemia may produce symptoms of weakness, mental confusion, and seizures. These symptoms may be relieved almost immediately by oral or IV administration of glucose. The 5-hour glucose tolerance test is helpful to diagnose insulinoma and to distinguish this diagnosis from other causes of hypoglycemia.

Surgical Management

If a tumor of the islet cells has been diagnosed, surgical treatment with removal of the tumor is usually recommended (Zinner & Ashley, 2007). The tumors may be benign adenomas or they may be malignant. Complete removal usually results in almost immediate relief of symptoms. In some patients, symptoms may be produced by simple hypertrophy of this tissue rather than a tumor of the islet cells. In such cases, a partial pancreatectomy (removal of the tail and part of the body of the pancreas) is performed.

Nursing Management

In preparing the patient for surgery, the nurse must be alert for symptoms of hypoglycemia and be ready to administer glucose as prescribed if symptoms occur. Postoperatively, the nursing management is the same as after other upper abdominal surgical procedures, with special emphasis on monitoring serum glucose levels. Patient teaching is determined by the extent of surgery and alterations in pancreatic function.

Hyperinsulinism

Hyperinsulinism is caused by overproduction of insulin by the pancreatic islets. Symptoms resemble those of excessive doses of insulin and are attributable to the same mechanism: an abnormal reduction in blood glucose levels. Clinically it is characterized by episodes during which the patient experiences unusual hunger, nervousness, sweating, headache, and faintness; in severe cases, seizures and episodes of unconsciousness may occur. The findings at the time of surgery or at autopsy may indicate hyperplasia (overgrowth) of the islets of Langerhans or a benign or malignant tumor involving the islets that is capable of producing large amounts of insulin (see preceding discussion). Occasionally, tumors of nonpancreatic origin produce an insulin-like material that can cause severe hypoglycemia and may be responsible for seizures coinciding with blood glucose levels that are too low to sustain normal brain function (ie, lower than 30 mg/dL [1.6 mmol/L]).

All the symptoms that accompany spontaneous hypoglycemia are relieved by the oral or parenteral administration of glucose. Surgical removal of the hyperplastic or neoplastic tissue from the pancreas is the only successful method of treatment. About 15% of patients with spontaneous or functional hypoglycemia eventually develop diabetes mellitus.

Ulcerogenic Tumors

Some tumors of the islets of Langerhans are associated with hypersecretion of gastric acid that produces ulcers in the stomach, duodenum, and jejunum. This is referred to as **Zollinger-Ellison syndrome**. The hypersecretion is so excessive that even after partial gastric resection enough acid is produced to cause further ulceration. If a marked tendency to develop gastric and duodenal ulcers is noted, an ulcerogenic tumor of the islets of Langerhans is considered.

These tumors, which may be benign or malignant, are treated by excision, if possible. Frequently, however, removal is not possible because of extension beyond the pancreas. In

many patients, a total gastrectomy may be necessary to reduce the secretion of gastric acid sufficiently to prevent further ulceration. This procedure is also indicated to treat gastric carcinoid tumors that may arise from the effect of prolonged hypersecretion of gastric acids (Zinner & Ashley, 2007).

CRITICAL THINKING EXERCISES

1 A 72-year-old woman has confirmed cholelithiasis. She also has many other chronic medical conditions, including coronary artery disease, heart failure, and chronic obstructive pulmonary disease. She has been evaluated for treatment by her internist and a surgeon. Surgical treatment of her cholelithiasis is inappropriate for her at this time. What options exist for this patient? How would you educate and prepare her for nonsurgical interventions? What will her likely outcome be with this treatment approach? What are possible adverse effects of nonsurgical treatment?

2 A 44-year-old man is admitted to your unit with a diagnosis of pancreatitis. He had an ultrasound performed, and several large gallstones were identified. He reports severe epigastric pain (rates it at 9 on a 10-point scale) and nausea. He has a nasogastric tube in place because of several episodes of vomiting. What is the cause of this patient's pancreatitis? What medications and laboratory tests would you expect to see prescribed for this patient? What physical assessment findings will you see? What issues would be of high priority in caring for this patient during his hospital stay? What multisystem complications might arise that would necessitate this patient's transfer to an intensive care unit? What issues would be of high priority in preparing him for hospital discharge?

EBP 3 A 68-year-old woman has undergone a Whipple procedure. For what immediate postoperative complications must you be alert? What assessment strategies are used to monitor for the development of complications? Describe two evidence-based preventive interventions for postoperative care. What type of nutritional interventions might you expect? What education is needed prior to the patient's hospital discharge? What follow-up will be necessary?

EBP 4 A 35-year-old woman is scheduled for a laparoscopic cholecystectomy. She is being discharged on the day of surgery. What information should you collect regarding the patient's home situation before she is discharged? What information should you provide about expectations for postoperative pain and other complications, and what instructions should you provide to the patient about pharmacologic and nonpharmacologic pain management strategies? What is the evidence base for the pain management strategies you provide, and what is the strength of that evidence?

5 Compare and contrast the nursing care of a 46-year-old patient with a diagnosis of acute pancreatitis with that of a 64-year-old patient with a diagnosis of chronic pancreatitis. Explain the rationale for differences in care for patients with these two diagnoses.

chapter 41

Assessment and Management of Patients With Diabetes Mellitus

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Differentiate between type 1 and type 2 diabetes.
- 2 Describe etiologic factors associated with diabetes.
- 3 Relate the clinical manifestations of diabetes to the associated pathophysiologic alterations.
- 4 Identify the diagnostic and clinical significance of blood glucose test results.
- 5 Explain the dietary modifications used for management of people with diabetes.
- 6 Describe the relationships among diet, exercise, and medication (ie, insulin or oral antidiabetic agents) for people with diabetes.
- 7 Develop a plan for teaching insulin self-management.
- 8 Identify the role of oral antidiabetic agents in diabetic therapy.
- 9 Differentiate between hyperglycemia with diabetic ketoacidosis and hyperosmolar nonketotic syndrome.
- 10 Describe management strategies for a person with diabetes to use during “sick days.”
- 11 Describe the major macrovascular, microvascular, and neuropathic complications of diabetes and the self-care behaviors that are important in their prevention.
- 12 Identify the teaching aids and community support groups available for people with diabetes.

GLOSSARY

continuous glucose monitoring system (CGMS): a device worn for 72 hours that continuously monitors blood glucose levels; the data are downloaded and analyzed for blood glucose patterns for that time period; presently used diagnostically to elicit patterns and tailor treatment

continuous subcutaneous insulin infusion, insulin pump: a small device that delivers insulin on a 24-hour basis as basal insulin; it is also programmed by the patient to deliver a bolus dose before eating a meal in an attempt to mimic normal pancreatic function

diabetes mellitus: a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both

diabetic ketoacidosis (DKA): a metabolic derangement in type 1 diabetes that results from a deficiency of insulin; highly acidic ketone bodies are formed, resulting in acidosis; usually requires hospitalization for treatment and is usually caused by nonadherence to the insulin regimen, concurrent illness, or infection

fasting plasma glucose (FPG): blood glucose determination obtained in the laboratory after fasting for more than 8 hours

gestational diabetes mellitus (GDM): any degree of glucose intolerance with its onset during pregnancy

glycated hemoglobin (glycosylated hemoglobin, Hgb A_{1c} or A_{1C}): a long-term measure of glucose control that is a result of glucose attaching to hemoglobin for the life of the red blood cell (120 days).

GLOSSARY (Continued)

The goal of diabetes therapy is a normal to near-normal level of glycated hemoglobin, the same as in the nondiabetic population

hyperglycemia: elevated blood glucose level; fasting level greater than 110 mg/dL (6.1 mmol/L); 2-hour postprandial level greater than 140 mg/dL (7.8 mmol/L)

hyperglycemic hyperosmolar nonketotic syndrome (HHNS): a metabolic disorder of type 2 diabetes resulting from a relative insulin deficiency initiated by an intercurrent illness that raises the demand for insulin; associated with polyuria and severe dehydration

hypoglycemia: low blood glucose level (less than 60 mg/dL [less than 2.7 mmol/L])

impaired fasting glucose (IFG), impaired glucose tolerance (IGT): a metabolic stage intermediate between normal glucose homeostasis and diabetes; now referred to as prediabetes

insulin: a hormone secreted by the beta cells of the islets of Langerhans of the pancreas that is necessary for the metabolism of carbohydrates, proteins, and fats; a deficiency of insulin results in diabetes mellitus

islet cell transplantation: an investigational procedure in which purified islet cells from cadaver donors are injected into the portal vein of the liver, with the goal of having these cells secrete insulin and cure type 1 diabetes

ketone: a highly acidic substance formed when the liver breaks down free fatty acids in the absence of insulin; the result is diabetic ketoacidosis

medical nutrition therapy (MNT): nutritional therapy prescribed by the physician for management of diabetes

nephropathy: a long-term complication of diabetes in which the kidney cells are damaged; characterized by microalbuminuria in early stages and progressing to end-stage renal disease

neuropathy: a long-term complication of diabetes resulting from damage to the nerve cell

prediabetes: impaired glucose metabolism in which blood glucose concentrations fall between normal levels and those considered diagnostic for diabetes; includes IFG and IGT, not clinical entities in their own right but risk factors for future diabetes and cardiovascular disease

retinopathy: a long-term complication of diabetes in which the microvascular system of the eye is damaged

self-monitoring of blood glucose (SMBG): a method of capillary blood glucose testing in which the patient pricks his or her finger and applies a drop of blood to a test strip that is read by a meter

sulfonylurea: a classification of oral antidiabetic medication for treating type 2 diabetes; stimulates insulin secretion and insulin action

thiazolidinedione: a class of oral antidiabetic medications that reduce insulin resistance in target tissues, enhancing insulin action without directly stimulating insulin secretion

type 1 diabetes: a metabolic disorder characterized by an absence of insulin production and secretion from autoimmune destruction of the beta cells of the islets of Langerhans in the pancreas; formerly called insulin-dependent, juvenile, or type I diabetes

type 2 diabetes: a metabolic disorder characterized by the relative deficiency of insulin production and a decreased insulin action and increased insulin resistance; formerly called non-insulin-dependent, adult-onset, or type II diabetes

Diabetes mellitus is a group of metabolic diseases characterized by increased levels of glucose in the blood (**hyperglycemia**) resulting from defects in insulin secretion, insulin action, or both (American Diabetes Association [ADA], 2009a). Normally, a certain amount of glucose circulates in the blood. The major sources of this glucose are absorption of ingested food in the gastrointestinal tract and formation of glucose by the liver from food substances.

DIABETES

Epidemiology

Diabetes is becoming more common in the United States. From 1980 through 2002, the number of Americans with diabetes more than doubled and increased in all age groups. Currently, it is estimated that more than 23 million people in the United States have diabetes, although almost one third of these cases are undiagnosed. The number of people newly diagnosed with diabetes increases by about 1 million people per year (Centers for Disease Control and Prevention [CDC], 2008). By 2030, the number of cases is expected to exceed 30 million. In 2000, the worldwide estimate of the prevalence of diabetes was 171 million people, and by 2030, this is expected to increase to more than 360 million (World Health Organization, 2008). Diabetes is especially prevalent in the elderly; as many as 50% of people older than 65 years of age have some degree of glucose intolerance. People 65 years and older account for almost 40% of people with diabetes.

Minority populations are disproportionately affected by diabetes. From 1980 through 2002, the age-adjusted prevalence of diabetes increased among all gender and race groups, but compared to Caucasians, African Americans and members of other racial and ethnic groups (Native Americans and persons of Hispanic origin) are more likely to develop diabetes, are at greater risk for many of the complications, and have higher death rates due to diabetes (CDC, 2008). Chart 41-1 summarizes risk factors for diabetes mellitus.

CHART
41-1

Risk Factors for Diabetes Mellitus

- Family history of diabetes (ie, parents or siblings with diabetes)
- Obesity (ie, $\geq 20\%$ over desired body weight or BMI ≥ 27 kg/m²)
- Race/ethnicity (eg, African Americans, Hispanic Americans, Native Americans, Asian Americans, Pacific Islanders)
- Age ≥ 45 y
- Previously identified impaired fasting glucose or impaired glucose tolerance
- Hypertension ($\geq 140/90$ mm Hg)
- HDL cholesterol level ≤ 35 mg/dL (0.90 mmol/L) and/or triglyceride level ≥ 250 mg/dL (2.8 mmol/L)
- History of gestational diabetes or delivery of babies over 9 lb

Used with permission of American Diabetes Association. (2009a). Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care*, 32(Suppl 1), S62–S67.

Diabetes has far-reaching and devastating physical, social, and economic consequences, including the following:

- In the United States, diabetes is the leading cause of nontraumatic amputations, blindness in working-age adults, and end-stage renal disease (CDC, 2008).
- Diabetes is the third leading cause of death from disease, primarily because of the high rate of cardiovascular disease (myocardial infarction, stroke, and peripheral vascular disease) among people with diabetes.
- Hospitalization rates for people with diabetes are 2.4 times greater for adults and 5.3 times greater for children than for the general population.

The economic cost of diabetes continues to increase because of increasing health care costs and an aging population. Half of all people who have diabetes and are older than 65 years of age are hospitalized each year, and severe and life-threatening complications often contribute to the increased rates of hospitalization. Costs related to diabetes are estimated to be almost \$174 billion annually, including direct medical care expenses and indirect costs attributable to disability and premature death (ADA, 2008a).

Classification

The major classifications of diabetes are type 1 diabetes, type 2 diabetes, gestational diabetes, and diabetes mellitus associated with other conditions or syndromes (ADA, 2009a). The different types of diabetes mellitus vary in cause, clinical course, and treatment (Table 41-1). The classification system is dynamic in two ways. First, research findings suggest many differences among individuals within each category. Second, except for people with type 1 diabetes, patients may move from one category to another. For example, a woman with gestational diabetes may, after delivery, move into the type 2 category. **Prediabetes** is classified as **impaired glucose tolerance (IGT)** or **impaired fasting glucose (IFG)** and refers to a condition in which blood glucose concentrations fall between normal levels and those considered diagnostic for diabetes.

Pathophysiology

Insulin is secreted by beta cells, which are one of four types of cells in the islets of Langerhans in the pancreas. Insulin is an anabolic, or storage, hormone. When a person eats a meal, insulin secretion increases and moves glucose from the blood into muscle, liver, and fat cells. In those cells, insulin

- Transports and metabolizes glucose for energy
- Stimulates storage of glucose in the liver and muscle (in the form of glycogen)
- Signals the liver to stop the release of glucose
- Enhances storage of dietary fat in adipose tissue
- Accelerates transport of amino acids (derived from dietary protein) into cells

Insulin also inhibits the breakdown of stored glucose, protein, and fat.

During fasting periods (between meals and overnight), the pancreas continuously releases a small amount of insulin (basal insulin); another pancreatic hormone called glucagon (secreted by the alpha cells of the islets of Langerhans) is released when blood glucose levels decrease and stimulates the liver to release stored glucose. The insulin

Table 41-1 CLASSIFICATION OF DIABETES MELLITUS AND RELATED GLUCOSE INTOLERANCES	
Current Classification	Clinical Characteristics and Clinical Implications
Type 1 (5–10% of all diabetes) (Previously classified as juvenile diabetes, juvenile-onset diabetes, ketosis-prone diabetes, brittle diabetes, and insulin-dependent diabetes mellitus [IDDM])	<p>Onset any age, but usually young (<30 y)</p> <p>Usually thin at diagnosis; recent weight loss</p> <p>Etiology includes genetic, immunologic, and environmental factors (eg, virus)</p> <p>Often have islet cell antibodies</p> <p>Often have antibodies to insulin even before insulin treatment</p> <p>Little or no endogenous insulin</p> <p>Need insulin to preserve life</p> <p>Ketosis prone when insulin absent</p> <p>Acute complication of hyperglycemia: diabetic ketoacidosis</p>
Type 2 (90–95% of all diabetes: obese—80% of type 2; nonobese—20% of type 2) (Previously classified as adult-onset diabetes, maturity-onset diabetes, ketosis-resistant diabetes, stable diabetes, and non-insulin-dependent diabetes [NIDDM])	<p>Onset any age, usually over 30 y</p> <p>Usually obese at diagnosis</p> <p>Causes include obesity, heredity, and environmental factors</p> <p>No islet cell antibodies</p> <p>Decrease in endogenous insulin, or increased with insulin resistance</p> <p>Most patients can control blood glucose through weight loss if obese</p> <p>Oral antidiabetic agents may improve blood glucose levels if dietary modification and exercise are unsuccessful</p> <p>May need insulin on a short-term or long-term basis to prevent hyperglycemia</p> <p>Ketosis uncommon, except in stress or infection</p> <p>Acute complication: hyperglycemic hyperosmolar nonketotic syndrome</p>
Diabetes mellitus associated with other conditions or syndromes (Previously classified as secondary diabetes)	<p>Accompanied by conditions known or suspected to cause the disease: pancreatic diseases, hormonal abnormalities, medications such as corticosteroids and estrogen-containing preparations</p> <p>Depending on the ability of the pancreas to produce insulin, the patient may require treatment with oral antidiabetic agents or insulin</p>
Gestational diabetes	<p>Onset during pregnancy, usually in the second or third trimester</p> <p>Due to hormones secreted by the placenta, which inhibit the action of insulin</p> <p>Above-normal risk for perinatal complications, especially macrosomia (abnormally large babies)</p> <p>Treated with diet and, if needed, insulin to strictly maintain normal blood glucose levels</p> <p>Occurs in about 2–5% of all pregnancies</p> <p>Glucose intolerance transitory but may recur:</p> <ul style="list-style-type: none"> • In subsequent pregnancies • 30–40% will develop overt diabetes (usually type 2) within 10 years (especially if obese) <p>Risk factors include obesity, age older than 30 years, family history of diabetes, previous large babies (>9 lb)</p> <p>Screening tests (glucose challenge test) should be performed on all pregnant women between 24- and 28-weeks gestation</p> <p>Should be screened for diabetes periodically</p>
Prediabetes (Previously classified as previous abnormality of glucose tolerance [PrevAGT])	<p>Previous history of hyperglycemia (eg, during pregnancy or illness)</p> <p>Current normal glucose metabolism</p> <p>Impaired glucose tolerance or impaired fasting glucose screening after age 40 years if there is a family history of diabetes or if symptomatic</p> <p>Encourage ideal body weight, because loss of 10–15 lb may improve glycemic control</p>

and the glucagon together maintain a constant level of glucose in the blood by stimulating the release of glucose from the liver.

Initially, the liver produces glucose through the breakdown of glycogen (glycogenolysis). After 8 to 12 hours without food, the liver forms glucose from the breakdown of noncarbohydrate substances, including amino acids (gluconeogenesis).

Type 1 Diabetes

Type 1 diabetes affects approximately 5% to 10% of people with the disease; it is characterized by an acute onset, usually before 30 years of age (CDC, 2008). Type 1 diabetes is characterized by destruction of the pancreatic beta cells. Combined genetic, immunologic, and possibly environmental (eg, viral) factors are thought to contribute to beta-cell destruction. Although the events that lead to beta-cell destruction are not fully understood, it is generally accepted that a genetic susceptibility is a common underlying factor

in the development of type 1 diabetes. People do not inherit type 1 diabetes itself but rather a genetic predisposition, or tendency, toward development of type 1 diabetes. This genetic tendency has been found in people with certain human leukocyte antigen (HLA) types. There is also evidence of an autoimmune response in type 1 diabetes. This is an abnormal response in which antibodies are directed against normal tissues of the body, responding to these tissues as if they were foreign. Autoantibodies against islet cells and against endogenous (internal) insulin have been detected in people at the time of diagnosis and even several years before the development of clinical signs of type 1 diabetes. In addition to genetic and immunologic components, environmental factors, such as viruses or toxins, that may initiate destruction of the beta cell are being investigated.

Regardless of the specific cause, the destruction of the beta cells results in decreased insulin production, unchecked glucose production by the liver, and fasting

hyperglycemia. In addition, glucose derived from food cannot be stored in the liver but instead remains in the bloodstream and contributes to postprandial (after meals) hyperglycemia. If the concentration of glucose in the blood exceeds the renal threshold for glucose, usually 180 to 200 mg/dL (9.9 to 11.1 mmol/L), the kidneys may not reabsorb all of the filtered glucose; the glucose then appears in the urine (glycosuria). When excess glucose is excreted in the urine, it is accompanied by excessive loss of fluids and electrolytes. This is called osmotic diuresis.

Because insulin normally inhibits glycogenolysis (breakdown of stored glucose) and gluconeogenesis (production of new glucose from amino acids and other substrates), these processes occur in an unrestrained fashion in people with insulin deficiency and contribute further to hyperglycemia. In addition, fat breakdown occurs, resulting in an increased production of ketone bodies, which are the byproducts of fat breakdown.

NURSING ALERT

Ketone bodies are acids that disturb the acid–base balance of the body when they accumulate in excessive amounts. The resulting **diabetic ketoacidosis (DKA)** may cause signs and symptoms such as abdominal pain, nausea, vomiting, hyperventilation, a fruity breath odor, and, if left untreated, altered level of consciousness, coma, and death. Initiation of insulin treatment, along with fluid and electrolytes as needed, is essential to treat hyperglycemia and DKA and rapidly improves the metabolic abnormalities.

Type 2 Diabetes

Type 2 diabetes affects approximately 90% to 95% of people with the disease (CDC, 2008). It occurs more commonly among people who are older than 30 years of age and obese (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2005), although its incidence is rapidly increasing in younger people because of the growing epidemic of obesity in children, adolescents, and young adults (CDC, 2008). The two main problems related to insulin in type 2 diabetes are insulin resistance and impaired insulin secretion. Insulin resistance refers to a decreased tissue sensitivity to insulin. Normally, insulin binds to special receptors on cell surfaces and initiates a series of reactions involved in glucose metabolism. In type 2 diabetes, these intracellular reactions are diminished, making insulin less effective at stimulating glucose uptake by the tissues and at regulating glucose release by the liver (Fig. 41-1). The exact mechanisms that lead to insulin resistance and impaired insulin secretion in type 2 diabetes are unknown, although genetic factors are thought to play a role.

To overcome insulin resistance and to prevent the buildup of glucose in the blood, increased amounts of insulin must be secreted to maintain the glucose level at a normal or slightly elevated level. This is called metabolic syndrome, which includes hypertension, hypercholesterolemia, and abdominal obesity. However, if the

Physiology Pathophysiology

Figure 41-1 Pathogenesis of type 2 diabetes.

beta cells cannot keep up with the increased demand for insulin, the glucose level rises and type 2 diabetes develops.

Despite the impaired insulin secretion that is characteristic of type 2 diabetes, there is enough insulin present to prevent the breakdown of fat and the accompanying production of ketone bodies. Therefore, DKA does not typically occur in type 2 diabetes. However, uncontrolled type 2 diabetes may lead to another acute problem—hyperglycemic hyperosmolar nonketotic syndrome (see later discussion).

Because type 2 diabetes is associated with a slow, progressive glucose intolerance, its onset may go undetected for many years. If the patient experiences symptoms, they are frequently mild and may include fatigue, irritability, polyuria, polydipsia, poorly healing skin wounds, vaginal infections, or blurred vision (if glucose levels are very high).

For most patients (approximately 75%), type 2 diabetes is detected incidentally (eg, when routine laboratory tests or ophthalmoscopic examinations are performed). One consequence of undetected diabetes is that long-term diabetes complications (eg, eye disease, peripheral neuropathy, peripheral vascular disease) may have developed before the actual diagnosis of diabetes is made (ADA, 2009a), signifying that the blood glucose has been elevated for a time before diagnosis.

Gestational Diabetes

Gestational diabetes mellitus (GDM) is any degree of glucose intolerance with its onset during pregnancy. Hyperglycemia develops during pregnancy because of the secretion of placental hormones, which causes insulin resistance. Gestational diabetes occurs in as many as 14% of pregnant women and increases their risk for hypertensive disorders during pregnancy (ADA, 2009a).

Women who are considered to be at high risk for GDM and who should be screened by blood glucose testing at their

first prenatal visit are those with marked obesity, a personal history of GDM, glycosuria, or a strong family history of diabetes. High-risk ethnic groups include Hispanic Americans, Native Americans, Asian Americans, African Americans, and Pacific Islanders. If these high-risk women do not have GDM at initial screening, they should be retested between 24 and 28 weeks of gestation. All women of average risk should be tested at 24 to 28 weeks of gestation. Testing is not specifically recommended for women identified as being at low risk. Low-risk women are those who meet all of the following criteria: age younger than 25 years, normal weight before pregnancy, member of an ethnic group with low prevalence of GDM, no history of abnormal glucose tolerance, no known history of diabetes in first-degree relatives, and no history of poor obstetric outcome (ADA, 2009a). Women considered to be at high risk or average risk should have either an oral glucose tolerance test (OGTT) or a glucose challenge test (GCT) followed by OGTT in women who exceed the glucose threshold value of 140 mg/dL (7.8 mmol/L) (ADA, 2009a).

Initial management includes dietary modification and blood glucose monitoring. If hyperglycemia persists, insulin is prescribed. Goals for blood glucose levels during pregnancy are 105 mg/dL (5.8 mmol/L) or less before meals and 130 mg/dL (7.2 mmol/L) or less 2 hours after meals (ADA, 2009a).

After delivery, blood glucose levels in women with GDM usually return to normal. However, many women who have had GDM develop type 2 diabetes later in life. For this reason, a woman who has had GDM should be counseled to maintain her ideal body weight and to exercise regularly to reduce her risk for type 2 diabetes (Kitzmilller, Dang-Kilduff & Taslimi, 2007).

Prevention

In 2002 the Diabetes Prevention Program Research Group reported that type 2 diabetes can be prevented with appropriate changes in lifestyle. Persons at high risk for type 2 diabetes (BMI 24 or greater, fasting and postprandial plasma glucose levels elevated but not to levels diagnostic of diabetes) received either standard lifestyle recommendations plus metformin, standard lifestyle recommendations plus placebo, or an intensive program of lifestyle modifications. The 16-lesson curriculum of the intensive program of lifestyle modifications focused on weight reduction of greater than 7% of initial body weight and physical activity of moderate intensity. It also included behavior modification strategies designed to help patients achieve the goals of weight reduction and participation in exercise. The lifestyle intervention group had a 58% lower incidence of diabetes and the metformin group had a 31% lower incidence of diabetes compared to the placebo group. These findings were found in both genders and all racial and ethnic groups. These findings demonstrate that type 2 diabetes can be prevented or delayed in persons at high risk for the disease.

Clinical Manifestations

Clinical manifestations depend on the patient's level of hyperglycemia. Classic clinical manifestations of all types of

diabetes include the “three Ps”: polyuria, polydipsia, and polyphagia. Polyuria (increased urination) and polydipsia (increased thirst) occur as a result of the excess loss of fluid associated with osmotic diuresis. Patients also experience polyphagia (increased appetite) that results from the catabolic state induced by insulin deficiency and the breakdown of proteins and fats. Other symptoms include fatigue and weakness, sudden vision changes, tingling or numbness in hands or feet, dry skin, skin lesions or wounds that are slow to heal, and recurrent infections. The onset of type 1 diabetes may also be associated with sudden weight loss or nausea, vomiting, or abdominal pains, if DKA has developed.

Assessment and Diagnostic Findings

An abnormally high blood glucose level is the basic criterion for the diagnosis of diabetes. **Fasting plasma glucose (FPG)**, random plasma glucose, and glucose level 2 hours after receiving glucose (2-hour postload) may be used. The OGTT and the intravenous (IV) glucose tolerance test are no longer recommended for routine clinical use. See Chart 41-2 for the ADA's diagnostic criteria for diabetes mellitus (ADA, 2009a).

In addition to the assessment and diagnostic evaluation performed to diagnose diabetes, ongoing specialized assessment of patients with known diabetes and evaluation for complications in patients with newly diagnosed diabetes are important components of care. Parameters that should be regularly assessed are discussed in Chart 41-3.

Chart 41-2 • Criteria for the Diagnosis of Diabetes Mellitus

1. Symptoms of diabetes plus casual plasma glucose concentration equal to or greater than 200 mg/dL (11.1 mmol/L). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
 - or**
 2. Fasting plasma glucose greater than or equal to 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.
 - or**
 3. Two-hour postload glucose equal to or greater than 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.
- In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The third measure is not recommended for routine clinical use.

CHART
41-3

Assessing the Patient With Diabetes

History

- Symptoms related to the diagnosis of diabetes:
 - Symptoms of hyperglycemia
 - Symptoms of hypoglycemia
 - Frequency, timing, severity, and resolution
- Results of blood glucose monitoring
- Status, symptoms, and management of chronic complications of diabetes:
 - Eye; kidney; nerve; genitourinary and sexual, bladder, and gastrointestinal
 - Cardiac; peripheral vascular; foot complications associated with diabetes
- Adherence to/ability to follow prescribed dietary management plan
- Adherence to prescribed exercise regimen
- Adherence to/ability to follow prescribed pharmacologic treatment (insulin or oral antidiabetic agents)
- Use of tobacco, alcohol, and prescribed and over-the-counter medications/drugs
- Lifestyle, cultural, psychosocial, and economic factors that may affect diabetes treatment
- Effects of diabetes or its complications on functional status (eg, mobility, vision)

Physical Examination

- Blood pressure (sitting and standing to detect orthostatic changes)

- Body mass index (height and weight)
- Fundoscopic examination and visual acuity
- Foot examination (lesions, signs of infection, pulses)
- Skin examination (lesions and insulin-injection sites)
- Neurologic examination
 - Vibratory and sensory examination using monofilament
 - Deep tendon reflexes
- Oral examination

Laboratory Examination

- HgbA_{1c} (A1C)
- Fasting lipid profile
- Test for microalbuminuria
- Serum creatinine level
- Urinalysis
- Electrocardiogram

Need for Referrals

- Ophthalmology
- Podiatry
- Dietitian
- Diabetes educator
- Others if indicated

**Gerontologic Considerations**

Elevated blood glucose levels appear to be age related and occur in both men and women throughout the world. Elevated blood glucose levels commonly appear in the fifth decade of life and increase in frequency with advancing age. Approximately 10% to 30% of elderly people have age-related hyperglycemia, not counting those with overt diabetes. What causes age-related changes in carbohydrate metabolism is not known. Possibilities include poor diet, physical inactivity, a decrease in the lean body mass in which ingested carbohydrate may be stored, altered insulin secretion, and increase in fat tissue, which increases insulin resistance (ADA, 2009b).

Medical Management

The main goal of diabetes treatment is to normalize insulin activity and blood glucose levels to reduce the development of vascular and neuropathic complications. The Diabetes Control and Complications Trial (DCCT), a 10-year prospective clinical trial conducted from 1983 to 1993, demonstrated the importance of achieving blood glucose control in the normal, nondiabetic range. This landmark trial demonstrated that intensive glucose control dramatically reduced the development and progression of complications such as **retinopathy**, **nephropathy**, and **neuropathy**. Intensive treatment is defined as three or four insulin injections per day or **continuous subcutaneous insulin infusion**, **insulin pump** therapy plus frequent blood glucose

monitoring and weekly contacts with diabetes educators. The American Diabetes Association now recommends that all patients with diabetes strive for glucose control to reduce their risk of complications (ADA, 2009b).

Intensive therapy must be initiated with caution and must be accompanied by thorough education of the patient and family and by responsible behavior of the patient. Careful screening of patients is a key step in initiating intensive therapy.

A study conducted in the United Kingdom demonstrated a decrease in complications among patients with type 2 diabetes receiving intensive therapy compared to those receiving conventional therapy (United Kingdom Prospective Diabetes Study Group [UKPDS], 1998; see also ADA, 2009b).

The results of the DCCT and UKPDS have been supported by follow-up studies, including the Epidemiology of Diabetes Interventions and Complications (EDIC) study (Nathan, Cleary, Backlund, et al., 2005). Therefore, the therapeutic goal for diabetes management is to achieve normal blood glucose levels (euglycemia) without hypoglycemia while maintaining a high quality of life. Diabetes management has five components: nutritional therapy, exercise, monitoring, pharmacologic therapy, and education. Diabetes management involves constant assessment and modification of the treatment plan by health professionals and daily adjustments in therapy by the patient. Although the health care team directs the treatment, it is the individual patient who must manage the complex therapeutic regimen. For this reason, patient and family education is an

essential component of diabetes treatment and is as important as all other components of the regimen.

Nutritional Therapy

Nutrition, meal planning, and weight control are the foundation of diabetes management. The most important objectives in the dietary and nutritional management of diabetes are control of total caloric intake to attain or maintain a reasonable body weight, control of blood glucose levels, and normalization of lipids and blood pressure to prevent heart disease. Success in this area alone is often associated with reversal of hyperglycemia in type 2 diabetes. However, achieving these goals is not always easy. Because **medical nutrition therapy** (MNT, nutritional management) of diabetes is complex, a registered dietitian who understands diabetes management has the major responsibility for designing and teaching this aspect of the therapeutic plan. Nurses and all other members of the health care team must be knowledgeable about nutritional therapy and supportive of patients who need to implement nutritional and lifestyle changes. Nutritional management of diabetes includes the following goals (ADA, 2008b).

1. To achieve and maintain
 - Blood glucose levels in the normal range or as close to normal as is safely possible
 - A lipid and lipoprotein profile that reduces the risk for vascular disease
 - Blood pressure levels in the normal range or as close to normal as is safely possible
2. To prevent, or at least slow, the rate of development of the chronic complications of diabetes by modifying nutrient intake and lifestyle
3. To address individual nutrition needs, taking into account personal and cultural preferences and willingness to change
4. To maintain the pleasure of eating by only limiting food choices when indicated by scientific evidence.

For obese patients with diabetes (especially those with type 2 diabetes), weight loss is the key to treatment. (It is also a major factor in preventing diabetes.) In general, overweight is considered to be a body mass index (BMI) of 25 to 29; obesity is defined as 20% above ideal body weight or a BMI equal to or greater than 30 (National Institutes of Health, 2000). BMI is a weight-to-height ratio calculated by dividing body weight (in kilograms) by the square of the height (in meters). Calculation of BMI is discussed in Chapter 5. Obese patients who have type 2 diabetes and who require insulin or oral agents to control blood glucose levels may be able to reduce or eliminate the need for medication through weight loss. A weight loss as small as 5% to 10% of total weight may significantly improve blood glucose levels (ADA, 2009b). For obese patients with diabetes who do not take insulin or sulfonylureas, consistent meal content or timing is important but not as critical. Rather, decreasing the overall caloric intake assumes more importance. However, meals should not be skipped. Pacing food intake throughout the day places more manageable demands on the pancreas.

Consistently following a meal plan is one of the most challenging aspects of diabetes management. It may be more realistic to restrict calories only moderately. For pa-

tients who have lost weight, maintaining the weight loss may be difficult. To help these patients incorporate new dietary habits into their lifestyles, diet education, behavioral therapy, group support, and ongoing nutrition counseling are encouraged.

Meal Planning and Related Teaching

The meal plan must consider the patient's food preferences, lifestyle, usual eating times, and ethnic and cultural background. For patients who require insulin to help control blood glucose levels, maintaining as much consistency as possible in the amount of calories and carbohydrates ingested at each meal is essential. In addition, consistency in the approximate time intervals between meals, with the addition of snacks if necessary, helps prevent hypoglycemic reactions and maintain overall blood glucose control. For patients who can master the insulin-to-carbohydrate calculations, lifestyle can be more flexible and diabetes control more predictable. For those using intensive insulin therapy, there may be greater flexibility in the timing and content of meals by allowing adjustments in insulin dosage for changes in eating and exercise habits. Advances in insulin management (new insulin analogues, insulin algorithms, insulin pumps) permit greater flexibility of schedules than was previously possible. This contrasts with the older concept of maintaining a constant dose of insulin, which required strict scheduling of meals to match the actions and duration of the insulin.

The first step in preparing a meal plan is a thorough review of the patient's diet history to identify his or her eating habits and lifestyle. This includes a thorough assessment of the patient's need for weight loss, gain, or maintenance. In most instances, people with type 2 diabetes require weight reduction.

In teaching about meal planning, clinical dietitians use various educational tools, materials, and approaches. Initial education addresses the importance of consistent eating habits, the relationship of food and insulin, and the provision of an individualized meal plan. In-depth follow-up education then focuses on management skills, such as eating at restaurants, reading food labels, and adjusting the meal plan for exercise, illness, and special occasions. The nurse plays an important role in communicating pertinent information to the dietitian and reinforcing the patient's understanding.

Certain aspects of meal planning, such as the food exchange system, may be difficult to learn. This may be related to limitations in the patient's intellectual level or to emotional issues, such as difficulty accepting the diagnosis of diabetes or feelings of deprivation and undue restriction in eating. In any case, it helps to emphasize that using the exchange system (or any food classification system) provides a new way of thinking about food rather than a new way of eating. It is also important to simplify information as much as possible and to provide opportunities for the patient to practice and repeat activities and information.

Caloric Requirements. Calorie-controlled diets are planned by first calculating a person's energy needs and caloric requirements based on age, gender, height, and weight. An activity element is then factored in to provide

the actual number of calories required for weight maintenance. To promote a 1- to 2-pound weight loss per week, 500 to 1000 calories are subtracted from the daily total. The calories are distributed into carbohydrates, proteins, and fats, and a meal plan is then developed, taking into account the patient's lifestyle and food preferences.

In contrast to the priority for the obese person with type 2 diabetes, the priority for a young patient with type 1 diabetes should be a diet with enough calories to maintain normal growth and development. Some patients may be underweight at the onset of type 1 diabetes because of rapid weight loss from severe hyperglycemia. The goal initially may be to provide a higher-calorie diet to regain lost weight and blood glucose control.

Caloric Distribution. A meal plan for diabetes focuses on the percentages of calories that come from carbohydrates, proteins, and fats.

Carbohydrates. The caloric distribution currently recommended is higher in carbohydrates than in fat and protein. In general, carbohydrate foods have the greatest effect on blood glucose levels because they are more quickly digested than other foods and are converted into glucose rapidly. However, research into the appropriateness of a higher-carbohydrate diet in patients with decreased glucose tolerance is ongoing, and recommendations may change accordingly. Currently, the ADA and the American Dietetic Association recommend that for all levels of caloric intake, 50% to 60% of calories should be derived from carbohydrates, 20% to 30% from fat, and the remaining 10% to 20% from protein. The majority of the selections for carbohydrates should come from whole grains. These recommendations are also consistent with those of the American Heart Association and American Cancer Society.

Carbohydrates consist of sugars (eg, sucrose) and starches (eg, rice, pasta, bread). Low glycemic index diets (described later) may reduce postprandial glucose levels. Therefore, the nutrition guidelines recommend that all carbohydrates should be eaten in moderation to avoid high postprandial blood glucose levels (ADA, 2008b).

Foods high in carbohydrates, such as sucrose (concentrated sweets), are not totally eliminated from the diet but should be eaten in moderation (up to 10% of total calories), because they are typically high in fat and lack vitamins, minerals, and fiber.

Fats. The recommendations regarding fat content of the diabetic diet include both reducing the total percentage of calories from fat sources to less than 30% of total calories and limiting the amount of saturated fats to 10% of total calories. Additional recommendations include limiting the total intake of dietary cholesterol to less than 300 mg/day. This approach may help reduce risk factors such as increased serum cholesterol levels, which are associated with the development of coronary artery disease, the leading cause of death and disability among people with diabetes (ADA, 2008c).

Protein. The meal plan may include the use of some nonanimal sources of protein (eg, legumes, whole grains), to help reduce saturated fat and cholesterol intake. In addition, the amount of protein intake may be reduced in patients with early signs of renal disease.

Fiber. Increased fiber in the diet may improve blood glucose levels, decrease the need for exogenous insulin, and lower total cholesterol and low-density lipoprotein levels in the blood (ADA, 2008b).

There are two types of dietary fibers: soluble and insoluble. Soluble fiber—in foods such as legumes, oats, and some fruits—plays more of a role in lowering blood glucose and lipid levels than does insoluble fiber, although the clinical significance of this effect is probably small (ADA, 2008b). Soluble fiber slows stomach emptying and the movement of food through the upper digestive tract. The potential glucose-lowering effect of fiber may be caused by the slower rate of glucose absorption from foods that contain soluble fiber. Insoluble fiber is found in whole-grain breads and cereals and in some vegetables. This type of fiber along with soluble fiber increases satiety, which is helpful for weight loss. At least 25 g of fiber should be ingested daily.

One risk involved in suddenly increasing fiber intake is that it may require adjusting the dosage of insulin or oral agents to prevent hypoglycemia. Other problems may include abdominal fullness, nausea, diarrhea, increased flatulence, and constipation if fluid intake is inadequate. If fiber is added to or increased in the meal plan, it should be done gradually and in consultation with a dietitian. The exchange lists (ADA, 2008b) serve as an excellent guide for increasing fiber intake. Fiber-rich food choices within the vegetable, fruit, and starch/bread exchanges are highlighted in the lists.

Food Classification Systems. To teach diet principles and to help in meal planning, several systems have been developed in which foods are organized into groups with common characteristics, such as number of calories, composition of foods (ie, amount of protein, fat, or carbohydrate in the food), or effect on blood glucose levels. Several of these are listed here.

Exchange Lists. A commonly used tool for nutritional management is the exchange lists for meal planning (ADA, 2008b). There are six main exchange lists: bread/starch, vegetable, milk, meat, fruit, and fat. Foods within one group (in the portion amounts specified) contain equal numbers of calories and are approximately equal in grams of protein, fat, and carbohydrate. Meal plans can be based on a recommended number of choices from each exchange list. Foods on one list may be interchanged with one another, allowing for variety while maintaining as much consistency as possible in the nutrient content of foods eaten. Table 41-2 presents three sample lunch menus that are interchangeable in terms of carbohydrate, protein, and fat content.

Exchange list information on combination foods such as pizza, chili, and casseroles, as well as convenience foods, desserts, snack foods, and fast foods, is available from the American Diabetes Association (see Resources). Some food manufacturers and restaurants publish exchange lists that describe their products.

Nutrition Labels. Food manufacturers are required to have the nutrition content of foods listed on package labels, and reading food labels is an important skill for patients to learn and use when food shopping. The label includes information about how many grams of carbohydrate are in a serving

Table 41-2 SELECTED SAMPLE MENUS FROM EXCHANGE LISTS

Exchanges	Sample Lunch #1	Sample Lunch #2	Sample Lunch #3
2 starch	2 slices bread	Hamburger bun	1 cup cooked pasta
3 meat	2 oz sliced turkey and 1 oz lowfat cheese	3 oz lean beef patty	3 oz boiled shrimp
1 vegetable	Lettuce, tomato, onion	Green salad	½ cup plum tomatoes
1 fat	1 tsp mayonnaise	1 tbsp salad dressing	1 tsp olive oil
1 fruit	1 medium apple	1¼ cup watermelon	1¼ cup fresh strawberries
“Free” items (optional)	Unsweetened iced tea	Diet soda	Ice water with lemon
	Mustard, pickle, hot pepper	1 tbsp catsup, pickle, onions	Garlic, basil

of food. This information can be used to determine how much medication is needed. For example, a patient who takes premeal insulin may use the algorithm, 1 unit of insulin for 15 g of carbohydrate. Patients can also be taught to have a “carbohydrate budget” per meal (eg, 45 to 60 g).

Carbohydrate counting is a nutritional tool used for blood glucose management because carbohydrates are the main nutrients in food that influence blood glucose levels. This method provides flexibility in food choices, can be less complicated to understand than the diabetic food exchange list, and allows more accurate management with multiple daily injections (insulin before each meal). However, if carbohydrate counting is not used with other meal-planning techniques, weight gain can result. A variety of methods are used to count carbohydrates. When developing a diabetic meal plan using carbohydrate counting, all food sources should be considered.

Once digested, 100% of carbohydrates are converted to glucose. Approximately 50% of protein foods (meat, fish, and poultry) are also converted to glucose, but this has minimal effect on blood glucose levels.

Carbohydrate counting consists of counting grams of carbohydrates. If target goals are not reached by counting carbohydrates alone, protein is factored into the calculations. This is especially true if the meal consists only of meat, fish, and nonstarchy vegetables.

Although carbohydrate counting is now commonly used for blood glucose management with type 1 and type 2 diabetes, it is not a perfect system. All carbohydrates affect the blood glucose level to different degrees, regardless of equivalent serving size. When carbohydrate counting is used, reading labels on food items is the key to success. Knowing what the “carbohydrate budget” for the meal is and knowing how many grams of carbohydrate are in a serving of a food, the patient can calculate the amount in one serving.

Healthy Food Choices. An alternative to counting grams of carbohydrate is measuring servings or choices. This method is used more often by people with type 2 diabetes. It is similar to the food exchange list and emphasizes portion control of total servings of carbohydrate at meals and snacks. One carbohydrate serving is equivalent to 15 g of carbohydrate. Examples of one serving are an apple 2 inches in diameter and one slice of bread. Vegetables and meat are counted as one third of a carbohydrate serving. This system works well for those who have difficulty with the other complicated systems.

Food Guide Pyramid. The Food Guide Pyramid (ie, MyPyramid) is another tool used to develop meal plans. It

is commonly used for patients with type 2 diabetes who have a difficult time following a calorie-controlled diet. The 2005 food pyramid consists of the following food groups: (1) grains, (2) vegetables, (3) fruits, (4) milk and other dairy products, and (5) meats and beans. Oils and other high-fat foods comprise another food group on the pyramid (see Chapter 5). Foods (starches, fruits, and vegetables) that are lowest in calories and fat and highest in fiber should make up the basis of the diet. For those with diabetes, as well as for the general population, 50% to 60% of the daily caloric intake should be from these three groups. Foods higher in fat (particularly saturated fat) should account for a smaller percentage of the daily caloric intake. Fats, oils, and sweets should be used sparingly to obtain weight and blood glucose control and to reduce the risk for cardiovascular disease. Reliance on the MyPyramid may result in fluctuations in blood glucose levels, however, because high-carbohydrate foods may be grouped with low-carbohydrate foods. The pyramid is appropriately used only as a first-step teaching tool for patients who are learning how to control food portions and how to identify which foods contain carbohydrate, protein, and fat.

Glycemic Index. One of the main goals of diet therapy in diabetes is to avoid sharp, rapid increases in blood glucose levels after food is eaten. The term glycemic index is used to describe how much a given food increases the blood glucose level compared with an equivalent amount of glucose. The effects of use of the glycemic index on blood glucose levels and on long-term patient outcomes are unclear, but it may be beneficial (ADA, 2008b). Although more research is necessary, the following guidelines may be helpful when making dietary recommendations:

- Combining starchy foods with protein-containing and fat-containing foods tends to slow their absorption and lower the glycemic response.
- In general, eating foods that are raw and whole results in a lower glycemic response than eating chopped, puréed, or cooked foods.
- Eating whole fruit instead of drinking juice decreases the glycemic response, because fiber in the fruit slows absorption.
- Adding foods with sugars to the diet may result in a lower glycemic response if these foods are eaten with foods that are more slowly absorbed.

Patients can create their own glycemic index by monitoring their blood glucose level after ingestion of a particular food. This can help improve blood glucose control through individualized manipulation of the diet. Many

patients who use frequent monitoring of blood glucose levels can use this information to adjust their insulin doses in accordance with variations in food intake.

Other Dietary Concerns

Alcohol Consumption. Patients with diabetes do not need to give up alcoholic beverages entirely, but they and health care professionals must be aware of the potential adverse effects of alcohol specific to diabetes. Alcohol is absorbed before other nutrients and does not require insulin for absorption. Large amounts can be converted to fats, increasing the risk for DKA. In general, the same precautions regarding the use of alcohol by people without diabetes should be applied to patients with diabetes. Moderation is recommended. A major danger of alcohol consumption by the patient with diabetes is hypoglycemia, especially for patients who take insulin or insulin secretagogues (medications that increase the secretion of insulin by the pancreas). Alcohol may decrease the normal physiologic reactions in the body that produce glucose (gluconeogenesis). Therefore, if a patient with diabetes consumes alcohol on an empty stomach, there is an increased likelihood of hypoglycemia. In addition, excessive alcohol intake may impair the patient's ability to recognize and treat hypoglycemia or to follow a prescribed meal plan to prevent hypoglycemia. To reduce the risk of hypoglycemia, the patient should be cautioned to consume food along with the alcohol; however, carbohydrate consumed with alcohol may raise blood glucose (ADA, 2008b).

Alcohol consumption may lead to excessive weight gain (from the high caloric content of alcohol), hyperlipidemia, and elevated glucose levels (especially with mixed drinks and liqueurs). Patient teaching regarding alcohol intake must emphasize moderation in the amount of alcohol consumed. Moderate intake is considered to be one alcoholic beverage per day for women and two per day for men. Lower-calorie or less sweet drinks (eg, light beer, dry wine) and food intake along with alcohol consumption are advised. Especially for patients with type 2 diabetes who wish to control their weight, it is important to incorporate the calories from alcohol into the overall meal plan.

Sweeteners. Use of artificial sweeteners is acceptable, especially if it assists in overall dietary adherence. Moderation in the amount of sweetener used is encouraged to avoid potential adverse effects. There are two main types of sweeteners: nutritive and nonnutritive. The nutritive sweeteners contain calories, and the nonnutritive sweeteners have few or no calories in the amounts normally used.

Nutritive sweeteners include fructose (fruit sugar), sorbitol, and xylitol, all of which provide calories in amounts similar to those in sucrose (table sugar). They cause less elevation in blood sugar levels than sucrose does and are often used in "sugar-free" foods. Sweeteners containing sorbitol may have a laxative effect.

Nonnutritive sweeteners have minimal or no calories. They are used in food products and are also available for table use. They produce minimal or no elevation in blood glucose levels and have been approved by the U.S. Food and Drug Administration (FDA) as safe for people with diabetes. Nonnutritive sweeteners include saccharin, aspar-

tame (NutraSweet), acesulfame-K (Sunette), and sucralose (Splenda) (ADA, 2009b).

Misleading Food Labels. Foods labeled "sugarless" or "sugar-free" may still provide calories equal to those of the equivalent sugar-containing products if they are made with nutritive sweeteners. Therefore, these foods should not be considered "free" foods to be eaten in unlimited quantity, because they can elevate blood glucose levels. Foods labeled "dietetic" are not necessarily reduced-calorie foods. Patients are advised that foods labeled "dietetic" may still contain significant amounts of sugar or fat.

It is important that patients read the labels of "health foods"—especially snacks—because they often contain carbohydrates (eg, honey, brown sugar, corn syrup) and saturated vegetable fats (eg, coconut or palm oil), hydrogenated vegetable fats, or animal fats, which may be contraindicated in people with elevated blood lipid levels.

Exercise

Exercise is extremely important in diabetes management because of its effects on lowering blood glucose and reducing cardiovascular risk factors. Exercise lowers blood glucose levels by increasing the uptake of glucose by body muscles and by improving insulin utilization. It also improves circulation and muscle tone. Resistance (strength) training, such as weight lifting, can increase lean muscle mass, thereby increasing the resting metabolic rate. These effects are useful in diabetes in relation to losing weight, easing stress, and maintaining a feeling of well-being. Exercise also alters blood lipid concentrations, increasing levels of high-density lipoproteins and decreasing total cholesterol and triglyceride levels. This is especially important for people with diabetes because of their increased risk of cardiovascular disease (Nathan, et al., 2005).

Exercise Recommendations

Ideally, a person with diabetes should exercise at the same time (preferably when blood glucose levels are at their peak) and in the same amount each day. Regular daily exercise, rather than sporadic exercise, should be encouraged. Exercise recommendations must be altered as necessary for patients with diabetic complications such as retinopathy, autonomic neuropathy, sensorimotor neuropathy, and cardiovascular disease (ADA, 2009b). Increased blood pressure associated with exercise may aggravate diabetic retinopathy and increase the risk of a hemorrhage into the vitreous or retina. Patients with ischemic heart disease risk triggering angina or a myocardial infarction, which may be silent. Avoiding trauma to the lower extremities is especially important in patients with numbness related to neuropathy.

In general, a slow, gradual increase in the exercise period is encouraged. For many patients, walking is a safe and beneficial form of exercise that requires no special equipment (except for proper shoes) and can be performed anywhere. People with diabetes should discuss an exercise program with their health care providers and undergo a careful medical evaluation with appropriate diagnostic studies before beginning program (ADA, 2009b).

For patients who are older than 30 years and who have two or more risk factors for heart disease, an exercise stress

test is recommended. Risk factors for heart disease include hypertension, obesity, high cholesterol levels, abnormal resting electrocardiogram (ECG), sedentary lifestyle, smoking, male gender, and a family history of heart disease. An abnormal stress test may indicate cardiac ischemia. Typically, an abnormal stress test is followed up with a cardiac catheterization and, in some cases, with an intervention such as angioplasty, stent replacement, or cardiac surgery.

Exercise Precautions

Patients who have blood glucose levels exceeding 250 mg/dL (14 mmol/L) and who have ketones in their urine should not begin exercising until the urine test results are negative for ketones and the blood glucose level is closer to normal. Exercising with elevated blood glucose levels increases the secretion of glucagon, growth hormone, and catecholamines. The liver then releases more glucose, and the result is an increase in the blood glucose level (ADA, 2009b).

The physiologic decrease in circulating insulin that normally occurs with exercise cannot occur in patients treated with insulin. Initially, patients who require insulin should be taught to eat a 15-g carbohydrate snack (a fruit exchange) or a snack of complex carbohydrates with a protein before engaging in moderate exercise to prevent unexpected hypoglycemia. The exact amount of food needed varies from person to person and should be determined by blood glucose monitoring.

Another potential concern for patients who take insulin is hypoglycemia that occurs many hours after exercise. To avoid postexercise hypoglycemia, especially after strenuous or prolonged exercise, the patient may need to eat a snack at the end of the exercise session and at bedtime and monitor the blood glucose level more frequently. Patients who are capable, knowledgeable, and responsible can learn to adjust their own insulin doses by working closely with a diabetes educator. Others need specific instructions on what to do when they exercise.

Patients taking insulin and participating in extended periods of exercise should test their blood glucose levels before, during, and after the exercise period, and they should snack on carbohydrates as needed to maintain blood glucose levels (ADA, 2006a). Other participants or observers should be aware that the person exercising has diabetes, and they should know what assistance to give if severe hypoglycemia occurs.

In obese people with type 2 diabetes, exercise in addition to dietary management both improves glucose metabolism and enhances loss of body fat. Exercise coupled with weight loss improves insulin sensitivity and may decrease the need for insulin or oral antidiabetic agents (ADA, 2006a). Eventually, the patient's glucose tolerance may return to normal. Patients with type 2 diabetes who are not taking insulin or an oral agent may not need extra food before exercise.

General precautions for exercise in diabetes are presented in Chart 41-4.

Gerontologic Considerations

Physical activity that is consistent and realistic is beneficial to elderly people with diabetes. Physical fitness in the elderly population with diabetes may lead to improved

CHART
41-4

PATIENT EDUCATION

General Precautions for Exercise in People With Diabetes

- Use proper footwear and, if appropriate, other protective equipment.
- Avoid exercise in extreme heat or cold.
- Inspect feet daily after exercise.
- Avoid exercise during periods of poor metabolic control.

glycemic control, decreased risk for chronic vascular disease, and an improved quality of life (ADA, 2006a). Advantages of exercise in this population include a decrease in hyperglycemia, a general sense of well-being, and better use of ingested calories, resulting in weight reduction. Because there is an increased incidence of cardiovascular problems in the elderly, a physical examination and exercise stress test may be warranted before an exercise program is initiated. A pattern of gradual, consistent exercise, including resistance exercise, should be planned that does not exceed the patient's physical capacity. Physical impairment due to other chronic diseases must also be considered. In some cases, a physical therapy evaluation may be indicated, with the goal of determining exercises specific to the patient's needs and abilities. Tools such as the "Armchair Fitness" video may be helpful. For more information about age-related changes that affect diabetes management, see Chart 41-5.

Monitoring Glucose Levels and Ketones

Blood glucose monitoring is a cornerstone of diabetes management, and **self-monitoring of blood glucose (SMBG)** levels has dramatically altered diabetes care.

Self-Monitoring of Blood Glucose

Using frequent SMBG and learning how to respond to the results enable people with diabetes to adjust their treatment regimen to obtain optimal blood glucose control. This allows for detection and prevention of hypoglycemia and hyperglycemia and plays a crucial role in normalizing blood glucose levels, which in turn may reduce the risk of long-term diabetic complications.

Various methods for SMBG are available. Most involve obtaining a drop of blood from the fingertip, applying the blood to a special reagent strip, and allowing the blood to stay on the strip for the amount of time specified by the manufacturer (usually 5 to 30 seconds). The meter gives a digital readout of the blood glucose value. The meters available for SMBG offer various features and benefits such as monthly averages, tracking of events like exercise and food consumption, and downloading capacity. Some meters are biosensors that can use blood obtained from alternative test sites, such as the forearm. They have a special lancing device that is useful for patients who have painful fingertips or experience pain with fingersticks.

Because laboratory methods measure plasma glucose, most blood glucose monitors approved for patients' use in the home and some test strips calibrate blood glucose readings to plasma values. Plasma glucose values are 10% to 15% higher than whole blood glucose values, and it is

CHART

41-5

GERONTOLOGIC CONSIDERATIONS

Age-Related Changes That May Affect Diabetes and Its Management

Sensory Changes

Decreased vision
Decreased smell
Taste changes
Decreased proprioception
Diminished thirst

Gastrointestinal Changes

Dental problems
Appetite changes
Delayed gastric emptying
Decreased bowel motility

Activity/exercise Pattern Changes

More sedentary

Renal Function Changes

Decreased function
Decreased drug clearance

Affective/cognitive Changes

Medications/meals omitted or taken erratically

Socioeconomic Factors

Fad diets
Loneliness/living alone
Lack of money/lack of support system

Chronic Diseases

Hypertension
Arthritis
Neoplasms
Acute/chronic infections

Potential Drug Interactions

Use of another person's medications
Consulting multiple physicians for different illnesses
Alcohol use/abuse

crucial for patients with diabetes to know whether their monitor and strips provide whole blood or plasma results.

Methods for SMBG must match the skill level of patients. Factors affecting SMBG performance include visual acuity, fine motor coordination, cognitive ability, comfort with technology and willingness to use it, and cost. Some meters can be used by patients with visual impairments that have audio components to assist in performing the test and obtaining the result. In addition, meters are available to check both blood glucose and blood ketone levels by those who are particularly susceptible to DKA. Most insurance companies cover some or all of the costs of meters and strips.

A potential hazard of all methods of SMBG is that the patient may obtain and report erroneous blood glucose values as a result of using incorrect techniques. Some common sources of error include improper application of blood (eg, drop too small), damage to the reagent strips caused by heat or humidity, use of outdated strips, and improper meter cleaning and maintenance.

Nurses play an important role in providing initial teaching about SMBG techniques. Equally important is evaluating the techniques of patients who are experienced in self-monitoring. Every 6 to 12 months, patients should conduct a comparison of their meter result with a simultaneous laboratory-measured blood glucose level in their physician's office and have their technique observed. The accuracy of the meter and strips can also be assessed with control solutions specific to that meter whenever a new vial of strips is used and whenever the validity of the reading is in doubt.

Candidates for Self-Monitoring of Blood Glucose. SMBG is a useful tool for managing self-care for everyone with diabetes. It is a key component of treatment for any intensive insulin therapy regimen (ie, two to four injections per day or use of an insulin pump) and for diabetes management during pregnancy. It is also recommended for patients with the following conditions:

- Unstable diabetes (severe swings from very high to very low blood glucose levels within a 24-hour day)
- A tendency to develop severe ketosis or hypoglycemia
- Hypoglycemia without warning symptoms

For patients not taking insulin, SMBG is helpful for monitoring the effectiveness of exercise, diet, and oral antidiabetic agents. It can also help motivate patients to continue with treatment. For patients with type 2 diabetes, SMBG is recommended during periods of suspected hyperglycemia (eg, illness) or hypoglycemia (eg, unusual increased activity levels) and when the medication or dosage of medication is modified (ADA, 2009b).

Frequency of Self-Monitoring of Blood Glucose. For most patients who require insulin, SMBG is recommended two to four times daily (usually before meals and at bedtime). For patients who take insulin before each meal, SMBG is required at least three times daily before meals to determine each dose (ADA, 2009b). Those not receiving insulin may be instructed to assess their blood glucose levels at least two or three times per week, including a 2-hour postprandial test. For all patients, testing is recommended whenever hypoglycemia or hyperglycemia is suspected, with changes in medications, activity, or diet, and with stress or illness.

Responding to Self-Monitoring of Blood Glucose Results. Patients are asked to keep a record or logbook of blood glucose levels so that they can detect patterns. Testing is done at the peak action time of the medication to evaluate the need for dosage adjustments. To evaluate basal insulin and determine bolus insulin doses, testing is performed before meals. To determine bolus doses of regular or rapid-acting insulin (lispro [Humalog], aspart [Novolog], or glulisine [Apidra]), testing is done 2 hours after meals. Patients with type 2 diabetes are encouraged to test daily before and 2 hours after the largest meal of the day until stabilized. Thereafter, testing should be done periodically before and after meals. Patients who take insulin at bedtime or who use an insulin infusion pump should also test at 3 AM once a

week to document that the blood glucose level is not decreasing during the night. If the patient is unwilling or cannot afford to test frequently, then once or twice a day may be sufficient if the time of testing is varied (eg, before breakfast one day and before lunch the next day).

A tendency to discontinue SMBG is more likely to occur if the patient does not receive instruction about using the results to alter the treatment regimen, if positive reinforcement is not given, and if costs of testing increase. At the very least, the patient should be given parameters for contacting the physician. Patients using intensive insulin therapy regimens may be instructed in the use of algorithms (rules or decision trees) for changing the insulin doses based on patterns of values greater or less than the target range and the amount of carbohydrate to be consumed. Baseline patterns should be established by SMBG for 1 to 2 weeks.

Using a Continuous Glucose Monitoring System

A **continuous glucose monitoring system (CGMS)** can be used to continuously monitor blood glucose levels (Fig. 41-2). A sensor attached to an infusion set, which is similar to an insulin pump infusion set, is inserted subcutaneously in the abdomen and connected to the device worn on a belt. After 72 hours, the data from the device are downloaded, and blood glucose readings are analyzed. Although the CGMS cannot be used for making decisions about specific insulin doses, it can be used to determine whether treatment is adequate over a 24-hour period. This device will be refined in the future so that it can be used by patients to make daily treatment decisions.

Testing for Glycated Hemoglobin

Glycated hemoglobin (also referred to as **glycosylated hemoglobin, HgbA_{1C}, or A1C**) is a blood test that reflects average blood glucose levels over a period of approximately

Figure 41-2 MiniMed CGMS System Gold Continuous Glucose Monitoring System. (Courtesy of Medtronic Diabetes.)

2 to 3 months (ADA, 2009b). When blood glucose levels are elevated, glucose molecules attach to hemoglobin in red blood cells. The longer the amount of glucose in the blood remains above normal, the more glucose binds to hemoglobin and the higher the glycated hemoglobin level becomes. This complex (hemoglobin attached to the glucose) is permanent and lasts for the life of an individual red blood cell, approximately 120 days. If near-normal blood glucose levels are maintained, with only occasional increases, the overall value will not be greatly elevated. However, if the blood glucose values are consistently high, then the test result is also elevated. If the patient reports mostly normal SMBG results but the glycated hemoglobin is high, there may be errors in the methods used for glucose monitoring, errors in recording results, or frequent elevations in glucose levels at times during the day when the patient is not usually monitoring blood sugar levels. Normal values typically range from 4% to 6% and indicate consistently near-normal blood glucose concentrations. The target range for people with diabetes is less than 7% (ADA, 2009b).

Testing for Ketones

Ketones (or ketone bodies) are byproducts of fat breakdown, and they accumulate in the blood and urine. Ketones in the urine signal that there is a deficiency of insulin and control of type 1 diabetes is deteriorating. The risk of DKA is high. When there is almost no effective insulin available, the body starts to break down stored fat for energy. Urine testing is the most common method used for self-testing of ketone bodies by patients. A meter that enables testing of blood for ketones is available.

Most commonly, the patient uses a urine dipstick (Ketostix or Chemstrip uK) to detect ketonuria. The reagent pad on the strip turns purple when ketones are present. (One of the ketone bodies is called acetone, and this term is frequently used interchangeably with the term ketones.) Other strips are available for measuring both urine glucose and ketones (Keto-Diastix or Chemstrip uGK). Large amounts of ketones may depress the color response of the glucose test area.

Urine ketone testing should be performed whenever patients with type 1 diabetes have glycosuria or persistently elevated blood glucose levels (more than 240 mg/dL or 13.2 mmol/L for two testing periods in a row) and during illness, in pregnancy with preexisting diabetes, and in gestational diabetes (ADA, 2009b).

Pharmacologic Therapy

As previously stated, insulin is secreted by the beta cells of the islets of Langerhans and works to lower the blood glucose level after meals by facilitating the uptake and utilization of glucose by muscle, fat, and liver cells. In the absence of adequate insulin, pharmacologic therapy is essential.

Insulin Therapy

In type 1 diabetes, exogenous insulin must be administered for life because the body loses the ability to produce insulin. In type 2 diabetes, insulin may be necessary on a long-term basis to control glucose levels if meal planning and oral agents are ineffective. In addition, some patients in whom type 2 diabetes is usually controlled by meal planning alone

or by meal planning and an oral antidiabetic agent may require insulin temporarily during illness, infection, pregnancy, surgery, or some other stressful event. In many cases, insulin injections are administered two or more times daily to control the blood glucose level. Because the insulin dose required by the individual patient is determined by the level of glucose in the blood, accurate monitoring of blood glucose levels is essential; thus, SMBG is a cornerstone of insulin therapy.

Preparations. A number of insulin preparations are available. They vary according to three main characteristics: time course of action, species (source), and manufacturer.

Time Course of Action. Insulins may be grouped into several categories based on the onset, peak, and duration of action (Table 41-3). Human insulin preparations have a shorter duration of action than insulin from animal sources because the presence of animal proteins triggers an immune response that results in the binding of animal insulin, which slows its availability.

Rapid-acting insulins produce a more rapid effect that is of shorter duration than regular insulin. Because of their rapid onset, the patient should be instructed to eat no more than 5 to 15 minutes after injection. Because of the short duration of action of these insulin analogues, patients with type 1 diabetes and some patients with type 2 or gestational diabetes also require a long-acting insulin (basal insulin) to maintain glucose control. Basal insulin is necessary to maintain blood glucose levels irrespective of meals. A constant level of insulin is required at all times. Intermediate-acting insulins function as basal insulins but may have to be split into two injections to achieve 24-hour coverage.

Short-acting insulins are called regular insulin (marked R on the bottle). Regular insulin is a clear solution and is usually administered 20 to 30 minutes before a meal, either alone or in combination with a longer-acting insulin. Regular insulin is the only insulin approved for IV use.

Intermediate-acting insulins are called NPH insulin (neutral protamine Hagedorn) or Lente insulin. Intermediate-acting insulins, which are similar in their time course of

action, appear white and cloudy. If NPH or Lente insulin is taken alone, it is not crucial that it be taken 30 minutes before the meal. However, it is important that patients eat some food around the time of the onset and peak of these insulins.

“Peakless” basal or very long-acting insulins are approved by the FDA for use as a basal insulin—that is, the insulin is absorbed very slowly over 24 hours and can be given once a day. Because the insulin is in a suspension with a pH of 4, it cannot be mixed with other insulins because this would cause precipitation. It was originally approved to be given once a day at bedtime; however, it has now been approved to be given once a day at any time of the day but must be given at the same time each day to prevent overlap of action. Many patients fall asleep, forgetting to take their bedtime insulin or may be wary of taking insulin before going to sleep. Having these patients take their insulin in the morning ensures that the dose is taken.

NURSING ALERT

When administering insulin, it is very important to read the label carefully and to be sure that the correct type of insulin is administered. It is also important to avoid mistaking Lantus insulin for Lente insulin and vice versa.

The nurse should emphasize which meals—and snacks—are being “covered” by which insulin doses. In general, the rapid-acting and short-acting insulins are expected to cover the increase in glucose levels after meals, immediately after the injection; the intermediate-acting insulins are expected to cover subsequent meals; and the long-acting insulins provide a relatively constant level of insulin and act as a basal insulin.

Species (Source). In the past, all insulins were obtained from beef (cow) and pork (pig) pancreases. Human insulins are now widely available. They are produced by recombinant

Time Course	Agent	Onset	Peak	Duration	Indications
Rapid-acting	Lispro (Humalog)	10–15 min	1 h	2–4 h	Used for rapid reduction of glucose level, to treat postprandial hyperglycemia, and/or to prevent nocturnal hypoglycemia
	Aspart (Novolog)	5–15 min	40–50 min	2–4 h	
	Glulisine (Apidra)	5–15 min	30–60 min	2 h	
Short-acting	Regular (Humalog R, Novolin R, Iletin II Regular)	½–1 h	2–3 h	4–6 h	Usually administered 20–30 min before a meal; may be taken alone or in combination with longer-acting insulin
Intermediate-acting	NPH (neutral protamine Hagedorn)	2–4 h	4–12 h	16–20 h	Usually taken after food
	(Humulin N, Iletin II Lente, Iletin II NPH, Novolin L [Lente], Novolin N [NPH])	3–4 h	4–12 h	16–20 h	
Very long-acting	Glargine (Lantus) Detemir (Levemir)	1 h	Continuous (no peak)	24 h	Used for basal dose

DNA technology and have largely replaced insulin from animal sources. These insulins are preferable to animal source insulins because they are not antigenic and do not depend on sufficient animal sources. Human insulin preparations have a shorter duration of action than insulin from animal sources because the presence of animal proteins triggers an immune response that results in the binding of animal insulin, which slows its availability.

Insulin Regimens. Insulin regimens vary from one to four injections per day. Usually there is a combination of a short-acting insulin and a longer-acting insulin. The normally functioning pancreas continuously secretes small amounts of insulin during the day and night. In addition, whenever blood glucose increases after ingestion of food, there is a rapid burst of insulin secretion in proportion to the glucose-raising effect of the food. The goal of all but the simplest, one-injection insulin regimens is to mimic this normal pattern of insulin secretion in response to food intake and activity patterns. Table 41-4 describes several insulin regimens and the advantages and disadvantages of each.

There are two general approaches to insulin therapy: conventional and intensive (described in detail below). The patient can learn to use SMBG results and carbohydrate counting to vary the insulin doses. This allows more flexibility in timing and content of meals and exercise periods. However, complex insulin regimens require a strong level of commitment, intensive education, and close follow-up by the health care team.

The patient should be very involved in the decision regarding which insulin regimen to use. The patient should compare the potential benefits of different regimens with the potential costs (eg, time involved, number of injections or fingersticks for glucose testing, amount of record keeping). There are no set guidelines as to which insulin regimen should be used for which patient. It must not be assumed that elderly patients should automatically be given a simplified regimen. Likewise, it must not be assumed that all people want to be involved in a complex treatment regimen. The nurse plays an important role in educating the patient about the various approaches to insulin therapy. The nurse should refer the patient to a diabetes specialist or a diabetes education center, if available, for further training and education in the insulin treatment regimens.

Conventional Regimen. One approach is to simplify the insulin regimen as much as possible, with the aim of avoiding the acute complications of diabetes (hypoglycemia and symptomatic hyperglycemia). With this type of simplified regimen (eg, one or more injections of a mixture of short-acting and intermediate-acting insulins per day), the patient should not vary meal patterns and activity levels. The simplified regimen would be appropriate for the terminally ill, the frail elderly with limited self-care abilities, or patients who are completely unwilling or unable to engage in the self-management activities that are part of a more complex insulin regimen.

Intensive Regimen. The second approach is to use a more complex insulin regimen to achieve as much control over blood glucose levels as is safe and practical. A more complex insulin regimen allows the patient more flexibility to

change the insulin doses from day to day in accordance with changes in eating and activity patterns, with stress and illness, and as needed for variations in the prevailing glucose level.

Although the DCCT Research Group (1993) found that intensive treatment (three or four injections of insulin per day) reduced the risk of complications, not all people with diabetes are candidates for very tight control of blood glucose. The DCCT also found that the risk of severe hypoglycemia was increased threefold in patients receiving intensive treatment (ADA, 2009b). Patients who have received a kidney transplant because of nephropathy and chronic renal failure should follow an intensive insulin regimen to preserve function of the new kidney.

Those who are not candidates include those with:

- Nervous system disorders rendering them unaware of hypoglycemic episodes (eg, those with autonomic neuropathy)
- Recurring severe hypoglycemia
- Irreversible diabetic complications, such as blindness or end-stage renal disease
- Cerebrovascular or cardiovascular disease
- Ineffective self-care skills

Complications of Insulin Therapy

Local Allergic Reactions. A local allergic reaction (redness, swelling, tenderness, and induration or a 2- to 4-cm wheal) may appear at the injection site 1 to 2 hours after the insulin administration. These reactions, which usually occur during the beginning stages of therapy and disappear with continued use of insulin, are becoming rare because of the increased use of human insulins. The physician may prescribe an antihistamine to be taken 1 hour before the injection if such a local reaction occurs.

Systemic Allergic Reactions. Systemic allergic reactions to insulin are rare. When they do occur, there is an immediate local skin reaction that gradually spreads into generalized urticaria (hives). These rare reactions are occasionally associated with generalized edema or anaphylaxis. The treatment is desensitization, with small doses of insulin administered in gradually increasing amounts using a desensitization kit.

Insulin Lipodystrophy. Lipodystrophy refers to a localized reaction, in the form of either lipoatrophy or lipohypertrophy, occurring at the site of insulin injections. Lipoatrophy is loss of subcutaneous fat; it appears as slight dimpling or more serious pitting of subcutaneous fat. The use of human insulin has almost eliminated this disfiguring complication.

Lipohypertrophy, the development of fibrofatty masses at the injection site, is caused by the repeated use of an injection site. If insulin is injected into scarred areas, absorption may be delayed. This is one reason that rotation of injection sites is so important. Patients should avoid injecting insulin into these areas until the hypertrophy disappears.

Resistance to Injected Insulin. Most patients have some degree of insulin resistance at one time or another. This may occur for various reasons, the most common being obesity, which can be overcome by weight loss. Clinical insulin resistance has been defined as a daily insulin requirement of

200 units or more. In most patients with diabetes who take insulin, immune antibodies develop and bind the insulin, thereby decreasing the insulin available for use. All animal insulins, and human insulins to a lesser degree, cause antibody production in humans.

Very few resistant patients develop high levels of antibodies. Many of these patients have a history of insulin therapy interrupted for several months or longer. Treatment consists of administering a more concentrated insulin preparation, such as U500, which is available by special order. Occasionally, prednisone is needed to block the production of antibodies. This may be followed by a gradual reduction in the insulin requirement. Therefore, patients must monitor their blood for hypoglycemia.

Morning Hyperglycemia. An elevated blood glucose level on arising in the morning is caused by an insufficient level of insulin, which may be caused by several factors: the dawn phenomenon, the Somogyi effect, or insulin waning. The dawn phenomenon is characterized by a relatively normal blood glucose level until approximately 3 AM, when blood glucose levels begin to rise. The phenomenon is thought to result from nocturnal surges in growth hormone secretion, which create a greater need for insulin in the early morning hours in patients with type 1 diabetes. It must be distinguished from insulin waning (the progressive increase in blood glucose from bedtime to morning) and from the Somogyi effect (nocturnal hypoglycemia followed by rebound hyperglycemia). Insulin waning is frequently seen if the evening NPH dose is administered before dinner; it is prevented by moving the evening dose of NPH insulin to bedtime.

It may be difficult to tell from a patient's history which of these causes is responsible for morning hyperglycemia. To determine the cause, the patient must be awakened once or twice during the night to test blood glucose levels. Testing at bedtime, at 3 AM, and on awakening provides information that can be used to make adjustments in insulin to avoid morning hyperglycemia. Table 41-5 summarizes the differences among insulin waning, the dawn phenomenon, and the Somogyi effect.

Methods of Insulin Delivery. Methods of insulin delivery include traditional subcutaneous injections, insulin pens, jet injectors, and insulin pumps. See the nursing management section for discussion of traditional subcutaneous injections.

Insulin Pens. Insulin pens use small (150- to 300-unit) prefilled insulin cartridges that are loaded into a penlike holder. A disposable needle is attached to the device for insulin injection. Insulin is delivered by dialing in a dose or pushing a button for every 1- or 2-unit increment administered. People using these devices still need to insert the needle for each injection (Fig. 41-3); however, they do not need to carry insulin bottles or draw up insulin before each injection. These devices are most useful for patients who need to inject only one type of insulin at a time (eg, pre-meal rapid-acting insulin three times a day and bedtime NPH insulin) or who can use the premixed insulins. These pens are convenient for those who administer insulin before dinner if eating out or traveling. They are also useful for patients with impaired manual dexterity, vision, or cognitive function, which makes the use of traditional syringes difficult.

Table 41-5 CAUSES OF MORNING HYPERGLYCEMIA

Characteristic	Treatment
Insulin Waning	
Progressive rise in blood glucose from bedtime to morning	Increase evening (predinner or bedtime) dose of intermediate-acting or long-acting insulin, or institute a dose of insulin before the evening meal if one is not already part of the treatment regimen.
Dawn Phenomenon	
Relatively normal blood glucose until about 3 AM, when the level begins to rise	Change time of injection of evening intermediate-acting insulin from dinnertime to bedtime.
Somogyi Effect	
Normal or elevated blood glucose at bedtime, a decrease at 2–3 AM to hypoglycemic levels, and a subsequent increase caused by the production of counterregulatory hormones	Decrease evening (predinner or bedtime) dose of intermediate-acting insulin, or increase bedtime snack.

Jet Injectors. As an alternative to needle injections, jet injection devices deliver insulin through the skin under pressure in an extremely fine stream. These devices are more expensive and require thorough training and supervision when first used. In addition, patients should be cautioned

Figure 41-3 Prefilled insulin syringe.

Figure 41-4 MiniMed Paradigm real-time insulin pump and continuous glucose monitoring system. (Courtesy of Medtronic Diabetes.)

that absorption rates, peak insulin activity, and insulin levels may be different when changing to a jet injector. (Insulin administered by jet injector is usually absorbed faster.) Use of jet injectors has been associated with bruising in some patients.

Insulin Pumps. Continuous subcutaneous insulin infusion involves the use of small, externally worn devices (insulin pumps) that closely mimic the functioning of the normal pancreas (ADA, 2009b). Insulin pumps contain a 3-mL syringe attached to a long (24- to 42-in), thin, narrow-lumen tube with a needle or Teflon catheter attached to the end (Fig. 41-4). The patient inserts the needle or catheter into subcutaneous tissue (usually on the abdomen) and secures it with tape or a transparent dressing. The needle or catheter is changed at least every 3 days. The pump is then worn either on a belt or in a pocket. Some women keep the pump tucked into the front or side of the bra or wear it on a garter belt on the thigh.

When an insulin pump is used, insulin is delivered by subcutaneous infusion at a basal rate (eg, 0.5 to 2.0 units/h). When a meal is consumed, the patient calculates a dose of insulin to metabolize the meal by counting the total amount of carbohydrate for the meal using a predetermined insulin-to-carbohydrate ratio; for example, a ratio of 1 unit of insulin for every 15 g of carbohydrate would require 3 units for a meal with 45 g of carbohydrate. This allows flexibility of meal timing and content.

Possible disadvantages of insulin pumps are unexpected disruptions in the flow of insulin from the pump that may occur if the tubing or needle becomes occluded, if the supply of insulin runs out, or if the battery is depleted, increasing the risk of DKA. Effective teaching to produce knowledgeable patients minimizes this risk. Another disadvantage is the potential for infection at needle insertion sites. Hypoglycemia may occur with insulin pump therapy; however, this is usually related to the lowered blood glucose levels many patients achieve rather than to a specific problem with the pump itself. The tight diabetes control associated

with use of an insulin pump may increase the incidence of hypoglycemia unawareness because of the very gradual decline in serum glucose level, from more than 70 mg/dL (3.9 mmol/L) to less than 60 mg/dL (3.3 mmol/L).

Some patients find that wearing the pump for 24 hours each day is inconvenient. However, the pump can easily be disconnected, per patient preference, for limited periods, such as for showering, exercise, or sexual activity.

Candidates for the insulin pump must be willing to assess their blood glucose level several times daily. In addition, they must be psychologically stable and open about having diabetes, because the insulin pump is often a visible sign to others and a constant reminder to patients that they have diabetes. Most important, patients using insulin pumps must have extensive education in the use of the pump and in self-management of blood glucose and insulin doses. They must work closely with a team of health care professionals who are experienced in insulin pump therapy—specifically, a diabetologist/endocrinologist, a dietitian, and a certified diabetes educator.

The most common risk of insulin pump therapy is ketoacidosis, which can occur if there is an occlusion in the infusion set or tubing. Because only rapid-acting insulin is used in the pump, any interruption in the flow of insulin may rapidly cause the patient to be without insulin. The patient should be taught to administer insulin by manual injection if an insulin interruption is suspected (eg, no response in blood glucose level after a meal bolus).

Many insurance companies cover the cost of pump therapy. If not, the extra expense of the pump and associated supplies may be a deterrent for some patients. Medicare covers insulin pump therapy for patients with type 1 diabetes.

Insulin pumps have been used in patients with type 2 diabetes whose beta-cell function has diminished and who require insulin. Patients with a hectic lifestyle often do well with an insulin pump. There is no risk of DKA when there is an interruption of the flow of insulin in people with type 2 diabetes wearing an insulin pump.

Future Insulin Delivery. Research into mechanical delivery of insulin has involved implantable insulin pumps that can be externally programmed according to blood glucose test results. Clinical trials with these devices are continuing. In addition, there is research into the development of implantable devices that both measure the blood glucose level and deliver insulin as needed. Methods of administering insulin by the oral route (oral spray or capsule) and skin patch are undergoing intensive study.

Transplantation of Pancreatic Cells. Transplantation of the whole pancreas or a segment of the pancreas is being performed on a limited population (mostly patients with diabetes who are receiving a kidney transplantation simultaneously). One main issue is weighing the risks of antirejection medications against the advantages of pancreas transplantation. Implantation of insulin-producing pancreatic islet cells is another approach under investigation. This latter approach involves a less extensive surgical procedure and a potentially lower incidence of immunogenic problems (ADA, 2006b). However, thus far, independence from exogenous insulin has been limited to 2 years after transplantation of islet cells. Results of recent studies of patients with

islet cell transplants using less toxic antirejection drugs have shown some promise (NIDDK, 2007).

Oral Antidiabetic Agents

Oral antidiabetic agents may be effective for patients who have type 2 diabetes that cannot be treated effectively with MNT and exercise alone. In the United States, oral antidiabetic agents include first-generation and second-generation **sulfonylureas**, biguanides, alpha-glucosidase inhibitors, non-sulfonylurea insulin secretagogues (meglitinides and phenylalanine derivatives), **thiazolidinediones** (glitazones), and dipeptide-peptidase-4 (DPP-4) inhibitors (Table 41-6). Sulfonylureas and meglitinides are considered insulin secretagogues because their action increases the secretion of insulin by the pancreatic beta cells.

Patients must understand that oral agents are prescribed as an addition to (not as a substitute for) other treatment modalities, such as MNT and exercise. Use of oral antidiabetic medications may need to be halted temporarily and insulin prescribed if hyperglycemia develops that is attributable to infection, trauma, or surgery.

In time, oral antidiabetic agents may no longer be effective in controlling diabetes because of decline in function of beta cells. In such cases, the patient is treated with insulin. Approximately half of all patients who initially use oral antidiabetic agents eventually require insulin. This is referred to as a secondary failure. Primary failure occurs when the blood glucose level remains high 1 month after initial medication use.

Because mechanisms of action vary (Fig. 41-5), effects may be enhanced with the use of multidose, multiple medications. Use of multiple medications with different mechanisms of action is very common today. A combination of oral agents with insulin, usually glargine at bedtime, has also been used frequently as a treatment for some patients with type 2 diabetes.

Other Pharmacologic Therapy

Two new medications became available in 2005 for use in the pharmacologic management of diabetes. Both are injectable medications; neither is a substitute for insulin if insulin is required to control diabetes.

Pramlintide (Symlin), a synthetic analogue of human amylin, a hormone that is secreted by the beta cells of the pancreas, has recently been approved for treatment of both type 1 and type 2 diabetes. It is used to control hyperglycemia in adults who have not achieved acceptable levels of glucose control despite the use of insulin at mealtimes. It is used with insulin, not in place of insulin. Although pramlintide is not yet widely used, it is anticipated that it will be useful to minimize fluctuations in daily glucose levels and provide better glucose control. Risks associated with pramlintide include hypoglycemia; therefore, a source of glucose must be available if hypoglycemia occurs. Pramlintide must be injected into the abdomen or thigh because of variable absorption rates if it is injected into the arm. It should not be injected close to an insulin injection site. Caution must be exercised in preparing and administering pramlintide to avoid errors in dosing. Patients are instructed to monitor their blood glucose level before each meal, 2 hours afterward,

and at bedtime during the initial period of use of pramlintide.

Exenatide (Byetta) is another medication approved for the treatment of type 2 diabetes in combination with metformin or sulfonylureas. It is derived from a hormone that is produced in the small intestine and has been found to be deficient in type 2 diabetes. It is normally released after food is ingested to delay gastric emptying and enhance insulin secretion, resulting in dampening of the rise in blood glucose levels after meals and a feeling of satiety. The return of the blood glucose level to normal results in decreased production of the hormone. Hypoglycemia is not a side effect of exenatide if adjustments are made in the sulfonylurea dose. Exenatide has been shown to result in weight loss because of the increased satiety produced. Exenatide must be injected twice a day within 1 hour before breakfast and dinner. It is not a substitute for insulin in patients who require insulin to control their diabetes.

Nursing Management

Nursing management of patients with diabetes can involve treatment of a wide variety of physiologic disorders, depending on the patient's health status and whether the patient is newly diagnosed or seeking care for an unrelated health problem. Nursing management of patients with DKA and hyperglycemic hyperosmolar nonketotic syndrome and of those with diabetes as a secondary diagnosis is discussed in subsequent sections of this chapter.

Because all patients with diabetes must master the concepts and skills necessary for long-term management and avoidance of potential complications of diabetes, a solid educational foundation is necessary for competent self-care and is an ongoing focus of nursing care.

Providing Patient Education

Diabetes mellitus is a chronic illness that requires a lifetime of special self-management behaviors. Because MNT, physical activity, and physical and emotional stress affect diabetic control, patients must learn to balance a multitude of factors.

Developing a Diabetic Teaching Plan

Changes in the health care system as a whole have had a major impact on diabetes education and training. Patients with new-onset type 1 diabetes are hospitalized for much shorter periods or may be managed completely on an outpatient basis. Patients with new-onset type 2 diabetes are rarely hospitalized for initial care. There has been a proliferation of outpatient diabetes education and training programs, with increasing support of third-party reimbursement. All encounters with patients with diabetes are opportunities for reinforcement of self-management skills, regardless of the setting.

Many hospitals employ nurses who specialize in diabetes education and management and who are certified by the National Certification Board of Diabetes Educators as Certified Diabetes Educators (CDEs). However, because of the large number of patients with diabetes who are admitted to every unit of a hospital for reasons other than diabetes or its complications, staff nurses play a vital role in identifying patients with diabetes, assessing self-care skills, providing

Table 41-6 ORAL ANTIDIABETIC AGENTS

Generic (Trade) Name	Action/Indications	Side Effects	Implications
First-Generation Sulfonylureas Acetohexamide (Dymelor) Chlorpropamide (Diabinese) Tolazamide (Tolinase) Tolbutamide (Orinase)	Used infrequently in U.S. today Used in type 2 diabetes to control blood glucose levels Stimulate beta cells of the pancreas to secrete insulin; may improve binding between insulin and insulin receptors or increase the number of insulin receptors	Hypoglycemia Mild GI symptoms Weight gain Drug–drug interactions (NSAIDs, warfarin, sulfonamides) Sulfa allergy Skin reactions	Monitor patient for hypoglycemia Monitor blood glucose and urine ketone levels to assess effectiveness of therapy Patients at high risk for hypoglycemia: advanced age, renal insufficiency When taken with beta-adrenergic blocking agents may mask usual warning signs and symptoms of hypoglycemia Instruct patients to avoid use of alcohol Check for interactions with other medications
Second-Generation Sulfonylureas Glipizide (Glucotrol, Glucotrol XL) Glyburide (Micronase, Glynase, Dia-Beta) Glimpiride (Amaryl)	Stimulate beta cells of the pancreas to secrete insulin; may improve binding between insulin and insulin receptors or increase the number of insulin receptors Used in type 2 diabetes to control blood glucose levels Have more potent effects than first-generation sulfonylureas May be used in combination with metformin or insulin to improve glucose control	Hypoglycemia Mild GI symptoms Weight gain Drug–drug interactions (NSAIDs, warfarin, sulfonamides) Sulfa allergy	Monitor patient for hypoglycemia Monitor blood glucose and urine ketone levels to assess effectiveness of therapy Patients at high risk for hypoglycemia: advanced age, renal insufficiency When taken with beta-adrenergic blocking agents, may mask usual warning signs and symptoms of hypoglycemia Instruct patients to avoid use of alcohol
Biguanides Metformin (Glucophage, Glucophage XL, Fortamet) Metformin with glyburide (Glucovance)	Inhibit production of glucose by the liver Increase body tissues' sensitivity to insulin Decrease hepatic synthesis of cholesterol Used in type 2 diabetes to control blood glucose levels	Lactic acidosis Hypoglycemia if metformin is used in combination with insulin or other antidiabetic agents Drug–drug interaction GI disturbances Contraindicated in patients with impaired renal or liver function, respiratory insufficiency, severe infection, or alcohol abuse	Monitor for lactic acidosis and hypoglycemia Monitor renal function Patients taking metformin are at increased risk of acute renal failure and lactic acidosis with use of iodinated contrast material for diagnostic studies; metformin should be stopped 48 h prior to and for 48 h after use of contrast agent or until renal function is evaluated and normal Check for interactions with other medications
Alpha-Glucosidase Inhibitors Acarbose (Precose) Miglitol (Glyset)	Delay absorption of complex carbohydrates in the intestine and slow entry of glucose into systemic circulation Do not increase insulin secretion Used in type 2 diabetes to control blood glucose levels Can be used alone or in combination with sulfonylureas, metformin, or insulin to improve glucose control	Hypoglycemia (risk increased if used with insulin or other antidiabetic agents) GI side effects (abdominal discomfort or distention, diarrhea, flatulence) Drug–drug interactions	Must be taken with first bite of food to be effective Monitor for GI side effects (diarrhea, abdominal distention) Monitor for blood glucose levels to assess effectiveness of therapy Monitor liver function studies every 3 mo for 1 y, then periodically Contraindicated in patients with GI or renal dysfunction, or cirrhosis Alert: Hypoglycemia must be treated with glucose, not sucrose

Continued on following page

Table 41-6  ORAL ANTIDIABETIC AGENTS (Continued)			
Generic (Trade) Name	Action/Indications	Side Effects	Implications
Non-Sulfonylurea Insulin Secretagogues			
Repaglinide (Prandin) categorized as a meglitinide	Stimulate pancreas to secrete insulin	Hypoglycemia/weight gain less likely than sulfonylureas	Monitor blood glucose levels to assess effectiveness of therapy
Nateglinide (Starlix) categorized as a D-phenylalanine derivative	Used in type 2 diabetes to control blood glucose levels Can be used alone or in combination with metformin or thiazolidinediones to improve glucose control	Drug–drug interactions (with ketoconazole, fluconazole, erythromycin, rifampin, isoniazid)	Has rapid action and short half-life Should be taken only if able to eat a meal immediately Teach patients symptoms of hypoglycemia Monitor patients with impaired liver function and renal impairment Has no effect on plasma lipids Is taken before each meal Check for interactions with other medications
Thiazolidinediones (or glitazones)			
Pioglitazone (Actos)	Sensitize body tissue to insulin; stimulate insulin receptor sites to lower blood glucose and improve action of insulin	Hypoglycemia (risk increased with use of insulin or other antidiabetic agents)	Monitor blood glucose levels to assess effectiveness of therapy
Rosiglitazone (Avandia)	May be used alone or in combination with sulfonylurea, metformin, or insulin	Anemia Weight gain, edema Decrease effectiveness of oral contraceptives Possible liver dysfunction Drug–drug interactions Hyperlipidemia (has variable effect on lipids; pioglitazone may be preferred choice in patients with lipid abnormalities) Impaired platelet function	Monitor liver function tests Arrange dietary teaching to establish weight control program Instruct patient taking oral contraceptives about increased risk of pregnancy
Dipeptidyl Peptidase-4 (DPP-4) Inhibitor			
Sitagliptin (Januvia)	Increase and prolongs the action of incretin, a hormone that increases insulin release and decreases glucagon levels, with the result of improved glucose control	Upper respiratory infection Stuffy or runny nose and sore throat Headache Stomach discomfort and diarrhea Hypoglycemia, if used with sulfonylurea	Usually administered once a day Used alone or with other oral antidiabetic agents Instruct patient about signs and symptoms of hypoglycemia and other adverse effects to report Monitor renal function

basic education, reinforcing the teaching provided by the specialist, and referring patients for follow-up care after discharge. Diabetes patient education programs that have been peer-reviewed by the ADA as meeting National Standards for Diabetes Education can be reimbursed for education.

Organizing Information. There are various strategies for organizing and prioritizing the vast amount of information that must be taught to patients with diabetes. In addition, many hospitals and outpatient diabetes centers have devised written guidelines, care plans, and documentation forms (often based on ADA guidelines) that may be used to document and evaluate teaching. One approach is to organize education using the seven tips for managing diabetes identified and developed by the American Association of Diabetes Educators (AADE, 2005): healthy eating, being active, monitoring, taking medication, problem solving, healthy coping, and reducing risks. The AADE can be contacted for additional information about assessment and documentation of outcomes of this approach to teaching.

Another general approach is to organize information and skills into two main types: basic, initial, or “survival” skills and information, and in-depth (advanced) or continuing education.

Teaching Survival Skills. Survival skills must be taught to all patients with newly diagnosed type 1 or type 2 diabetes and all patients receiving insulin for the first time. This basic information is literally what patients must know to survive (eg, to avoid severe hypoglycemic or acute hyperglycemic complications after discharge). An outline of survival information includes the following:

1. Simple pathophysiology
 - a. Basic definition of diabetes (having a high blood glucose level)
 - b. Normal blood glucose ranges and target blood glucose levels
 - c. Effect of insulin and exercise (decrease glucose)
 - d. Effect of food and stress, including illness and infections (increase glucose)
 - e. Basic treatment approaches

Figure 41-5 Action sites of hypoglycemic agents and mechanisms of lowering blood glucose in type 2 diabetes. The incretins are the dipeptidyl peptidase-4 (DPP-4) inhibitors and glucagon-like peptide-1 (GLP-1) agonists.

2. Treatment modalities
 - a. Administration of insulin and oral antidiabetes medications
 - b. Meal planning (food groups, timing of meals)
 - c. Monitoring of blood glucose and urine ketones
3. Recognition, treatment, and prevention of acute complications
 - a. Hypoglycemia
 - b. Hyperglycemia
4. Pragmatic information
 - a. Where to buy and store insulin, syringes, and glucose monitoring supplies
 - b. When and how to contact the physician

For patients with newly diagnosed type 2 diabetes, emphasis is initially placed on meal planning and exercise. Those who are starting to take oral sulfonylureas or insulin secretagogues need to know about detecting, preventing, and treating hypoglycemia. If diabetes has gone undetected for many years, the patient may already be experiencing some chronic diabetic complications. Therefore, for some patients with newly diagnosed type 2 diabetes, basic diabetes teaching must include information on preventive skills, such as foot care and eye care (eg, planning yearly or more frequent complete [dilated eye] examinations by an ophthalmologist, understanding that retinopathy is largely asymptomatic until advanced stages).

Patients also need to realize that once they master the basic skills and information, further diabetes education must be pursued. Acquiring in-depth and advanced diabetes knowledge occurs throughout the patient's lifetime, both formally through programs of continuing education and informally through experience and sharing of information with other people with diabetes.

Planning In-Depth and Continuing Education. This education involves teaching more detailed information related to survival skills (eg, learning to vary food choices and insulin, preparing for travel) as well as learning preventive measures for avoiding long-term diabetic complications. Preventive measures include foot care, eye care, general hygiene (eg, skin care and oral hygiene), and risk factor management (eg, blood pressure control and blood glucose normalization).

More advanced continuing education may include alternative methods for insulin delivery, such as the insulin pump, and algorithms or rules for evaluating and adjusting insulin doses. The degree of advanced diabetes education to be provided depends on the patient's interest and ability. However, learning preventive measures (especially foot care and eye care) is mandatory for early detection and treatment to reduce the occurrence of amputations and blindness in patients with diabetes.

Assessing Readiness to Learn

Before initiating diabetes education, the nurse assesses the patient's (and family's) readiness to learn. When patients are first diagnosed with diabetes (or first told of their need for insulin), they often go through various stages of the grieving process. These stages may include shock and denial, anger, depression, negotiation, and acceptance. The amount of time it takes for the patient and family members to work through the grieving process varies from patient to patient. They may experience helplessness, guilt, altered body image, loss of self-esteem, and concern about the future. The nurse must assess the patient's coping strategies and reassure the patient and family that feelings of depression and shock are normal (Chart 41-6).

Asking the patient and family about their major concerns or fears is an important way to learn about any

CHART
41-6NURSING RESEARCH PROFILE
Psychological Impact of Diabetes in Women

Penckofer, S., Ferrans, C. & Velsor-Friedrich, B. (2007). The psychological impact of living with diabetes: Women's day-to-day experiences. *The Diabetes Educator*, 33(4), 680–690.

Purpose

Diabetes is a leading cause of heart disease and cardiovascular-related deaths among women; further, depression is often associated with diabetes. Depression may serve as a barrier for women with diabetes to obtain treatment to ensure control of diabetes or to follow the recommended treatment regimen. In an effort to gain an understanding of how psychological issues influence diabetes management, this study was undertaken. Its specific purpose was to identify the feelings experienced by women with diabetes and the impact these feelings have on the quality of life.

Design

A descriptive, exploratory design using a focus groups approach for data collection was undertaken. Four focus groups were conducted by professional moderators. The sessions were audiotaped and transcriptions were analyzed. Forty-one women with type 2 diabetes participated; their mean age was 55.6 years. Guidelines for focus groups published by the American Diabetes Association were used. A

moderator guide was used to explore depression, anger, and anxiety.

Findings

Five major themes were identified: (1) struggling with health challenges, (2) challenges in relationships, (3) worrying about the present and the future, (4) multiple responsibilities for self and others, and (5) choosing to take a break from caring for their diabetes. Struggling with health situations was the most prevalent theme. The difficulty of carrying on a normal life in the context of experiencing hypoglycemia and complications promoted angry feelings.

Nursing Implications

The incidence of depression is high in people with diabetes and more so in women than in men. The burden to take on self-care responsibilities while being responsible for others may result in anger. The findings support the need to address the psychological impact of having diabetes on treatment. Tending to the psychological component of diabetes and its effect on patients and families is important because of the potential negative effect of unresolved psychological issues on overall health and prevention of long-term complications.

misinformation that may be contributing to anxiety. Some common misconceptions regarding diabetes and its treatment are listed in Table 41-7. Simple, direct information should be provided to dispel misconceptions. More information can be provided once the patient masters survival skills.

Nurses whose patients are in the hospital rarely have the luxury of waiting until the patient feels ready to learn; short hospital stays necessitate initiation of survival skill education as early as possible. This gives the patient the opportunity to practice skills with supervision by the nurse before discharge. Follow-up by home health nurses is often necessary for reinforcement of survival skills.

The nurse evaluates the patient's social situation for factors that may influence the diabetes treatment and education plan, such as

- Low literacy level (may be evaluated while assessing for visual deficits by having the patient read from teaching materials)
- Limited financial resources or lack of health insurance
- Presence or absence of family support
- Typical daily schedule (the patient is asked about timing and number of usual daily meals, work and exercise schedule, plans for travel)
- Neurologic deficits caused by stroke, other neurologic disorders, or other disabling conditions, obtained from the patient's health history and physical assessment (the patient is assessed for aphasia or decreased ability to follow simple commands)

Teaching Experienced Patients

Nurses should continue to assess the skills and self-care behaviors of patients who have had diabetes for many years,

because it is estimated that as many as 50% of patients make errors in self-care. Assessment of these patients must include direct observation of skills, not just the patient's self-report of self-care behaviors. In addition, these patients must be fully aware of preventive measures related to foot care, eye care, and risk factor management. Those experiencing long-term diabetic complications for the first time may go through the grieving process again. Some patients may have a renewed interest in diabetes self-care in the hope of delaying further complications. Others may be overwhelmed by feelings of guilt and depression. The patient is encouraged to discuss feelings and fears related to complications. Meanwhile, the nurse provides appropriate information regarding diabetic complications.

Determining Teaching Methods

Maintaining flexibility with regard to teaching approaches is important. Teaching skills and information in a logical sequence is not always the most helpful method for patients. For example, many patients fear self-injection. Before they learn how to prepare, purchase, store, and mix insulins, they should be taught to insert the needle and inject insulin (or practice with saline solution).

Various tools can be used to complement teaching. Many of the companies that manufacture products for diabetes self-care also provide booklets and videotapes to assist in patient teaching. Teaching/educational materials are also available from the AADE and the ADA. It is important to use a variety of written handouts that match the patient's learning needs (including different languages, low-literacy information, large print) and reading level and to ensure that these materials are technically accurate. Patients can continue learning about diabetes care by participating in

Table 41-7 MISCONCEPTIONS RELATED TO INSULIN TREATMENT

Misconception	Response
Once insulin injections are started (for treatment of type 2 diabetes), they can never be discontinued	During periods of acute stress (eg, illness, infection, surgery) or when receiving certain medications that cause elevations in blood glucose, some patients with type 2 diabetes require insulin. If the diabetes had previously been well controlled with diet alone or diet with oral antidiabetic agents, the patient should be able to resume previous methods for control of diabetes after the stress is resolved. In addition, insulin is sometimes used to control blood glucose levels in obese type 2 diabetic patients who have been unsuccessful at weight loss. If the patient can lose weight after insulin therapy is initiated, the insulin doses may be tapered and the patient may be able to switch to diet and exercise alone or with oral antidiabetic agents for control of blood glucose. (For patients with type 1 diabetes, insulin is needed on an ongoing basis. For thin patients with type 2 diabetes, once insulin has to be started, it is usually required permanently.)
If increasing doses of insulin are needed to control the blood glucose, the diabetes must be getting “worse”	Explain to the patient that unlike other medications that are given in standard doses, there is not a standard dose of insulin that is effective for all patients. Rather, the dose must be adjusted according to blood glucose test results. If the initial insulin dose prescribed for the patient does not adequately decrease the glucose level, the patient may assume that he or she has a “bad” case of diabetes or that the diabetes is getting worse. It is important to instruct patients that many different factors may affect the ability of insulin to lower the glucose, including obesity, puberty, pregnancy, illness, and certain medications. In addition, to avoid hypoglycemia, physicians frequently initiate insulin therapy with smaller dosages than will eventually be needed. The doses are then increased in small increments until blood glucose levels are in the desired range.
Insulin causes blindness (or other diabetic complications)	If the patient has a diabetic acquaintance in whom the initiation of insulin therapy happened to coincide with the onset of diabetic complications, the patient may view insulin as the cause of complications such as blindness or amputation. In these situations, the acquaintance probably had type 2 diabetes that was no longer controllable with diet and oral hypoglycemic agents. It must be explained to the patient that factors such as elevated blood glucose (and not insulin therapy) contribute to some of the diabetic complications. Further, emphasize that insulin is a natural hormone that is present in every person’s body, helps control blood glucose levels, and definitely does <i>not</i> cause long-term complications of diabetes.
Insulin must be injected directly into the vein	When patients first learn that one area used for insulin injections is on the arm, they may envision inserting the needle directly into a vein in the antecubital area, as in blood withdrawal. The patient must be reassured that insulin is injected into the fat tissue on the <i>back</i> of the arm (or on the abdomen, thigh, or hip) and that the needle is much shorter than that used for venipuncture.
There is extreme danger in injecting insulin if there are any air bubbles in the syringe	Patients may have a fear of dying if air bubbles are injected with a syringe. (This may be related to the misconception that insulin is injected directly into the vein.) Reassure patients that the main danger in having air bubbles in the insulin syringe is that the amount of insulin being injected is less than the required dose. It is often difficult to remove every small “champagne” bubble from the syringe. Thus, patients should be reassured that injection of insulin when these bubbles are present does not cause any harm.
Insulin always causes people to have bad (hypoglycemic) reactions	First, make sure that patients are aware that low blood sugar reactions are often related to an imbalance with the insulin, food, and activity and can often be avoided. Thus, before starting on insulin, patients should discuss their usual schedule of meals and activities as well as the content of meals with the health care team. Make sure that patients are aware that various different insulins and insulin schedules can be used to try to allow patients to maintain some of their usual lifestyle habits. Reassure patients that avoiding hypoglycemic reactions is a high priority for the diabetes team. In addition, tell patients of the importance of reporting any hypoglycemic reactions to the health care team immediately so that early adjustments can be made in the insulin dosage. Focus early insulin education on treatment and prevention of hypoglycemia.
People who take insulin must travel only where there is a refrigerator to store the insulin	Insulin bottles in use may be kept at room temperature. Therefore, for most business trips or vacations, keeping the insulin in a purse or briefcase (or special diabetes supply case) is acceptable. If a prolonged trip is planned (more than 2 to 3 months), patients may want to consult the pharmacist or insulin manufacturer for suggestions. Most importantly, emphasize with patients that taking insulin should never deter them from pursuing activities they enjoy.

Pearce, M. A., Rosenberg, C. S. & Davidson, M. B. (2003). Patient education. In Davidson, M. B. (Ed.). *Diabetes mellitus: Diagnosis and treatment* (4th ed.). New York: Churchill Livingstone. Reprinted with permission from Elsevier Science.

activities sponsored by local hospitals and diabetes organizations. In addition, magazines and Web sites with information on diabetes management are available (see Resources).

Teaching Patients to Self-Administer Insulin

Insulin injections are self-administered into the subcutaneous tissue with the use of special insulin syringes. Basic information includes explanations of the equipment, insulins, and syringes and how to mix insulin.

Storing Insulin. Whether insulin is the short-acting or the long-acting preparation, vials not in use, including spare vials, should be refrigerated. Extremes of temperature

should be avoided; insulin should not be allowed to freeze and should not be kept in direct sunlight or in a hot car. The insulin vial in use should be kept at room temperature to reduce local irritation at the injection site, which may occur if cold insulin is injected. If a vial of insulin will be used up within 1 month, it may be kept at room temperature. The patient should be instructed to always have a spare vial of the type or types of insulin he or she uses (ADA, 2004). Cloudy insulins should be thoroughly mixed by gently inverting the vial or rolling it between the hands before drawing the solution into a syringe or a pen.

Bottles of intermediate-acting insulin should also be inspected for flocculation, which is a frosted, whitish coating

inside the bottle. This occurs most commonly with human insulins that are exposed to extremes of temperature. If a frosted, adherent coating is present, some of the insulin is bound, and it should not be used.

Selecting Syringes. Syringes must be matched with the insulin concentration (eg, U-100). Currently, three sizes of U-100 insulin syringes are available:

- 1-mL syringes that hold 100 units
- 0.5-mL syringes that hold 50 units
- 0.3-mL syringes that hold 30 units

The concentration of insulin used in the United States is U-100; that is, there are 100 units per milliliter (or cubic centimeter). Small syringes allow patients who require small amounts of insulin to measure and draw up the amount of insulin accurately. Patients who require large amounts of insulin use larger syringes. There is a U-500 (500 units/mL) concentration of insulin available by special order for patients who have severe insulin resistance and require massive doses of insulin.

Most insulin syringes have a disposable 27- to 29-gauge needle that is approximately 0.5 inch long. The smaller syringes are marked in 1-unit increments and may be easier to use for patients with visual deficits and those taking very small doses of insulin. The 1-mL syringes are marked in 1- and 2-unit increments. A small disposable insulin needle (31 gauge, 8 mm long) is available for very thin patients and children.

Mixing Insulins. When rapid-acting or short-acting insulins are to be given simultaneously with longer-acting insulins, they are usually mixed together in the same syringe; the longer-acting insulins must be mixed thoroughly before drawing into the syringe. The most important issue is that patients be consistent in how they prepare their insulin injections from day to day.

There are varying opinions regarding which type of insulin (short-acting or longer-acting) should be drawn up into the syringe first when they are going to be mixed, but the ADA recommends that the regular insulin be drawn up first. Again, the most important issues are (1) that patients be consistent in technique, so as not to draw up the wrong dose in error or the wrong type of insulin, and (2) that patients not inject one type of insulin into the bottle containing a different type of insulin (ADA, 2004). Injecting cloudy insulin into a vial of clear insulin contaminates the entire vial of clear insulin and alters its action.

For patients who have difficulty mixing insulins, several options are available: they may use a premixed insulin, they may have prefilled syringes prepared (see Fig. 41-3), or they may take 2 injections. Premixed insulins are available in several different ratios of NPH insulin to regular insulin. The ratio of 70/30 (70% NPH and 30% regular insulin in one bottle) is most common; this combination is available as Novolin 70/30 (Novo-Nordisk) and Humulin 70/30 (Lilly). Combinations with a ratio of 75% NPL (neutral protamine lispro) and 25% insulin lispro are also available (ADA, 2004). NPL is used only in the mix with Humalog; its action is the same as NPH. The appropriate initial dosage of premixed insulin must be calculated so that the ratio of NPH to regular insulin most closely approximates the separate doses needed.

For patients who can inject insulin but who have difficulty drawing up a single or mixed dose, syringes may be prefilled with the help of home care nurses or family and friends. A 3-week supply of insulin syringes may be prepared and kept in the refrigerator. The prefilled syringes should be stored with the needle in an upright position to avoid clogging of the needle (ADA, 2004); they should be mixed thoroughly before the insulin is injected.

Withdrawing Insulin. Most (if not all) of the printed materials available on insulin dose preparation instruct patients to inject air into the bottle of insulin equivalent to the number of units of insulin to be withdrawn. The rationale for this is to prevent the formation of a vacuum inside the bottle, which would make it difficult to withdraw the proper amount of insulin.

Selecting and Rotating the Injection Site. The four main areas for injection are the abdomen, upper arms (posterior surface), thighs (anterior surface), and hips (Fig. 41-6). Insulin is absorbed faster in some areas of the body than others. The speed of absorption is greatest in the abdomen and decreases progressively in the arm, thigh, and hip, respectively.

Systematic rotation of injection sites within an anatomic area is recommended to prevent localized changes in fatty tissue (lipodystrophy). In addition, to promote consistency in insulin absorption, the patient should be encouraged to use all available injection sites within one area rather than randomly rotating sites from area to area (ADA, 2004). For example, some patients almost exclusively use the abdominal area, administering each injection 0.5 to 1 inch away from the previous injection. Another approach to rotation is always to use the same area at the same time of day. For example, patients may inject morning doses into the abdomen and evening doses into the arms or legs.

A few general principles apply to all rotation patterns. First, the patient should try not to use the same site more than once in 2 to 3 weeks. In addition, if the patient is planning to exercise, insulin should not be injected into

Figure 41-6 Suggested areas for insulin injection.

the limb that will be exercised because this will cause the drug to be absorbed faster, which may result in hypoglycemia.

In the past, patients were taught to rotate injections from one area to the next (eg, injecting once in the right arm, then once in the right abdomen, then once in the right thigh). Patients who still use this system must be taught to avoid repeated injections into the same site within an area. However, as previously stated, it is preferable for patients to use the same anatomic area at the same time of day consistently; this reduces day-to-day variation in blood glucose levels caused by different absorption rates.

Preparing the Skin. Use of alcohol to cleanse the skin is not recommended, but patients who have learned this technique often continue to use it. They should be cautioned to

allow the skin to dry after cleansing with alcohol. If the skin is not allowed to dry before the injection, the alcohol may be carried into the tissues, resulting in a localized reddened area and a burning sensation.

Inserting the Needle. There are varying approaches to inserting the needle for insulin injections. The correct technique is based on the need for the insulin to be injected into the subcutaneous tissue (Chart 41-7). Injection that is too deep (eg, intramuscular) or too shallow may affect the rate of absorption of the insulin. For a normal or overweight person, a 90-degree angle is the best insertion angle. Aspiration (inserting the needle and then pulling back on the plunger to assess for blood being drawn into the syringe) is generally not recommended with self-injection of insulin. Many patients who have been using insulin for an extended

41-7

PATIENT EDUCATION
Self-Injection of Insulin

1. With one hand, stabilize the skin by spreading it or pinching up a large area.

Pinching the skin

2. Pick up syringe with the other hand and hold it as you would a pencil. Insert needle straight into the skin.*

Inserting the needle into the skin

3. To inject the insulin, push the plunger all the way in.

Injecting the insulin

4. Pull needle straight out of skin. Press cotton ball over injection site for several seconds.

Removing the needle and holding cotton ball over site

5. Use disposable syringe *only once* and discard into hard plastic container (with a tight-fitting top) such as an empty bleach or detergent container.[†] Follow state regulations for disposal of syringes and needles.

Disposing of syringe

*Some patients may be taught to insert the needle at a 45-degree angle.

[†]Although some studies suggest that reusing disposable syringes may be safe, it is recommended that this be done only in the absence of poor personal hygiene, an acute concurrent illness, open wounds on the hands, or decreased resistance to infection.

period have eliminated this step from their insulin injection routine with no apparent adverse effects.

Disposing of Syringes and Needles. Insulin syringes and pens, needles, and lancets should be disposed of according to local regulations. If community disposal programs are unavailable, used sharps should be placed in a puncture-resistant container. The patient should contact local trash authorities for instructions about proper disposal of filled containers, which should not be mixed with containers to be recycled.

Promoting Home and Community-Based Care

Promoting Self-Care

If problems exist with glucose control or with the development of preventable complications, it is the nurse's responsibility to assess the reasons for the patient's ineffective management of the treatment regimen. It should not be assumed that problems with diabetes management are related to the patient's willful decision to ignore self-management. The patient may have forgotten or never learned certain information. The problem may be correctable simply through providing complete information and ensuring that the patient understands the information. The focus of diabetes education should be patient empowerment. Patient education should address behavior change, self-efficacy, and health beliefs. Chart 41-8 details how to evaluate the effectiveness of self-injection of insulin education.

If knowledge deficit is not the problem, certain physical or emotional factors may be impairing the patient's ability to perform self-care skills. For example, decreased visual acuity may impair the patient's ability to administer insulin accurately, measure the blood glucose level, or inspect the skin and feet. In addition, decreased joint mobility (especially in the elderly) or preexisting disability may impair the patient's ability to inspect the bottom of the feet. Denial of the diagnosis or depression may impair the patient's ability to carry out multiple daily self-care measures. The patient whose family, personal, or work problems may be of higher priority may benefit from assistance in establishing priorities. It is also important to assess the patient for infection or emotional stress, which may lead to elevated blood glucose levels despite adherence to the treatment regimen.

The following approaches are helpful for promoting self-care management skills:

- Address any underlying factors (eg, knowledge deficit, self-care deficit, illness) that may affect diabetic control.
- Simplify the treatment regimen if it is too difficult for the patient to follow.
- Adjust the treatment regimen to meet patient requests (eg, adjust diet or insulin schedule to allow increased flexibility in meal content or timing).
- Establish a specific plan or contract with each patient with simple, measurable goals.
- Provide positive reinforcement of self-care behaviors performed instead of focusing on behaviors that were neglected (eg, positively reinforce blood glucose tests that were performed instead of focusing on the number of missed tests).

- Help the patient identify personal motivating factors rather than focusing on wanting to please physicians or nurses.
- Encourage the patient to pursue life goals and interests, and discourage an undue focus on diabetes.

Continuing Care

The degree to which patients interact with health care providers to obtain ongoing care depends on many factors. Age, socioeconomic level, existing complications, type of diabetes, and comorbid conditions all may dictate the frequency of follow-up visits. Many patients with diabetes are seen by home health nurses for diabetes education, wound care, insulin preparation, or assistance with glucose monitoring. Even patients who achieve excellent glucose control and have no complications can expect to see their primary health care provider at least twice a year for ongoing evaluation and should receive routine nutrition updates. In addition, the nurse should remind the patient to participate in recommended health promotion activities (eg, immunizations) and age-appropriate health screenings (eg, pelvic examinations, mammograms).

In addition, participation in support groups is encouraged for patients who have had diabetes for many years as well as for those who are newly diagnosed. Such participation may help the patient and family cope with changes in lifestyle that occur with the onset of diabetes and its complications. People who participate in support groups often share valuable information and experiences and learn from others. Support groups provide an opportunity for discussion of strategies to deal with diabetes and its management and to clarify and verify information with nurses or other health care professionals. Participation in support groups may also promote healthy activities.

ACUTE COMPLICATIONS OF DIABETES

There are three major acute complications of diabetes related to short-term imbalances in blood glucose levels: hypoglycemia, DKA, and hyperglycemic hyperosmolar nonketotic syndrome, which is also called hyperglycemic hyperosmolar syndrome or state.

Hypoglycemia (Insulin Reactions)

Hypoglycemia occurs when the blood glucose falls to less than 50 to 60 mg/dL (2.7 to 3.3 mmol/L), because of too much insulin or oral hypoglycemic agents, too little food, or excessive physical activity. Hypoglycemia may occur at any time of the day or night. It often occurs before meals, especially if meals are delayed or snacks are omitted. For example, midmorning hypoglycemia may occur when the morning regular insulin is peaking, whereas hypoglycemia that occurs in the late afternoon coincides with the peak of the morning NPH or Lente insulin. Middle-of-the-night hypoglycemia may occur because of peaking evening or predinner NPH or Lente insulins, especially in patients who have not eaten a bedtime snack.

Chart 41-8 • Outcome Criteria for Determining Effectiveness of Self-Injection of Insulin Education

Equipment

Insulin

- Identifies information on label of insulin bottle:
 - Type (eg, NPH, regular, 70/30)
 - Species (human, biosynthetic, pork)
 - Manufacturer (Lilly, Novo Nordisk)
 - Concentration (eg, U-100)
 - Expiration date
- Checks appearance of insulin:
 - Clear or milky white
 - Checks for flocculation (clumping, frosted appearance)
- Identifies where to purchase and store insulin:
 - Indicates approximately how long bottle will last (1,000 units per bottle U-100 insulin)
 - Indicates how long opened bottles can be used

Syringes

- Identifies concentration (U-100) marking on syringe
- Identifies size of syringe (eg, 100-unit, 50-unit, 30-unit)
- Describes appropriate disposal of used syringe

Preparation and Administration of Insulin Injection

- Draws up correct amount and type of insulin
- Properly mixes two insulins if necessary
- Inserts needle and injects insulin
- Describes site rotation:
 - Demonstrates injection with all anatomic areas to be used
 - Describes pattern for rotation, such as using abdomen only or using certain areas at the same time of day
 - Describes system for remembering site locations, such as horizontal pattern across the abdomen as if drawing a dotted line

Knowledge of Insulin Action

- Lists prescription:
 - Type and dosage of insulin
 - Timing of insulin injections
- Describes approximate time course of insulin action:
 - Identifies long- and short-acting insulins by name
 - States approximate time delay until onset of insulin action
 - Identifies need to delay food until 5 to 15 min after injection of rapid-acting insulin (lispro, aspart, glulisine [Apidra])
 - Knows that longer time delays are safe when blood glucose level is high, and time delays may need to be shortened when blood glucose level is low

Incorporation of Insulin Injections Into Daily Schedule

- Recites proper order of premeal diabetes activities:
 - May use mnemonic device such as the word “tie,” which helps the patient remember the order of activities (“t” = test [blood glucose], “i” = insulin injection, “e” = eat)
 - Describes daily schedule, such as test, insulin, eat before breakfast and dinner; test and eat, before lunch and bedtime
- Describes information regarding hypoglycemia:
 - Symptoms: shakiness, sweating, nervousness, hunger, weakness
 - Causes: too much insulin, too much exercise, not enough food
 - Treatment: 15 g concentrated carbohydrate, such as two or three glucose tablets, 1 tube glucose gel, 0.5 cup juice
 - After initial treatment, follow with snack including starch and protein, such as cheese and crackers, milk and crackers, half sandwich
- Describes information regarding prevention of hypoglycemia:
 - Avoids delays in meal timing
 - Eats a meal or snack approximately every 4 to 5 h (while awake)
 - Does not skip meals
 - Increases food intake before exercise if blood glucose level is <100 mg/dL
 - Checks blood glucose regularly
 - Identifies safe modification of insulin doses consistent with management plan
 - Carries a form of fast-acting sugar at all times
 - Wears a medical identification bracelet
 - Teaches family, friends, coworkers about signs and treatment of hypoglycemia
 - Has family, roommates, traveling companions learn to use injectable glucagon for severe hypoglycemic reactions
- Maintains regular follow-up for evaluation of diabetes control:
 - Keeps written record of blood glucose, insulin doses, hypoglycemic reactions, variations in diet
 - Keeps all appointments with health professionals
 - Sees health care provider regularly (usually two to four times per year)
 - States how to contact health care provider in case of emergency
 - States when to call health care provider to report variations in blood glucose levels

Gerontologic Considerations

In elderly patients with diabetes, hypoglycemia is a particular concern for many reasons:

- Elderly people frequently live alone and may not recognize the symptoms of hypoglycemia.
- With decreasing renal function, it takes longer for oral hypoglycemic agents to be excreted by the kidneys.
- Skipping meals may occur because of decreased appetite or financial limitations.

- Decreased visual acuity may lead to errors in insulin administration.

Clinical Manifestations

The clinical manifestations of hypoglycemia may be grouped into two categories: adrenergic symptoms and central nervous system (CNS) symptoms.

In mild hypoglycemia, as the blood glucose level falls, the sympathetic nervous system is stimulated, resulting in a surge of epinephrine and norepinephrine. This causes symptoms

such as sweating, tremor, tachycardia, palpitation, nervousness, and hunger.

In moderate hypoglycemia, the drop in blood glucose level deprives the brain cells of needed fuel for functioning. Signs of impaired function of the CNS may include inability to concentrate, headache, lightheadedness, confusion, memory lapses, numbness of the lips and tongue, slurred speech, impaired coordination, emotional changes, irrational or combative behavior, double vision, and drowsiness. Any combination of these symptoms (in addition to adrenergic symptoms) may occur with moderate hypoglycemia.

In severe hypoglycemia, CNS function is so impaired that the patient needs the assistance of another person for treatment of hypoglycemia. Symptoms may include disoriented behavior, seizures, difficulty arousing from sleep, or loss of consciousness.

Assessment and Diagnostic Findings

Symptoms of hypoglycemia may occur suddenly and vary considerably from person to person. To some degree, this may be related to the actual level to which the blood glucose falls or to the rate at which it falls. For example, patients who usually have a blood glucose level in the hyperglycemic range (eg, 200 mg/dL or greater) may feel hypoglycemic (adrenergic) symptoms when their blood glucose falls rapidly to 120 mg/dL (6.6 mmol/L) or less. Conversely, patients who frequently have a glucose level in the low range of normal (eg, 80 to 100 mg/dL) may be asymptomatic when the blood glucose falls slowly to less than 50 mg/dL (2.7 mmol/L).

Decreased hormonal (adrenergic) response to hypoglycemia may also contribute to lack of symptoms of hypoglycemia. This occurs in some patients who have had diabetes for many years. It may be related to autonomic neuropathy, a chronic diabetic complication (see later discussion). As the blood glucose level falls, the normal surge in adrenalin does not occur, and the usual adrenergic symptoms, such as sweating and shakiness, do not take place. The hypoglycemia may not be detected until moderate or severe CNS impairment occurs. Affected patients must perform SMBG on a frequent regular basis, especially before driving or engaging in other potentially dangerous activities.

Management

Treating with Carbohydrates

Immediate treatment must be given when hypoglycemia occurs. The usual recommendation is for 15 g of a fast-acting concentrated source of carbohydrate such as the following, given orally:

- Three or four commercially prepared glucose tablets
- 4 to 6 oz of fruit juice or regular soda
- 6 to 10 hard candies
- 2 to 3 teaspoons of sugar or honey

It is not necessary to add sugar to juice, even if it is labeled as unsweetened juice: the fruit sugar in juice contains enough carbohydrate to raise the blood glucose level. Adding table sugar to juice may cause a sharp increase in the blood glucose level, and patients may experience hypoglycemia for hours after treatment.

The blood glucose level should be retested in 15 minutes and retreated if it is less than 70 to 75 mg/dL (3.8 to 4 mmol/L). If the symptoms persist for longer than 10 to 15 minutes after initial treatment, the treatment is repeated even if blood glucose testing is not possible. Once the symptoms resolve, a snack containing protein and starch (eg, milk or cheese and crackers) is recommended unless the patient plans to eat a regular meal or snack within 30 to 60 minutes.

Initiating Emergency Measures

In emergency situations, for adults who are unconscious and cannot swallow, an injection of glucagon 1 mg can be administered either subcutaneously or intramuscularly. Glucagon is a hormone produced by the alpha cells of the pancreas that stimulates the liver to breakdown glycogen, the stored glucose. Injectable glucagon is packaged as a powder in 1-mg vials and must be mixed with a diluent immediately before being injected. After injection of glucagon, the patient may take as long as 20 minutes to regain consciousness. A concentrated source of carbohydrate followed by a snack should be given to the patient on awakening to prevent recurrence of hypoglycemia (because the duration of the action of 1 mg of glucagon is brief—its onset is 8 to 10 minutes, and its action lasts 12 to 27 minutes) and to replenish liver stores of glucose. Some patients experience nausea after the administration of glucagon. If this occurs, the patient should be turned to the side to prevent aspiration in case the patient vomits.

Glucagon is sold by prescription only and should be part of the emergency supplies available to patients with diabetes who require insulin. Family members, friends, neighbors, and coworkers should be instructed in the use of glucagon, especially for patients who have little or no warning of hypoglycemic episodes. Patients should be instructed to notify their physician after severe hypoglycemia has occurred and been treated.

In hospitals and emergency departments, for patients who are unconscious or cannot swallow, 25 to 50 mL of 50% dextrose in water (D₅₀W) may be administered IV. The effect is usually seen within minutes. The patient may complain of a headache and of pain at the injection site. Assuring patency of the IV line used for injection of 50% dextrose is essential because hypertonic solutions such as 50% dextrose are very irritating to veins.

Providing Patient Education

Hypoglycemia is prevented by a consistent pattern of eating, administering insulin, and exercising. Between-meal and bedtime snacks may be needed to counteract the maximum insulin effect. In general, the patient should cover the time of peak activity of insulin by eating a snack and by taking additional food when physical activity is increased. Routine blood glucose tests are performed so that changing insulin requirements may be anticipated and the dosage adjusted. Because unexpected hypoglycemia can occur, all patients treated with insulin should wear an identification bracelet or tag stating that they have diabetes.

Patients and family members must be instructed to recognize the symptoms of hypoglycemia. Family members in particular must be made aware that any subtle (but unusual)

change in behavior may be an indication of hypoglycemia. They should be taught to encourage and even insist that the person with diabetes assess blood glucose levels if hypoglycemia is suspected. When some patients are hypoglycemic, they become very resistant to testing or eating and become angry at family members who are trying to treat the hypoglycemia. Family members must be taught to persevere and to understand that the hypoglycemia can cause irrational behavior.

Autonomic neuropathy or beta-blockers such as propranolol (Inderal) to treat hypertension or cardiac dysrhythmias may mask the typical symptoms of hypoglycemia. It is very important that these patients perform blood glucose tests on a frequent and regular basis. Patients who have type 2 diabetes and who take oral sulfonylurea agents may also develop hypoglycemia, which can be prolonged and severe; this is a particular risk for elderly patients.

It is important that patients with diabetes, especially those receiving insulin, learn to carry some form of simple sugar with them at all times (ADA, 2008b). There are many different commercially prepared glucose tablets and gels that the patient may find convenient to carry. If the patient has a hypoglycemic reaction and does not have any of the recommended emergency foods available, he or she should eat any available food (preferably a carbohydrate food).

Patients are advised to refrain from eating high-calorie, high-fat dessert foods (eg, cookies, cakes, doughnuts, ice cream) to treat hypoglycemia because their high fat content may slow the absorption of the glucose and resolution of the hypoglycemic symptoms. The patient may subsequently eat more of the foods when symptoms do not resolve rapidly, which may cause very high blood glucose levels for several hours and may contribute to weight gain.

Patients who feel unduly restricted by their meal plan may view hypoglycemic episodes as a time to reward themselves with desserts. It may be more prudent to teach these patients to incorporate occasional desserts into the meal plan. This may make it easier for them to limit their treatment of hypoglycemic episodes to simple (low-calorie) carbohydrates such as juice or glucose tablets.

Diabetic Ketoacidosis

DKA is caused by an absence or markedly inadequate amount of insulin. This deficit in available insulin results in disorders in the metabolism of carbohydrate, protein, and fat. The three main clinical features of DKA are

- Hyperglycemia
- Dehydration and electrolyte loss
- Acidosis

Pathophysiology

Without insulin, the amount of glucose entering the cells is reduced, and production and release of glucose by the liver (gluconeogenesis) is increased, leading to hyperglycemia (Fig. 41-7). In an attempt to rid the body of the excess glucose, the kidneys excrete the glucose along with water and electrolytes (eg, sodium, potassium). This osmotic diuresis, which is characterized by excessive urination (polyuria),

Physiology Pathophysiology

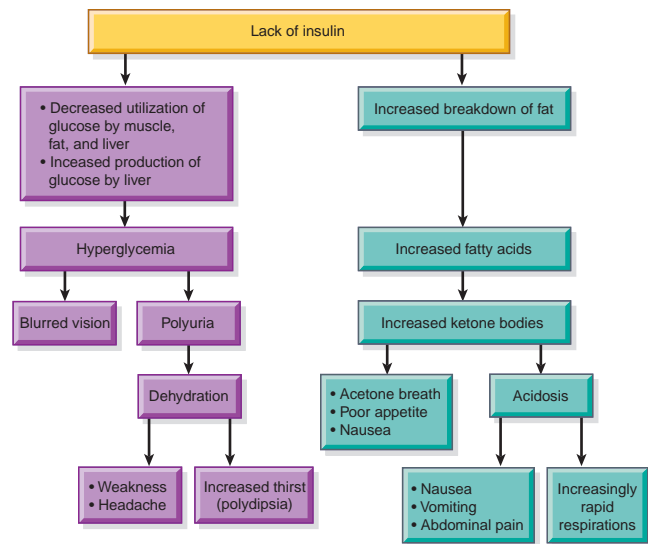

Figure 41-7 Abnormal metabolism that causes signs and symptoms of diabetic ketoacidosis. (Redrawn from Pearce, M. A., Rosenberg, C. S. & Davidson, M. D. (2003). Patient education. In Davidson, M. B. (Ed.). *Diabetes mellitus: Diagnosis and treatment*. New York: Churchill Livingstone.)

leads to dehydration and marked electrolyte loss. Patients with severe DKA may lose up to 6.5 L of water and up to 400 to 500 mEq each of sodium, potassium, and chloride over a 24-hour period.

Another effect of insulin deficiency or deficit is the breakdown of fat (lipolysis) into free fatty acids and glycerol. The free fatty acids are converted into ketone bodies by the liver. Ketone bodies are acids; their accumulation in the circulation due to lack of insulin leads to metabolic acidosis.

Three main causes of DKA are decreased or missed dose of insulin, illness or infection, and undiagnosed and untreated diabetes (DKA may be the initial manifestation of diabetes). An insulin deficit may result from an insufficient dosage of insulin prescribed or from insufficient insulin being administered by the patient. Errors in insulin dosage may be made by patients who are ill and who assume that if they are eating less or if they are vomiting, they must decrease their insulin doses. (Because illness, especially infections, can cause increased blood glucose levels, the patient does not need to decrease the insulin dose to compensate for decreased food intake when ill and may even need to increase the insulin dose.)

Other potential causes of decreased insulin include patient error in drawing up or injecting insulin (especially in patients with visual impairments), intentional skipping of insulin doses (especially in adolescents with diabetes who are having difficulty coping with diabetes or other aspects of their lives), or equipment problems (eg, occlusion of insulin pump tubing). Illness and infections are associated with insulin resistance. In response to physical (and emotional) stressors, there is an increase in the level of “stress”

CHART
41-9

PATIENT EDUCATION

Guidelines to Follow During Periods of Illness (“Sick Day Rules”)

- Take insulin or oral antidiabetic agents as usual.
- Test blood glucose and test urine ketones every 3 to 4 h.
- Report elevated glucose levels (>300 mg/dL [16.6 mmol/L] or as otherwise specified) or urine ketones to your health care provider.
- If you take insulin, you may need supplemental doses of regular insulin every 3 to 4 h.
- If you cannot follow your usual meal plan, substitute soft foods (eg, $\frac{1}{3}$ cup regular gelatin, 1 cup cream soup, $\frac{1}{2}$ cup

- custard, 3 squares graham crackers) six to eight times per day.
- If vomiting, diarrhea, or fever persists, take liquids (eg, $\frac{1}{2}$ cup regular cola or orange juice, $\frac{1}{2}$ cup broth, 1 cup Gatorade) every $\frac{1}{2}$ to 1 hour to prevent dehydration and to provide calories.
- Report nausea, vomiting, and diarrhea to your health care provider, because extreme fluid loss may be dangerous.
- If you are unable to retain oral fluids, you may require hospitalization to avoid diabetic ketoacidosis and possibly coma.

hormones—glucagon, epinephrine, norepinephrine, cortisol, and growth hormone. These hormones promote glucose production by the liver and interfere with glucose utilization by muscle and fat tissue, counteracting the effect of insulin. If insulin levels are not increased during times of illness and infection, hyperglycemia may progress to DKA (ADA, 2006c).

Prevention

For prevention of DKA related to illness, “sick day” rules for managing their diabetes when ill (Chart 41-9) should be reviewed. The most important concept in this is to never eliminate insulin doses when nausea and vomiting occur. Instead, the patient should take the usual insulin dose (or previously prescribed special “sick day” doses) and then attempt to consume frequent small portions of carbohydrates (including foods usually avoided, such as juices, regular sodas, and gelatin). Drinking fluids every hour is important to prevent dehydration. Blood glucose and urine ketones must be assessed every 3 to 4 hours.

If the patient cannot take fluids without vomiting, or if elevated glucose or ketone levels persist, the physician must be contacted. Patients are taught to have foods available for use on sick days. In addition, a supply of urine test strips (for ketone testing) and blood glucose test strips should be available. The patient must know how to contact his or her physician 24 hours a day. These materials should be assembled in a “sick day” kit.

After the acute phase of DKA has resolved, the nurse should assess for underlying causes of DKA. If there are psychological reasons for the patient’s deliberately missing insulin doses, the patient and family may be referred for evaluation and counseling or therapy.

Clinical Manifestations

The hyperglycemia of DKA leads to polyuria and polydipsia (increased thirst). In addition, the patient may experience blurred vision, weakness, and headache. Patients with marked intravascular volume depletion may have orthostatic hypotension (drop in systolic blood pressure of 20 mm Hg or more on changing from a reclining to a standing position). Volume depletion may also lead to frank hypotension with a weak, rapid pulse.

The ketosis and acidosis of DKA lead to gastrointestinal symptoms such as anorexia, nausea, vomiting, and abdominal pain. The abdominal pain and physical findings on

examination can be so severe that they resemble an acute abdominal disorder that requires surgery. The patient may have acetone breath (a fruity odor), which occurs with elevated ketone levels. In addition, hyperventilation (with very deep, but not labored, respirations) may occur. These Kussmaul respirations represent the body’s attempt to decrease the acidosis, counteracting the effect of the ketone buildup. In addition, mental status in DKA varies widely. The patient may be alert, lethargic, or comatose.

Assessment and Diagnostic Findings

Blood glucose levels may vary between 300 and 800 mg/dL (16.6 to 44.4 mmol/L). Some patients have lower glucose values, and others have values of 1000 mg/dL (55.5 mmol/L) or higher (usually depending on the degree of dehydration). The severity of DKA is not necessarily related to the blood glucose level. Evidence of ketoacidosis is reflected in low serum bicarbonate (0 to 15 mEq/L) and low pH (6.8 to 7.3) values. A low partial pressure of carbon dioxide (PCO₂; 10 to 30 mm Hg) reflects respiratory compensation (Kussmaul respirations) for the metabolic acidosis. Accumulation of ketone bodies (which precipitates the acidosis) is reflected in blood and urine ketone measurements.

Sodium and potassium concentrations may be low, normal, or high, depending on the amount of water loss (dehydration). Despite the plasma concentration, there has been a marked total body depletion of these (and other) electrolytes and they will need to be replaced.

Increased levels of creatinine, blood urea nitrogen (BUN), and hematocrit may also be seen with dehydration. After rehydration, continued elevation in the serum creatinine and BUN levels suggests underlying renal insufficiency.

Management

In addition to treating hyperglycemia, management of DKA is aimed at correcting dehydration, electrolyte loss, and acidosis.

Rehydration

In dehydrated patients, rehydration is important for maintaining tissue perfusion. In addition, fluid replacement enhances the excretion of excessive glucose by the kidneys. The patient may need as much as 6 to 10 L of IV fluid to replace fluid losses caused by polyuria, hyperventilation, diarrhea, and vomiting.

Initially, 0.9% sodium chloride (normal saline) solution is administered at a rapid rate, usually 0.5 to 1 L/h for 2 to 3 hours. Half-strength normal saline (0.45%) solution (also known as hypotonic saline solution) may be used for patients with hypertension or hypernatremia and those at risk for heart failure. After the first few hours, half-strength normal saline solution is the fluid of choice for continued rehydration, provided the blood pressure is stable and the sodium level is not low. Moderate to high rates of infusion (200 to 500 mL/h) may be needed for several more hours. When the blood glucose level reaches 300 mg/dL (16.6 mmol/L) or less, the IV solution may be changed to dextrose 5% in water (D₅W) to prevent a precipitous decline in the blood glucose level (Fowler, 2009).

Monitoring of fluid volume status involves frequent measurements of vital signs (including monitoring for orthostatic changes in blood pressure and heart rate), lung assessment, and monitoring of intake and output. Initial urine output lags behind IV fluid intake as dehydration is corrected. Plasma expanders may be necessary to correct severe hypotension that does not respond to IV fluid treatment. Monitoring for signs of fluid overload is especially important for patients who are older, have renal impairment, or are at risk for heart failure.

Restoring Electrolytes

The major electrolyte of concern during treatment of DKA is potassium. Although the initial plasma concentration of potassium may be low, normal, or even high, there is a major loss of potassium from body stores and an intracellular-to-extracellular shift of potassium. Furthermore, the serum level of potassium decreases as potassium reenters the cells during the course of treatment of DKA; therefore, the serum potassium level must be monitored frequently. Some of the factors related to treating DKA that reduce the serum potassium concentration include rehydration, which leads to increased plasma volume and subsequent decreases in the concentration of serum potassium. Rehydration also leads to increased urinary excretion of potassium. Insulin administration enhances the movement of potassium from the extracellular fluid into the cells.

Cautious but timely potassium replacement is vital to avoid dysrhythmias that may occur with hypokalemia. As much as 40 mEq/h may be needed for several hours. Because extracellular potassium levels decrease during DKA treatment, potassium must be infused even if the plasma potassium level is normal.

Frequent (every 2 to 4 hours initially) ECGs and laboratory measurements of potassium are necessary during the first 8 hours of treatment. Potassium replacement is withheld only if hyperkalemia is present or if the patient is not urinating.

NURSING ALERT

Because a patient's serum potassium level may drop quickly as a result of rehydration and insulin treatment, potassium replacement must begin once potassium levels drop to normal.

Reversing Acidosis

Ketone bodies (acids) accumulate as a result of fat breakdown. The acidosis that occurs in DKA is reversed with insulin, which inhibits fat breakdown, thereby stopping

acid buildup. Insulin is usually infused intravenously at a slow, continuous rate (eg, 5 units/h). Hourly blood glucose values must be measured. IV fluid solutions with higher concentrations of glucose, such as normal saline (NS) solution (eg, D₅NS, D₅.45NS), are administered when blood glucose levels reach 250 to 300 mg/dL (13.8 to 16.6 mmol/L) to avoid too rapid a drop in the blood glucose level (ie, hypoglycemia) during treatment.

Regular insulin, the only type of insulin approved for IV use, may be added to IV solutions. The nurse must convert hourly rates of insulin infusion (frequently prescribed as units per hour) to IV drip rates. For example, if 100 units of regular insulin are mixed into 500 mL of 0.9% NS, then 1 unit of insulin equals 5 mL; therefore, an initial insulin infusion rate of 5 units/h would equal 25 mL/h. The insulin is often infused separately from the rehydration solutions to allow frequent changes in the rate and content of the latter.

Insulin must be infused continuously until subcutaneous administration of insulin can be resumed. Any interruption in administration may result in the reaccumulation of ketone bodies and worsening acidosis. Even if blood glucose levels are decreasing and returning to normal, the insulin drip must not be stopped until subcutaneous insulin therapy has been started. Rather, the rate or concentration of the dextrose infusion should be increased. Blood glucose levels are usually corrected before the acidosis is corrected. Therefore, IV insulin may be continued for 12 to 24 hours, until the serum bicarbonate level increases (to at least 15 to 18 mEq/L) and until the patient can eat. In general, bicarbonate infusion to correct severe acidosis is avoided during treatment of DKA because it precipitates further, sudden (and potentially fatal) decreases in serum potassium levels. Continuous insulin infusion is usually sufficient for reversal of DKA (ADA, 2006c).

NURSING ALERT

When mixing the insulin drip, it is important to flush the insulin solution through the entire IV infusion set and to discard the first 50 mL of fluid. Insulin molecules adhere to the inner surface of IV infusion sets; therefore, the initial fluid may contain a decreased concentration of insulin.

Hyperglycemic Hyperosmolar Nonketotic Syndrome

Hyperglycemic hyperosmolar nonketotic syndrome (HHNS) is a serious condition in which hyperosmolarity and hyperglycemia predominate, with alterations of the sensorium (sense of awareness). At the same time, ketosis is usually minimal or absent. The basic biochemical defect is lack of effective insulin (ie, insulin resistance). Persistent hyperglycemia causes osmotic diuresis, which results in losses of water and electrolytes. To maintain osmotic equilibrium, water shifts from the intracellular fluid space to the

Table 41-8 COMPARISON OF DIABETIC KETOACIDOSIS (DKA) AND HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC SYNDROME (HHNS)

Characteristics	DKA	HHNS
Patients most commonly affected	Can occur in type 1 or type 2 diabetes; more common in type 1 diabetes	Can occur in type 1 or type 2 diabetes; more common in type 2 diabetes, especially elderly patients with type 2 diabetes
Precipitating event	Omission of insulin; physiologic stress (infection, surgery, CVA, MI)	Physiologic stress (infection, surgery, CVA, MI)
Onset	Rapid (<24 h)	Slower (over several days)
Blood glucose levels	Usually >250 mg/dL (>13.9 mmol/L)	Usually >600 mg/dL (>33.3 mmol/L)
Arterial pH level	<7.3	Normal
Serum and urine ketones	Present	Absent
Serum osmolality	300–350 mOsm/L	>350 mOsm/L
Plasma bicarbonate level	<15 mEq/L	Normal
BUN and creatinine levels	Elevated	Elevated
Mortality rate	<5%	10–40%

BUN, blood urea nitrogen; CVA, cerebrovascular accident; MI, myocardial infarction.

extracellular fluid space. With glycosuria and dehydration, hyponatremia and increased osmolality occur. Table 41-8 compares DKA and HHNS.

HHNS occurs most often in older people (50 to 70 years of age) who have no known history of diabetes or who have type 2 diabetes. HHNS often can be traced to a precipitating event such as an acute illness (eg, pneumonia, cerebrovascular accident [CVA]), medications that exacerbate hyperglycemia (eg, thiazides), or treatments such as dialysis. The history includes days to weeks of polyuria with adequate fluid intake. What distinguishes HHNS from DKA is that ketosis and acidosis generally do not occur in HHNS, partly because of differences in insulin levels. In DKA, no insulin is present, and this promotes the breakdown of stored glucose, protein, and fat, which leads to the production of ketone bodies and ketoacidosis. In HHNS, the insulin level is too low to prevent hyperglycemia (and subsequent osmotic diuresis), but it is high enough to prevent fat breakdown. Patients with HHNS do not have the ketosis-related gastrointestinal symptoms that lead them to seek medical attention. Instead, they may tolerate polyuria and polydipsia until neurologic changes or an underlying illness (or family members or others) prompts them to seek treatment. Because of possible delays in therapy, hyperglycemia, dehydration, and hyperosmolality may be more severe in HHNS.

Clinical Manifestations

The clinical picture of HHNS is one of hypotension, profound dehydration (dry mucous membranes, poor skin turgor), tachycardia, and variable neurologic signs (eg, alteration of sensorium, seizures, hemiparesis). The mortality rate ranges from 10% to 40%, usually related to an underlying illness, the vulnerability of the elderly patient, and the severity of HHNS.

Assessment and Diagnostic Findings

Diagnostic assessment includes a range of laboratory tests, including blood glucose, electrolytes, BUN, complete blood count, serum osmolality, and arterial blood gas analysis. The blood glucose level is usually 600 to 1200 mg/dL, and the osmolality exceeds 350 mOsm/kg. Electrolyte and

BUN levels are consistent with the clinical picture of severe dehydration. Mental status changes, focal neurologic deficits, and hallucinations are common secondary to the cerebral dehydration that results from extreme hyperosmolality. Postural hypotension accompanies the dehydration.

Management

The overall approach to the treatment of HHNS is similar to that of DKA: fluid replacement, correction of electrolyte imbalances, and insulin administration. Because patients with HHNS are typically older, close monitoring of volume and electrolyte status is important for prevention of fluid overload, heart failure, and cardiac dysrhythmias. Fluid treatment is started with 0.9% or 0.45% NS, depending on the patient's sodium level and the severity of volume depletion. Central venous or hemodynamic pressure monitoring guides fluid replacement. Potassium is added to IV fluids when urinary output is adequate and is guided by continuous ECG monitoring and frequent laboratory determinations of potassium.

Extremely elevated blood glucose concentrations decrease as the patient is rehydrated. Insulin plays a less important role in the treatment of HHNS because it is not needed for reversal of acidosis, as in DKA. Nevertheless, insulin is usually administered at a continuous low rate to treat hyperglycemia, and replacement IV fluids with dextrose are administered (as in DKA) after the glucose level has decreased to the range of 250 to 300 mg/dL (13.8 to 16.6 mmol/L) (ADA, 2008d; Fowler, 2009).

Other therapeutic modalities are determined by the underlying illness and the results of continuing clinical and laboratory evaluation. It may take 3 to 5 days for neurologic symptoms to clear, and treatment of HHNS usually continues well after metabolic abnormalities have resolved. After recovery from HHNS, many patients can control their diabetes with MNT alone or with MNT and oral antidiabetic medications. Insulin may not be needed once the acute hyperglycemic complication is resolved. Frequent SBGM is important in prevention of recurrence of HHNS.

NURSING PROCESS

THE PATIENT WITH DIABETIC KETOACIDOSIS OR HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC SYNDROME

Assessment

For the patient with DKA, the nurse monitors the ECG for dysrhythmias indicating abnormal potassium levels. Vital signs (especially blood pressure and pulse), arterial blood gases, breath sounds, and mental status are assessed every hour and recorded on a flow sheet. Neurologic status checks are included as part of the hourly assessment as cerebral edema can be a severe and sometimes fatal outcome.

For the patient with HHNS, the nurse assesses vital signs, fluid status, and laboratory values. Fluid status and urine output are closely monitored because of the high risk of renal failure secondary to severe dehydration. Because HHNS tends to occur in older patients, the physiologic changes that occur with aging should be considered. Careful assessment of cardiovascular, pulmonary, and renal function throughout the acute and recovery phases of HHNS is important.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for fluid volume deficit related to polyuria and dehydration
- Fluid and electrolyte imbalance related to fluid loss or shifts
- Deficient knowledge about diabetes self-care skills or information
- Anxiety related to loss of control, fear of inability to manage diabetes, misinformation related to diabetes, fear of diabetes complications

Collaborative Problems/Potential Complications

Based on assessment data, potential complications may include the following:

- Fluid overload, pulmonary edema, and heart failure
- Hypokalemia
- Hyperglycemia and ketoacidosis
- Hypoglycemia
- Cerebral edema

Planning and Goals

The major goals for the patient may include maintenance of fluid and electrolyte balance, optimal control of blood glucose levels, ability to perform diabetes survival skills and self-care activities, and absence of complications.

Nursing Interventions

Maintaining Fluid and Electrolyte Balance

Intake and output are measured. IV fluids and electrolytes are administered as prescribed, and oral fluid

intake is encouraged when it is permitted. Laboratory values of serum electrolytes (especially sodium and potassium) are monitored. Vital signs are monitored hourly for signs of dehydration (tachycardia, orthostatic hypotension) along with assessment of breath sounds, level of consciousness, presence of edema, and cardiac status (ECG rhythm strips).

Increasing Knowledge About Diabetes Management

The development of DKA or HHNS suggests the need for the nurse to carefully assess the patient's understanding of and adherence to the diabetes management plan. Further, factors that may have led to the development of DKA or HHNS are explored with the patient and family. If the patient's blood glucose monitoring, dietary intake, use of antidiabetes (insulin or oral agents) medications, and exercise patterns differ from those identified in the diabetes management plan, their relationship to the development of DKA or HHNS is discussed, along with early manifestations of DKA or HHNS. If other factors, such as trauma, illness, surgery, or stress, are implicated, appropriate strategies to respond to these and similar situations in the future are described so that the patient can respond in the future without developing life-threatening complications. It may be necessary to reteach survival skills to patients who may not be able to recall them. If the patient has omitted insulin or oral antidiabetes agents that have been prescribed, it is important to explore the reasons for doing so and address those issues to prevent future recurrence and readmissions for treatment of these complications.

If the patient has not previously been diagnosed with diabetes, the opportunity is used to teach the patient about the need for maintaining blood glucose at a normal level and learning about diabetes management and survival skills.

Monitoring and Managing Potential Complications

FLUID OVERLOAD. Fluid overload can occur because of the administration of a large volume of fluid at a rapid rate, which is often required to treat patients with DKA or HHNS. This risk is increased in elderly patients and in those with preexisting cardiac or renal disease. To avoid fluid overload and resulting heart failure and pulmonary edema, the nurse monitors the patient closely during treatment by measuring vital signs and intake and output at frequent intervals. Central venous pressure monitoring and hemodynamic monitoring may be initiated to provide additional measures of fluid status. Physical examination focuses on assessment of cardiac rate and rhythm, breath sounds, venous distention, skin turgor, and urine output. The nurse monitors fluid intake and keeps careful records of IV and other fluid intake, along with urine output measurements.

HYPOKALEMIA. As previously described, hypokalemia is a potential complication during the treatment of DKA as potassium is lost from body stores. Low serum potassium levels may result from rehydration, increased urinary excretion of potassium, and movement of potassium from the extracellular fluid into the cells with insulin administration.

Prevention of hypokalemia includes cautious replacement of potassium; however, before its administration, it is important to ensure that a patient's kidneys are functioning. Because of the adverse effects of hypokalemia on cardiac function, monitoring of the cardiac rate, cardiac rhythm, ECG, and serum potassium levels is essential.

CEREBRAL EDEMA. Although the cause of cerebral edema is unknown, rapid correction of hyperglycemia, resulting in fluid shifts, is thought to be the cause. Cerebral edema, which occurs more often in children than in adults, can be prevented by gradual reduction in the blood glucose level (ADA, 2006c). An hourly flow sheet is used to enable close monitoring of the blood glucose level, serum electrolyte levels, urine output, mental status, and neurologic signs. Precautions are taken to minimize activities that could increase intracranial pressure.

Teaching Patients Self-Care

The patient is taught survival skills, including treatment modalities (diet, insulin administration, monitoring of blood glucose, and, for type 1 diabetes, monitoring of urine ketones); recognition, treatment, and prevention of DKA and HHNS. Teaching addresses those factors leading to DKA or HHNS. Follow-up education is arranged with a home care nurse and dietitian or an outpatient diabetes education center. This is particularly important for patients who have experienced DKA or HHNS because of the need to address factors that led to its occurrence. The importance of self-monitoring and of monitoring and follow-up by primary health care providers is reinforced, and the patient is reminded about the importance of keeping follow-up appointments.

Evaluation

Expected Outcomes

1. Achieves fluid and electrolyte balance
 - a. Demonstrates intake and output balance
 - b. Exhibits electrolyte values within normal limits
 - c. Exhibits vital signs that remain stable, with resolution of orthostatic hypotension and tachycardia
2. Demonstrates knowledge about DKA and HHNS
 - a. Identifies factors leading to DKA and HHNS
 - b. Describes signs and symptoms of DKA and HHNS
 - c. Describes short-term and long-term consequences of DKA and HHNS
 - d. Identifies strategies to prevent the development of DKA and HHNS
 - e. States when contact with health care provider is needed to treat early signs of DKS and HHNS
3. Absence of complications
 - a. Exhibits normal cardiac rate and rhythm and normal breath sounds
 - b. Exhibits no jugular venous distention
 - c. Exhibits blood glucose and urine ketone levels within target range
 - d. Exhibits no manifestations of hypoglycemia or hyperglycemia
 - e. Shows improved mental status without signs of cerebral edema

LONG-TERM COMPLICATIONS OF DIABETES

There has been a steady decline in the number of deaths attributable to ketoacidosis and infection in patients with diabetes but an alarming increase in the number of deaths from cardiovascular and renal complications. Long-term complications, which are becoming more common as more people live longer with diabetes, can affect almost every organ system of the body and are a major cause of disability. The general categories of long-term diabetic complications are macrovascular disease, microvascular disease, and neuropathy.

The specific causes and pathogenesis of each type of complication are still being investigated. However, it appears that increased levels of blood glucose may play a role in neuropathic disease, microvascular complications, and risk factors contributing to macrovascular complications. Hypertension may also be a major contributing factor, especially in macrovascular and microvascular diseases.

Long-term complications are seen in both type 1 and type 2 diabetes but usually do not occur within the first 5 to 10 years after diagnosis. However, evidence of these complications may be present at the time of diagnosis of type 2 diabetes, because patients may have had undiagnosed diabetes for many years. Renal (microvascular) disease is more prevalent in patients with type 1 diabetes, and cardiovascular (macrovascular) complications are more prevalent in older patients with type 2 diabetes.

Macrovascular Complications

Diabetic macrovascular complications result from changes in the medium to large blood vessels. Blood vessel walls thicken, sclerose, and become occluded by plaque that adheres to the vessel walls. Eventually, blood flow is blocked. These atherosclerotic changes tend to occur more often and at an earlier age in patients with diabetes. Coronary artery disease, cerebrovascular disease, and peripheral vascular disease are the three main types of macrovascular complications that occur frequently in the diabetic population.

Myocardial infarction (MI) is twice as common in men with diabetes and three times as common in women with diabetes, compared to people without diabetes. There is also an increased risk for complications resulting from MI and an increased likelihood of a second MI. Coronary artery disease may account for 50% to 60% of all deaths among patients with diabetes. The typical ischemic symptoms may be absent in patients with diabetes. Therefore, the patient may not experience the early warning signs of decreased coronary blood flow and may have "silent" MIs, which may be discovered only as changes on the ECG. However, ECG changes may not be apparent. This lack of ischemic symptoms may be secondary to autonomic neuropathy (see later discussion). Cardiac disease is discussed in detail in Chapter 28.

Cerebral blood vessels are similarly affected by accelerated atherosclerosis. Occlusive changes or the formation of an embolus elsewhere in the vasculature that lodges in a

cerebral blood vessel can lead to transient ischemic attacks and strokes. People with diabetes have twice the risk of developing cerebrovascular disease, and an increased risk of death from CVA. In addition, recovery from a stroke may be impaired in patients who have elevated blood glucose levels at the time of and immediately after a stroke. Because symptoms of CVA may be similar to symptoms of acute diabetic complications (HHNS or hypoglycemia), it is very important to assess the blood glucose level (and treat abnormal levels) rapidly in patients with these symptoms, so that testing and treatment of CVA (stroke) can be initiated promptly if indicated.

Atherosclerotic changes in the large blood vessels of the lower extremities are responsible for the increased incidence (two to three times higher than in nondiabetic people) of occlusive peripheral arterial disease in patients with diabetes. Signs and symptoms of peripheral vascular disease include diminished peripheral pulses and intermittent claudication (pain in the buttock, thigh, or calf during walking). The severe form of arterial occlusive disease in the lower extremities is largely responsible for the increased incidence of gangrene and subsequent amputation in patients with diabetes. Neuropathy and impairments in wound healing also play a role in diabetic foot disease (see later discussion).

Role of Diabetes in Macrovascular Diseases

Researchers continue to investigate the relationship between diabetes and macrovascular diseases. The main feature unique to diabetes is elevated blood glucose; however, a direct link has not been found between hyperglycemia and atherosclerosis. Although it may be tempting to attribute the increased prevalence of macrovascular diseases to the increased prevalence of certain risk factors (eg, obesity, increased triglyceride levels, hypertension) in patients with diabetes, there is a higher-than-expected rate of macrovascular diseases among patients with diabetes compared with patients without diabetes who have the same risk factors (ADA, 2009b). Therefore, diabetes itself is seen as an independent risk factor for accelerated atherosclerosis. Other potential factors that may play a role in diabetes-related atherosclerosis include platelet and clotting factor abnormalities, decreased flexibility of red blood cells, decreased oxygen release, changes in the arterial wall related to hyperglycemia, and possibly hyperinsulinemia.

Management

The focus of management is aggressive modification and reduction of risk factors. This involves prevention and treatment of the commonly accepted risk factors for atherosclerosis. MNT and exercise are important in managing obesity, hypertension, and hyperlipidemia. In addition, the use of medications to control hypertension and hyperlipidemia is indicated. Smoking cessation is essential. Control of blood glucose levels may reduce triglyceride concentrations and can significantly reduce the incidence of complications.

When macrovascular complications do occur, patients may require increased amounts of insulin or may need to switch from oral antidiabetic agents to insulin during illnesses.

Microvascular Complications

Diabetic microvascular disease (or microangiopathy) is characterized by capillary basement membrane thickening. The basement membrane surrounds the endothelial cells of the capillary. Researchers believe that increased blood glucose levels react through a series of biochemical responses to thicken the basement membrane to several times its normal thickness. Two areas affected by these changes are the retina and the kidneys.

DIABETIC RETINOPATHY

Diabetic retinopathy is the leading cause of blindness among people between 20 and 74 years of age in the United States; it occurs in both type 1 and type 2 diabetes (ADA, 2009b; CDC, 2008).

People with diabetes are subject to many visual complications (Table 41-9). The eye pathology referred to as diabetic retinopathy is caused by changes in the small blood vessels in the retina, the area of the eye that receives images and sends information about the images to the brain (Fig. 41-8). The retina is richly supplied with blood vessels of all

Table 41-9 OCULAR COMPLICATIONS OF DIABETES

Eye Disorder	Characteristics
Retinopathy	Deterioration of the small blood vessels that nourish the retina.
Background	Early stage, asymptomatic retinopathy. Blood vessels within the retina develop microaneurysms that leak fluid, causing swelling and forming deposits (exudates). In some cases, macular edema causes distorted vision.
Preproliferative	Represents increased destruction of retinal blood vessels.
Proliferative	Abnormal growth of new blood vessels on the retina. New vessels rupture, bleeding into the vitreous and blocking light. Ruptured blood vessels in the vitreous form scar tissue, which can pull on and detach the retina.
Cataracts	Opacity of the lens of the eye; cataracts occur at an earlier age in patients with diabetes.
Lens Changes	The lens of the eye can swell when blood glucose levels are elevated. For some patients, visual changes related to lens swelling may be the first symptoms of diabetes. It may take up to 2 months of improved blood glucose control before hyperglycemic swelling subsides and vision stabilizes. Therefore, patients are advised not to change eyeglass prescriptions during the 2 months after discovery of hyperglycemia.
Extraocular Muscle Palsy	This may occur as a result of diabetic neuropathy. The involvement of various cranial nerves responsible for ocular movements may lead to double vision. This usually resolves spontaneously.
Glaucoma	Results from occlusion of the outflow channels by new blood vessels. Glaucoma may occur with slightly higher frequency in the diabetic population.

Figure 41-8 Diabetic retinopathy. **A**, In the fundus photograph of a normal eye, the light circular area over which a number of blood vessels converge is the optic disk, where the optic nerve meets the back of the eye. **B**, The fundus photograph of a patient with diabetic retinopathy shows characteristic waxy-looking retinal lesions, microaneurysms of the vessels, and hemorrhages. (Courtesy of American Optometric Association.)

kinds: small arteries and veins, arterioles, venules, and capillaries. Retinopathy has three main stages: nonproliferative (background), preproliferative, and proliferative.

Almost all patients with type 1 diabetes and more than 60% of patients with type 2 diabetes have some degree of retinopathy after 20 years (ADA, 2009b). Changes in the microvasculature include microaneurysms, intraretinal hemorrhage, hard exudates, and focal capillary closure. Although most patients do not develop visual impairment, it can be devastating if it occurs. A complication of nonproliferative retinopathy, macular edema, occurs in approximately 10% of people with type 1 or type 2 diabetes and may lead to visual distortion and loss of central vision (ADA, 2008e).

An advanced form of background retinopathy, preproliferative retinopathy, is considered to be a precursor to the more serious proliferative retinopathy. In preproliferative retinopathy, there are more widespread vascular changes and loss of nerve fibers. Epidemiologic evidence suggests that 10% to 50% of patients with preproliferative retinopathy will develop proliferative retinopathy within a short time (possibly as little as 1 year). As with background retinopathy, if visual changes occur during the preproliferative stage, they are usually caused by macular edema.

Proliferative retinopathy represents the greatest threat to vision and is characterized by the proliferation of new blood vessels growing from the retina into the vitreous. These new vessels are prone to bleeding. The visual loss associated with proliferative retinopathy is caused by this vitreous hemorrhage, retinal detachment, or both. The vitreous is normally clear, allowing light to be transmitted to the retina. When there is a hemorrhage, the vitreous becomes clouded and cannot transmit light, resulting in loss of vision. Another consequence of vitreous hemorrhage is that resorption of the blood in the vitreous leads to the formation of fibrous scar tissue. This scar tissue may place traction on the retina, resulting in retinal detachment and subsequent visual loss.

Clinical Manifestations

Retinopathy is a painless process. In nonproliferative and preproliferative retinopathy, blurry vision secondary to macular edema occurs in some patients, although many

patients are asymptomatic. Even patients with a significant degree of proliferative retinopathy and some hemorrhaging may not experience major visual changes. However, symptoms indicative of hemorrhaging include floaters or cobwebs in the visual field, sudden visual changes including spotty or hazy vision, or complete loss of vision.

Assessment and Diagnostic Findings

Diagnosis is by direct visualization of the retina through dilated pupils with an ophthalmoscope or with a technique known as fluorescein angiography. Fluorescein angiography can document the type and activity of the retinopathy. Dye is injected into an arm vein and is carried to various parts of the body through the blood, but especially through the vessels of the retina of the eye. This technique allows an ophthalmologist, using special instruments, to see the retinal vessels in bright detail and gives useful information that cannot be obtained with just an ophthalmoscope.

Side effects of this diagnostic procedure may include nausea during the dye injection; yellowish, fluorescent discoloration of the skin and urine lasting 12 to 24 hours; and occasionally allergic reactions, usually manifested by hives or itching. However, the diagnostic procedure is generally safe.

Medical Management

The first focus of management of retinopathy is on primary and secondary prevention. The DCCT study (1993) demonstrated that in patients without preexisting retinopathy, maintenance of blood glucose to a normal or near-normal level in type 1 diabetes through intensive insulin therapy and patient education decreased the risk of retinopathy by 76%, compared with conventional therapy. The progression of retinopathy was decreased by 54% in patients with very mild to moderate nonproliferative retinopathy at the time of initiation of treatment. Similarly, the UKPDS study (1998) demonstrated that better control of blood glucose levels in patients with type 2 diabetes led to reduced risk of retinopathy.

Other strategies that may slow the progression of diabetic retinopathy include control of hypertension, control of blood glucose, and cessation of smoking.

For advanced cases of diabetic retinopathy, the main treatment is argon laser photocoagulation. The laser treatment

destroys leaking blood vessels and areas of neovascularization. For patients who are at increased risk for hemorrhage, panretinal photocoagulation may significantly reduce the rate of progression to blindness. Panretinal photocoagulation involves the systematic application of multiple (more than 1000) laser burns throughout the retina (except in the macular region). This stops the widespread growth of new vessels and hemorrhaging of damaged vessels. The role of “mild” panretinal photocoagulation (with only one-third to one-half as many laser burns) in the early stages of proliferative retinopathy or in patients with preproliferative changes is being investigated. For patients with macular edema, focal photocoagulation is used to apply smaller laser burns to specific areas of microaneurysms in the macular region. This may reduce the rate of visual loss from macular edema by 50% (ADA, 2008e).

Photocoagulation treatments are usually performed on an outpatient basis, and most patients can return to their usual activities by the next day. Limitations may be placed on activities involving weight bearing or bearing down. In most cases, the treatment does not cause intense pain, although patients may report varying degrees of discomfort. Usually an anesthetic eye drop is all that is needed during the treatment. A few patients may experience slight visual loss, loss of peripheral vision, or impairments in adaptation to the dark. However, the risk of slight visual changes from the laser treatment itself is much less than the potential for loss of vision from progression of retinopathy.

A major hemorrhage into the vitreous may occur, with the vitreous fluid becoming mixed with blood, preventing light from passing through the eye; this can cause blindness. A vitrectomy is a surgical procedure in which vitreous humor filled with blood or fibrous tissue is removed with a special drill-like instrument and replaced with saline or another liquid. A vitrectomy is performed for patients who already have visual loss and in whom the vitreous hemorrhage has not cleared on its own after 6 months. The purpose is to restore useful vision; recovery to near-normal vision is not usually expected.

Nursing Management

Nursing management of patients with diabetic retinopathy or other eye disorders involves implementing the individual plan of care and providing patient education. Education focuses on prevention through regular ophthalmologic examinations and blood glucose control and self-management of eye care regimens. The effectiveness of early diagnosis and prompt treatment is emphasized in teaching the patient and family. If vision loss occurs, nursing care must also address the patient’s adjustment to impaired vision and use of adaptive devices for diabetes self-care as well as activities of daily living. Nursing care for patients with low vision or loss of vision is discussed in detail in Chapter 58.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Because the course of the retinopathy may be long and stressful, patient teaching is essential. In teaching and counseling patients, it is important to stress the following:

- Retinopathy may appear after many years of diabetes, and its appearance does not necessarily mean that the diabetes is on a downhill course.
- The odds for maintaining vision are in the patient’s favor, especially with adequate control of glucose levels and blood pressure.
- Frequent eye examinations allow for the detection and prompt treatment of retinopathy.

A patient’s response to vision loss depends on personality, self-concept, and coping mechanisms. Acceptance of blindness occurs in stages; some patients may learn to accept blindness in a rather short period, and others may never do so. An important issue in teaching patients is that several complications of diabetes occur simultaneously. For example, a patient who is blind due to diabetic retinopathy may also have peripheral neuropathy and may experience impairment of manual dexterity and tactile sensation. To prevent further losses, glycemic control remains a priority.

Continuing Care

The importance of careful diabetes management is emphasized as one means of slowing the progression of visual changes. The patient is reminded of the need to see an ophthalmologist regularly. If eye changes are progressive and unrelenting, the patient should be prepared for inevitable blindness. Therefore, consideration is given to making referrals for teaching the patient Braille and for training him or her with guide (ie, service) dogs. Referral to state agencies should be made to ensure that the patient receives services for the blind. Family members are also taught how to assist the patient to remain as independent as possible despite decreasing visual acuity.

Referral for home care may be indicated for some patients, particularly those who live alone, those who are not coping well, and those who have other health problems or complications of diabetes that may interfere with their ability to perform self-care. During home visits, the nurse can assess the patient’s home environment and his or her ability to manage diabetes despite visual impairments. Medical management and nursing care of patients with visual disturbances are discussed in detail in Chapter 58.

NEPHROPATHY

Nephropathy, or renal disease secondary to diabetic microvascular changes in the kidney, is a common complication of diabetes (ADA, 2008f, 2009b). In the United States each year, people with diabetes account for almost 50% of new cases of end-stage renal disease (ESRD) and about 25% of those require dialysis or transplantation. About 20% to 30% of people with type 1 or type 2 diabetes develop nephropathy, but fewer of those with type 2 diabetes progress to ESRD. Native American, Latino, African American, Asian American, and Pacific Island people with type 2 diabetes are at greater risk for ESRD than non-Latino whites (ADA, 2009b).

Patients with type 1 diabetes frequently show initial signs of renal disease after 10 to 15 years; patients with type 2 diabetes develop renal disease within 10 years after the diagnosis of diabetes. Many patients with type 2 diabetes have

had diabetes for many years before the diabetes is diagnosed and treated. Therefore, they may have evidence of nephropathy at the time of diagnosis (ADA, 2008f). If blood glucose levels are elevated consistently for a significant period of time, the kidney's filtration mechanism is stressed, allowing blood proteins to leak into the urine. As a result, the pressure in the blood vessels of the kidney increases. It is thought that this elevated pressure serves as the stimulus for the development of nephropathy. Various medications and diets are being tested to prevent these complications.

The DCCT (1993) results showed that intensive treatment of type 1 diabetes with a goal of achieving a hemoglobin A_{1C} level as close to the nondiabetic range as possible reduced the occurrence of early signs of nephropathy. Similarly, the UKPDS study (1998) demonstrated a reduced incidence of overt nephropathy in patients with type 2 diabetes who controlled their blood glucose levels.

Clinical Manifestations

Most of the signs and symptoms of renal dysfunction in patients with diabetes are similar to those seen in patients without diabetes (see Chapter 44). In addition, as renal failure progresses, the catabolism (breakdown) of both exogenous and endogenous insulin decreases, and frequent hypoglycemic episodes may result. Insulin needs change as a result of changes in the catabolism of insulin, changes in diet related to the treatment of nephropathy, and changes in insulin clearance that occur with decreased renal function. The stress of renal disease affects self-esteem, family relationships, marital relations, and virtually all aspects of daily life. As renal function decreases, patients commonly have multiple-system failure (eg, declining visual acuity, impotence, foot ulcerations, heart failure, nocturnal diarrhea).

Assessment and Diagnostic Findings

Albumin is one of the most important blood proteins that leaks into the urine. Although small amounts may leak undetected for years, its leakage into the urine is among the earliest signs that can be detected. Clinical nephropathy eventually develops in more than 85% of people with microalbuminuria but in fewer than 5% of people without microalbuminuria. The urine should be checked annually for the presence of microalbumin. If the microalbuminuria exceeds 30 mg/24 hours on two consecutive random urine tests, a 24-hour urine sample should be obtained and tested. If results are positive, treatment is indicated (see later discussion).

In addition, tests for serum creatinine and BUN levels should be conducted annually. Diagnostic testing for cardiac or other systemic disorders may also be required with progression of other complications, and caution is indicated if contrast agents are used with these tests. Contrast agents and dyes used for some diagnostic tests may not be easily cleared by the damaged kidney, and the potential benefits of these diagnostic tests must be weighed against their potential risks.

Hypertension often develops in patients (with and without diabetes) who are in the early stages of renal disease. However, hypertension occurs in as many as 50% of all people with diabetes (for unknown reasons). Therefore, this symptom may or may not be due to renal disease; other diagnostic criteria must also be present.

Management

In addition to achieving and maintaining near-normal blood glucose levels, management for all patients with diabetes should include careful attention to the following:

- Control of hypertension (the use of angiotensin-converting enzyme [ACE] inhibitors, such as captopril [Capoten]), because control of hypertension may also decrease or delay the onset of early proteinuria
- Prevention or vigorous treatment of urinary tract infections
- Avoidance of nephrotoxic substances (eg, antibiotics, other selected medications)
- Adjustment of medications as renal function changes
- Low-sodium diet
- Low-protein diet

If the patient has already developed microalbuminuria and its level exceeds 30 mg/24 hours on two consecutive tests, an ACE inhibitor should be prescribed. ACE inhibitors lower blood pressure and reduce microalbuminuria, thereby protecting the kidney. Alternatively, angiotensin-receptor blocking (ARB) agents may be prescribed. This preventive strategy should be part of the standard of care for all people with diabetes. Carefully designed low-protein diets also appear to reverse early leakage of small amounts of protein from the kidney.

In chronic or end-stage renal failure, two types of treatment are available: dialysis (hemodialysis or peritoneal dialysis) and transplantation from a relative or a cadaver. Hemodialysis for patients with diabetes is similar to that for patients without the disease (see Chapter 44). Because hemodialysis creates additional stress on patients with cardiovascular disease, it may not be appropriate for some patients.

Continuous ambulatory peritoneal dialysis is being used by an increasing number of patients with diabetes, mainly because of the independence it allows. In addition, insulin can be mixed into the dialysate, which may result in better blood glucose control and end the need for insulin injections. In some cases, they may require higher doses of insulin because the dialysate contains glucose. Major risks of peritoneal dialysis are infection and peritonitis. The mortality rate for patients with diabetes undergoing dialysis is higher than that for patients without diabetes undergoing dialysis and is closely related to the severity of cardiovascular problems.

Renal disease is frequently accompanied by advancing retinopathy that may require laser treatments and surgery. Severe hypertension also worsens eye disease because of the additional stress it places on the blood vessels. Patients being treated with hemodialysis who require eye surgery may be changed to peritoneal dialysis and have their hypertension aggressively controlled for several weeks before surgery to prevent bleeding and damage to the retina. The rationale for this change is that hemodialysis requires anticoagulants that can increase the risk of bleeding after the surgery, and peritoneal dialysis minimizes pressure changes in the eyes.

The success rate for kidney transplantation in patients with diabetes has improved. In medical centers performing large numbers of transplantations, the chances are 75% to 80% that the transplanted kidney will continue to function in patients with diabetes for at least 5 years. Like the

original kidneys, transplanted kidneys can eventually be damaged if blood glucose levels are consistently high after the transplantation. Therefore, monitoring blood glucose levels frequently and adjusting insulin levels in patients with diabetes are essential for long-term success of kidney transplantation.

Diabetic Neuropathies

Diabetic neuropathy refers to a group of diseases that affect all types of nerves, including peripheral (sensorimotor), autonomic, and spinal nerves. The disorders appear to be clinically diverse and depend on the location of the affected nerve cells. The prevalence increases with the age of the patient and the duration of the disease and may be as high as 50% in patients who have had diabetes for 25 years (NIDDK, 2008a).

The etiology of neuropathy may involve elevated blood glucose levels over a period of years. The DCCT results (1993) showed that control of blood glucose levels to normal or near-normal levels decreased the incidence of neuropathy by 60%. The pathogenesis of neuropathy may be attributed to either a vascular or metabolic mechanism or both. Capillary basement membrane thickening and capillary closure may be present. In addition, there may be demyelination of the nerves, which is thought to be related to hyperglycemia. Nerve conduction is disrupted when there are aberrations of the myelin sheaths.

The two most common types of diabetic neuropathy are sensorimotor polyneuropathy and autonomic neuropathy. Sensorimotor polyneuropathy is also called peripheral neuropathy. Cranial mononeuropathies—those affecting the oculomotor nerve—also occur in diabetes, especially in the elderly.

Peripheral Neuropathy

Peripheral neuropathy most commonly affects the distal portions of the nerves, especially the nerves of the lower extremities; it affects both sides of the body symmetrically and may spread in a proximal direction.

Clinical Manifestations

Although approximately half of patients with diabetic neuropathy do not have symptoms, initial symptoms may include paresthesias (prickling, tingling, or heightened sensation) and burning sensations (especially at night). As the neuropathy progresses, the feet become numb. In addition, a decrease in proprioception (awareness of posture and movement of the body and of position and weight of objects in relation to the body) and a decreased sensation of light touch may lead to an unsteady gait. Decreased sensations of pain and temperature place patients with neuropathy at increased risk for injury and undetected foot infections. Deformities of the foot may also occur; neuropathy-related joint changes produce Charcot joints. These joint deformities result from the abnormal weight distribution on joints resulting from lack of proprioception.

On physical examination, a decrease in deep tendon reflexes and vibratory sensation is found. For patients who have few or no symptoms of neuropathy, these physical findings

may be the only indication of neuropathic changes. For patients with signs or symptoms of neuropathy, it is important to rule out other possible causes, including alcohol-induced and vitamin-deficiency neuropathies.

Management

The results of the DCCT study (1993) demonstrated that intensive insulin therapy and control of blood glucose levels delay the onset and slow the progression of neuropathy. Pain, particularly of the lower extremities, is a disturbing symptom in some people with neuropathy secondary to diabetes. In some cases, neuropathic pain spontaneously resolves within 6 months; for others, pain persists for many years. Various approaches to pain management can be tried. These include analgesics (preferably nonopioid); tricyclic antidepressants; antiseizure medications (phenytoin [Dilantin], carbamazepine [Tegretol], or gabapentin [Neurontin]); mexiletine (Mexitil, an antiarrhythmic); and transcutaneous electrical nerve stimulation (TENS).

Duloxetine (Cymbalta), an antidepressant medication, has been approved for treatment of peripheral diabetic neuropathy.

Autonomic Neuropathies

Neuropathy of the autonomic nervous system results in a broad range of dysfunctions affecting almost every organ system of the body (NIDDK, 2008a).

Clinical Manifestations

Three manifestations of autonomic neuropathy are related to the cardiac, gastrointestinal, and renal systems. Cardiovascular symptoms range from a fixed, slightly tachycardic heart rate and orthostatic hypotension to silent, or painless, myocardial ischemia and infarction. Delayed gastric emptying may occur with the typical gastrointestinal symptoms of early satiety, bloating, nausea, and vomiting. “Diabetic” constipation or diarrhea (especially nocturnal diarrhea) may occur as a result. In addition, there may be unexplained wide swings in blood glucose levels related to inconsistent absorption of the glucose from ingested foods secondary to the inconsistent gastric emptying.

Urinary retention, a decreased sensation of bladder fullness, and other urinary symptoms of neurogenic bladder result from autonomic neuropathy. The patient with a neurogenic bladder is predisposed to development of urinary tract infections because of the inability to empty the bladder completely. This is especially true of patients with poorly controlled diabetes because hyperglycemia impairs resistance to infection.

Hypoglycemic Unawareness

Autonomic neuropathy that affects the adrenal medulla is responsible for diminished or absent adrenergic symptoms of hypoglycemia. Patients may report that they no longer feel the typical shakiness, sweating, nervousness, and palpitations associated with hypoglycemia. Frequent blood glucose monitoring is recommended for these patients. Their inability to detect and treat these warning signs of hypoglycemia puts them at risk for development of dangerously low blood glucose levels. Therefore, their goals for blood glucose levels may need to be adjusted to reduce the risk for hypoglycemia. Patients and families need to be taught to recognize subtle

and atypical symptoms of hypoglycemia, such as numbness around the mouth and impaired ability to concentrate.

Sudomotor Neuropathy

The neuropathic condition called sudomotor neuropathy refers to a decrease or absence of sweating (anhidrosis) of the extremities, with a compensatory increase in upper body sweating. Dryness of the feet increases the risk for the development of foot ulcers.

Sexual Dysfunction

Sexual dysfunction, especially erectile dysfunction in men, is a complication of diabetes. The effects of autonomic neuropathy on female sexual functioning are not well documented. Reduced vaginal lubrication has been mentioned as a possible neuropathic effect. Other possible changes in sexual function in women with diabetes include decreased libido and lack of orgasm. Vaginal infection, which increases in incidence in women with diabetes, may be associated with decreased lubrication and vaginal pruritus (itching) and tenderness. Urinary tract infections and vaginitis may also affect sexual function.

Impotence (inability of the penis to become rigid and sustain an erection adequate for penetration) occurs with greater frequency in men with diabetes than in other men of the same age. Some men with autonomic neuropathy have normal erectile function and can experience orgasm but do not ejaculate normally. Retrograde ejaculation occurs; seminal fluid is propelled backward through the posterior urethra and into the urinary bladder. Examination of the urine confirms the diagnosis because of the large number of active sperm present. Fertility counseling may be necessary for couples attempting conception.

Diabetic neuropathy is not the only cause of impotence in men with diabetes. Medications such as antihypertensive agents, psychological factors, and other medical conditions (eg, vascular insufficiency) that may affect other men also play a role in impotence in men with diabetes (see Chapter 49).

Management

Management strategies for autonomic neuropathy focus on alleviating symptoms and on modification and management of risk factors. The prognosis for painless cardiac ischemia is poor. However, detection is important so that education about avoiding strenuous exercise can be provided. Orthostatic hypotension may respond to a diet high in sodium, discontinuation of medications that impede autonomic nervous system responses, use of sympathomimetics and other agents (eg, caffeine) that stimulate an autonomic response, mineralocorticoid therapy, and use of lower-body elastic garments that maximize venous return and prevent pooling of blood in the extremities.

Treatment of delayed gastric emptying includes a low-fat diet, frequent small meals, frequent blood glucose monitoring, and use of agents that increase gastric motility (eg, metoclopramide [Reglan], bethanechol [Myotonachol]). Treatment of diabetic diarrhea may include bulk-forming laxatives or antidiarrheal agents. Constipation is treated with a high-fiber diet and adequate hydration; medications, laxatives, and enemas may be necessary if consti-

pation is severe. Management of sexual dysfunction in women and men is discussed in Chapters 47 and 49, respectively.

Treatment of sudomotor dysfunction focuses on education about skin care and heat intolerance.

Foot and Leg Problems

Between 50% and 75% of lower extremity amputations are performed on people with diabetes. More than 50% of these amputations are thought to be preventable, provided patients are taught foot care measures and practice them on a daily basis (ADA, 2009b). Complications of diabetes that contribute to the increased risk of foot problems and infections include the following:

- **Neuropathy:** Sensory neuropathy leads to loss of pain and pressure sensation, and autonomic neuropathy leads to increased dryness and fissuring of the skin (secondary to decreased sweating). Motor neuropathy results in muscular atrophy, which may lead to changes in the shape of the foot.
- **Peripheral vascular disease:** Poor circulation of the lower extremities contributes to poor wound healing and the development of gangrene.
- **Immunocompromise:** Hyperglycemia impairs the ability of specialized leukocytes to destroy bacteria. Therefore, in poorly controlled diabetes, there is a lowered resistance to certain infections.

The typical sequence of events in the development of a diabetic foot ulcer begins with a soft tissue injury of the foot, formation of a fissure between the toes or in an area of dry skin, or formation of a callus (Fig. 41-9). Patients with an insensitive foot do not feel injuries, which may be thermal (eg, from using heating pads, walking barefoot on hot concrete, testing bath water with the foot), chemical (eg, burning the foot while using caustic agents on calluses, corns, or bunions), or traumatic (eg, injuring skin while cutting nails, walking with an undetected foreign object in the shoe, or wearing ill-fitting shoes and socks).

Figure 41-9 Neuropathic ulcers occur on pressure points in areas with diminished sensation in diabetic polyneuropathy. Because pain is absent, the ulcer may go unnoticed.

If the patient is not in the habit of thoroughly inspecting both feet on a daily basis, the injury or fissure may go unnoticed until a serious infection has developed. Drainage, swelling, redness of the leg (from cellulitis), or gangrene may be the first sign of foot problems that the patient notices. Treatment of foot ulcers involves bed rest, antibiotics, and débridement. In addition, controlling glucose levels, which tend to increase when infections occur, is important for promoting wound healing. When peripheral vascular disease is present, foot ulcers may not heal because of the decreased ability of oxygen, nutrients, and antibiotics to reach the injured tissue. Amputation may be necessary to prevent the spread of infection, particularly if it involves the bone (osteomyelitis).

Foot assessment and foot care instructions are most important when caring for patients who are at high risk for foot infections. Some of the high-risk characteristics include:

- Duration of diabetes more than 10 years
- Age older than 40 years
- History of smoking
- Decreased peripheral pulses
- Decreased sensation
- Anatomic deformities or pressure areas (eg, bunions, calluses, hammer toes)
- History of previous foot ulcers or amputation

Management

Teaching proper foot care is a nursing intervention that can prevent costly and painful complications that result in disability (Chart 41-10). Preventive foot care begins with careful daily assessment of the feet, which should be inspected on a daily basis for any redness, blisters, fissures, calluses, ulcerations, changes in skin temperature, or development of foot deformities (hammer toes, bunions). Visual impairment or decreased joint mobility (especially in the elderly) requires use of a mirror to inspect the bottoms of both feet or the help of a family member in foot inspection. The interior surfaces of shoes should also be inspected for any rough spots or foreign objects (NIDDK, 2008b).

In addition to the daily visual and manual inspection of the feet, the feet should be examined during every health care visit or at least once per year (more often if there is an increase in risk) by a podiatrist, physician, or nurse (ADA, 2009b). All patients should be assessed for neuropathy and undergo evaluation of neurologic status by an experienced examiner using a monofilament device (Fig. 41-10). Pressure areas, such as calluses, or thick toenails should be treated by a podiatrist in addition to routine trimming of nails.

Additional aspects of preventive foot care that are taught to patients and families include the following:

- Properly bathing, drying, and lubricating the feet, taking care not to allow moisture (water or lotion) to accumulate between the toes
- Wearing closed-toed shoes that fit well. A podiatrist can provide the patient with inserts (orthotics) to remove pressure from pressure points on the foot. New shoes should be broken in slowly (ie, worn for 1 to 2 hours initially, with gradual increases in the length of

CHART

PATIENT EDUCATION Foot Care Tips

1. Take care of your diabetes.
 - Work with your health care team to keep your blood glucose level within a normal range.
2. Inspect your feet every day.
 - Look at your bare feet every day for cuts, blisters, red spots, and swelling.
 - Use a mirror to check the bottoms of your feet or ask a family member for help if you have trouble seeing.
 - Check for changes in temperature.
3. Wash your feet every day.
 - Wash your feet in warm, not hot, water.
 - Dry your feet well. Be sure to dry between the toes.
 - Do not soak your feet.
 - Do not check water temperature with your feet; use a thermometer or elbow.
4. Keep the skin soft and smooth.
 - Rub a thin coat of skin lotion over the tops and bottoms of your feet, but not between your toes.
5. Smooth corns and calluses gently.
 - Use a pumice stone to smooth corns and calluses.
6. Trim your toenails each week or when needed.
 - Trim your toenails straight across and file the edges with an emery board or nail file.
7. Wear shoes and socks at all times.
 - Never walk barefoot.
 - Wear comfortable shoes that fit well and protect your feet.
 - Feel inside your shoes before putting them on each time to make sure the lining is smooth and there are no objects inside.
8. Protect your feet from hot and cold.
 - Wear shoes at the beach or on hot pavement.
 - Wear socks at night if your feet get cold.
9. Keep the blood flowing to your feet.
 - Put your feet up when sitting.
 - Wiggle your toes and move your ankles up and down for 5 minutes, 2 or 3 times a day.
 - Do not cross your legs for long periods of time.
 - Do not smoke.
10. Check with your health care provider.
 - Have your health care provider check your bare feet and find out whether you are likely to have serious foot problems. Remember that you may not feel the pain of an injury.
 - Call your health care provider right away if a cut, sore, blister, or bruise on your foot does not begin to heal after one day.
 - Follow your health care provider's advice about foot care.
 - Do not self-medicate or use home remedies or over-the-counter agents to treat foot problems.

time worn) to avoid blister formation. Patients with bony deformities may need custom-made shoes with extra width or depth. High-risk behaviors, such as walking barefoot, using heating pads on the feet, wearing open-toed shoes, soaking the feet, and shaving calluses, should be avoided.

- Trimming toenails straight across and filing sharp corners to follow the contour of the toe. If the patient has

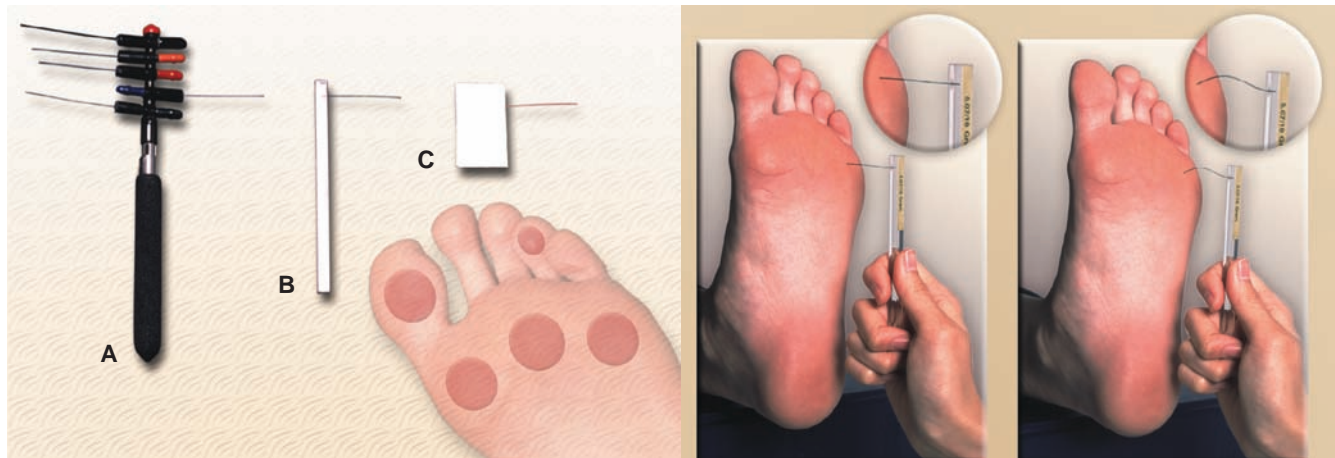

Figure 41-10 The monofilament test is used to assess the sensory threshold in patients with diabetes. The test instrument—a monofilament—is gently applied to about five pressure points on the foot (as shown in image on left). **A**, Example of a monofilament used for advanced quantitative assessment. **B**, Semmes-Weinstein monofilament used by clinicians. **C**, Disposable monofilament used by patients. The examiner applies the monofilament to the test area to determine whether the patient feels the device. (Adapted with permission from Cameron, B. L. (2002). Making diabetes management routine. *American Journal of Nursing*, 102(2), 26–32.)

visual deficits, is unable to reach the feet because of disability, or has thickened toenails, a podiatrist should cut the nails.

- Reducing risk factors, such as smoking and elevated blood lipids, that contribute to peripheral vascular disease.
- Avoiding home remedies, over-the-counter agents, and self-medicating to treat foot problems.

Blood glucose control is important for avoiding decreased resistance to infections and for preventing diabetic neuropathy.

SPECIAL ISSUES IN DIABETES CARE

Patients With Diabetes Who Are Undergoing Surgery

During periods of physiologic stress, such as surgery, blood glucose levels tend to increase, because levels of stress hormones (epinephrine, norepinephrine, glucagon, cortisol, and growth hormone) increase. If hyperglycemia is not controlled during surgery, the resulting osmotic diuresis may lead to excessive loss of fluids and electrolytes. Patients with type 1 diabetes also risk developing ketoacidosis during periods of stress.

Hypoglycemia is also a concern in patients with diabetes who are undergoing surgery. For example, this is a special concern during the preoperative period if surgery is delayed beyond the morning in a patient who received a morning injection of intermediate-acting insulin.

There are various approaches to managing glucose control during the perioperative period. Frequent blood glucose monitoring is essential throughout the preoperative and postoperative periods, regardless of the method used for glucose control. Examples of these approaches are described in Chart 41-11. The use of IV insulin and dextrose has become widespread with the increased availability of meters for intraoperative glucose monitoring.

During the postoperative period, patients with diabetes must also be closely monitored for cardiovascular complications because of the increased prevalence of atherosclerosis, wound infections, and skin breakdown (especially in patients with decreased sensation in the extremities due to neuropathy). Maintaining adequate nutrition and blood glucose control promote wound healing.

Management of Hospitalized Patients With Diabetes

At any one time, 10% to 20% of hospitalized general medical-surgical patients have diabetes. This number may increase as elderly patients make up an increasing proportion of the hospitalized population. Often diabetes is not the primary medical diagnosis, yet problems with control of diabetes frequently result from changes in the patient's normal routine or from surgery or illness. During the course of treatment for the primary medical diagnosis, blood glucose control may worsen. In addition, the only opportunity for some patients with diabetes to update their knowledge about diabetes self-care and prevention of complications may be during hospitalization. It is important for nurses caring for patients with diabetes to focus attention on the diabetes as well as the primary health issue. Control of blood glucose levels is important because hyperglycemia impairs resistance to certain infections and impedes wound healing.

Self-Care Issues

For patients who are actively involved in diabetes self-management (especially insulin dose adjustment), relinquishing control over meal timing, insulin timing, and insulin dosage can be particularly difficult and anxiety provoking. The patient may fear hypoglycemia and express much concern over possible delays in receiving attention from the nurse if hypoglycemic symptoms occur or may disagree with a planned dose of insulin.

Chart 41-11 • Approaches to Management of Glucose Control During the Perioperative Period

- Monitor blood glucose levels frequently (every 1 to 2 h).
- For patients taking insulin
 1. The morning of surgery, all subcutaneous insulin doses are withheld, unless the blood glucose level is elevated (eg, >200 mg/dL [11.1 mmol/L]), in which case a small dose of subcutaneous regular insulin may be prescribed. The blood glucose level is controlled during surgery with the IV infusion of regular insulin, which is balanced by an infusion of dextrose. The insulin and dextrose infusion rates are adjusted according to frequent (hourly) capillary glucose determinations. After surgery, the insulin infusion may be continued until the patient can eat. If IV insulin is discontinued, subcutaneous regular insulin may be administered at set intervals (every 4–6 h), or intermediate-acting insulin may be administered every 12 h with supplemental regular insulin as necessary until the patient is eating and the usual pattern of insulin dosing is resumed.
 - Carefully monitor the insulin infusion rate and blood glucose levels in a patient with diabetes who is receiving IV insulin. IV insulin has a much shorter duration of action than subcutaneous insulin. If the infusion is interrupted or discontinued, hyperglycemia will develop rapidly (within 1 h in type 1 diabetes and within a few hours in type 2 diabetes).
 - Ensure that subcutaneous insulin is administered 30 min before the IV insulin infusion is discontinued.
 2. One half to two thirds of the patient's usual morning dose of insulin (either intermediate-acting insulin alone or both short-act and intermediate-acting insulins) is administered subcutaneously in the morning before surgery. The remainder is then administered after surgery.
 3. The patient's usual daily dose of subcutaneous insulin is divided into four equal doses of regular insulin. These are then administered at 6-h intervals. The last two approaches do not provide the control achieved by IV administration of insulin and dextrose.
- Patients with type 2 diabetes who do not usually take insulin may require insulin during the perioperative period to control blood glucose elevations. Patients who are taking metformin may be instructed to discontinue the oral agent 24 to 48 h before surgery, if possible. Some of these patients may resume their usual regimen of diet and oral agent during the recovery period. Other patients (whose diabetes is probably not well controlled with diet and an oral antidiabetic agent before surgery) need to continue with insulin injections after discharge.
- For patients with type 2 diabetes who are undergoing minor surgery but who do not normally take insulin, glucose levels may remain stable provided no dextrose is infused during the surgery. After surgery, these patients may require small doses of regular insulin until the usual diet and oral agent are resumed.

It is important for the nurse to acknowledge the patient's concerns and involve the patient in the plan of care as much as possible. If the patient disagrees with certain aspects of the nursing or medical care related to diabetes, the nurse must communicate this to other members of the health care team. Nurses and other health care providers must pay particular attention to patients who are successful in managing self-care; they should assess these patients' self-care management skills and encourage them to continue if their performance is correct and effective.

Hospitalization of a patient with diabetes should be considered an opportunity to evaluate the patient's self-care skills and to reinforce teaching that might be needed. The nurse observes the patient preparing and injecting the insulin, monitoring blood glucose, and performing foot care. (Simply questioning the patient about these skills without actually observing performance of the skills is not sufficient.) The patient's knowledge about diet can be assessed with the help of a dietitian through direct questioning and review of the patient's menu choices. The patient's understanding about signs and symptoms, treatment, and prevention of hypoglycemia and hyperglycemia is assessed, along with knowledge of risk factors for macrovascular disease, including hypertension, increased lipids, and smoking. In addition, the patient is asked the date of his or her last eye examination (including dilation of the pupils). Teaching about these issues is critical.

Hyperglycemia During Hospitalization

Hyperglycemia may occur in hospitalized patients as a result of the original illness that led to the need for hospitalization. A number of other factors may contribute to hyperglycemia; examples include:

- Changes in the usual treatment regimen (eg, increased food, decreased insulin, decreased activity)
- Medications (eg, corticosteroids such as prednisone, which are used in the treatment of a variety of inflammatory disorders)
- IV dextrose, which may be part of the maintenance fluids or may be used for the administration of antibiotics and other medications, without adequate insulin therapy
- Overly vigorous treatment of hypoglycemia
- Inappropriate withholding of insulin or inappropriate use of "sliding scales"
- Mismatched timing of meals and insulin (eg, post-meal hyperglycemia may occur if short-acting insulin is administered immediately before or even after a meal)

Nursing actions to correct some of these factors are important for avoiding hyperglycemia. Assessment of the patient's usual home routine is important. The nurse should try to approximate as much as possible the home schedule of insulin, meals, and activities. Monitoring blood glucose levels has been identified by the ADA as an additional "vital sign" essential in assessment of patients (ADA, 2009b). The results of blood glucose monitoring provide information needed to obtain orders for extra doses of insulin (at times when insulin is usually taken), an important nursing function. Insulin doses must not be withheld when blood glucose levels are normal.

Short-acting insulin is usually needed to avoid postprandial hyperglycemia (even in patients with normal premeal glucose levels), and NPH insulin does not peak until many hours after the dose is given. IV antibiotics should be mixed

NURSING RESEARCH PROFILE

Hypoglycemia in Hospitalized Patients With Diabetes

Anthony, M. (2007). Treatment of hypoglycemia in hospitalized adults, A descriptive study. *The Diabetes Educator*, 33(4), 709–715.

Purpose

Diabetes mellitus is a primary or secondary reason for over 24 million days spent in the hospital. The goal of achieving normal blood glucose levels is a challenge in hospitalized patients but has the potential to improve patient outcomes.

This goal may, however, result in increased risk of hypoglycemia in patients with diabetes who are hospitalized. The purpose of this study was to describe the treatment of hypoglycemia in two Midwestern hospitals to determine patterns and adherence to policies and procedures.

Design

A retrospective chart audit was conducted on 210 patients who had experienced hypoglycemia while hospitalized. The purpose of the audit was to examine adherence to five steps identified in hospital policies and procedures for treatment of hypoglycemia. The five steps were: (1) administer 15 g of carbohydrates, (2) retest blood glucose in 15 minutes, (3) retest in 1 hour, (4) notify the physician, and (5) document the event in the patient's record. A checklist of expected behaviors was derived from the practice manual and used as the evaluation tool.

Findings

A total of 484 episodes of hypoglycemia in 105 patients at two hospitals were analyzed. Hypoglycemia was defined as a blood glucose level of less than 70 mg/dL. Adherence to practice guidelines for treatment of hypoglycemia was low. There was not one case where all five steps were followed. The adherence ranged from 2.1% for the 1-hour retest to a high of 70.9% for documentation.

Nursing Implications

Nursing policy and procedures are put in place to ensure that a standard of care is followed for patient safety. The treatment of hypoglycemia is an important patient safety issue because severe hypoglycemia can threaten the patient's well-being and lead to seizures, coma, or a fall. Following guidelines provides for the treatment of the condition and a return of blood glucose levels to normal without causing hyperglycemia. Although it is possible that all five steps of the guidelines were taken but not documented, if actions are not documented it is assumed that the actions were not taken. The findings indicate that staff education is needed to increase the likelihood that important guidelines are followed to improve patient safety and prevent catastrophic outcomes.

in normal saline (if possible) to avoid excess infusion of dextrose (especially in patients who are eating). It is important to avoid overly vigorous treatment of hypoglycemia, which may lead to hyperglycemia.

Hypoglycemia During Hospitalization

Hypoglycemia in hospitalized patients is usually the result of too much insulin or delays in eating (Chart 41-12). Specific examples include:

- Overuse of “sliding scale” regular insulin, particularly as a supplement to regularly scheduled, twice-daily short-acting and intermediate-acting insulins
- Lack of change in insulin dosage when dietary intake is changed (eg, in the patient taking nothing by mouth [NPO])
- Overly vigorous treatment of hyperglycemia (eg, giving too-frequent successive doses of regular insulin before the time of peak insulin activity is reached), resulting in a cumulative effect
- Delayed meal after administration of lispro, aspart, or glulisine [Apidra] insulin (the patient should eat within 5 to 15 minutes after insulin administration)

Treatment of hypoglycemia should be based on the established hospital protocol. If the initial treatment does not increase the glucose level adequately, the same treatment may be repeated after 15 minutes. The nurse must assess the pattern of glucose values and avoid giving doses of insulin that repeatedly lead to hypoglycemia. Successive doses of subcutaneous regular insulin should be administered no more frequently than every 3 to 4 hours. For patients receiving NPH or Lente insulin before breakfast and dinner, the nurse must use caution in administering supplemental doses of regular

insulin at lunch and bedtime. Hypoglycemia may occur when two insulins peak at similar times (eg, morning NPH peaks with lunchtime regular insulin and may lead to late-afternoon hypoglycemia; dinnertime NPH peaks with bedtime regular insulin and may lead to nocturnal hypoglycemia). To avoid hypoglycemic reactions caused by delayed food intake, the nurse should arrange for snacks to be given to the patient if meals are going to be delayed because of procedures, physical therapy, or other activities.

Common Alterations in Diet

Dietary modifications commonly prescribed during hospitalization require special consideration for patients who have diabetes (ADA, 2008b).

Nothing by Mouth

For patients who must be NPO in preparation for diagnostic or surgical procedures, the nurse must ensure that the usual insulin dosage has been changed. These changes may include eliminating the rapid-acting insulin and giving a decreased amount (eg, half the usual dose) of intermediate-acting NPH or Lente insulin. Another approach is to use frequent (every 3 to 4 hours) dosing of rapid-acting insulin only. IV dextrose may be administered to provide calories and to avoid hypoglycemia.

Even without food, glucose levels may increase as a result of hepatic glucose production, especially in patients with type 1 diabetes and lean patients with type 2 diabetes. Furthermore, in type 1 diabetes, elimination of the insulin dose may lead to the development of DKA. Therefore, administration of insulin to patients with type 1 diabetes who are NPO is an important nursing action.

For patients with type 2 diabetes who are taking insulin, DKA does not usually develop when insulin doses are eliminated because the patient's pancreas produces some insulin. Therefore, skipping the insulin dose altogether (when the patient is receiving IV dextrose) may be safe; however, close monitoring of blood glucose levels is essential.

For patients who are NPO for extended periods (24 hours), glucose testing and insulin administration should be performed at regular intervals, usually four times per day. Insulin regimens for the patient who is NPO for an extended period may include NPH insulin every 12 hours (with rapid-acting insulin added to the NPH, depending on the results of glucose testing) or rapid-acting insulin only every 4 to 6 hours. These patients should receive dextrose infusions to provide some calories and limit ketosis.

To prevent the problems that result from the need to withhold food, diagnostic tests and procedures and surgery should be scheduled early in the morning if possible.

Clear Liquid Diet

When the diet is advanced to include clear liquids, patients with diabetes receive more simple carbohydrate foods, such as juice and gelatin desserts, than are usually included in the diabetic diet. It is important for hospitalized patients to maintain their nutritional status as much as possible to promote healing. Therefore, the use of reduced-calorie substitutes such as diet soda or diet gelatin desserts would not be appropriate when the only source of calories is clear liquids. Simple carbohydrates, if eaten alone, cause a rapid rise in blood glucose levels; therefore, it is important to try to match peak times of insulin effect with peaks in the blood glucose concentration. If the patient receives insulin at regular intervals while NPO, the scheduled times for glucose tests and insulin injections must match meal times.

Enteral Tube Feedings

Tube feeding formulas contain more simple carbohydrates and less protein and fat than the typical meal plan for diabetes. This results in increased levels of glucose in patients with diabetes who are receiving tube feedings. It is important that insulin doses be administered at regular intervals (eg, NPH every 12 hours or regular insulin every 4 to 6 hours) when continuous tube feedings are administered. If insulin is administered at routine (prebreakfast and predinner) times, hypoglycemia during the day may result (because the patient receives more insulin without more calories); and hyperglycemia may occur during the night if feedings continue but insulin action decreases.

A common cause of hypoglycemia in patients receiving both continuous tube feedings and insulin is inadvertent or purposeful discontinuation of the feeding. The nurse must discuss with the medical team any plans for temporarily discontinuing the tube feeding (eg, when the patient is away from the unit). Planning ahead may allow for alterations to be made in the insulin dose or for administration of IV dextrose. In addition, if problems with the tube feeding develop unexpectedly (eg, the patient pulls out the tube, the tube clogs, the feeding is discontinued when residual gastric contents are found), the nurse must notify the physician, assess blood glucose levels more frequently, and administer IV dextrose if indicated.

Parenteral Nutrition

Patients receiving parenteral nutrition may receive both IV insulin (added to the parenteral nutrition container) and subcutaneous intermediate-acting or short-acting insulins. If the patient is receiving continuous parenteral nutrition, the blood glucose level should be monitored and insulin administered at regular intervals. If the parenteral nutrition is infused over a limited number of hours, subcutaneous insulin should be administered so that peak times of insulin action coincide with times of parenteral nutrition infusion.

Hygiene

Nurses caring for hospitalized patients with diabetes must focus attention on oral hygiene and skin care. Because these patients are at increased risk for periodontal disease, it is important for the nurse to assist the patient with daily dental care. The patient may also require assistance in keeping the skin clean and dry, especially in areas of contact between two skin surfaces (eg, groin, axilla, under the breasts), where chafing and fungal infections tend to occur.

Careful assessment of the skin, especially at pressure points and on the lower extremities, is important. The skin is assessed for dryness, cracks, skin breakdown, and redness. The patient is asked about symptoms of neuropathy, such as tingling and pain or numbness of the feet. Deep tendon reflexes are assessed.

As with any patient confined to bed, nursing care must emphasize the prevention of skin breakdown at pressure points. The heels are particularly susceptible to breakdown because of loss of sensation of pain and pressure associated with sensory neuropathy.

Feet should be cleaned, dried, lubricated with lotion (but not between the toes), and inspected frequently. If the patient is in the supine position, pressure on the heels can be alleviated by elevating the lower legs on a pillow, with the heels positioned over the edge of the pillow. When the patient is seated in a chair, the feet should be positioned so that pressure is not placed on the heels. If the patient has an ulcer on one foot, it is important to provide preventive care to the unaffected foot as well as special care of the affected foot.

As always, every opportunity should be taken to teach the patient about diabetes self-management, including daily oral, skin, and foot care. Female patients should also be instructed about measures for the avoidance of vaginal infections, which occur more frequently when blood glucose levels are elevated. Patients often take their cues from nurses and realize the importance of daily personal hygiene if this is emphasized during their hospitalization.

Stress

Physiologic stress, such as infections and surgery, contributes to hyperglycemia and may precipitate DKA or HHNS. Emotional stress related to hospitalization for any reason can also have a negative impact on diabetic control. An increase in stress hormones leads to an increase in glucose levels, especially if intake of food and insulin remains unchanged. In addition, during periods of emotional stress,

people with diabetes may alter their usual pattern of meals, exercise, and medication. This can contribute to hyperglycemia or even hypoglycemia (eg, in the patient taking insulin or oral antidiabetic agents who stops eating in response to stress).

People with diabetes must be made aware of the potential deterioration in diabetic control that can accompany emotional stress. They must be encouraged to follow the diabetes treatment plan as much as possible during times of stress. In addition, learning strategies for minimizing stress and coping with stress when it does occur are important aspects of diabetes education. Healthy coping is one of the seven steps to managing diabetes identified by the AADE (2007).

Gerontologic Considerations

Because people with diabetes are living longer, both type 1 and type 2 diabetes are being seen more frequently in elderly patients hospitalized for various reasons. Regardless of the type or duration of diabetes, the goals of diabetes treatment may need to be altered when caring for hospitalized elderly patients. The focus is on quality-of-life issues, such as maintaining independent functioning and promoting general well-being.

Some of the barriers to learning and self-care during hospital stays and in preparing patients for discharge include decreased vision, hearing loss, memory deficits, decreased mobility and fine motor coordination, increased tremors, depression and isolation, decreased financial resources, and limitations related to disabilities and other medical disorders. Assessing these barriers is important in planning diabetes treatment and educational activities. Presenting brief, simplified instructions with ample opportunity for practice of skills is important. The use of special devices such as a magnifier for the insulin syringe, an insulin pen, or a mirror for foot inspection is helpful. Frequent evaluation of self-care skills (insulin administration, blood glucose monitoring, foot care, diet planning) is essential, especially in patients with deteriorating vision and memory.

If appropriate, family members may be called on to assist with diabetes survival skills, and referral to community resources may be made. It is preferable to teach the patient or family members to test blood glucose at home; the choice of meter should be tailored to the patient's visual and cognitive status and dexterity.

NURSING ALERT

Careful monitoring for diabetes complications must not be neglected in elderly patients. Hypoglycemia is especially dangerous, because it may go undetected and result in falls. Dehydration is a concern in patients who have chronically elevated blood glucose levels. Assessment for long-term complications, especially eye and foot problems, is important. Avoiding blindness and amputation through early detection and treatment of retinopathy and foot ulcers may mean the difference between placement in a long-term care facility and continued independent living for the elderly person with diabetes.

Monitoring and Managing Potential Complications

Assessment for hypoglycemia and hyperglycemia involves frequent blood glucose monitoring (usually prescribed before meals and at bedtime) and monitoring for signs and symptoms of hypoglycemia or prolonged hyperglycemia (including DKA or HHNS), as described previously. Inadequate control of blood glucose levels may hinder recovery from the primary health problem. Blood glucose levels are monitored, and insulin is administered as prescribed. It is important for the nurse to ensure that prescribed insulin dosage is modified as needed to compensate for changes in the patient's schedule or eating pattern. Treatment is given for hypoglycemia (with oral glucose) or hyperglycemia (with supplemental regular insulin no more often than every 3 to 4 hours). Blood glucose records are assessed for patterns of hypoglycemia and hyperglycemia at the same time of day, and findings are reported to the physician for modification in insulin orders. In the patient with prolonged elevations in blood glucose, laboratory values and the patient's physical condition are monitored for signs and symptoms of DKA or HHNS.

Promoting Home and Community-Based Case

Teaching Patients Self-Care

Even if the patient has had diabetes for many years, it is important to assess his or her knowledge and adherence to the plan of care. A new plan of care may need to be devised using concepts mentioned earlier. The nurse also reminds the patient and family about the importance of health promotion activities and recommended health screening.

Continuing Care

A patient who is hospitalized may require referral for home care. The home care nurse can use this opportunity to assess the patient's knowledge about diabetes management and the patient's and family's ability to carry out that management. The nurse reinforces the teaching provided in the hospital, clinic, office, or diabetes education center and assesses the home care environment to determine its adequacy for self-care and safety.

CRITICAL THINKING EXERCISES

1 A 35-year-old pregnant woman with type 2 diabetes is admitted to the hospital for an elective Caesarean section. What modifications in her diabetes care are needed before, during, and after her Caesarean section? How would her care differ if she had type 1 diabetes?

EBP 2 A 25-year-old patient is newly diagnosed with type 1 diabetes. His physician has discussed intensive insulin therapy with him, although the patient indicates that he needs more information about the advantages and disadvantages of intensive therapy before he can make a decision about therapy. What is the evidence base for intensive insulin therapy and the strength of that evidence?

How would you present information to him about the advantages and disadvantages of intensive therapy?

3 You are the nurse in a diabetes education center with many patients with type 1 and type 2 diabetes. Identify strategies you would use to provide diabetes education for the following patients: (1) a patient who has managed her diabetes well for 20 years, but has recently been prescribed insulin for the first time, (2) a patient who has cerebral palsy that affects her lower extremities and one hand, (3) a patient who speaks very little English, and (4) a patient who is angry and resentful that he has developed diabetes.

4 You are providing discharge instructions for a 55-year-old executive being discharged from the hospital after carotid endarterectomy and cardiac artery bypass surgery. He indicates that although he has had diabetes for 10 years, he has only “a little diabetes” because until recently he has not required insulin. He is a smoker and travels extensively. Develop a teaching plan for this patient and identify the priorities of teaching for him.

5 A 68-year-old woman who was found at home unresponsive by her neighbors is admitted to the emergency department with possible diabetic ketoacidosis. She is well known to the emergency department personnel because of repeated episodes of hypoglycemia in the past. Compare the pathophysiology and signs and symptoms of diabetic ketoacidosis and hypoglycemia. How would assessment, medical management, and nursing care for these two disorders compare? What would be your priorities for patient teaching once she has recovered from the acute medical problem?

Assessment and Management of Patients With Endocrine Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the functions of each of the endocrine glands and their hormones.
- 2 Identify the diagnostic tests used to determine alterations in function of each of the endocrine glands.
- 3 Compare hypothyroidism and hyperthyroidism: their causes, clinical manifestations, management, and nursing interventions.
- 4 Develop a plan of nursing care for the patient undergoing thyroidectomy.
- 5 Compare hyperparathyroidism and hypoparathyroidism: their causes, clinical manifestations, management, and nursing interventions.
- 6 Compare Addison's disease with Cushing's syndrome: their causes, clinical manifestations, management, and nursing interventions.
- 7 Describe nursing management of patients with adrenal insufficiency.
- 8 Use the nursing process as a framework for care of patients with Cushing's syndrome.
- 9 Identify the teaching needs of patients requiring corticosteroid therapy.

GLOSSARY

acromegaly: disease process resulting from excessive secretion of somatotropin; causes progressive enlargement of peripheral body parts

addisonian crisis: acute adrenocortical insufficiency; characterized by hypotension, cyanosis, fever, nausea/vomiting, and classic signs of shock; precipitated by stress or abrupt withdrawal of therapeutic glucocorticoids

Addison's disease: chronic adrenocortical insufficiency secondary to destruction of the adrenal glands

adrenalectomy: surgical removal of one or both adrenal glands

adrenocorticotrophic hormone (ACTH): hormone secreted by the anterior pituitary, essential for growth and development

adrenogenital syndrome: masculinization in women, feminization in men, or premature sexual development in children; result of abnormal secretion of adrenocortical hormones, especially androgens

androgens: hormones secreted by the adrenal cortex; stimulate activity of accessory male sex organs and development of male sex characteristics

basal metabolic rate: chemical reactions occurring when the body is at rest

calcitonin: hormone secreted by the parafollicular cells of the thyroid gland; participates in calcium regulation

Chvostek's sign: spasm of the facial muscles produced by sharply tapping over the facial nerve in front of the parotid gland and anterior to the ear; suggestive of latent tetany in patients with hypocalcemia

corticosteroids: hormones produced by the adrenal cortex or their synthetic equivalents; also referred to as adrenal-cortical hormone and adrenocorticosteroid; consist of glucocorticoids, mineralocorticoids, and androgens

cretinism: stunted body growth and mental development appearing during the first year of life as a result of congenital hypothyroidism

Cushing's syndrome: group of symptoms produced by an excess of free circulating cortisol from the adrenal cortex; characterized by truncal obesity, "moon face," acne, abdominal striae, and hypertension

GLOSSARY (Continued)

diabetes insipidus: condition in which abnormally large volumes of dilute urine are excreted as a result of deficient production of vasopressin

dwarfism: generalized limited growth resulting from insufficient secretion of growth hormone during childhood

endocrine: secreting internally; hormonal secretion of a ductless gland

euthyroid: state of normal thyroid hormone production

exocrine: secreting externally; hormonal secretion from excretory ducts

exophthalmos: abnormal protrusion of one or both eyeballs

glucocorticoids: steroid hormones secreted by the adrenal cortex in response to ACTH; produce a rise of liver glycogen and blood glucose

goiter: enlargement of the thyroid gland; usually caused by an iodine-deficient diet

Graves' disease: a form of hyperthyroidism; characterized by a diffuse goiter and exophthalmos

hormones: chemical transmitter substances produced in one organ or part of the body and carried by the bloodstream to other cells or organs on which they have a specific regulatory effect; produced mainly by endocrine glands

hypophysectomy: removal or destruction of all or part of the pituitary gland

mineralocorticoid: steroid of the adrenal cortex

myxedema: severe hypothyroidism characterized by an accumulation of mucopolysaccharides in interstitial tissues, a masklike expression, puffy eyelids, loss of eyebrow hair, thick lips, and a broad tongue

negative feedback: regulating mechanism in which an increase or decrease in the level of a substance decreases or increases the function of the organ producing the substance

oxytocin: hormone secreted by the posterior pituitary; causes myometrial contraction at term and milk release during lactation

pheochromocytoma: chromaffin cell tumor, usually benign, located in the adrenal medulla; characterized by secretion of catecholamines resulting in hypertension, severe headache, profuse sweating, visual blurring, anxiety, and nausea

syndrome of inappropriate antidiuretic hormone (SIADH) secretion: excessive secretion of antidiuretic hormone (ADH) from the pituitary gland despite low serum osmolality level

thyroidectomy: surgical removal of all or part of the thyroid gland

thyroiditis: inflammation of the thyroid gland; may lead to chronic hypothyroidism or may resolve spontaneously

thyroid-stimulating hormone: released from the pituitary gland; causes stimulation of the thyroid, resulting in release of T₃ and T₄

thyroid storm: severe life-threatening hyperthyroidism precipitated by stress; characterized by high fever, extreme tachycardia, and altered mental state

thyrotoxicosis: condition produced by excessive endogenous or exogenous thyroid hormone

thyroxine (T₄): thyroid hormone; active iodine compound formed and stored in the thyroid; deiodinated in peripheral tissues to form triiodothyronine; maintains body metabolism in a steady state

triiodothyronine (T₃): thyroid hormone; formed and stored in the thyroid; released in smaller quantities, biologically more active and with faster onset of action than T₄; widespread effect on cellular metabolism

Trousseau's sign: carpopedal spasm induced when blood flow to the arm is occluded using a blood pressure cuff or tourniquet, causing ischemia to the distal nerves; suggestive sign for latent tetany in hypocalcemia

vasopressin: ADH secreted by the posterior pituitary; causes contraction of smooth muscle, particularly blood vessels

The endocrine system plays a vital role in growth and development, the metabolism of energy, muscle and adipose tissue distribution, sexual development, fluid and electrolyte balance, and inflammation and immune responses (Porth & Matfin, 2009). This interconnected network of glands is closely linked with the nervous and immune systems regulating the functions of multiple body organs. Disorders of the endocrine system are common and are manifested as hyperfunction and hypofunction.

Nursing interventions are essential in the management of patients with endocrine disorders. This chapter focuses on the anatomy and physiology of the endocrine system; the most common endocrine disorders of the pituitary, thyroid, parathyroid, and adrenal glands; clinical manifestations; diagnostic studies; medical management; and nursing interventions. The unique endocrine and exocrine functions of the pancreas, pancreatic function, and associated pancreatic disorders are discussed in Chapters 40 and 41, and reproductive structures, including the ovaries and testes, are discussed in Chapters 46 and 49.

ASSESSMENT OF THE ENDOCRINE SYSTEM

Anatomic and Physiologic Overview

The **endocrine** system involves the release of chemical substances known as **hormones** to regulate and integrate body functions. Generally, these hormones are produced by the endocrine glands, but some are also produced by other tis-

sues. The gastrointestinal (GI) mucosa produces hormones (eg, gastrin, enterogastrone, secretin, cholecystokinin) that are important in the digestive process; the kidneys produce erythropoietin, a hormone that stimulates the bone marrow to produce red blood cells; and the white blood cells produce cytokines (hormonelike proteins) that actively participate in inflammatory and immune responses.

The immune system and the nervous system have unique relationships with the endocrine system. Chemicals such as neurotransmitters (eg, epinephrine) released by the nervous system can also function as hormones when needed. The immune system responds to the introduction of foreign agents by means of chemical messengers (cytokines), which are hormonelike proteins, while it is also subject to regulation by adrenal corticosteroid hormones (Porth & Matfin, 2009).

Glands of the Endocrine System

The endocrine system is composed of several glands: the pituitary, the thyroid gland, parathyroid glands, adrenal glands, pancreatic islets, ovaries, and testes (Fig. 42-1). Unlike the **exocrine** glands, most hormones secreted from endocrine glands are released directly into the bloodstream. Exocrine glands, such as sweat glands, secrete their products through ducts onto epithelial surfaces or into the GI tract.

Function and Regulation of Hormones

Hormones help regulate organ function in concert with the nervous system. This dual regulatory system, in which rapid action by the nervous system is balanced by slower hormonal action, permits precise control of organ functions in

Figure 42-1 Major hormone-secreting glands of the endocrine system.

Table 42-1 MAJOR ACTION AND SOURCE OF SELECTED HORMONES

Source	Hormone	Major Action
Hypothalamus	Releasing and inhibiting hormones Corticotropin-releasing hormone (CRH) Thyrotropin-releasing hormone (TRH) Growth hormone–releasing hormone (GHRH) Gonadotropin–releasing hormone (GnRH)	Controls the release of pituitary hormones
Anterior pituitary	Somatostatin Growth hormone (GH)	Inhibits growth hormone and thyroid-stimulating hormone Stimulates growth of bone and muscle, promotes protein synthesis and fat metabolism, decreases carbohydrate metabolism
	Adrenocorticotropic hormone (ACTH) Thyroid-stimulating hormone (TSH) Follicle-stimulating hormone (FSH)	Stimulates synthesis and secretion of adrenal cortical hormones Stimulates synthesis and secretion of thyroid hormone Female: stimulates growth of ovarian follicle, ovulation Male: stimulates sperm production
	Luteinizing hormone (LH)	Female: stimulates development of corpus luteum, release of oocyte, production of estrogen and progesterone Male: stimulates secretion of testosterone, development of interstitial tissue of testes
Posterior pituitary	Prolactin Antidiuretic hormone (ADH) Oxytocin	Prepares female breast for breast-feeding Increases water reabsorption by kidney Stimulates contraction of pregnant uterus, milk ejection from breasts after childbirth
Adrenal cortex	Mineralocorticosteroids, mainly aldosterone Glucocorticoids, mainly cortisol	Increase sodium absorption, potassium loss by kidney Affect metabolism of all nutrients; regulates blood glucose levels, affects growth, has anti-inflammatory action, and decreases effects of stress
Adrenal medulla	Adrenal androgens, mainly dehydroepiandrosterone (DHEA) and androstenedione Epinephrine Norepinephrine	Have minimal intrinsic androgenic activity; they are converted to testosterone and dihydrotestosterone in the periphery Serve as neurotransmitters for the sympathetic nervous system
Thyroid (follicular cells)	Thyroid hormones: triiodothyronine (T ₃), thyroxine (T ₄)	Increase the metabolic rate; increase protein and bone turnover; increase responsiveness to catecholamines; necessary for fetal and infant growth and development
Thyroid C cells	Calcitonin	Lowers blood calcium and phosphate levels
Parathyroid glands	Parathormone (PTH, parathyroid hormone)	Regulates serum calcium
Pancreatic islet cells	Insulin	Lowers blood glucose by facilitating glucose transport across cell membranes of muscle, liver, and adipose tissue
	Glucagon	Increases blood glucose concentration by stimulation of glycogenolysis and glyconeogenesis
Kidney	Somatostatin 1,25-Dihydroxyvitamin D Renin	Delays intestinal absorption of glucose Stimulates calcium absorption from the intestine Activates renin–angiotensin–aldosterone system
Ovaries	Erythropoietin Estrogen	Increases red blood cell production Affects development of female sex organs and secondary sex characteristics
	Progesterone	Influences menstrual cycle; stimulates growth of uterine wall; maintains pregnancy
Testes	Androgens, mainly testosterone	Affect development of male sex organs and secondary sex characteristics; aid in sperm production

Reproduced with permission from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

response to varied changes within and outside the body. Table 42-1 lists the major hormones, their target tissues, and some of their properties.

The endocrine glands are composed of secretory cells arranged in minute clusters known as acini. No ducts are present, but the glands have a rich blood supply, so the hormones they produce enter the bloodstream rapidly. In the healthy physiologic state, hormone concentration in the bloodstream is maintained at a relatively constant level. **Negative feedback** is the mechanism for regulating hormone concentration in the bloodstream. When the hormone concentration increases, further production of that hormone is inhibited. Conversely, when the hormone concentration decreases, the rate of production of that hormone increases.

Hormones are generally transported in body fluids, and the amount of specific hormones circulating at any given time depends on the body’s needs. Hormones are special in that particular ones may affect different tissues in various ways or that several may be necessary for the regulation of a certain body function.

Classification and Action of Hormones

Hormones are classified into four categories according to their structure: (1) amines and amino acids (eg, epinephrine, norepinephrine, and thyroid hormones); (2) peptides, polypeptides, proteins, and glycoproteins (eg, thyrotropin-releasing hormone, follicle-stimulating hormone, and growth hormone); (3) steroids (eg, corticosteroids); and (4) fatty acid derivatives (eg, eicosanoid, retinoids) (Porth &

Matfin, 2009). These different classes of hormones act on the target tissues by different mechanisms.

Hormones can alter the function of the target tissue by interacting with chemical receptors located either on the cell membrane or in the interior of the cell. For example, *peptide and protein hormones* interact with receptor sites on the cell surface, resulting in stimulation of the intracellular enzyme adenylyl cyclase. This causes increased production of cyclic 3',5'-adenosine monophosphate (cyclic AMP). The cyclic AMP inside the cell alters enzyme activity. Thus, cyclic AMP is the “second messenger” that links the peptide hormone at the cell surface to a change in the intracellular environment. Some protein and peptide hormones also act by changing membrane permeability and act within seconds or minutes. The mechanism of action for *amine hormones* is similar to that for peptide hormones.

Steroid hormones, because of their smaller size and higher lipid solubility, penetrate cell membranes and interact with intracellular receptors. The steroid–receptor complex modifies cell metabolism and the formation of messenger ribonucleic acid (mRNA) from deoxyribonucleic acid (DNA). The mRNA then stimulates protein synthesis within the cell. Steroid hormones require several hours to exert their effects, because they exert their action by the modification of protein synthesis.

Although most hormones released by endocrine glands can be transported to distant target sites for action, some hormones and hormonelike substances never enter the

bloodstream. Some hormones act locally in the area where they are released; this is called paracrine action (eg, the effect of sex hormones on the ovaries). Others may act on the actual cells from which they were released; this is called autocrine action (eg, the effect of insulin from pancreatic beta cells on those cells) (Porth & Matfin, 2009).

Assessment

Health History

Although specific endocrine disorders are often accompanied by specific clinical symptoms, more general manifestations may also occur. Some common signs and symptoms of endocrine imbalances include changes in energy level, tolerance to heat or cold, weight, fat and fluid distribution, secondary sexual characteristics, sexual dysfunction, memory, concentration, sleep patterns, and mood. The health history should include information regarding (1) the severity of these changes, (2) the length of time the patient has experienced these changes, (3) the way in which these changes have affected the patient's ability to carry out activities of daily living, and (4) the effect of the changes on the patient's self-perception. Specific symptoms of various endocrine disorders are discussed with each disorder. Possible genetics-related issues may also be important (Chart 42-1).

CHART
42-1

GENETICS IN NURSING PRACTICE

Metabolic Disorders

Some examples of metabolic and endocrine disorders influenced by genetic factors include the following:

- Alpha-1 antitrypsin deficiency
- Cystic fibrosis
- Diabetes mellitus type 1 and type 2
- Hereditary hemochromatosis
- Multiple endocrine neoplasia (MEN) type I and type II
- Von Hippel-Lindau syndrome
- Wilson's disease

Nursing Assessments

Family History Assessment

- Assess family history for relatives with early-onset hepatic, pancreatic, or endocrine disease.
- Inquire about family members with diabetes and their ages at onset.
- Assess family history of other related genetic conditions such as cystic fibrosis, alpha-1 antitrypsin deficiency, and hereditary hemochromatosis.

Patient Assessment

- Assess for physical symptoms such as mucosal neuromas, hypertrophied lips, skeletal abnormalities, and marfanoid appearance.
- Assess for signs of arthritis and bronze pigmentation of the skin (hereditary hemochromatosis).

Management Issues Specific to Genetics

- Inquire whether DNA mutation testing has been performed on any affected family member.

- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, and availability of genetic testing and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetics-related metabolic and endocrine conditions.
- Participate in management and coordination of care of patients with genetic conditions and people predisposed to develop or pass on a genetic condition.

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions, www.ncbi.nlm.nih.gov/projects/omim

Physical Assessment

The physical examination should include vital signs, a visual head-to-toe assessment, and tactile examination. Findings should be compared with previous findings if available. Changes in physical characteristics such as appearance of facial hair in women, “moon face,” “buffalo hump,” exophthalmos, edema, thinning of the skin, obesity of the trunk, thinness of the extremities, increased size of the feet and hands, and edema may signify disorders of the thyroid, adrenal cortex, or pituitary gland. Exophthalmos and other eye symptoms may occur with hyperthyroidism and Graves’ disease. Alteration in skin texture is associated with hypofunction and hyperfunction of the thyroid gland. Elevated blood pressure may occur with hyperfunction of the adrenal cortex or tumor of the adrenal medulla. Decreased blood pressure may occur with hypofunction of the adrenal cortex. Behavioral changes such as agitation, nervousness, a flat affect, or a lack of concern about personal appearance may also be present.

Diagnostic Evaluation

A variety of diagnostic studies are used to evaluate the endocrine system. The most common tests are discussed in this section.

Blood tests are used to determine hormone blood levels. Knowing the serum levels of a specific hormone may provide information about whether there is hypofunction or hyperfunction of the endocrine system and the site of dysfunction. Other blood tests are used to detect autoantibodies or to assess the effect of the hormone on other substances (eg, the effect of insulin on blood glucose levels). Radioimmunoassays are radioisotope-labeled antigen tests used to measure the levels of hormones or other substances.

Urine tests may be used to measure the amount of hormones or the end products of hormones excreted by the kidneys. One-time specimens are obtained, or in some disorders 24-hour urine specimens are collected to measure hormones or their metabolites. For example, urinary levels of free catecholamines (norepinephrine, epinephrine, and dopamine) may be measured in patients with suspected tumors of the adrenal medulla (**pheochromocytoma**). Urine tests have several disadvantages, such as the inability of patients to urinate at scheduled intervals and the effect of some medications or disease states on the test results (Porth & Matfin, 2009).

Stimulation tests can determine how an endocrine gland responds to the administration of stimulating hormones that are normally produced or released by the hypothalamus or pituitary gland. If the endocrine gland responds to this stimulation, the specific disorder may be in the hypothalamus or pituitary. Failure of the endocrine gland to respond to this stimulation helps identify the problem as being in the endocrine gland itself.

Suppression tests may be used to determine whether negative feedback mechanisms that normally control secretion of hormones from the hypothalamus or pituitary gland are intact. They test the effect of administration of an exogenous dose of the hormone on the endogenous secretion of

the hormone or on the secretion of stimulation hormones from the hypothalamus or pituitary gland.

Imaging studies include radioactive scanning, magnetic resonance imaging (MRI), computed tomography (CT), ultrasonography, positron emission tomography (PET), and dual-energy x-ray absorptiometry (DEXA).

Genetic screening is increasingly becoming more available. DNA testing is expected to lead to the identification of specific genes associated with endocrine disorders, selective targeting for drug development, and increased understanding of the function of the endocrine system (Porth & Matfin, 2009). Genetic screening is used to determine the presence of a gene mutation that may predispose an individual to a certain condition. The use of genetic screening must be considered carefully by the physician and patient.

THE PITUITARY GLAND

Anatomic and Physiologic Overview

The pituitary gland, or hypophysis, is commonly referred to as the master gland because of the influence it has on secretion of hormones by other endocrine glands (Fig. 42-2) (Porth & Matfin, 2009). The round structure, about 1.27 cm (1/2 inch) in diameter, is located on the inferior aspect of the brain. The pituitary gland is divided into anterior and posterior lobes. It is controlled by the hypothalamus, an adjacent area of the brain that is connected to the pituitary by the pituitary stalk.

Anterior Pituitary

The major hormones of the anterior pituitary gland are follicle-stimulating hormone (FSH), luteinizing hormone (LH), prolactin, **adrenocorticotropic hormone (ACTH)**, **thyroid-stimulating hormone (TSH)**, and growth hormone (GH) (also referred to as somatotropin). The secretion of these major hormones is controlled by releasing factors secreted by the hypothalamus. These releasing factors reach the anterior pituitary by way of the bloodstream in a special circulation called the pituitary portal blood system. Other hormones include melanocyte-stimulating hormone and beta-lipotropin; the function of lipotropin is poorly understood.

The hormones released by the anterior pituitary enter the general circulation and are transported to their target organs. The main function of TSH, ACTH, FSH, and LH is the release of hormones from other endocrine glands. Prolactin acts on the breast to stimulate milk production. Hormones that stimulate other organs and tissues are discussed in conjunction with their target organs.

GH is a protein hormone that increases protein synthesis in many tissues, increases the breakdown of fatty acids in adipose tissue, and increases the glucose level in the blood. These actions of GH are essential for normal growth, although other hormones, such as thyroid hormone and insulin, are required as well. Stress, exercise, and low blood glucose levels increase the secretion of GH. The half-life of GH activity in the blood is 20 to 30 minutes; the hormone is largely inactivated in the liver.

Figure 42-2 The pituitary gland, the relationship of the brain to pituitary action, and the hormones secreted by the anterior and posterior pituitary lobes. ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; ICSH, interstitial cell-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

Posterior Pituitary

The important hormones secreted by the posterior lobe of the pituitary gland are **vasopressin**, also called antidiuretic hormone (ADH), and **oxytocin**. These hormones are synthesized in the hypothalamus and travel from the hypothalamus to the posterior pituitary gland for storage. Vasopressin controls the excretion of water by the kidney; its secretion is stimulated by an increase in the osmolality of the blood or by a decrease in blood pressure. Oxytocin secretion is stimulated during pregnancy and at childbirth. It

facilitates milk ejection during lactation and increases the force of uterine contractions during labor and delivery.

Pathophysiology

Abnormalities of pituitary function are caused by oversecretion or undersecretion of any of the hormones produced or released by the gland. Abnormalities of the anterior and posterior portions of the gland may occur independently.

Hypofunction of the pituitary gland (hypopituitarism) can result from disease of the pituitary gland itself or disease of the hypothalamus; the result is essentially the same. Hypopituitarism can result from radiation therapy to the head and neck area. The total destruction of the pituitary gland by trauma, tumor, or vascular lesion removes all stimuli that are normally received by the thyroid, the gonads, and the adrenal glands. The result is extreme weight loss, emaciation, atrophy of all endocrine glands and organs, hair loss, impotence, amenorrhea, hypometabolism, and hypoglycemia. Coma and death occur if the missing hormones are not replaced.

Anterior Pituitary

Oversecretion (hypersecretion) of the anterior pituitary gland most commonly involves ACTH or GH and results in **Cushing's syndrome** or **acromegaly**, respectively. Acromegaly, an excess of GH in adults, results in bone and soft tissue deformities and enlargement of the viscera without an increase in height. It occurs in approximately 3 cases per 1 million people per year (Melmed, 2006). Oversecretion of GH results in gigantism in children; a person may be 7 or even 8 feet tall. Conversely, insufficient secretion of GH during childhood results in generalized limited growth and **dwarfism** (Porth & Matfin, 2009). Undersecretion (hyposecretion) commonly involves all of the anterior pituitary hormones and is termed *panhypopituitarism*. In this condition, the thyroid gland, the adrenal cortex, and the gonads atrophy (shrink) because of loss of the trophic-stimulating hormones. Hypopituitarism may result from destruction of the anterior lobe of the pituitary gland. Postpartum pituitary necrosis (Sheehan's syndrome) is another uncommon cause of failure of the anterior pituitary. It is more likely to occur in women with severe blood loss, hypovolemia, and hypotension at the time of delivery.

Posterior Pituitary

The most common disorder related to posterior lobe dysfunction is **diabetes insipidus**, a condition in which abnormally large volumes of dilute urine are excreted as a result of deficient production of vasopressin.

Specific Disorders of the Pituitary Gland

PITUITARY TUMORS

Pituitary tumors are usually benign and may be primary or secondary (Porth & Matfin, 2009). Functionality is also important. Functional tumors secrete pituitary hormones, whereas nonfunctional tumors do not. The location and effects of these tumors on hormone production by target organs can have life-threatening effects. Three principal types of pituitary tumors represent an overgrowth of (1) eosinophilic cells, (2) basophilic cells, or (3) chromophobic cells (ie, cells with no affinity for either eosinophilic or basophilic stains).

Clinical Manifestations

Eosinophilic tumors that develop early in life result in gigantism. The affected person may be more than 7 feet tall and large in all proportions, yet so weak and lethargic that

he or she can hardly stand. If the disorder begins during adult life, the excessive skeletal growth occurs only in the feet, the hands, the superciliary ridge, the molar eminences, the nose, and the chin, giving rise to the clinical picture called acromegaly. However, enlargement involves all tissues and organs of the body (Melmed, 2006). Many of these patients suffer from severe headaches and visual disturbances because the tumors exert pressure on the optic nerves (Porth & Matfin, 2009). Assessment of central vision and visual fields may reveal loss of color discrimination, diplopia (double vision), or blindness in a portion of a field of vision. Decalcification of the skeleton, muscular weakness, and endocrine disturbances, similar to those occurring in patients with hyperthyroidism, also are associated with this type of tumor.

Basophilic tumors give rise to Cushing's syndrome with features largely attributable to hyperadrenalism, including masculinization and amenorrhea in females, truncal obesity, hypertension, osteoporosis, and polycythemia.

Chromophobic tumors represent 90% of pituitary tumors. These tumors usually produce no hormones but destroy the rest of the pituitary gland, causing hypopituitarism. People with this disease are often obese and somnolent and exhibit fine, scanty hair; dry, soft skin; a pasty complexion; and small bones. They also experience headaches, loss of libido, and visual defects progressing to blindness. Other signs and symptoms include polyuria, polyphagia, a lowering of the **basal metabolic rate**, and a subnormal body temperature.

Assessment and Diagnostic Findings

Diagnostic evaluation requires a careful history and physical examination, including assessment of visual acuity and visual fields. CT and MRI are used to diagnose the presence and extent of pituitary tumors. Serum levels of pituitary hormones may be obtained along with measurements of hormones of target organs (eg, thyroid, adrenal) to assist in diagnosis.

Medical Management

Surgical removal of the pituitary tumor (**hypophysectomy**) through a transsphenoidal approach is the usual treatment. Stereotactic radiation therapy, which requires use of a neurosurgery-type stereotactic frame, may be used to deliver external beam radiation therapy precisely to the pituitary tumor with minimal effect on normal tissue (see Chapter 16). Other treatments include conventional radiation therapy, bromocriptine (Parlodel, a dopamine antagonist), and octreotide (Sandostatin, a synthetic analogue of GH). These medications inhibit the production or release of GH and may bring about marked improvement of symptoms. Octreotide and lanreotide (Somatuline Depot, a somatostatin analogue) may also be used preoperatively to improve the patient's clinical condition and to shrink the tumor (Melmed, 2006).

Surgical Management

Hypophysectomy is the treatment of choice in patients with Cushing's syndrome resulting from excessive production of ACTH by a pituitary tumor. Hypophysectomy may also be performed on occasion as a palliative measure to relieve

bone pain secondary to metastasis of malignant lesions of the breast and prostate.

Several approaches are used to remove or destroy the pituitary gland, including surgical removal by transfrontal, subcranial, or oronasal–transsphenoidal approaches; irradiation; and cryosurgery. (The transsphenoidal approach and the nursing management of a patient undergoing cranial surgery are discussed in Chapter 61.) Features or symptoms of acromegaly are unaffected by surgical removal of the tumor.

The absence of the pituitary gland alters the function of many body systems. Menstruation ceases and infertility occurs after total or near-total ablation of the pituitary gland. Replacement therapy with corticosteroids and thyroid hormone is necessary; therefore, patient teaching is imperative (see later discussion).

DIABETES INSIPIDUS

Diabetes insipidus (DI) is a disorder of the posterior lobe of the pituitary gland that is characterized by a deficiency of ADH (vasopressin). Excessive thirst (polydipsia) and large volumes of dilute urine characterize the disorder. It may occur secondary to head trauma, brain tumor, or surgical ablation or irradiation of the pituitary gland. It may also occur with infections of the central nervous system (meningitis, encephalitis, tuberculosis) or with tumors (eg, metastatic disease, lymphoma of the breast or lung). Another cause of DI is failure of the renal tubules to respond to ADH; this nephrogenic form may be related to hypokalemia, hypercalcemia, and a variety of medications (eg, lithium, demeclocycline [Declomycin]).

Clinical Manifestations

Without the action of ADH on the distal nephron of the kidney, an enormous daily output of very dilute, waterlike urine with a specific gravity of 1.001 to 1.005 occurs. The urine contains no abnormal substances such as glucose or albumin. Because of the intense thirst, the patient tends to drink 2 to 20 L of fluid daily and craves cold water. In the hereditary form of DI, the primary symptoms may begin at birth. In adults, the onset of DI may be insidious or abrupt.

The disease cannot be controlled by limiting fluid intake, because the high-volume loss of urine continues even without fluid replacement. Attempts to restrict fluids cause the patient to experience an insatiable craving for fluid and to develop hypernatremia and severe dehydration.

Assessment and Diagnostic Findings

The fluid deprivation test is carried out by withholding fluids for 8 to 12 hours or until 3% to 5% of the body weight is lost. The patient is weighed frequently during the test. Plasma and urine osmolality studies are performed at the beginning and end of the test. The inability to increase the specific gravity and osmolality of the urine is characteristic of DI. The patient continues to excrete large volumes of urine with low specific gravity and experiences weight loss, increasing serum osmolality, and elevated serum sodium levels. The patient's condition needs to be monitored frequently during the test, and the test is terminated if tachycardia, excessive weight loss, or hypotension develops.

Other diagnostic procedures include concurrent measurements of plasma levels of ADH and plasma and urine osmolality as well as a trial of desmopressin (synthetic vasopressin) therapy and intravenous (IV) infusion of hypertonic saline solution. If the diagnosis is confirmed and the cause (eg, head injury) is not obvious, the patient is carefully assessed for tumors that may be causing the disorder.

Medical Management

The objectives of therapy are (1) to replace ADH (which is usually a long-term therapeutic program), (2) to ensure adequate fluid replacement, and (3) to identify and correct the underlying intracranial pathology. Nephrogenic causes require different management approaches.

Pharmacologic Therapy

Desmopressin (DDAVP), a synthetic vasopressin without the vascular effects of natural ADH, is particularly valuable because it has a longer duration of action and fewer adverse effects than other preparations previously used to treat the disease. It is administered intranasally; the patient sprays the solution into the nose through a flexible calibrated plastic tube. One or two administrations daily (ie, every 12 to 24 hours) usually control the symptoms (Tierney, McPhee & Papadakis, 2005). Vasopressin causes vasoconstriction; thus, it must be used cautiously in patients with coronary artery disease.

Intramuscular administration of ADH, vasopressin tannate in oil, is used if the intranasal route is not possible. The medication is administered every 24 to 96 hours. The vial of medication should be warmed or shaken vigorously before administration. The injection is administered in the evening so that maximum results are obtained during sleep. Abdominal cramps are a side effect of this medication. Rotation of injection sites is necessary to prevent lipodystrophy.

Clofibrate (Atromid-S), a hypolipidemic agent, has been found to have an antidiuretic effect on patients with DI who have some residual hypothalamic vasopressin. Chlorpropamide (Diabinese) and thiazide diuretics are also used in mild forms of the disease because they potentiate the action of vasopressin. Hyperglycemia is possible.

If the DI is renal in origin, the previously described treatments are ineffective. Thiazide diuretics, mild salt depletion, and prostaglandin inhibitors (ibuprofen [Advil, Motrin], indomethacin [Indocin], and aspirin) are used to treat the nephrogenic form of DI.

Nursing Management

The nurse must teach the patient and family about follow-up care and emergency measures and provide specific verbal and written instructions, including the actions and side effects of all medications. In addition to demonstrating correct medication administration, the nurse should observe return demonstrations. It is necessary to provide information regarding the signs and symptoms of hyponatremia. Finally, the nurse should advise wearing a medical identification bracelet and carrying medication and information about DI at all times.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

The **syndrome of inappropriate antidiuretic hormone (SIADH) secretion** includes excessive ADH secretion from the pituitary gland even in the face of subnormal serum osmolality. Patients cannot excrete a dilute urine, retain fluids, and develop a sodium deficiency known as dilutional hyponatremia. SIADH is often of nonendocrine origin; for instance, the syndrome may occur in patients with bronchogenic carcinoma in which malignant lung cells synthesize and release ADH. SIADH has also occurred in patients with severe pneumonia, pneumothorax, and other disorders of the lungs, as well as malignant tumors that affect other organs (Porth & Matfin, 2009).

Disorders of the central nervous system, such as head injury, brain surgery or tumor, and infection, are thought to produce SIADH by direct stimulation of the pituitary gland. Some medications (eg, vincristine [Oncovin], phenothiazines, tricyclic antidepressants, thiazide diuretics) and nicotine have been implicated in SIADH; they either directly stimulate the pituitary gland or increase the sensitivity of renal tubules to circulating ADH.

Interventions include the elimination of the underlying cause, if possible, and restricting fluid intake. Because retained water is excreted slowly through the kidneys, the extracellular fluid volume contracts and the serum sodium concentration gradually increases toward normal. Diuretics such as furosemide (Lasix) may be used along with fluid restriction if severe hyponatremia is present.

Close monitoring of fluid intake and output, daily weight, urine and blood chemistries, and neurologic status is indicated for the patient at risk for SIADH. Supportive measures and explanations of procedures and treatments assist the patient in managing this disorder.

THE THYROID GLAND

The thyroid gland is a butterfly-shaped organ located in the lower neck, anterior to the trachea (Fig. 42-3). It consists of two lateral lobes connected by an isthmus. The gland is about

Figure 42-3 The thyroid gland and surrounding structures.

5 cm long and 3 cm wide and weighs about 30 g. The blood flow to the thyroid is very high (about 5 mL/min per gram of thyroid tissue), approximately five times the blood flow to the liver. This reflects the high metabolic activity of the thyroid gland. The thyroid gland produces three hormones: **thyroxine (T₄)**, **triiodothyronine (T₃)**, and **calcitonin**.

Anatomic and Physiologic Overview

Various hormones and chemicals are responsible for normal thyroid function. Key among them are thyroid hormone, calcitonin, and iodine.

Thyroid Hormone

T₄ and T₃, which are referred to collectively as thyroid hormone, are two separate hormones produced by the thyroid gland. Both are amino acids that contain iodine molecules bound to the amino acid structure; T₄ contains four iodine atoms in each molecule, and T₃ contains three. These hormones are synthesized and stored bound to proteins in the cells of the thyroid gland until needed for release into the bloodstream. About 75% of bound thyroid hormone is bound to thyroxine-binding globulin (TBG); the remaining bound thyroid hormone is bound to thyroid-binding prealbumin and albumin.

Synthesis of Thyroid Hormone

Iodine is essential to the thyroid gland for synthesis of its hormones. The major use of iodine in the body is by the thyroid, and the major derangement in iodine deficiency is alteration of thyroid function. Iodide is ingested in the diet and absorbed into the blood in the GI tract. The thyroid gland is extremely efficient at taking up iodide from the blood and concentrating it within the cells, where iodide ions are converted to iodine molecules, which react with tyrosine (an amino acid) to form the thyroid hormones.

Regulation of Thyroid Hormone

The secretion of T₃ and T₄ by the thyroid gland is controlled by TSH (also called thyrotropin) from the anterior pituitary gland. TSH controls the rate of thyroid hormone release through a negative feedback mechanism. In turn, the level of thyroid hormone in the blood determines the release of TSH. If the thyroid hormone concentration in the blood decreases, the release of TSH increases, which causes increased output of T₃ and T₄. The term **euthyroid** refers to thyroid hormone production that is within normal limits.

Thyrotropin-releasing hormone (TRH), secreted by the hypothalamus, exerts a modulating influence on the release of TSH from the pituitary. Environmental factors, such as a decrease in temperature, may lead to increased secretion of TRH, resulting in elevated secretion of thyroid hormones. Figure 42-4 shows the hypothalamic–pituitary–thyroid axis, which regulates thyroid hormone production.

Function of Thyroid Hormone

The primary function of thyroid hormone is to control cellular metabolic activity. T₄, a relatively weak hormone, maintains body metabolism in a steady state. T₃ is about five

Figure 42-4 The hypothalamic–pituitary–thyroid axis. Thyroid-releasing hormone (TRH) from the hypothalamus stimulates the pituitary gland to secrete thyroid-stimulating hormone (TSH). TSH stimulates the thyroid to produce thyroid hormone (triiodothyronine [T₃] and thyroxine [T₄]). High circulating levels of T₃ and T₄ inhibit further TSH secretion and thyroid hormone production through a negative feedback mechanism (*dashed lines*).

times as potent as T₄ and has a more rapid metabolic action. These hormones accelerate metabolic processes by increasing the level of specific enzymes that contribute to oxygen consumption and altering the responsiveness of tissues to other hormones. The thyroid hormones influence cell replication and are important in brain development. Thyroid hormone is also necessary for normal growth. The thyroid hormones, through their widespread effects on cellular metabolism, influence every major organ system.

Calcitonin

Calcitonin, or thyrocalcitonin, is another important hormone secreted by the thyroid gland. It is secreted in response to high plasma levels of calcium, and it reduces the plasma level of calcium by increasing its deposition in bone.

Pathophysiology

Inadequate secretion of thyroid hormone during fetal and neonatal development results in stunted physical and mental growth (**cretinism**) because of general depression of metabolic activity. In adults, hypothyroidism manifests as lethargy, slow mentation, and generalized slowing of body functions.

Oversecretion of thyroid hormones (hyperthyroidism) is manifested by a greatly increased metabolic rate. Many of the other characteristics of hyperthyroidism result from the increased response to circulating catecholamines (epinephrine and norepinephrine). Oversecretion of thyroid hormones is usually associated with an enlarged thyroid gland known as a **goiter**. Goiter also commonly occurs with iodine deficiency. In this latter condition, lack of iodine results in

low levels of circulating thyroid hormones, which causes increased release of TSH; the elevated TSH causes overproduction of thyroglobulin (a precursor of T₃ and T₄) and hypertrophy of the thyroid gland.

Assessment and Diagnostic Findings

Physical Examination

The thyroid gland is inspected and palpated routinely in all patients. Inspection begins with identification of landmarks. The lower neck region between the sternocleidomastoid muscles is inspected for swelling or asymmetry. The patient is instructed to extend the neck slightly and swallow. Thyroid tissue rises normally with swallowing. The thyroid is then palpated for size, shape, consistency, symmetry, and the presence of tenderness (Bickley, 2007).

The clinician may examine the thyroid from an anterior or a posterior position. In the posterior position, both hands encircle the patient's neck. The thumbs rest on the nape of the neck, while the index and middle fingers palpate for the thyroid isthmus and the anterior surfaces of the lateral lobes. When palpable, the isthmus is perceived as firm and of a rubber-band consistency.

The left lobe is examined by positioning the patient so that the neck flexes slightly forward and to the left. The thyroid cartilage is then displaced to the left with the fingers of the right hand. This maneuver displaces the left lobe deep into the sternocleidomastoid muscle, where it can be more easily palpated. The left lobe is then palpated by placing the left thumb deep into the posterior area of the sternocleidomastoid muscle, while the index and middle fingers exert opposite pressure in the anterior portion of the muscle. Having the patient swallow during the maneuver may assist the examiner to locate the thyroid as it ascends in the neck. The procedure is reversed to examine the right lobe. The isthmus is the only portion of the thyroid that is normally palpable. If a patient has a very thin neck, two thin, smooth, nontender lobes may also be palpable.

If palpation discloses an enlarged thyroid gland, both lobes are auscultated using the diaphragm of the stethoscope. Auscultation identifies the localized audible vibration of a bruit. This is indicative of increased blood flow through the thyroid gland associated with hyperthyroidism and necessitates referral to a physician. Other abnormal findings that require referral for further evaluation may include a soft texture (Graves' disease), firmness (Hashimoto's thyroiditis or malignancy), and tenderness (thyroiditis) (Table 42-2) (Bickley, 2007).

Laboratory and Diagnostic Studies

Assessment measures in addition to palpation and auscultation include thyroid function tests, such as laboratory measurement of thyroid hormones, thyroid scanning, biopsy, and ultrasonography. The most widely used tests are serum immunoassay for TSH and free T₄ (Tierney, et al., 2005). Measurement of TSH has a sensitivity of 98% and specificity of greater than 92% (U.S. Department of Health & Human Services [USDHHS], 2006). Free T₄ levels correlate with metabolic status; they are elevated in hyperthyroidism and decreased in

Table 42-2 SUMMARY OF FINDINGS ON PHYSICAL EXAMINATION OF THE THYROID GLAND

Physical Finding	Differential Diagnosis	Special Features
Single nodule	Autonomously functioning adenoma Adenoma or adenomatous nodule Cancer Hyperplasia secondary to unilobar agenesis	Opposite lobe not palpable Rubbery, firm; tenderness suggests recent hemorrhage or infarction Usually hard; may have associated lymph node enlargement or vocal cord palsy Opposite lobe not palpable
Multiple nodules	Multinodular goiter Hashimoto's thyroiditis	Firm lobes or irregular surface may be misinterpreted as multiple nodules
Diffuse goiter	Graves' disease Hashimoto's thyroiditis Thyroid lymphoma Multinodular goiter	Bruit or thrill; pyramidal lobe Irregular surface; pyramidal lobe; rubbery or firm; occasionally tender; fibrous variant may be hard Rapidly growing goiter, particularly in setting of preexisting Hashimoto's thyroiditis Nodules may be hidden within gland and may become apparent with thyroid hormone suppression
Tenderness	Subacute thyroiditis Hemorrhagic or infarcted adenoma Hashimoto's thyroiditis Cancer	Unilateral or bilateral; tenderness often severe Discrete nodule with tenderness Mild tenderness Irregular, firm thyroid nodule with chronic tenderness

hypothyroidism. Ultrasound, CT, and MRI may be used to clarify or confirm the results of other diagnostic studies.

Thyroid Tests

Serum Thyroid-Stimulating Hormone

Measurement of the serum TSH concentration is the single best screening test of thyroid function in outpatients because of its high sensitivity. The ability to detect minute changes in serum TSH makes it possible to distinguish subclinical thyroid disease from euthyroid states in patients with low or high normal values. Measurement of TSH is also used for monitoring thyroid hormone replacement therapy and for differentiating between disorders of the thyroid gland itself and disorders of the pituitary or hypothalamus. Current recommendations suggest TSH screening for all adults beginning at 35 years of age and every 5 years thereafter (USDHHS, 2006).

Serum Free T₄

The test most commonly used to confirm an abnormal TSH result is free T₄. It is a direct measurement of free (unbound) thyroxine, the only metabolically active fraction of T₄. The range of free T₄ in serum is normally 0.9 to 1.7 ng/dL (11.5 to 21.8 pmol/L). When measured by the dialysis method, free T₄ is not affected by variations in protein binding and is the procedure of choice for monitoring the changes in T₄ secretion during treatment of hyperthyroidism.

Serum T₃ and T₄

Measurement of total T₃ or T₄ includes protein-bound and free hormone levels that occur in response to TSH secretion. T₄ is 70% bound to TBG; T₃ is bound less firmly. Only 0.03% of T₄ and 0.3% of T₃ are unbound. Serious systemic illnesses, medications (eg, oral contraceptives, corticosteroids, phenytoin, salicylates) and protein wasting as a result of nephrosis or use of androgens may interfere with accurate test results. Normal range for T₄ is 4.5 to 11.5 μg/dL (58.5 to 150 nmol/L). Although serum T₃ and T₄ levels generally increase or decrease together, the T₃ level appears to be a more accurate indicator of hyperthyroidism, which

causes a greater increase in T₃ than in T₄ levels. The normal range for serum T₃ is 70 to 220 ng/dL (1.15 to 3.10 nmol/L).

T₃ Resin Uptake Test

The T₃ resin uptake test is an indirect measure of unsaturated TBG. Its purpose is to determine the amount of thyroid hormone bound to TBG and the number of available binding sites. This provides an index of the amount of thyroid hormone already present in the circulation. Normally, TBG is not fully saturated with thyroid hormone, and additional binding sites are available to combine with radioiodine-labeled T₃ added to the blood specimen. The normal T₃ uptake value is 25% to 35% (relative uptake fraction, 0.25 to 0.35), which indicates that about one third of the available sites of TBG are occupied by thyroid hormone. If the number of free or unoccupied binding sites is low, as in hyperthyroidism, the T₃ uptake is greater than 35% (0.35). If the number of available sites is high, as occurs in hypothyroidism, the test result is less than 25% (0.25).

T₃ uptake is useful in the evaluation of thyroid hormone levels in patients who have received diagnostic or therapeutic doses of iodine. The test results may be altered by the use of estrogens, androgens, salicylates, phenytoin, anticoagulants, or corticosteroids.

Thyroid Antibodies

Autoimmune thyroid diseases include both hypothyroid and hyperthyroid conditions. Results of testing by immunoassay techniques for antithyroid antibodies are positive in chronic autoimmune thyroid disease (90%), Hashimoto's thyroiditis (100%), Graves' disease (80%), and other organ-specific autoimmune diseases, such as lupus erythematosus and rheumatoid arthritis. Antithyroid antibody titers are normally present in 5% to 10% of the population and increase with age.

Radioactive Iodine Uptake

The radioactive iodine uptake test measures the rate of iodine uptake by the thyroid gland. The patient is administered a tracer dose of iodine 123 (¹²³I) or another

radionuclide, and a count is made over the thyroid gland with a scintillation counter, which detects and counts the gamma rays released from the breakdown of ^{123}I in the thyroid. It measures the proportion of the administered dose that is present in the thyroid gland at a specific time after its administration. It is a simple test and provides reliable results. It is affected by the patient's intake of iodide or thyroid hormone; therefore, a careful preliminary clinical history is essential in evaluating results. Normal values vary from one geographic region to another and with the intake of iodine. Patients with hyperthyroidism exhibit a high uptake of the ^{123}I (in some patients, as high as 90%), whereas patients with hypothyroidism exhibit a very low uptake.

Fine-Needle Aspiration Biopsy

Use of a small-gauge needle to sample the thyroid tissue for biopsy is a safe and accurate method of detecting malignancy. It is often the initial test for evaluation of thyroid masses. Results are reported as (1) negative (benign), (2) positive (malignant), (3) indeterminate (suspicious), and (4) inadequate (nondiagnostic).

Thyroid Scan, Radioscan, or Scintiscan

In a thyroid scan, a scintillation detector or gamma camera moves back and forth across the area to be studied in a series of parallel tracks, and a visual image is made of the distribution of radioactivity in the area being scanned. Although ^{123}I has been the most commonly used isotope, technetium $^{99\text{m}}\text{Tc}$ pertechnetate, thallium, and americium are also used.

Scans are helpful in determining the location, size, shape, and anatomic function of the thyroid gland, particularly when thyroid tissue is substernal or large. Identifying areas of increased function ("hot" areas) or decreased function ("cold" areas) can assist in diagnosis. Although most areas of decreased function do not represent malignancies, lack of function increases the likelihood of malignancy, particularly if only one nonfunctioning area is present. Scanning of the entire body, to obtain the total body profile, may be carried out in a search for a functioning thyroid metastasis (ie, a lesion that produces thyroid hormones).

Serum Thyroglobulin

Thyroglobulin (Tg) can be measured reliably in the serum by radioimmunoassay. Clinically, it is used to detect persistence or recurrence of thyroid carcinoma.

Nursing Implications

When thyroid tests are scheduled, it is necessary to determine whether the patient has taken medications or agents that contain iodine, because these may alter the test results. Iodine-containing medications include contrast agents and those used to treat thyroid disorders. Less obvious sources of iodine are topical antiseptics, multivitamin preparations, and food supplements frequently found in health food stores; cough syrups; and amiodarone (Cordarone), an antiarrhythmic agent. Other medications that may affect test results are estrogens, salicylates, amphetamines, chemotherapeutic agents, antibiotics, corticosteroids, and mercurial diuretics. The nurse asks the patient about the use of these medications and notes their use on the laboratory requisition.

CHART
42-2

PHARMACOLOGY Partial List of Medications That May Alter Thyroid Test Results

Estrogens	Opioids
Sulfonylureas	Androgens
Corticosteroids	Salicylates
Iodine	Lithium
Propranolol	Amiodarone
Cimetidine	Clofibrate
5-Fluorouracil	Furosemide
Phenytoin	Diazepam
Heparin	Danazol
Chloral hydrate	Dopamine antagonists
X-ray contrast agents	Propylthiouracil

tion. Chart 42-2 gives a partial list of agents that may interfere with accurate testing of thyroid gland function.

Specific Disorders of the Thyroid Gland

HYPOTHYROIDISM

Hypothyroidism results from suboptimal levels of thyroid hormone. Thyroid deficiency can affect all body functions and can range from mild, subclinical forms to **myxedema**, an advanced form. The most common cause of hypothyroidism in adults is autoimmune thyroiditis (Hashimoto's disease), in which the immune system attacks the thyroid gland. Symptoms of hyperthyroidism may later be followed by those of hypothyroidism and myxedema. Hypothyroidism also commonly occurs in patients with previous hyperthyroidism that has been treated with radioiodine or antithyroid medications or thyroidectomy. The condition occurs most frequently in older women. In addition, there is an increased incidence of thyroid cancer in men who have undergone radiation therapy for head and neck cancer. Therefore, testing of thyroid function is recommended for all patients who receive such treatment. Other causes of hypothyroidism are presented in Chart 42-3.

Chart 42-3 • Causes of Hypothyroidism

Autoimmune disease (Hashimoto's thyroiditis, post-Graves' disease)
Atrophy of thyroid gland with aging
Therapy for hyperthyroidism
Radioactive iodine (^{131}I)
Thyroidectomy
Medications
Lithium
Iodine compounds
Antithyroid medications
Radiation to head and neck for treatment of head and neck cancers, lymphoma
Infiltrative diseases of the thyroid (amyloidosis, scleroderma, lymphoma)
Iodine deficiency and iodine excess

More than 95% of patients with hypothyroidism have primary or thyroidal hypothyroidism, which refers to dysfunction of the thyroid gland itself. If the cause of the thyroid dysfunction is failure of the pituitary gland, the hypothalamus, or both, the hypothyroidism is known as central hypothyroidism. If the cause is entirely a pituitary disorder, it may be referred to as pituitary or secondary hypothyroidism. If the cause is a disorder of the hypothalamus resulting in inadequate secretion of TSH due to decreased stimulation of TRH, it is referred to as hypothalamic or tertiary hypothyroidism. If thyroid deficiency is present at birth, it is referred to as cretinism. In such instances, the mother may also have thyroid deficiency.

The term *myxedema* refers to the accumulation of mucopolysaccharides in subcutaneous and other interstitial tissues. Although myxedema occurs in long-standing hypothyroidism, the term is used appropriately only to describe the extreme symptoms of severe hypothyroidism.

Clinical Manifestations

Extreme fatigue makes it difficult for the person to complete a full day's work or participate in usual activities. Reports of hair loss, brittle nails, and dry skin are common, and numbness and tingling of the fingers may occur. On occasion, the voice may become husky, and the patient may complain of hoarseness. Menstrual disturbances such as menorrhagia or amenorrhea occur, in addition to loss of libido. Hypothyroidism affects women five times more frequently than men and occurs most often between 40 and 70 years of age. The prevalence of the disease increases with increasing age.

Severe hypothyroidism results in a subnormal body temperature and pulse rate. The patient usually begins to gain weight even without an increase in food intake, although he or she may be cachectic. The skin becomes thickened because of an accumulation of mucopolysaccharides in the subcutaneous tissues. The hair thins and falls out, and the face becomes expressionless and masklike. The patient often complains of being cold even in a warm environment.

At first, the patient may be irritable and may complain of fatigue, but as the condition progresses, the emotional responses are subdued. The mental processes become dulled, and the patient appears apathetic. Speech is slow, the tongue enlarges, the hands and feet increase in size, and deafness may occur. The patient frequently complains of constipation.

Advanced hypothyroidism may produce personality and cognitive changes characteristic of dementia. Inadequate ventilation and sleep apnea can occur with severe hypothyroidism. Pleural effusion, pericardial effusion, and respiratory muscle weakness may also occur.

Severe hypothyroidism is associated with an elevated serum cholesterol level, atherosclerosis, coronary artery disease, and poor left ventricular function. The patient with advanced hypothyroidism is hypothermic and abnormally sensitive to sedatives, opioids, and anesthetic agents, which must be administered with extreme caution.

Patients with unrecognized hypothyroidism who are undergoing surgery are at increased risk for intraoperative hypotension, postoperative heart failure, and altered mental status.

Myxedema coma is a rare life-threatening condition. It is the decompensated state of severe hypothyroidism in which

the patient is hypothermic and unconscious (Kwaku & Burman, 2007). This condition may develop with undiagnosed hypothyroidism and may be precipitated by infection or other systemic disease or by use of sedatives or opioid analgesic agents. The condition occurs most often among elderly women in the winter months and appears to be precipitated by cold. However, the disorder can affect any age group.

In myxedema coma, the patient may initially show signs of depression, diminished cognitive status, lethargy, and somnolence (Kwaku & Burman, 2007). Increasing lethargy may progress to stupor. The patient's respiratory drive is depressed, resulting in alveolar hypoventilation, progressive carbon dioxide retention, narcosis, and coma. These symptoms, along with cardiovascular collapse and shock, require aggressive and intensive supportive and hemodynamic therapy if the patient is to survive. Although there has been a decline in mortality rates over the past two decades due to early intervention and improved therapies, the mortality rate (20% to 25%) remains high even with vigorous treatment (Kwaku & Burman, 2007).

NURSING ALERT

In all patients with hypothyroidism, the effects of analgesic agents, sedatives, and anesthetic agents are prolonged; special caution is necessary in administering these agents to elderly patients because of concurrent changes in liver and renal function.

Medical Management

The primary objective in the management of hypothyroidism is to restore a normal metabolic state by replacing the missing hormone.

Pharmacologic Therapy

Synthetic levothyroxine (Synthroid or Levothroid) is the preferred preparation for treating hypothyroidism and suppressing nontoxic goiters. Its dosage is based on the patient's serum TSH concentration. Desiccated thyroid is used infrequently today, because it often results in transient elevated serum concentrations of T_3 , with occasional symptoms of hyperthyroidism. If replacement therapy is adequate, the symptoms of myxedema disappear and normal metabolic activity is resumed.

Prevention of Cardiac Dysfunction

Any patient who has had hypothyroidism for a long period is almost certain to have elevated serum cholesterol, atherosclerosis, and coronary artery disease. As long as metabolism is subnormal and the tissues, including the myocardium, require relatively little oxygen, a reduction in blood supply is tolerated without overt symptoms of coronary artery disease. When thyroid hormone is administered, the oxygen demand increases, but oxygen delivery cannot be increased unless, or until, the atherosclerosis improves. This occurs very slowly, if at all. The occurrence of angina is the signal that the oxygen needs of the myocardium exceed its blood supply. Angina or dysrhythmias can occur

when thyroid replacement is initiated because thyroid hormones enhance the cardiovascular effects of catecholamines.

NURSING ALERT

The nurse must monitor for myocardial ischemia or infarction, which can occur in response to therapy in patients with severe, long-standing hypothyroidism or myxedema coma. The nurse must also be alert for signs of angina, especially during the early phase of treatment; if detected, it must be reported and treated at once to avoid a fatal myocardial infarction.

Obviously, if angina or dysrhythmias occur, thyroid hormone administration must be discontinued immediately. Later, when it can be resumed safely, it should be prescribed cautiously at a lower dosage and under the close observation of the physician and the nurse.

Prevention of Medication Interactions

Precautions must be taken during the course of therapy because thyroid hormones may interact with other medications. Thyroid hormones may increase blood glucose levels, which may necessitate adjustment in the dosage of insulin or oral antidiabetic agents in patients with diabetes. Thyroid hormones may also increase the pharmacologic effects of digitalis glycosides, anticoagulant agents, and indomethacin (Indocin). Phenytoin (Dilantin) and tricyclic antidepressant agents may increase the effects of thyroid hormone. Bone loss and osteoporosis may also occur with thyroid therapy.

Even in small doses, hypnotic and sedative agents may induce profound somnolence, lasting far longer than anticipated and leading to narcosis (stuporlike condition). Furthermore, they are likely to cause respiratory depression, which can easily be fatal because of decreased respiratory reserve and alveolar hypoventilation. The dose of these medications should be one half or one third of that typically prescribed for patients of similar age and weight with normal thyroid function.

Supportive Therapy

In severe hypothyroidism and myxedema coma, management includes maintaining vital functions. Arterial blood gases may be measured to determine carbon dioxide retention and to guide the use of assisted ventilation to combat hypoventilation. Oxygen saturation levels should be monitored using pulse oximetry. Fluids are administered cautiously because of the danger of water intoxication. Application of external heat (eg, heating pads) is avoided, because it increases oxygen requirements and may lead to vascular collapse. If hypoglycemia is evident, concentrated glucose may be prescribed to provide glucose without precipitating fluid overload. If myxedema has progressed to myxedema coma, thyroid hormone (usually levothyroxine [Synthroid]) is administered intravenously until consciousness is restored. Treatment then continues with oral thyroid hormone therapy. Because of an associated adrenocortical insufficiency, corticosteroid therapy may be necessary.

Nursing Management

Nursing care of the patient with hypothyroidism and myxedema is summarized in the plan of nursing care in Chart 42-4.

NURSING ALERT

Medications are administered to the patient with hypothyroidism with extreme caution because of the potential for altered metabolism and excretion as well as depressed metabolic rate and respiratory status.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient and family require education and support to manage this complex disorder at home. Oral and written instructions should be provided regarding the following:

- Desired actions and side effects of medications
- Correct medication administration
- Importance of continuing to take the medications as prescribed even after symptoms improve
- When to seek medical attention
- Importance of nutrition and diet to promote weight loss and normal bowel patterns
- Importance of periodic follow-up testing

The patient and family should be informed that many of the symptoms observed during the course of the disorder will disappear with effective treatment (Chart 42-5).

Continuing Care

If indicated, a referral is made for home care. The home care nurse monitors the patient's recovery and ability to cope with the recent changes, along with the patient's physical and cognitive status and the patient's and family's understanding of the instructions provided before hospital discharge. The home care nurse documents and reports to the patient's primary health care provider subtle signs and symptoms that may indicate either inadequate or excessive thyroid hormone.

Gerontologic Considerations

The prevalence of hypothyroidism increases with age, most often among women. The higher prevalence of hypothyroidism among elderly people may be related to alterations in immune function with age and complicated by multiple comorbidities. Screening of TSH levels is recommended for women older than 50 years of age who have one or more symptoms, because they are at high risk for hypothyroidism (USDHHS, 2006). It is estimated that approximately 10% of women 65 years of age and 15% of those older than 75 years of age experience hypothyroidism (Singer, 2006).

Most patients with primary hypothyroidism present with long-standing mild to moderate hypothyroidism. Subclinical disease is common among older women and can be asymptomatic or mistaken for other medical conditions. Subtle symptoms of hypothyroidism, such as fatigue, muscle aches, and mental confusion, may be attributed to the normal aging process by patients, families, and health care

CHART
42-4

PLAN OF NURSING CARE
Care of the Patient With Hypothyroidism

NURSING DIAGNOSIS: Activity intolerance related to fatigue and depressed cognitive process
GOAL: Increased participation in activities and increased independence

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Promote independence in self-care activities. <ol style="list-style-type: none"> a. Space activities to promote rest and exercise as tolerated. b. Assist with self-care activities when patient is fatigued. c. Provide stimulation through conversation and nonstressful activities. d. Monitor patient's response to increasing activities 	<ol style="list-style-type: none"> 1. Encouragement needed in fatigued, often depressed patient <ol style="list-style-type: none"> a. Encourages activities while allowing time for adequate rest b. Permits patient to participate to the extent possible in self-care activities c. Promotes interest without overly stressing the patient d. Guards against over- and under-exertion by the patient 	<ul style="list-style-type: none"> • Participates in self-care activities • Reports decreased level of fatigue • Displays interest and awareness in environment • Participates in activities and events in environment • Participates in family events and activities • Reports no chest pain, increased fatigue, or breathlessness with increased level of activity

NURSING DIAGNOSIS: Risk for imbalanced body temperature
GOAL: Maintenance of normal body temperature

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Provide extra layer of clothing or extra blanket. 2. Avoid and discourage use of external heat source (eg, heating pads, electric or warming blankets). 3. Monitor patient's body temperature and report decreases from patient's baseline value. 4. Protect from exposure to cold and drafts. 	<ol style="list-style-type: none"> 1. Minimizes heat loss 2. Reduces risk of peripheral vasodilation and vascular collapse 3. Detects decreased body temperature and onset of myxedema coma 4. Increases patient's level of comfort and decreases further heat loss 	<ul style="list-style-type: none"> • Experiences relief of discomfort and cold intolerance • Maintains baseline body temperature • Reports adequate feeling of warmth and lack of chilling • Uses extra layer of clothing or extra blanket • Explains rationale for avoiding external heat source

NURSING DIAGNOSIS: Constipation related to depressed gastrointestinal function
GOAL: Return of normal bowel function

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Encourage increased fluid intake within limits of fluid restriction. 2. Provide foods high in fiber. 3. Instruct patient about foods with high water content. 4. Monitor bowel function. 5. Encourage increased mobility within patient's exercise tolerance. 6. Encourage patient to use laxatives and enemas sparingly. 	<ol style="list-style-type: none"> 1. Promotes passage of soft stools 2. Increases bulk of stools and more frequent bowel movements 3. Provides rationale for patient to increase fluid intake 4. Permits detection of constipation and return to normal bowel pattern 5. Promotes evacuation of the bowel 6. Minimizes patient's dependence on laxatives and enemas and encourages normal pattern of bowel evacuation 	<ul style="list-style-type: none"> • Reports normal bowel function • Identifies and consumes foods high in fiber • Drinks recommended amount of fluid each day • Participates in gradually increasing exercises • Uses laxatives as prescribed and avoids excessive dependence on laxatives and enemas

NURSING DIAGNOSIS: Deficient knowledge about the therapeutic regimen for lifelong thyroid replacement therapy
GOAL: Knowledge and acceptance of the prescribed therapeutic regimen

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Explain rationale for thyroid hormone replacement. 2. Describe desired effects of medication to patient. 	<ol style="list-style-type: none"> 1. Provides rationale for patient to use thyroid hormone replacement as prescribed 2. Provides encouragement to patient by identifying improved physical status and well-being that will occur with thyroid hormone therapy and return to a euthyroid state 	<ul style="list-style-type: none"> • Describes therapeutic regimen correctly • Explains rationale for thyroid hormone replacement • Identifies positive outcomes of thyroid hormone replacement

 CHART
42-4

PLAN OF NURSING CARE
Care of the Patient With Hypothyroidism (Continued)

Nursing Interventions <ol style="list-style-type: none"> 3. Assist patient to develop schedule and checklist to ensure self-administration of thyroid replacement. 4. Describe signs and symptoms of over- and underdose of medication. 5. Explain the necessity for long-term follow-up to patient and family 	Rationale <ol style="list-style-type: none"> 3. Increases chances that medication will be taken as prescribed 4. Serves as check for patient to determine if therapeutic goals are met 5. Increases likelihood that hypo- or hyperthyroidism will be detected and treated 	Expected Outcomes <ul style="list-style-type: none"> • Administers medication to self as prescribed • Identifies adverse side effects that should be reported promptly to physician: recurrence of symptoms of hypothyroidism and occurrence of symptoms of hyperthyroidism • Restates need for periodic/long-term follow-up visits to physician
NURSING DIAGNOSIS: Ineffective breathing pattern related to depressed ventilation GOAL: Improved respiratory status and maintenance of normal breathing pattern		
Nursing Interventions <ol style="list-style-type: none"> 1. Monitor respiratory rate, depth, pattern, pulse oximetry, and arterial blood gases. 2. Encourage deep breathing, coughing, and use of incentive spirometry. 3. Administer medications (hypnotics and sedatives) with caution. 4. Maintain patent airway through suction and ventilatory support if indicated (see Chapter 25 for care of patients requiring mechanical ventilation). 	Rationale <ol style="list-style-type: none"> 1. Identifies patient's baseline to monitor further changes and evaluate effectiveness of interventions 2. Prevents atelectasis and promotes adequate ventilation 3. Patients with hypothyroidism are very susceptible to respiratory depression with use of hypnotics and sedatives. 4. Use of an artificial airway and ventilatory support may be necessary with respiratory depression. 	Expected Outcomes <ul style="list-style-type: none"> • Shows improved respiratory status and maintenance of normal breathing pattern • Demonstrates normal respiratory rate, depth, and pattern • Takes deep breaths, coughs, and uses incentive spirometry when encouraged • Demonstrates normal breath sounds without adventitious sounds on auscultation • Explains rationale for cautious use of medications • Cooperates with suction procedure and ventilator support when necessary
NURSING DIAGNOSIS: Disturbed thought processes related to depressed metabolism and altered cardiovascular and respiratory status GOAL: Improved thought processes		
Nursing Interventions <ol style="list-style-type: none"> 1. Orient patient to time, place, date, and events around him or her. 2. Provide stimulation through conversation and nonthreatening activities. 3. Explain to patient and family that change in cognitive and mental functioning is a result of disease process. 4. Monitor cognitive and mental processes and response of these to medication and other therapy. 	Rationale <ol style="list-style-type: none"> 1. Provides reality orientation to patient 2. Provides stimulation within patient's level of tolerance for stress 3. Reassures patient and family about the cause of the cognitive changes and that a positive outcome is possible with appropriate treatment 4. Permits evaluation of the effectiveness of treatment 	Expected Outcomes <ul style="list-style-type: none"> • Shows improved cognitive functioning • Identifies time, place, date, and events correctly • Responds when stimulated • Responds spontaneously as treatment becomes effective • Interacts spontaneously with family and environment • Explains that change in mental and cognitive processes is a result of disease processes • Takes medications as prescribed to prevent decrease in cognitive processes
COLLABORATIVE PROBLEM: Myxedema and myxedema coma GOAL: Absence of complications		
Nursing Interventions <ol style="list-style-type: none"> 1. Monitor patient for increasing severity of signs and symptoms of hypothyroidism: <ol style="list-style-type: none"> a. Decreased level of consciousness; dementia b. Decreased vital signs (blood pressure, respiratory rate, temperature, pulse rate) c. Increasing difficulty in awakening or arousing patient 	Rationale <ol style="list-style-type: none"> 1. Extreme hypothyroidism may lead to myxedema, myxedema coma, and slowing of all body systems if untreated. 	Expected Outcomes <ul style="list-style-type: none"> • Exhibits reversal of myxedema and myxedema coma • Responds appropriately to questions and surroundings • Vital signs return to normal or near-normal ranges • Respiratory status improves with adequate spontaneous ventilatory effort

PLAN OF NURSING CARE
Care of the Patient With Hypothyroidism (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> Assist in ventilatory support if respiratory depression and failure occur. Administer prescribed medications (eg, thyroxine) with extreme caution. Turn and reposition patient at intervals. Avoid use of hypnotic, sedative, and analgesic agents. 	<ol style="list-style-type: none"> Ventilatory support is necessary to maintain adequate oxygenation and maintenance of airway. The slow metabolism and atherosclerosis of myxedema may result in angina with administration of thyroxine. Minimizes risks associated with immobility Altered metabolism of these agents greatly increases the risks of their use in myxedema. 	<ul style="list-style-type: none"> Reports no episodes of angina or other indicators of cardiac insufficiency Experiences minimal or no complications caused by immobility

providers; therefore, these symptoms require close attention (Dominguez, Bevilacqua, DiBella, et al., 2008). In addition, signs and symptoms of hypothyroidism in elderly people are often atypical, and manifestations of hypothyroidism and hyperthyroidism may blur. Patients may have few or no symptoms until dysfunction is severe. Depression, apathy, and decreased mobility or activity may be the major initial symptoms and may be accompanied by significant weight loss. Constipation affects one fourth of elderly patients.

In elderly patients with mild to moderate hypothyroidism, thyroid hormone replacement is individually tailored and must be started with low dosages and increased gradually to prevent serious cardiovascular and neurologic side effects. Angina, for example, may occur with rapid thyroid replacement in the presence of coronary artery disease secondary to the hypothyroid state. Heart failure and tachy-dysrhythmias may worsen during the transition from the hypothyroid state to the normal metabolic state. Dementia

may become more apparent during early thyroid hormone replacement in elderly patients.

Elderly patients with severe hypothyroidism and atherosclerosis may become confused and agitated if their metabolic rate is increased too quickly. Marked clinical improvement follows the administration of hormone replacement; such medication must be continued for life, even though signs of hypothyroidism disappear within 3 to 12 weeks.

Myxedema and myxedema coma usually occur exclusively in patients older than 50 years of age (Kwaku & Burman, 2007). The high mortality rate of myxedema coma mandates immediate IV administration of high doses of thyroid hormone as well as supportive care.

Elderly patients require periodic follow-up monitoring of serum TSH levels, because poor compliance with therapy may occur or the patient may take the medications erratically. A careful history can identify the need for further teaching about the importance of the medication.

CHART
42-5

HOME CARE CHECKLIST
The Patient With Hypothyroidism (Myxedema)

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State present and potential effects of hypothyroidism on the body.	✓	✓
• State precipitating factors and interventions for complications (hyperthyroidism, myxedema coma).	✓	✓
• Explain the purpose, dose, route, schedule, side effects, and precautions of prescribed medication (synthetic thyroid hormone).	✓	✓
• State that compliance with medical regimen is lifelong.	✓	✓
• State the need to avoid extreme cold temperature until condition is stable.	✓	✓
• State importance of regular follow-up visits with health care provider.	✓	✓
• Identify dietary strategies to promote weight reduction and prevent constipation (high fiber, low calorie, adequate fluid intake).	✓	✓
• State potential for menstrual irregularities and potential for pregnancy for women.	✓	✓
• State the importance of avoiding infection.	✓	✓
• Identify changes in personality as related to hypothyroidism.	✓	✓
• Identify areas of activity limitations and impact on lifestyle.	✓	✓

HYPERTHYROIDISM

Hyperthyroidism is the second most prevalent endocrine disorder, after diabetes mellitus. **Graves' disease**, the most common type of hyperthyroidism, results from an excessive output of thyroid hormones caused by abnormal stimulation of the thyroid gland by circulating immunoglobulins (Porth & Matfin, 2009). It affects women eight times more frequently than men, with onset usually between the second and fourth decades (Tierney, et al., 2005). The disorder may appear after an emotional shock, stress, or an infection, but the exact significance of these relationships is not understood. Other common causes of hyperthyroidism include thyroiditis and excessive ingestion of thyroid hormone.

Clinical Manifestations

Patients with well-developed hyperthyroidism exhibit a characteristic group of signs and symptoms (sometimes referred to as **thyrotoxicosis**). The presenting symptom is often nervousness. These patients are often emotionally hyperexcitable, irritable, and apprehensive; they cannot sit quietly; they suffer from palpitations; and their pulse is abnormally rapid at rest as well as on exertion. They tolerate heat poorly and perspire unusually freely. The skin is flushed continuously, with a characteristic salmon color, and is likely to be warm, soft, and moist. However, patients may report dry skin and diffuse pruritus. A fine tremor of the hands may be observed. Patients may exhibit ophthalmopathy, such as **exophthalmos** (bulging eyes), which produces a startled facial expression. Despite treatment, these ocular changes are not always reversible. Patients should be informed that smoking has been shown to aggravate ocular changes (Asvold, Bjoro, Nilsen, et al., 2007).

Other manifestations include an increased appetite and dietary intake, progressive weight loss, abnormal muscular fatigability and weakness (difficulty in climbing stairs and rising from a chair), amenorrhea, and changes in bowel function. The pulse rate ranges constantly between 90 and 160 bpm; the systolic, but characteristically not the diastolic, blood pressure is elevated; atrial fibrillation may occur; and cardiac decompensation in the form of heart failure is common, especially in elderly patients. Osteoporosis and fracture are also associated with hyperthyroidism.

Cardiac effects may include sinus tachycardia or dysrhythmias, increased pulse pressure, and palpitations; these changes may be related to increased sensitivity to catecholamines or to changes in neurotransmitter turnover. Myocardial hypertrophy and heart failure may occur if the hyperthyroidism is severe and untreated.

The course of the disease may be mild, characterized by remissions and exacerbations, and terminate with spontaneous recovery in a few months or years. Conversely, it may progress relentlessly, with the untreated person becoming emaciated, intensely nervous, delirious, and even disoriented; eventually, the heart fails.

Symptoms of hyperthyroidism may occur with the release of excessive amounts of thyroid hormone as a result of inflammation after irradiation of the thyroid or destruction of thyroid tissue by tumor. Such symptoms may also occur with excessive administration of thyroid hormone for treatment of hypothyroidism. Long-standing use of thyroid hor-

none in the absence of close monitoring may be a cause of symptoms of hyperthyroidism. It is also likely to result in premature osteoporosis, particularly in women.

Assessment and Diagnostic Findings

The thyroid gland invariably is enlarged to some extent. It is soft and may pulsate; a thrill often can be palpated, and a bruit is heard over the thyroid arteries. These are signs of greatly increased blood flow through the thyroid gland. In advanced cases, the diagnosis is made on the basis of the symptoms, a decrease in serum TSH, increased free T₄, and an increase in radioactive iodine uptake.

Medical Management

Appropriate treatment of hyperthyroidism depends on the underlying cause and often consists of a combination of therapies, including antithyroid agents, radioactive iodine, and surgery. Treatment of hyperthyroidism is directed toward reducing thyroid hyperactivity to relieve symptoms and preventing complications. Use of radioactive iodine is the most common form of treatment for Graves' disease in North America. Beta-adrenergic blocking agents (eg, propranolol [Inderal]) are used as adjunctive therapy for symptomatic relief, particularly in transient thyroiditis (Cooper, 2005). Surgical removal of most of the thyroid gland is a nonpharmacologic alternative.

No treatment for thyrotoxicosis is without side effects, and all three treatments (radioactive iodine therapy, antithyroid medications, and surgery) share the same complications: relapse or recurrent hyperthyroidism and permanent hypothyroidism. The rate of relapse increases in patients who have had very severe disease, a long history of dysfunction, ocular and cardiac symptoms, large goiter, or relapse after previous treatment. The relapse rate after radioactive iodine therapy depends on the dose used in treatment. Patients receiving a lower dose of radioactive iodine are more likely to require subsequent treatment than those treated with a higher dose. The remission rate achieved with a single dose of radioactive iodine is 80% (Reid & Wheeler, 2005, Brent, 2008).

Pharmacologic Therapy

Two forms of pharmacotherapy are available for treating hyperthyroidism and controlling excessive thyroid activity: (1) use of irradiation by administration of the radioisotope iodine 131 (¹³¹I) for destructive effects on the thyroid gland and (2) antithyroid medications that interfere with the synthesis of thyroid hormones and other agents that control manifestations of hyperthyroidism.

Radioactive Iodine Therapy

The goal of radioactive iodine therapy (¹³¹I) is to destroy the overactive thyroid cells. Almost all the iodine that enters and is retained in the body becomes concentrated in the thyroid gland. Therefore, the radioactive isotope of iodine is concentrated in the thyroid gland, where it destroys thyroid cells without jeopardizing other radiosensitive tissues. Over a period of several weeks, thyroid cells exposed to the radioactive iodine are destroyed, resulting in reduction of the hyperthyroid state and inevitably hypothyroidism.

Chart 42-6 • Thyroid Storm (Thyrotoxic Crisis, Thyrotoxicosis)

Thyroid storm (thyrotoxic crisis) is a form of severe hyperthyroidism, usually of abrupt onset. Untreated, it is almost always fatal, but with proper treatment the mortality rate is reduced substantially. The patient with thyroid storm or crisis is critically ill and requires astute observation and aggressive and supportive nursing care during and after the acute stage of illness.

Clinical Manifestations

Thyroid storm is characterized by:

- High fever (hyperpyrexia) above 38.5°C (101.3°F)
 - Extreme tachycardia (more than 130 bpm)
 - Exaggerated symptoms of hyperthyroidism with disturbances of a major system—for example, gastrointestinal (weight loss, diarrhea, abdominal pain) or cardiovascular (edema, chest pain, dyspnea, palpitations)
 - Altered neurologic or mental state, which frequently appears as delirium psychosis, somnolence, or coma
- Life-threatening thyroid storm is usually precipitated by stress, such as injury, infection, thyroid and nonthyroid surgery, tooth extraction, insulin reaction, diabetic ketoacidosis, pregnancy, digitalis intoxication, abrupt withdrawal of antithyroid medications, extreme emotional stress, or vigorous palpation of the thyroid. These factors can precipitate thyroid storm in the partially controlled or completely untreated patient with hyperthyroidism. Current methods of diagnosis and treatment for hyperthyroidism have greatly decreased the incidence of thyroid storm, making it uncommon today.

Management

Immediate objectives are reduction of body temperature and heart rate and prevention of vascular collapse. Measures to accomplish these objectives include:

- A hypothermia mattress or blanket, ice packs, a cool environment, hydrocortisone, and acetaminophen (Tylenol). Salicylates (eg, aspirin) are not used because they displace thyroid hormone from binding proteins and worsen the hypermetabolism.
- Humidified oxygen is administered to improve tissue oxygenation and meet the high metabolic demands. Arterial blood gas levels or pulse oximetry may be used to monitor respiratory status.
- Intravenous fluids containing dextrose are administered to replace liver glycogen stores that have been decreased in the hyperthyroid patient.
- PTU or methimazole is administered to impede formation of thyroid hormone and block conversion of T_4 to T_3 , the more active form of thyroid hormone.
- Hydrocortisone is prescribed to treat shock or adrenal insufficiency.
- Iodine is administered to decrease output of T_4 from the thyroid gland. For cardiac problems such as atrial fibrillation, dysrhythmias, and heart failure, sympatholytic agents may be administered. Propranolol, combined with digitalis, has been effective in reducing severe cardiac symptoms.

The patient is instructed about what to expect with this tasteless, colorless radioiodine, which may be administered by the radiologist. Typically, a single dose is needed (Reid & Wheeler, 2005). About 95% of patients are cured by one dose of radioactive iodine. The additional 5% require two doses; rarely is a third dose necessary. Use of an ablative dose of radioactive iodine initially causes an acute release of thyroid hormone from the thyroid gland and may cause increased symptoms. The patient is observed for signs of **thyroid storm** (Chart 42-6), a life-threatening condition manifested by cardiac dysrhythmias, fever, and neurologic impairment (Harris, 2007). Propranolol (Inderal) is useful in controlling these symptoms.

After treatment with radioactive iodine, the patient is monitored closely until the euthyroid state is reached. In 3 to 4 weeks, symptoms of hyperthyroidism subside. Close follow-up is required to evaluate thyroid function, because the incidence of hypothyroidism after this form of treatment is very high. Approximately 20% of patients become hypothyroid within 2 years after treatment, and another 3% to 5% of patients each year thereafter (Reid & Wheeler, 2005). Thyroid hormone replacement is necessary; small doses are usually prescribed, with the dose gradually increased over a period of months (up to about 1 year) until the free T_4 and TSH levels stabilize within normal ranges.

Radioactive iodine has been used to treat toxic adenomas, multinodular goiter, and most varieties of thyrotoxicosis (rarely with permanent success). It is preferred for treat-

ing patients beyond the childbearing years who have diffuse toxic goiter. Radioactive iodine is contraindicated during pregnancy (because it crosses the placenta) and while breast-feeding (because it is secreted in breast milk) to prevent hypothyroidism in the fetus (Cooper, Doherty, Haugen, et al., 2006). Pregnancy should be postponed for at least 6 months after treatment.

A major advantage of treatment with radioactive iodine is that it avoids many of the side effects associated with antithyroid medications. However, some patients and their families fear medications that are radioactive. For this reason, patients may elect to take antithyroid medications rather than radioactive iodine.

Antithyroid Medications

Antithyroid medications are summarized in Table 42-3. The objective of pharmacotherapy is to inhibit one or more stages in thyroid hormone synthesis or hormone release. Antithyroid agents block the utilization of iodine by interfering with the iodination of tyrosine and the coupling of iodotyrosines in the synthesis of thyroid hormones. This prevents the synthesis of thyroid hormone. Most commonly, propylthiouracil (PTU) or methimazole (Tapazole) is used until the patient is euthyroid (ie, neither hyperthyroid nor hypothyroid). These medications block extrathyroidal conversion of T_4 to T_3 .

The therapeutic dose is determined on the basis of clinical criteria, including changes in pulse rate, pulse pressure, body weight, size of the goiter, and results of laboratory studies of thyroid function. Because antithyroid

Table 42-3 PHARMACOLOGIC AGENTS USED TO TREAT HYPERTHYROIDISM

Agent	Action	Nursing Considerations
Propylthiouracil (PTU)	Blocks synthesis of hormones (conversion of T ₃ to T ₄)	Monitor cardiac parameters. Observe for conversion to hypothyroidism. Must be given by mouth. Watch for rash, nausea, vomiting, agranulocytosis, lupus syndrome.
Methimazole	Blocks synthesis of thyroid hormone	More toxic than PTU. Watch for rash and other symptoms as for PTU.
Sodium iodide	Suppresses release of thyroid hormone	Given 1 h after PTU or methimazole. Watch for edema, hemorrhage, gastrointestinal upset.
Potassium iodide	Suppresses release of thyroid hormone	Discontinue for rash. Watch for signs of toxic iodism.
Saturated solution of potassium iodide (SSKI)	Suppresses release of thyroid hormone	Mix with juice or milk. Give by straw to prevent staining of teeth.
Dexamethasone	Suppresses release of thyroid hormone	Monitor input and output. Monitor glucose. May cause hypertension, nausea, vomiting, anorexia, infection.
Beta-blocker (eg, propranolol)	Beta-adrenergic blocking agent	Monitor cardiac status. Hold for bradycardia or decreased cardiac output. Use with caution in patients with heart failure.

Adapted from Morton, P. G. & Fontaine, D. K. (2009). *Critical care nursing: A holistic approach*. Philadelphia: Lippincott Williams & Wilkins.

medications do not interfere with release or activity of previously formed thyroid hormones, it may take several weeks until relief of symptoms occurs. At that time, the maintenance dose is established, and a gradual withdrawal of the medication over the next several months follows.

Toxic complications of antithyroid medications are relatively uncommon; nevertheless, the importance of periodic follow-up is emphasized, because medication sensitization, fever, rash, urticaria, or even agranulocytosis and thrombocytopenia (decrease in granulocytes and platelets) may develop. With any sign of infection, especially pharyngitis and fever or the occurrence of mouth ulcers, the patient is advised to stop the medication, notify the physician immediately, and undergo hematologic studies. Rash, arthralgias, and fever occur in 1% to 5% of patients (Reid & Wheeler, 2005). Agranulocytosis, the most serious toxic side effect, occurs in approximately 0.5% of patients. Its incidence is higher in patients older than 40 years of age. It usually occurs within the first 3 months but may occur up to 1 year after therapy is started.

Patients taking antithyroid medications are instructed not to use decongestants for nasal stuffiness, because these agents are poorly tolerated. PTU is the treatment of choice during pregnancy. Once the thyrotoxicity is under control, the dose is decreased to prevent fetal hypothyroidism. Antithyroid medications are contraindicated in late pregnancy, because they may produce goiter and cretinism in the fetus (Cooper, 2005).

Another goal of therapy is to reduce the amount of thyroid tissue, with resulting decreased thyroid hormone production. Thyroid hormone is occasionally administered with antithyroid medications to put the thyroid gland at rest. In this approach, hypothyroidism from excess antithyroid medication is avoided, as is stimulation of the thyroid gland by TSH. Levothyroxine sodium (Synthroid) is the most common thyroid hormone preparation used. It takes approximately 10 days of its administration to achieve full effect. Liothyronine sodium (Cytomel) has a more rapid

onset, and its action is of short duration. Antithyroid medications may also be used to normalize thyroid function before radioactive iodine is administered, to suppress symptoms of thyrotoxicosis that may occur with this therapy (Cooper, 2005).

Relapse usually occurs within the first 3 to 6 months after medication is stopped. Thereafter, the rate of recurrence decreases and stabilizes after 1 to 2 years, for an overall recurrence rate of approximately 50% to 60% (Cooper, 2005). Discontinuation of antithyroid medications before therapy is complete usually results in relapse within 6 months. The incidence of relapse with subtotal thyroidectomy is 19% at 18 months; an incidence of hypothyroidism of 25% has been reported at 18 months after surgery. The risk of these complications illustrates the importance of long-term follow-up of patients treated for hyperthyroidism. It is important that the possibility of relapse be discussed so that a treatment strategy will be in place if relapse occurs.

Adjunctive Therapy

Iodine or iodide compounds, once the only therapy available for patients with hyperthyroidism, are no longer used as the sole method of treatment. Such compounds decrease the release of thyroid hormones from the thyroid gland and reduce the vascularity and size of the thyroid. Compounds such as potassium iodide (KI), Lugol's solution, and saturated solution of potassium iodide (SSKI) may be used in combination with antithyroid agents or beta-adrenergic blockers to prepare the patient with hyperthyroidism for surgery. These agents reduce the activity of the thyroid hormone and the vascularity of the thyroid gland, making the surgical procedure safer (Brent, 2008). Solutions of iodine and iodide compounds are more palatable in milk or fruit juice and are administered through a straw to prevent staining of the teeth. These compounds reduce the metabolic rate more rapidly than antithyroid medications do, but their action does not last as long.

NURSING ALERT

Patients receiving iodide medications should be observed for the development of goiter and should be cautioned against use of iodide-containing over-the-counter medications that can increase the response to iodide therapy. Cough medications, expectorants, bronchodilators, and salt substitutes may contain iodide and should be avoided.

Beta-adrenergic blocking agents are important in controlling the sympathetic nervous system effects of hyperthyroidism. For example, propranolol is used to control nervousness, tachycardia, tremor, anxiety, and heat intolerance. The patient continues taking propranolol until the free T_4 is within the normal range and the TSH level approaches normal.

Surgical Management

Surgery to remove thyroid tissue was once the primary method of treating hyperthyroidism. Today, surgery is reserved for special circumstances—for example, in pregnant women who are allergic to antithyroid medications, in patients with large goiters, or in patients who are unable to take antithyroid agents. Surgery for treatment of hyperthyroidism is performed soon after the thyroid function has returned to normal (4 to 6 weeks).

The surgical removal of about five sixths of the thyroid tissue (subtotal thyroidectomy) reliably results in a prolonged remission in most patients with exophthalmic goiter. Its use today is reserved for patients with obstructive symptoms, for pregnant women in the second trimester, and for patients with a need for rapid normalization of thyroid function. Before surgery, PTU is administered until signs of hyperthyroidism have disappeared. A beta-adrenergic blocking agent (eg, propranolol) may be used to reduce the heart rate and other signs and symptoms of hyperthyroidism; however, this does not create a euthyroid state. Iodine (Lugol's solution or KI) may be prescribed in an effort to reduce blood loss; however, the effectiveness of this treatment is unknown. Medications that may prolong clotting (eg, aspirin) are stopped several weeks before surgery to reduce the risk for postoperative bleeding. Patients receiving iodine medication must be monitored for evidence of iodine toxicity (iodism), which requires immediate withdrawal of the medication. Symptoms of iodism include swelling of the buccal mucosa, excessive salivation, coryza, and skin eruptions.

Gerontologic Considerations

Although hyperthyroidism is much less common in elderly people than hypothyroidism, patients older than 60 years of age account for 10% to 15% of the cases of thyrotoxicosis. They often develop atypical signs and symptoms of endocrine disorders, including thyrotoxicosis. The only presenting manifestations may be anorexia and weight loss, absence of ocular signs, or isolated atrial fibrillation. (New or worsening heart failure or angina is more likely to occur in elderly than in younger patients.) These signs and symptoms may mask the underlying thyroid disease. Elderly

patients also tend to have symptoms for longer periods of time and commonly present with vague and nonspecific signs and symptoms, making disorders difficult to detect (Dominguez, et al., 2008). Symptoms such as tachycardia, fatigue, mental confusion, weight loss, change in bowel habits, and depression can be attributed to age and other illnesses that are common in elderly people. In addition, patients may report cardiovascular symptoms and difficulty climbing stairs or rising from a chair because of muscle weakness. Elderly patients may have only a single manifestation (eg, anorexia, weight loss) of thyroid disease.

Spontaneous remission of hyperthyroidism is rare in elderly patients. Measurement of TSH is indicated in elderly patients who have unexplained physical or mental deterioration. The use of radioactive iodine is generally recommended for treatment of thyrotoxicosis in elderly patients unless an enlarged thyroid gland is pressing on the airway. The hypermetabolic state of thyrotoxicosis must be controlled by antithyroid medications before radioactive iodine is administered, because radiation therapy may precipitate thyroid storm by increasing the release of hormone from the thyroid gland. Thyroid storm, if it occurs, has a mortality rate of 10% in elderly patients.

Long-term use of antithyroid medications is not generally recommended for elderly patients because of the increased incidence of side effects, such as granulocytopenia, and the need for frequent monitoring. The dosage of other medications used to treat other chronic illnesses in elderly patients may need to be modified because of the altered rate of metabolism in hyperthyroidism. In addition, antithyroid medications are considered to be less effective in the treatment of toxic nodular goiter, the most common cause of thyrotoxicosis in the elderly.

Use of beta-adrenergic blocking agents (eg, propranolol) may be indicated to decrease the cardiovascular and neurologic signs and symptoms of thyrotoxicosis. These agents must be used with extreme caution in elderly patients to minimize adverse effects on cardiac function that may produce heart failure.

NURSING PROCESS

THE PATIENT WITH HYPERTHYROIDISM

Assessment

The health history and examination focus on symptoms related to accelerated or exaggerated metabolism. These include the patient's and family's reports of irritability and increased emotional reaction and the impact these changes have had on the patient's interactions with family, friends, and coworkers. The history includes other stressors and the patient's ability to cope with stress.

The nurse assesses the patient's nutritional status and the presence of symptoms. Symptoms related to excessive nervous system output and changes in vision and appearance of the eyes are noted. The nurse periodically assesses and monitors the patient's cardiac status, including heart rate, blood pressure, heart sounds, and peripheral pulses.

Because emotional changes are associated with hyperthyroidism, the patient's emotional state and psychological

status are evaluated, as well as such symptoms as irritability, anxiety, sleep disturbances, apathy, and lethargy, all of which may occur with hyperthyroidism. The family may also provide information about recent changes in the patient's emotional status.

Diagnosis

Nursing Diagnoses

Based on all the assessment data, the major nursing diagnoses of the patient with hyperthyroidism may include the following:

- Imbalanced nutrition, less than body requirements, related to exaggerated metabolic rate, excessive appetite, and increased GI activity
- Ineffective coping related to irritability, hyperexcitability, apprehension, and emotional instability
- Low self-esteem related to changes in appearance, excessive appetite, and weight loss
- Altered body temperature

Collaborative Problems/Potential Complications

Based on assessment data, potential complications may include the following:

- Thyrotoxicosis or thyroid storm
- Hypothyroidism

Planning and Goals

The goals for the patient may be improved nutritional status, improved coping ability, improved self-esteem, maintenance of normal body temperature, and absence of complications.

Nursing Interventions

Improving Nutritional Status

Hyperthyroidism affects all body systems, including the GI system. The appetite is increased but may be satisfied by several well-balanced meals of small size, even up to six meals a day. Foods and fluids are selected to replace fluid lost through diarrhea and diaphoresis and to control the diarrhea that results from increased peristalsis. Rapid movement of food through the GI tract may result in nutritional imbalance and further weight loss. To reduce diarrhea, highly seasoned foods and stimulants such as coffee, tea, cola, and alcohol are discouraged. High-calorie, high-protein foods are encouraged. A quiet atmosphere during mealtime may aid digestion. Weight and dietary intake are recorded to monitor nutritional status.

Enhancing Coping Measures

The patient with hyperthyroidism needs reassurance that the emotional reactions being experienced are a result of the disorder and that with effective treatment those symptoms will be controlled. Because of the negative effect these symptoms have on family and friends, they too need reassurance that the symptoms are expected to disappear with treatment.

It is important to use a calm, unhurried approach with the patient. Stressful experiences are minimized; therefore, if hospitalized, the patient is not placed in a room with very ill or talkative patients. The environment is kept quiet and

uncluttered. Noises, such as loud music, conversation, and equipment alarms, are minimized. The nurse encourages relaxing activities if they do not overstimulate the patient.

If thyroidectomy is planned, the patient needs to know that pharmacologic therapy is necessary to prepare the thyroid gland for surgical treatment. The nurse instructs and reminds the patient to take the medications as prescribed. Because of hyperexcitability and shortened attention span, the patient may require repetition of this information and written instructions.

Improving Self-Esteem

The patient with hyperthyroidism is likely to experience changes in appearance, appetite, and weight. These factors, along with the patient's inability to cope well with family and the illness, may result in loss of self-esteem. The nurse conveys an understanding of the patient's concern about these problems and promotes use of effective coping strategies. The patient and family need to know that these changes are a result of the thyroid dysfunction and are, in fact, out of the patient's control.

If changes in appearance are very disturbing to the patient, mirrors may be covered or removed. In addition, the nurse reminds family members and personnel to avoid bringing these changes to the patient's attention. The nurse explains to the patient and family that most of these changes are expected to disappear with effective treatment.

If the patient experiences ocular changes secondary to hyperthyroidism, eye care and protection may be necessary. The patient may need instructions about instillation of eye drops or ointment prescribed to soothe the eyes and protect the exposed cornea. The patient should also be discouraged from smoking.

The patient may be embarrassed by the need to eat large meals. Therefore, the nurse arranges for the patient to eat alone if desired and avoids commenting on the patient's large dietary intake while making sure that the patient receives sufficient food.

Maintaining Normal Body Temperature

The patient with hyperthyroidism frequently finds a normal room temperature too warm because of an exaggerated metabolic rate and increased heat production. If the patient is hospitalized, the nurse maintains the environment at a cool, comfortable temperature and changes bedding and clothing as needed. Cool baths and cool or cold fluids are encouraged, because they may provide relief.

Monitoring and Managing Potential Complications

The nurse closely monitors the patient with hyperthyroidism for signs and symptoms that may be indicative of thyroid storm. Cardiac and respiratory function are assessed by measuring vital signs and cardiac output, electrocardiographic (ECG) monitoring, arterial blood gases, and pulse oximetry. Assessment continues after treatment is initiated because of the potential effects of treatment on cardiac function. Oxygen is administered to prevent hypoxia, to improve tissue oxygenation, and to meet the high metabolic demands. IV fluids may be necessary to maintain blood glucose levels and to replace lost fluids. Antithyroid medications (PTU or methimazole) may be prescribed to reduce

thyroid hormone levels. In addition, propranolol and digoxin may be prescribed to treat cardiac symptoms. If shock develops, treatment strategies must be implemented (see Chapter 15).

Hypothyroidism is likely to occur with any of the treatments used for hyperthyroidism. Therefore, the nurse periodically monitors the patient. Most patients report a greatly improved sense of well-being after treatment of hyperthyroidism, and some fail to continue to take prescribed thyroid replacement therapy. Therefore, part of patient and family teaching is instruction about the importance of continuing therapy indefinitely after discharge and a discussion of the consequences of failing to take medication.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The nurse teaches the patient with hyperthyroidism how and when to take prescribed medication and provides instruction about the essential role of the medication in the broader therapeutic plan. Because of the hyperexcitability and decreased attention span associated with hyperthyroidism, the nurse provides a written plan for the patient to use at home. The type and amount of information given depend on the patient’s stress and anxiety levels. The patient and family members receive verbal and written information about the actions and possible side effects of the medications. The nurse identifies adverse effects that should be reported if they occur (Chart 42-7).

If a total or subtotal thyroidectomy is anticipated, the patient needs information about what to expect. This information is repeated as the time of surgery approaches. The nurse also advises the patient to avoid stressful situations that may precipitate thyroid storm.

CONTINUING CARE. Referral for home care, if indicated, allows the home care nurse to assess the home and family

environment and the patient’s and family’s understanding of the importance of adhering to the therapeutic regimen and the recommended follow-up monitoring. The nurse reinforces to the patient and family the importance of long-term follow-up because of the risk of hypothyroidism after thyroidectomy or treatment with antithyroid medications or radioactive iodine. The nurse also assesses the patient for changes indicating return to normal thyroid function and signs and symptoms of hyperthyroidism and hypothyroidism. Furthermore, the nurse reminds the patient and family about the importance of health promotion activities and recommended health screening.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Improves nutritional status
 - a. Reports adequate dietary intake and decreased hunger
 - b. Identifies high-calorie, high-protein foods; identifies foods to be avoided
 - c. Avoids use of alcohol and other stimulants
 - d. Stops smoking
 - e. Reports decreased episodes of diarrhea
2. Demonstrates effective coping methods in dealing with family, friends, and coworkers
 - a. Explains reasons for irritability and emotional instability
 - b. Avoids stressful situations, events, and people
 - c. Participates in relaxing, nonstressful activities
3. Achieves increased self-esteem
 - a. Verbalizes feelings about self and illness
 - b. Describes feelings of frustration and loss of control
 - c. Describes reasons for increased appetite

CHART 42-7  **HOME CARE CHECKLIST**
The Patient With Hyperthyroidism

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State present and potential effects of hyperthyroidism on the body.	✓	✓
• State precipitating factors and interventions for complications (hypothyroidism, thyroid storm).	✓	✓
• State the purpose, dose, route, schedule, side effects, and precautions of prescribed medications (propylthiouracil, radioactive iodine).	✓	✓
• State the need to contact health care provider before taking over-the-counter medications.	✓	✓
• State need for regular follow-up visits with health care provider.	✓	✓
• Identify the need for planned rest periods and methods to improve sleep patterns.	✓	✓
• Identify the need for increased dietary intake until weight stabilizes.	✓	✓
• Identify areas of physical and emotional stress.	✓	✓
• State that emotional lability is part of disease process.	✓	✓
• Describe the potential benefits and risks of surgical intervention or radioactive iodine therapy.	✓	✓
• Identify potential for menstrual irregularities, increased risk for osteoporosis, and potential for pregnancy for women.	✓	✓
• State need to wear medical identification and carry medical information card.	✓	✓
• Identify rationale for smoking cessation and take steps to stop smoking.	✓	

4. Maintains normal body temperature
5. Absence of complications
 - a. Has serum thyroid hormone and TSH levels within normal limits
 - b. Identifies signs and symptoms of thyroid storm and hypothyroidism
 - c. Has vital signs and results of ECG, arterial blood gases, and pulse oximetry within normal limits
 - d. States importance of regular follow-up and life-long maintenance of prescribed therapy

THYROIDITIS

Thyroiditis, inflammation of the thyroid gland, can be acute, subacute, or chronic. Each type of thyroiditis is characterized by inflammation, fibrosis, or lymphocytic infiltration of the thyroid gland. Several forms of thyroiditis are characterized by autoimmune damage to the thyroid. The various forms of thyroiditis may cause thyrotoxicosis, hypothyroidism, or both (Bindra & Braunstein, 2006).

Acute Thyroiditis

Acute thyroiditis is a rare disorder caused by infection of the thyroid gland by bacteria, fungi, mycobacteria, or parasites. *Staphylococcus aureus* and other staphylococci are the most common causes. Infection typically causes anterior neck pain and swelling, fever, dysphagia, and dysphonia. Pharyngitis or pharyngeal pain is often present. Examination may reveal warmth, erythema (redness), and tenderness of the thyroid gland. Treatment of acute thyroiditis includes antimicrobial agents and fluid replacement. Surgical incision and drainage may be needed if an abscess is present.

Subacute Thyroiditis

Subacute thyroiditis may be subacute granulomatous thyroiditis (de Quervain's thyroiditis) or painless thyroiditis (silent thyroiditis or subacute lymphocytic thyroiditis). Subacute granulomatous thyroiditis is an inflammatory disorder of the thyroid gland that predominantly affects women between the ages of 40 and 50 years (Bindra & Braunstein, 2006). The condition is usually associated with a viral respiratory infection and has a summer peak incidence that coincides with coxsackievirus groups A and B and echovirus infections. Signs and symptoms include myalgias, pharyngitis, low-grade fever, and fatigue. These progress to a painful swelling in the anterior neck that lasts 1 to 2 months and then disappears spontaneously without residual effect. The thyroid enlarges symmetrically and may be painful. The overlying skin is often reddened and warm. Swallowing may be difficult and uncomfortable. Irritability, nervousness, insomnia, and weight loss—manifestations of hyperthyroidism—are common, and many patients experience chills and fever as well. There is no thrill or bruit found on physical examination of the thyroid gland in hyperthyroidism with subacute thyroiditis. The absence of this sign assists in the differentiation of hyperthyroidism associated with subacute thyroiditis and hyperthyroidism associated with Graves' disease (Bindra & Braunstein, 2006).

Treatment is directed toward control of the inflammation. In general, nonsteroidal anti-inflammatory drugs are

used to relieve neck pain. Acetylsalicylic acid (aspirin) is avoided if symptoms of hyperthyroidism occur, because aspirin displaces thyroid hormone from its binding sites and increases the amount of circulating hormone. Beta-blocking agents (eg, propranolol [Inderal]) may be used to control symptoms of hyperthyroidism. Antithyroid agents, which block the synthesis of T_3 and T_4 , are not effective because the associated thyrotoxicosis results from the release of stored thyroid hormones rather than from their increased synthesis. In cases that are more severe and do not respond to treatment within 5 weeks, oral corticosteroids may be prescribed to reduce swelling and relieve pain. However, corticosteroids do not usually affect the underlying cause (Bindra & Braunstein, 2006). In some cases, temporary hypothyroidism may develop and may necessitate thyroid hormone therapy. Follow-up monitoring is necessary to document the patient's return to a euthyroid state.

Painless thyroiditis (subacute lymphocytic thyroiditis) often occurs in the postpartum period and is thought to be an autoimmune process. Symptoms of hyperthyroidism or hypothyroidism are possible. Treatment is directed at symptoms, and yearly follow-up is recommended to determine the patient's need for treatment of subsequent hypothyroidism.

Chronic Thyroiditis (Hashimoto's Disease)

Chronic thyroiditis, which occurs most frequently in women between the ages of 30 and 50 years, has been termed Hashimoto's disease, or chronic lymphocytic thyroiditis. In contrast to acute thyroiditis, the chronic forms usually are not accompanied by pain, pressure symptoms, or fever, and thyroid activity usually is normal or low rather than increased. Cell-mediated immunity may play a significant role in the pathogenesis of chronic thyroiditis, and there may be a genetic predisposition to it. Diagnosis is based on the histologic appearance of the inflamed thyroid gland. Patients with Hashimoto's disease should also be evaluated for primary thyroid lymphoma if they present with a rapidly growing nodule, because they are 60 to 80 times more likely to develop this condition than the general population (Bindra & Braunstein, 2006). If untreated, the disease runs a slow, progressive course, leading eventually to hypothyroidism. Indications for treatment include goiter or clinical hypothyroidism.

The objective of treatment is to reduce the size of the thyroid gland and prevent hypothyroidism. Thyroid hormone therapy is prescribed to reduce thyroid activity and the production of thyroglobulin. If hypothyroid symptoms are present, thyroid hormone therapy is prescribed. Surgery may be required if pressure symptoms persist.

THYROID TUMORS

Tumors of the thyroid gland are classified on the basis of being benign or malignant, the presence or absence of associated thyrotoxicosis, and the diffuse or irregular quality of the glandular enlargement. If the enlargement is sufficient to cause a visible swelling in the neck, the tumor is referred to as a goiter.

All grades of goiter are encountered, from those that are barely visible to those producing disfigurement. Some are

symmetric and diffuse; others are nodular. Some are accompanied by hyperthyroidism, in which case they are described as toxic; others are associated with a euthyroid state and are called nontoxic goiters.

Endemic (Iodine-Deficient) Goiter

The most common type of goiter, once encountered chiefly in geographic regions where the natural supply of iodine is deficient (eg, the Great Lakes areas of the United States), is the so-called simple or colloid goiter. In addition to being caused by an iodine deficiency, simple goiter may be caused by an intake of large quantities of goitrogenic substances in patients with unusually susceptible glands. These substances include excessive amounts of iodine or lithium, which is used in treating bipolar disorders.

Simple goiter represents a compensatory hypertrophy of the thyroid gland, caused by stimulation by the pituitary gland. The pituitary gland produces thyrotropin or TSH, a hormone that controls the release of thyroid hormone from the thyroid gland. Its production increases if there is subnormal thyroid activity, as when insufficient iodine is available for production of the thyroid hormone. Such goiters usually cause no symptoms, except for the swelling in the neck, which may result in tracheal compression when excessive.

Many goiters of this type recede after the iodine imbalance is corrected. Supplementary iodine, such as SSKI, is prescribed to suppress the pituitary’s thyroid-stimulating activity. When surgery is recommended, the risk of postoperative complications is minimized by ensuring a preoperative euthyroid state through treatment with antithyroid medications and iodide to reduce the size and vascularity of the goiter.

Providing children in iodine-poor regions with iodine compounds can prevent simple or endemic goiter. Although the introduction of iodized salt has been the single most effective means of preventing goiter in at-risk populations, the World Health Organization (2007) is exploring

alternative strategies to ensure iodine intake because of the health risks associated with excessive salt intake.

Nodular Goiter

Some thyroid glands are nodular because of areas of hyperplasia (overgrowth). No symptoms may arise as a result of this condition, but not uncommonly these nodules slowly increase in size, with some descending into the thorax, where they cause local pressure symptoms. Some nodules become malignant, and some are associated with a hyperthyroid state. Therefore, the patient with many thyroid nodules may eventually require surgery.

Thyroid Cancer

Cancer of the thyroid is much less prevalent than other forms of cancer; however, it accounts for 90% of endocrine malignancies. According to the American Cancer Society (2009), more than 37,000 new cases of thyroid cancer are diagnosed each year, with one fourth of the cases occurring in men and three fourths in women. About 1600 people die annually from this malignancy. There are several types of cancer of the thyroid gland; the type determines the course and prognosis (Table 42-4).

External radiation of the head, neck, or chest in infancy and childhood increases the risk of thyroid carcinoma. The incidence of thyroid cancer appears to increase 5 to 40 years after irradiation. Consequently, people who underwent radiation treatment or were otherwise exposed to radiation as children should consult a physician, request an isotope thyroid scan as part of the evaluation, follow recommended treatment of abnormalities of the gland, and continue with annual checkups (Chart 42-8).

Assessment and Diagnostic Findings

Lesions that are single, hard, and fixed on palpation or associated with cervical lymphadenopathy suggest malignancy. Thyroid function tests may be helpful in evaluating thyroid nodules and masses; however, results are rarely

Table 42-4 TYPES OF THYROID CANCERS

Type of Thyroid Cancer	Incidence (%)	Characteristics
Papillary adenocarcinoma	70	Most common and least aggressive Asymptomatic nodule in a normal gland Starts in childhood or early adult life, remains localized Metastasizes along the lymphatics if untreated More aggressive in the elderly
Follicular adenocarcinoma	15	Appears after 40 y of age Encapsulated; feels elastic or rubbery on palpation Spreads through the bloodstream to bone, liver, and lung Prognosis is not as favorable as for papillary adenocarcinoma
Medullary	5	Appears after 50 y of age Occurs as part of multiple endocrine neoplasia (MEN) Hormone-producing tumor causing endocrine dysfunction symptoms Metastasizes by lymphatics and bloodstream Moderate survival rate
Anaplastic	5	50% of anaplastic thyroid carcinomas occur in patients older than 60 y Hard, irregular mass that grows quickly and spreads by direct invasion to adjacent tissues May be painful and tender Survival for patients with anaplastic cancer is usually less than 6 mo
Thyroid lymphoma	5	Appears after age 40 y May have history of goiter, hoarseness, dyspnea, pain, and pressure Good prognosis

Chart 42-8 • Radiation-Induced Thyroid Damage and Cancer

The thyroid gland has a very efficient mechanism to remove iodine from the bloodstream and concentrate or “trap” it for subsequent synthesis of thyroid hormone. The effectiveness of this mechanism to concentrate iodide is reflected in a concentration of iodide 20 to 40 times the concentration of iodide in the plasma.

If milk and other food sources become contaminated with radioactivity as a result of a nuclear detonation or a nuclear power plant incident or mishap, the radioactive iodide would become concentrated in the thyroid gland at a very high concentration and would irradiate the thyroid gland, increasing the risk for thyroid gland cancer. Therefore, in communities exposed to increased radioactivity, attempts have been made to block the uptake of radioactive iodide by flooding or saturating the thyroid gland with nonradioactive iodide.

Administration of potassium iodide (KI) or other iodide preparations as soon as possible after exposure almost completely inhibits thyroid absorption of the radioactive iodide and promotes rapid excretion of any that is absorbed. In 2001, the Food and Drug Administration issued a statement recommending KI administration in advance of exposure to radioactive iodine—that is, when exposure is imminent (Thyroid Carcinoma Task Force, 2001).

conclusive. Needle biopsy of the thyroid gland is used as an outpatient procedure to make a diagnosis of thyroid cancer, to differentiate cancerous thyroid nodules from noncancerous nodules, and to stage the cancer if detected. The procedure is safe and usually requires only a local anesthetic agent. However, patients who undergo the procedure are monitored closely, because cancerous tissues may be missed during the procedure. A second type of aspiration or biopsy uses a large-bore needle rather than the fine needle used in standard biopsy; it may be used when the results of the standard biopsy are inconclusive or with rapidly growing tumors. Additional diagnostic studies include ultrasound, MRI, CT, thyroid scans, radioactive iodine uptake studies, and thyroid suppression tests.

Medical Management

The treatment of choice for thyroid carcinoma is surgical removal. Total or near-total **thyroidectomy** is performed if possible. Modified neck dissection or more extensive radical neck dissection is performed if there is lymph node involvement.

Efforts are made to spare parathyroid tissue to reduce the risk of postoperative hypocalcemia and tetany. After surgery, ablation procedures are carried out with radioactive iodine to eradicate residual thyroid tissue if the tumor is radiosensitive. Radioactive iodine also maximizes the chance of discovering thyroid metastasis at a later date if total-body scans are carried out.

After surgery, thyroid hormone is administered in suppressive doses to lower the levels of TSH to a euthyroid state (Cooper, et al., 2006). If the remaining thyroid tissue is inadequate to produce sufficient thyroid hormone, thyroxine is required permanently.

Several routes are available for administering radiation to the thyroid or tissues of the neck, including oral administration of radioactive iodine and external administration of radiation therapy. The patient who receives external sources of radiation therapy is at risk for mucositis, dryness of the mouth, dysphagia, redness of the skin, anorexia, and fatigue (see Chapter 16). Chemotherapy is infrequently used to treat thyroid cancer.

Patients whose thyroid cancer is detected early and who are appropriately treated usually do very well. Patients who have had papillary cancer, the most common and least aggressive tumor, have a 10-year survival rate greater than 90%. Long-term survival is also common in follicular cancer, a more aggressive form of thyroid cancer (Tierney, et al., 2005). However, continued thyroid hormone therapy and periodic follow-up and diagnostic testing are important to ensure the patient’s well-being (Cooper, et al., 2006).

Postoperatively, the patient is instructed to take exogenous thyroid hormone to prevent hypothyroidism. Later follow-up includes clinical assessment for recurrence of nodules or masses in the neck and signs of hoarseness, dysphagia, or dyspnea. Total-body scans are performed 2 to 4 months after surgery to detect residual thyroid tissue or metastatic disease. Thyroid hormones are stopped for about 6 weeks before the tests. Care must be taken to avoid iodine-containing foods and contrast agents. A repeat scan is performed 1 year after the initial surgery. If measurements are stable, a final scan is obtained in 3 to 5 years.

Free T₄, TSH, and serum calcium and phosphorus levels are monitored to determine whether the thyroid hormone supplementation is adequate and to note whether calcium balance is maintained.

Although local and systemic reactions to radiation may occur and may include neutropenia or thrombocytopenia, these complications are rare when radioactive iodine is used. Patients who undergo surgery that is combined with radioactive iodine have a higher survival rate than those who undergo surgery alone. Patient teaching emphasizes the importance of taking prescribed medications and following recommendations for follow-up monitoring. The patient who is undergoing radiation therapy is also instructed in how to assess and manage side effects of treatment.

Nursing Management

Important preoperative goals are to gain the patient’s confidence and reduce anxiety. Often, the patient’s home life has become tense because of his or her restlessness, irritability, and nervousness secondary to hyperthyroidism. Efforts are necessary to protect the patient from such tension and stress to avoid precipitating thyroid storm. If the patient reports increased stress when with family or friends, suggestions are made to limit contact with them. Quiet and relaxing forms of recreation or occupational therapy may be helpful.

Providing Preoperative Care

The nurse instructs the patient about the importance of eating a diet high in carbohydrates and proteins. A high daily caloric intake is necessary because of the increased metabolic activity and rapid depletion of glycogen reserves. Supplementary vitamins, particularly thiamine and ascorbic

acid, may be prescribed. The patient is reminded to avoid tea, coffee, cola, and other stimulants.

The nurse also informs the patient about the purpose of preoperative tests, if they are to be performed, and explains what preoperative preparations to expect. This information should help to reduce the patient's anxiety about the surgery. In addition, special efforts are made to ensure a good night's rest before surgery, although many patients are admitted to the hospital on the day of surgery.

Preoperative teaching includes demonstrating to the patient how to support the neck with the hands after surgery to prevent stress on the incision. This involves raising the elbows and placing the hands behind the neck to provide support and reduce strain and tension on the neck muscles and the surgical incision.

Providing Postoperative Care

The nurse periodically assesses the surgical dressings and reinforces them if necessary. When the patient is in a recumbent position, the nurse observes the sides and the back of the neck as well as the anterior dressing for bleeding. In addition to monitoring the pulse and blood pressure for any indication of internal bleeding, it is important to be alert for complaints of a sensation of pressure or fullness at the incision site. Such symptoms may indicate subcutaneous hemorrhage and hematoma formation and should be reported.

Difficulty in respiration can occur as a result of edema of the glottis, hematoma formation, or injury to the recurrent laryngeal nerve. This complication requires that an airway be inserted. Therefore, a tracheostomy set is kept at the bedside at all times, and the surgeon is summoned at the first indication of respiratory distress. If the respiratory distress is caused by hematoma, surgical evacuation is required.

The intensity of pain is assessed, and analgesic agents are administered as prescribed for pain. The nurse should anticipate apprehension in the patient and should inform the patient that oxygen will assist breathing. When moving and turning the patient, the nurse carefully supports the patient's head and avoids tension on the sutures. The most comfortable position is the semi-Fowler's position, with the head elevated and supported by pillows.

IV fluids are administered during the immediate postoperative period. Water may be given by mouth as soon as nausea subsides. Usually, there is a little difficulty in swallowing; initially, cold fluids and ice may be taken better than other fluids. Often, patients prefer a soft diet to a liquid diet in the immediate postoperative period.

The patient is advised to talk as little as possible to reduce edema to the vocal cords; however, when the patient does speak, any voice changes are noted, which might indicate injury to the recurrent laryngeal nerve, which lies just behind the thyroid next to the trachea. An overbed table is provided for access to frequently used items so the patient avoids turning his or her head. The table can also be used to support a humidifier when vapor-mist inhalations are prescribed for the relief of excessive mucus accumulation.

The patient is usually permitted out of bed as soon as possible and is encouraged to eat foods that are easily swallowed. A high-calorie diet may be prescribed to promote weight gain. Sutures or skin clips are usually removed on the second day. The patient is usually discharged from the

hospital on the day of surgery or soon afterward if the postoperative course is uncomplicated.

Monitoring and Managing Potential Complications

Hemorrhage, hematoma formation, edema of the glottis, and injury to the recurrent laryngeal nerve are complications that have been reviewed previously in this chapter. Occasionally in thyroid surgery, the parathyroid glands are injured or removed, producing a disturbance in calcium metabolism. As the blood calcium level falls, hyperirritability of the nerves occurs, with spasms of the hands and feet and muscle twitching (see Chapter 14). This group of symptoms is termed tetany, and the nurse must immediately report its appearance, because laryngospasm, although rare, may occur and obstruct the airway. Tetany of this type is usually treated with IV calcium gluconate. This calcium abnormality is usually temporary after thyroidectomy unless all parathyroid tissue was removed.

Promoting Home and Community-Based Care

The patient is usually discharged within 1 or 2 days. Therefore, the patient and family need to be knowledgeable about the signs and symptoms of the complications that may occur and those that should be reported. Strategies are suggested for managing postoperative pain at home and for increasing humidification. The nurse explains to the patient and family the need for rest, relaxation, and nutrition. The patient is permitted to resume his or her former activities and responsibilities completely once recovered from surgery.

If indicated, a referral to home care is made. The home care nurse assesses the patient's recovery from surgery. The nurse also assesses the surgical incision and reinforces instruction about limiting activities that put strain on the incision and sutures. Family responsibilities and factors relating to the home environment that produce emotional tension have often been implicated as precipitating causes of thyrotoxicosis. A home visit provides an opportunity to evaluate these factors and to suggest ways to improve the home and family environment. The nurse instructs the patients about the importance of follow-up visits to the physician or the clinic for monitoring of thyroid status.

THE PARATHYROID GLANDS

Anatomic and Physiologic Overview

The parathyroid glands (normally four) are situated in the neck and embedded in the posterior aspect of the thyroid gland (Fig. 42-5). Parathormone (parathyroid hormone), the protein hormone produced by the parathyroid glands, regulates calcium and phosphorus metabolism. Increased secretion of parathormone results in increased calcium absorption from the kidney, intestine, and bones, which raises the blood calcium level. Some actions of this hormone are increased by the presence of vitamin D. Parathormone also tends to lower the blood phosphorus level. The serum level of ionized calcium regulates the output of parathormone. Increased serum calcium results in decreased parathormone secretion, creating a negative feedback system.

Figure 42-5 The parathyroid glands are located behind the thyroid gland. The parathyroids may be embedded in the thyroid tissue.

Pathophysiology

Excess parathormone can result in markedly increased levels of serum calcium, a potentially life-threatening situation. When the product of serum calcium and serum phosphorus (calcium \times phosphorus) rises, calcium phosphate may precipitate in various organs of the body (eg, the kidneys) and cause tissue calcification.

Specific Disorders of the Parathyroid Glands

HYPERPARATHYROIDISM

Hyperparathyroidism, which is caused by overproduction of parathormone by the parathyroid glands, is characterized by bone decalcification and the development of renal calculi (kidney stones) containing calcium.

Primary hyperparathyroidism occurs two to four times more often in women than in men and is most common in people between 60 and 70 years of age. Its incidence is approximately 25 cases per 100,000 (Suliburk & Perrier, 2007). The disorder is rare in children younger than 15 years of age, but its incidence increases 10-fold between the ages of 15 and 65 years. Half of the people diagnosed with hyperparathyroidism do not have symptoms.

Secondary hyperparathyroidism, with manifestations similar to those of primary hyperparathyroidism, occurs in patients who have chronic renal failure and so-called renal rickets as a result of phosphorus retention, increased stimulation of the parathyroid glands, and increased parathormone secretion.

Clinical Manifestations

The patient may have no symptoms or may experience signs and symptoms resulting from involvement of several body systems. Apathy, fatigue, muscle weakness, nausea, vomiting, constipation, hypertension, and cardiac dysrhythmias may occur. All these signs and symptoms are attributable to

the increased concentration of calcium in the blood. Psychological effects may vary from irritability and neurosis to psychoses caused by the direct action of calcium on the brain and nervous system. An increase in calcium produces a decrease in the excitation potential of nerve and muscle tissue.

The formation of stones in one or both kidneys, related to the increased urinary excretion of calcium and phosphorus, is one of the important complications of hyperparathyroidism and occurs in 55% of patients with primary hyperparathyroidism. Renal damage results from the precipitation of calcium phosphate in the renal pelvis and parenchyma, which causes renal calculi (kidney stones), obstruction, pyelonephritis, and renal failure.

Musculoskeletal symptoms accompanying hyperparathyroidism may be caused by demineralization of the bones or by bone tumors composed of benign giant cells resulting from overgrowth of osteoclasts. The patient may develop skeletal pain and tenderness, especially of the back and joints; pain on weight bearing; pathologic fractures; deformities; and shortening of body stature. Bone loss attributable to hyperparathyroidism increases the risk of fracture.

The incidence of peptic ulcer and pancreatitis is increased with hyperparathyroidism and may be responsible for many of the GI symptoms that occur.

Assessment and Diagnostic Findings

Primary hyperparathyroidism is diagnosed by persistent elevation of serum calcium levels and an elevated concentration of parathormone. Radioimmunoassays for parathormone are sensitive and differentiate primary hyperparathyroidism from other causes of hypercalcemia in more than 90% of patients with elevated serum calcium levels. An elevated serum calcium level alone is a nonspecific finding, because serum levels may be altered by diet, medications, and renal and bone changes. Bone changes may be detected on x-ray or bone scans in advanced disease. The double-antibody parathyroid hormone test is used to distinguish between primary hyperparathyroidism and malignancy as a cause of hypercalcemia. Ultrasound, MRI, thallium scan, and fine-needle biopsy have been used to evaluate the function of the parathyroids and to localize parathyroid cysts, adenomas, or hyperplasia.

Medical Management

Surgical Management

The recommended treatment for primary hyperparathyroidism is the surgical removal of abnormal parathyroid tissue (parathyroidectomy) (Rodgers, Lew & Solorzano, 2008; Suliburk & Perrier, 2007). In the past, the standard parathyroidectomy involved a bilateral neck exploration under general anesthesia. Today, minimally invasive parathyroidectomy techniques allow for unilateral neck exploration using local anesthesia; these are performed on an outpatient basis. In some cases only the removal of a single diseased gland is necessary, reducing morbidity rates associated with surgery. For asymptomatic patients who have only mildly elevated serum calcium concentrations and normal renal function, surgery may be delayed and the patient monitored closely for worsening of hypercalcemia, bone deterioration, renal impairment, or the development of kidney stones.

Surgery is recommended for asymptomatic patients who meet the following criteria: (1) younger than 50 years of age, (2) unable or unlikely to participate in follow-up care, (3) serum calcium level more than 1.0 mg/dL (0.25 mmol/L) above normal reference range, (4) urinary calcium level greater than 400 mg/day (10 mmol/day), (5) a 30% or greater decrease in renal function, or (6) with complaints of primary hyperparathyroidism, including nephrocalcinosis, osteoporosis, or a severe psychoneurologic disorder (AAACE/AAES Task Force on Primary Hyperparathyroidism, 2005).

However, according to several authors, these criteria are too conservative; there is little evidence to support long-term medical management of asymptomatic patients who do not meet these criteria (Rodgers, et al., 2008; Suliburk & Perrier, 2007).

Hydration Therapy

Because kidney involvement is possible, patients with hyperparathyroidism are at risk for renal calculi. Therefore, a daily fluid intake of 2000 mL or more is encouraged to help prevent calculus formation. Cranberry juice is suggested, because it may lower the urinary pH. It can be added to other juices or to ginger ale for variety. Cranberry extract tablets are an alternative to reduce urinary pH. The patient is instructed to report other manifestations of renal calculi, such as abdominal pain and hematuria. Thiazide diuretics are avoided, because they decrease the renal excretion of calcium and further elevate serum calcium levels. Because of the risk of hypercalcemic crisis (see later discussion), the patient is instructed to avoid dehydration and to seek immediate health care if conditions that commonly produce dehydration (eg, vomiting, diarrhea) occur.

Mobility

Mobility of the patient, with walking or use of a rocking chair for those with limited mobility, is encouraged as much as possible, because bones that are subjected to normal stress give up less calcium. Bed rest increases calcium excretion and the risk for renal calculi. Oral phosphates lower the serum calcium level in some patients; long-term use is not recommended because of the risk of ectopic calcium phosphate deposition in soft tissues.

Diet and Medications

Nutritional needs are met, but the patient is advised to avoid a diet with restricted or excess calcium. If the patient has a coexisting peptic ulcer, prescribed antacids and protein feedings are necessary. Because anorexia is common, efforts are made to improve the appetite. Prune juice, stool softeners, and physical activity, along with increased fluid intake, help offset constipation, which is common postoperatively.

Nursing Management

The insidious onset and chronic nature of hyperparathyroidism and its diverse and commonly vague symptoms may result in depression and frustration. The family may have considered the patient's illness to be psychosomatic. An awareness of the course of the disorder and an understanding approach by the nurse may help the patient and family deal with their reactions and feelings.

The nursing management of the patient undergoing parathyroidectomy is essentially the same as that of a patient undergoing thyroidectomy. However, the previously described precautions about airway patency, dehydration, immobility, and diet are particularly important in the patient who is awaiting or recovering from parathyroidectomy. Although not all parathyroid tissue is removed during surgery in an effort to control the calcium–phosphorus balance, the nurse closely monitors the patient to detect symptoms of tetany (which may be an early postoperative complication). Most patients quickly regain function of the remaining parathyroid tissue and experience only mild, transient postoperative hypocalcemia. In patients with significant bone disease or bone changes, a more prolonged period of hypocalcemia should be anticipated. The nurse reminds the patient and family about the importance of follow-up to ensure return of serum calcium levels to normal (Chart 42-9).

Complications: Hypercalcemic Crisis

Acute hypercalcemic crisis can occur with extreme elevation of serum calcium levels. Serum calcium levels greater than 15 mg/dL (3.7 mmol/L) result in neurologic, cardiovascular, and renal symptoms that can be life-threatening. Treatment includes rehydration with large volumes of IV fluids, diuretic agents to promote renal excretion of excess calcium, and phosphate therapy to correct hypophosphatemia and decrease serum calcium levels by promoting calcium deposition in bone and reducing the gastrointestinal absorption of calcium. Cytotoxic agents (eg, mithramycin), calcitonin, and dialysis may be used in emergency situations to decrease serum calcium levels quickly.

NURSING ALERT

The patient in acute hypercalcemic crisis requires close monitoring for life-threatening complications and prompt treatment to reduce serum calcium levels.

A combination of calcitonin and corticosteroids has been administered in emergencies to reduce the serum calcium level by increasing calcium deposition in bone. Other agents that may be administered to decrease serum calcium levels include bisphosphonates (eg, etidronate [Didronel], pamidronate [Aredia]).

Expert assessment and care are required to minimize complications and reverse the life-threatening hypercalcemia. Medications are administered with care, and attention is given to fluid balance to promote return of normal fluid and electrolyte balance. Supportive measures are necessary for the patient and family. (See Chapters 14 and 16 for further discussion of hypercalcemic crisis.)

HYPOPARATHYROIDISM

The most common cause of hypoparathyroidism is inadequate secretion of parathormone after interruption of the blood supply or surgical removal of parathyroid gland tissue during thyroidectomy, parathyroidectomy, or radical neck dissection. These small glands are easily overlooked and can be removed inadvertently during thyroid surgery. Atrophy

HOME CARE CHECKLIST

The Patient With Hyperparathyroidism

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State present and potential effects of hyperparathyroidism on the body.	✓	✓
• State precipitating factors and interventions for complications.	✓	✓
• State importance of regular follow-up visits with health care provider.	✓	✓
• Describe potential benefits and risks of parathyroidectomy.	✓	✓
• State the purpose, dose, route, schedule, side effects, and precautions of prescribed medications (loop diuretics, phosphate, calcitonin, mithramycin).	✓	✓
• State the need to contact health care provider before taking over-the-counter medication containing calcium.	✓	✓
• State need to take pain medications on a scheduled basis.	✓	✓
• Describe nonpharmacologic methods of pain management.	✓	✓
• Identify safety hazards and methods of injury prevention.	✓	✓
• Identify areas of activity limitations and impact on lifestyle.	✓	✓
• State need for increased fluid intake and diet low in calcium and vitamin D.	✓	✓

of the parathyroid glands of unknown cause is a less common cause of hypoparathyroidism.

Deficiency of parathormone results in increased blood phosphate (hyperphosphatemia) and decreased blood calcium (hypocalcemia) levels. In the absence of parathormone, there is decreased intestinal absorption of dietary calcium and decreased resorption of calcium from bone and through the renal tubules. Decreased renal excretion of phosphate causes hypophosphaturia, and low serum calcium levels result in hypocalciuria.

Clinical Manifestations

Hypocalcemia causes irritability of the neuromuscular system and contributes to the chief symptom of hypoparathyroidism—tetany. Tetany is a general muscle hypertonia, with tremor and spasmodic or uncoordinated contractions occurring with or without efforts to make voluntary movements. Symptoms of latent tetany are numbness, tingling, and cramps in the extremities, and the patient complains of stiffness in the hands and feet. In overt tetany, the signs include bronchospasm, laryngeal spasm, carpopedal spasm (flexion of the elbows and wrists and extension of the carpal joints and dorsiflexion of the feet), dysphagia, photophobia, cardiac dysrhythmias, and seizures. Other symptoms include anxiety, irritability, depression, and even delirium. ECG changes and hypotension also may occur.

Assessment and Diagnostic Findings

A positive Trousseau's sign or a positive Chvostek's sign suggests latent tetany. **Trousseau's sign** is positive when carpopedal spasm is induced by occluding the blood flow to the arm for 3 minutes with a blood pressure cuff. **Chvostek's sign** is positive when a sharp tapping over the facial nerve just in front of the parotid gland and anterior to the ear causes spasm or twitching of the mouth, nose, and eye (see Chapter 14).

The diagnosis of hypoparathyroidism often is difficult because of the vague symptoms, such as aches and pains. There-

fore, laboratory studies are especially helpful. Tetany develops at serum calcium levels of 5 to 6 mg/dL (1.2 to 1.5 mmol/L) or lower. Serum phosphate levels are increased, and x-rays of bone show increased density. Calcification is detected on x-rays of the subcutaneous or paraspinous basal ganglia of the brain.

Medical Management

The goal of therapy is to increase the serum calcium level to 9 to 10 mg/dL (2.2 to 2.5 mmol/L) and to eliminate the symptoms of hypoparathyroidism and hypocalcemia. When hypocalcemia and tetany occur after a thyroidectomy, the immediate treatment is administration of IV calcium gluconate. If this does not decrease neuromuscular irritability and seizure activity immediately, sedative agents such as pentobarbital may be administered.

Parenteral parathormone can be administered to treat acute hypoparathyroidism with tetany. However, the high incidence of allergic reactions to injections of parathormone limits its use to acute episodes of hypocalcemia. The patient receiving parathormone is monitored closely for allergic reactions and changes in serum calcium levels.

Because of neuromuscular irritability, the patient with hypocalcemia and tetany requires an environment that is free of noise, drafts, bright lights, or sudden movement. Tracheostomy or mechanical ventilation may become necessary, along with bronchodilating medications, if the patient develops respiratory distress.

Therapy for chronic hypoparathyroidism is determined after serum calcium levels are obtained. A diet high in calcium and low in phosphorus is prescribed. Although milk, milk products, and egg yolk are high in calcium, they are restricted because they also contain high levels of phosphorus. Spinach also is avoided because it contains oxalate, which would form insoluble calcium substances. Oral tablets of calcium salts, such as calcium gluconate, may be used to supplement the diet. Aluminum hydroxide gel or aluminum carbonate (Gelusil, Amphojel) also is administered after

CHART
42-10  HOME CARE CHECKLIST
The Patient With Hypoparathyroidism

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State present and potential effects of hypoparathyroidism on the body.	✓	✓
• State precipitating factors and interventions for complications (seizure, cardiac dysrhythmias, cardiac arrest).	✓	✓
• State necessary actions for seizure activity.		✓
• State importance of regular follow-up visits with health care provider.	✓	✓
• State purpose, dose, route, schedule, side effects, and precautions of prescribed medications (calcium, phosphate binders).	✓	✓
• State need to alternate activity and rest periods.	✓	✓
• Identify areas of activity limitations and impact on lifestyle.	✓	✓
• Identify foods high in calcium and vitamin D, low in phosphorus.	✓	✓

meals to bind phosphate and promote its excretion through the GI tract.

Variable dosages of a vitamin D preparation—dihydro-tachysterol (AT 10 or Hytakerol), ergocalciferol (vitamin D), or cholecalciferol (vitamin D)—are usually required and enhance calcium absorption from the GI tract.

Nursing Management

Nursing management of the patient with possible acute hypoparathyroidism includes the following:

- Care of postoperative patients who have undergone thyroidectomy, parathyroidectomy, or radical neck dissection is directed toward detecting early signs of hypocalcemia and anticipating signs of tetany, seizures, and respiratory difficulties.
- Calcium gluconate is kept at the bedside with equipment necessary for emergency IV administration. If the patient requiring administration of calcium gluconate has a cardiac disorder, is subject to dysrhythmias, or is receiving digitalis, the calcium gluconate is administered slowly and cautiously.
- Calcium and digitalis increase systolic contraction and also potentiate each other; this can produce potentially fatal dysrhythmias. Consequently, the cardiac patient requires continuous cardiac monitoring and careful assessment.

An important aspect of nursing care is teaching about medications and diet therapy. The patient needs to know the reason for high calcium and low phosphate intake and the symptoms of hypocalcemia and hypercalcemia; he or she should know to contact the physician immediately if these symptoms occur (Chart 42-10).

THE ADRENAL GLANDS

Anatomic and Physiologic Overview

Each person has two adrenal glands, one attached to the upper portion of each kidney (Porth & Matfin, 2009). Each adrenal gland is, in reality, two endocrine glands with sepa-

rate, independent functions. The adrenal medulla at the center of the gland secretes catecholamines, and the outer portion of the gland, the adrenal cortex, secretes steroid hormones (Fig. 42-6). The secretion of hormones from the adrenal cortex is regulated by the hypothalamic–pituitary–adrenal axis. The hypothalamus secretes corticotropin-releasing hormone (CRH), which stimulates the pituitary gland to secrete ACTH, which in turn stimulates

Figure 42-6 A, The adrenal glands sit on top of the kidneys. B, Each gland is composed of an outer cortex and an inner medulla. Each area secretes specific hormones. The adrenal medulla secretes catecholamines—epinephrine and norepinephrine; the adrenal cortex secretes glucocorticoids, mineralocorticoids, and sex hormones. Adapted from Porth, C. (2006). *Essentials of pathophysiology: Concepts of altered health states* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

the adrenal cortex to secrete glucocorticoid hormone (cortisol). Increased levels of the adrenal hormone then inhibit the production or secretion of CRH and ACTH. This system is an example of a negative feedback mechanism.

Adrenal Medulla

The adrenal medulla functions as part of the autonomic nervous system. Stimulation of preganglionic sympathetic nerve fibers, which travel directly to the cells of the adrenal medulla, causes release of the catecholamine hormones epinephrine and norepinephrine. About 90% of the secretion of the human adrenal medulla is epinephrine (also called adrenaline). Catecholamines regulate metabolic pathways to promote catabolism of stored fuels to meet caloric needs from endogenous sources. The major effects of epinephrine release are to prepare to meet a challenge (fight-or-flight response). Secretion of epinephrine causes decreased blood flow to tissues that are not needed in emergency situations, such as the GI tract, and increased blood flow to tissues that are important for effective fight or flight, such as cardiac and skeletal muscle. Catecholamines also induce the release of free fatty acids, increase the basal metabolic rate, and elevate the blood glucose level.

Adrenal Cortex

A functioning adrenal cortex is necessary for life; adrenocortical secretions make it possible for the body to adapt to stress of all kinds. The three types of steroid hormones produced by the adrenal cortex are **glucocorticoids**, the prototype of which is hydrocortisone; **mineralocorticoids**, mainly aldosterone; and sex hormones, mainly **androgens** (male sex hormones). Without the adrenal cortex, severe stress would cause peripheral circulatory failure, circulatory shock, and prostration. Survival in the absence of a functioning adrenal cortex is possible only with nutritional, electrolyte, and fluid replacement and appropriate replacement with exogenous adrenocortical hormones.

Glucocorticoids

The glucocorticoids are so named because they have an important influence on glucose metabolism: Increased hydrocortisone secretion results in elevated blood glucose levels. However, the glucocorticoids have major effects on the metabolism of almost all organs of the body. Glucocorticoids are secreted from the adrenal cortex in response to the release of ACTH from the anterior lobe of the pituitary gland. This system represents an example of negative feedback. The presence of glucocorticoids in the blood inhibits the release of CRH from the hypothalamus and also inhibits ACTH secretion from the pituitary. The resultant decrease in ACTH secretion causes diminished release of glucocorticoids from the adrenal cortex.

Glucocorticoids (in the form of **corticosteroids**) are administered frequently to inhibit the inflammatory response to tissue injury and to suppress allergic manifestations. Their side effects include the development of diabetes mellitus, osteoporosis, peptic ulcer, increased protein breakdown resulting in muscle wasting and poor wound healing, and redistribution of body fat. Large amounts of exogenously administered glucocorticoids in the blood inhibit the release of ACTH and endogenous glucocorticoids. Because

of this, the adrenal cortex can atrophy. If exogenous glucocorticoid administration is discontinued suddenly, adrenal insufficiency results because of the inability of the atrophied cortex to respond adequately.

Mineralocorticoids

Mineralocorticoids exert their major effects on electrolyte metabolism. They act principally on the renal tubular and GI epithelium to cause increased sodium ion absorption in exchange for excretion of potassium or hydrogen ions. ACTH only minimally influences aldosterone secretion. It is primarily secreted in response to the presence of angiotensin II in the bloodstream. Angiotensin II is a substance that elevates the blood pressure by constricting arterioles. Its concentration is increased when renin is released from the kidney in response to decreased perfusion pressure. The resultant increased aldosterone levels promote sodium reabsorption by the kidney and the GI tract, which tends to restore blood pressure to normal. The release of aldosterone is also increased by hyperkalemia. Aldosterone is the primary hormone for the long-term regulation of sodium balance.

Adrenal Sex Hormones (Androgens)

Androgens, the third major type of steroid hormones produced by the adrenal cortex, exert effects similar to those of male sex hormones. The adrenal gland may also secrete small amounts of some estrogens, or female sex hormones. ACTH controls the secretion of adrenal androgens. When secreted in normal amounts, the adrenal androgens probably have little effect, but when secreted in excess, as in certain inborn enzyme deficiencies, masculinization may result. This is termed the **adrenogenital syndrome**.

Specific Disorders of the Adrenal Glands

PHEOCHROMOCYTOMA

Pheochromocytoma is a tumor that is usually benign and originates from the chromaffin cells of the adrenal medulla. In 90% of patients (Porth & Matfin, 2009), the tumor arises in the medulla; in the remaining patients, it occurs in the extra-adrenal chromaffin tissue located in or near the aorta, ovaries, spleen, or other organs. Pheochromocytoma may occur at any age, but its peak incidence is between 40 and 50 years of age affecting men and women equally. Ten percent of the tumors are bilateral, and 10% are malignant. Because of the high incidence of pheochromocytoma in family members of affected people, the patient's family members should be alerted and screened for this tumor. Pheochromocytoma may occur in the familial form as part of multiple endocrine neoplasia type 2; therefore, it should be considered a possibility in patients who have medullary thyroid carcinoma and parathyroid hyperplasia or tumor.

Pheochromocytoma is the cause of high blood pressure in 0.1% of patients with hypertension. Although it is uncommon, it is one form of hypertension that is usually cured by surgery; however, without detection and treatment, it is usually fatal.

Clinical Manifestations

The nature and severity of symptoms of functioning tumors of the adrenal medulla depend on the relative proportions of epinephrine and norepinephrine secretion. The typical triad of symptoms is headache, diaphoresis, and palpitations in the patient with hypertension. Approximately 8% of patients are completely asymptomatic. Hypertension and other cardiovascular disturbances are common. The hypertension may be intermittent or persistent. However, only half of patients with pheochromocytoma have sustained or persistent hypertension. If the hypertension is sustained, it may be difficult to distinguish from other causes of hypertension. Other symptoms may include tremor, headache, flushing, and anxiety. Hyperglycemia may result from conversion of liver and muscle glycogen to glucose due to epinephrine secretion; insulin may be required to maintain normal blood glucose levels.

The clinical picture in the paroxysmal form of pheochromocytoma is usually characterized by acute, unpredictable attacks lasting seconds or several hours. Symptoms usually begin abruptly and subside slowly. During these attacks, the patient is extremely anxious, tremulous, and weak. The patient may experience headache, vertigo, blurring of vision, tinnitus, air hunger, and dyspnea. Other symptoms include polyuria, nausea, vomiting, diarrhea, abdominal pain, and a feeling of impending doom. Palpitations and tachycardia are common (Porth & Matfin, 2009). Blood pressures exceeding 250/150 mm Hg have been recorded. Such blood pressure elevations are life-threatening and can cause severe complications, such as cardiac dysrhythmias, dissecting aneurysm, stroke, and acute renal failure. Postural hypotension (decrease in systolic blood pressure, lightheadedness, dizziness on standing) occurs in 70% of patients with untreated pheochromocytoma.

Assessment and Diagnostic Findings

Pheochromocytoma is suspected if signs of sympathetic nervous system overactivity occur in association with marked elevation of blood pressure. These signs can be associated with the “five H’s”: hypertension, headache, hyperhidrosis (excessive sweating), hypermetabolism, and hyperglycemia. The presence of these signs is highly predictive of pheochromocytoma. Paroxysmal symptoms of pheochromocytoma commonly develop in the fifth decade of life.

Measurements of urine and plasma levels of catecholamines and metanephrine (MN), a catecholamine metabolite, are the most direct and conclusive tests for overactivity of the adrenal medulla. A new test for detecting pheochromocytoma has recently been developed that measures free MN in plasma by high-pressure liquid chromatography and electrochemical detection. A negative test result virtually excludes pheochromocytoma. However, increased levels of at least one catecholamine or MN can occur in 10% of patients with essential hypertension.

Measurements of catecholamine metabolites (MN and vanillylmandelic acid [VMA]) or free catecholamines have been extensively used in the clinical setting. In most cases, pheochromocytoma can be diagnosed or confirmed based on a properly collected 24-hour urine sample. Levels can be as high as two times the normal limit. A 24-hour specimen

of urine is collected for determination of free catecholamines, MN, and VMA; the use of combined tests increases the diagnostic accuracy of testing. A number of medications and foods, such as coffee and tea (including decaffeinated varieties), bananas, chocolate, vanilla, and aspirin, may alter the results of these tests; therefore, careful instructions to avoid restricted items must be given to the patient. Urine collected over a 2- or 3-hour period after an attack of hypertension can be assayed for catecholamine content.

The total plasma catecholamine (epinephrine and norepinephrine) concentration is measured with the patient supine and at rest for 30 minutes. To prevent elevation of catecholamine levels resulting from the stress of venipuncture, a butterfly needle, scalp vein needle, or venous catheter may be inserted 30 minutes before the blood specimen is obtained.

Factors that may elevate catecholamine concentrations must be controlled to obtain valid results; these factors include consumption of coffee or tea (including decaffeinated varieties), use of tobacco, emotional and physical stress, and use of many prescription and over-the-counter medications (eg, amphetamines, nose drops or sprays, decongestant agents, bronchodilators).

Normal plasma values of epinephrine are 100 pg/mL (590 pmol/L); normal values of norepinephrine are generally less than 100 to 550 pg/mL (590 to 3240 pmol/L). Values of epinephrine greater than 400 pg/mL (2180 pmol/L) or norepinephrine values greater than 2000 pg/mL (11,800 pmol/L) are considered diagnostic of pheochromocytoma. Values that fall between normal levels and those diagnostic of pheochromocytoma indicate the need for further testing.

A clonidine suppression test may be performed if the results of plasma and urine tests of catecholamines are inconclusive. Clonidine (Catapres) is a centrally acting antiadrenergic medication that suppresses the release of neurogenically mediated catecholamines. The suppression test is based on the principle that catecholamine levels are normally increased through the activity of the sympathetic nervous system. In pheochromocytoma, increased catecholamine levels result from the diffusion of excess catecholamines into the circulation, bypassing normal storage and release mechanisms. Therefore, in patients with pheochromocytoma, clonidine does not suppress the release of catecholamines.

Imaging studies, such as CT, MRI, and ultrasonography, may also be carried out to localize the pheochromocytoma and to determine whether more than one tumor is present. Use of ¹³¹I-metaiodobenzylguanidine (MIBG) scintigraphy may be required to determine the location of the pheochromocytoma and to detect metastatic sites outside the adrenal gland. MIBG is a specific isotope for catecholamine-producing tissue. It has been helpful in identifying tumors not detected by other tests or procedures. MIBG scintigraphy is a noninvasive, safe procedure that has increased the accuracy of diagnosis of adrenal tumors.

Other diagnostic studies may focus on evaluating the function of other endocrine glands because of the association of pheochromocytoma in some patients with other endocrine tumors.

Medical Management

During an episode or attack of hypertension, tachycardia, anxiety, and the other symptoms of pheochromocytoma, bed rest with the head of the bed elevated is prescribed to promote an orthostatic decrease in blood pressure.

Pharmacologic Therapy

The patient may be moved to the intensive care unit for close monitoring of ECG changes and careful administration of alpha-adrenergic blocking agents (eg, phentolamine [Regitine]) or smooth muscle relaxants (eg, sodium nitroprusside [Nipride]) to lower the blood pressure quickly.

Phenoxybenzamine (Dibenzyline), a long-acting alpha-blocker, may be used after the blood pressure is stable to prepare the patient for surgery. Calcium channel blockers such as nifedipine (Procardia) are usually well tolerated by patients and have reduced perioperative fluid requirements. They are also useful for prevention of cardiovascular complications, because they prevent catecholamine-induced coronary vasospasm and myocarditis. Beta-adrenergic blocking agents such as propranolol (Inderal) may be used in patients with cardiac dysrhythmias and in those not responsive to alpha-blockers. Alpha-adrenergic and beta-adrenergic blocking agents must be used with caution, because patients with pheochromocytoma may have increased sensitivity to them. Still other medications that may be used preoperatively are catecholamine synthesis inhibitors, such as alpha-methyl-*p*-tyrosine (metyrosine [Demser]). These are occasionally used if adrenergic blocking agents do not reduce the effects of catecholamines.

Surgical Management

The definitive treatment of pheochromocytoma is surgical removal of the tumor, usually with **adrenalectomy**. Bilateral adrenalectomy may be necessary if tumors are present in both adrenal glands. Patient preparation includes control of blood pressure and blood volumes; usually this is carried out over 4 to 7 days. Nifedipine (Procardia) and nicardipine (Cardene) may be used safely without causing undue hypotension. For episodes of severe hypertension, nifedipine is a fast and effective treatment, because the capsules can be pierced and chewed. The patient needs to be well hydrated before, during, and after surgery to prevent hypotension.

Manipulation of the tumor during surgical excision may cause release of stored epinephrine and norepinephrine, with marked increases in blood pressure and changes in heart rate. Therefore, use of sodium nitroprusside (Nipride) and alpha-adrenergic blocking agents may be required during and after surgery. Exploration of other possible tumor sites is frequently undertaken to ensure removal of all tumor tissue. As a result, the patient is subject to the stress and effects of a long surgical procedure, which may increase the risk of hypertension postoperatively.

Corticosteroid replacement is required if bilateral adrenalectomy has been necessary. Corticosteroids may also be required for the first few days or weeks after removal of a single adrenal gland. IV administration of corticosteroids (methylprednisolone sodium succinate [Solu-Medrol]) may begin on the evening before surgery and continue during

the early postoperative period to prevent adrenal insufficiency. Oral preparations of corticosteroids (prednisone) are prescribed after the acute stress of surgery diminishes.

Hypotension and hypoglycemia may occur in the postoperative period because of the sudden withdrawal of excessive amounts of catecholamines. Therefore, careful attention is directed toward monitoring and treating these changes. Blood pressure is expected to return to normal with treatment; however, one third of patients continue to be hypertensive after surgery. This may result if not all pheochromocytoma tissue was removed, if pheochromocytoma recurs, or if the blood vessels were damaged by severe and prolonged hypertension. Several days after surgery, urine and plasma levels of catecholamines and their metabolites are measured to determine whether the surgery was successful.

Nursing Management

The patient who has undergone surgery to treat pheochromocytoma has experienced a stressful preoperative and postoperative course and may remain fearful of repeated attacks. Although it is usually expected that all pheochromocytoma tissue has been removed, there is a possibility that other sites were undetected and that attacks may recur. The patient is monitored for several days in the intensive care unit with special attention given to ECG changes, arterial pressures, fluid and electrolyte balance, and blood glucose levels. Several IV lines are inserted for administration of fluids and medications.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

During the preoperative and postoperative phases of care, the nurse informs the patient about the importance of follow-up monitoring to ensure that pheochromocytoma does not recur undetected. After adrenalectomy, use of corticosteroids may be needed. Therefore, the nurse instructs the patient about their purpose, the medication schedule, and the risks of skipping doses or stopping their administration abruptly.

It is important to teach the patient and family how to measure the patient's blood pressure and when to notify the physician about changes in blood pressure. In addition, the nurse provides verbal and written instructions about the procedure for collecting 24-hour urine specimens to monitor urine catecholamine levels.

Continuing Care

A follow-up visit from a home care nurse may be indicated to assess the patient's postoperative recovery, surgical incision, and compliance with the medication schedule. This may help reinforce previous teaching about management and monitoring. The home care nurse also obtains blood pressure measurements and assists the patient in preventing or dealing with problems that may result from long-term use of corticosteroids.

Because of the risk of recurrence of hypertension, periodic checkups are required, especially in young patients and in those whose families have a history of pheochromocytoma. The patient is scheduled for periodic follow-up

appointments to observe for return of normal blood pressure and plasma and urine levels of catecholamines.

ADRENOCORTICAL INSUFFICIENCY (ADDISON'S DISEASE)

Addison's disease, or adrenocortical insufficiency, occurs when adrenal cortex function is inadequate to meet the patient's need for cortical hormones. Autoimmune or idiopathic atrophy of the adrenal glands is responsible for the vast majority of cases. Other causes include surgical removal of both adrenal glands and infection of the adrenal glands. Tuberculosis and histoplasmosis are the most common infections that destroy adrenal gland tissue. Although autoimmune destruction has replaced tuberculosis as the principal cause of Addison's disease, tuberculosis should be considered in the diagnostic workup because of its increasing incidence. Inadequate secretion of ACTH from the pituitary gland also results in adrenal insufficiency because of decreased stimulation of the adrenal cortex.

Therapeutic use of corticosteroids is the most common cause of adrenocortical insufficiency (Porth & Matfin, 2009). Symptoms of adrenocortical insufficiency may also result from the sudden cessation of exogenous adrenocortical hormonal therapy, which suppresses the body's normal response to stress and interferes with normal feedback mechanisms. Treatment with daily administration of corticosteroids for 2 to 4 weeks may suppress function of the adrenal cortex; therefore, adrenal insufficiency should be considered in any patient who has been treated with corticosteroids.

Clinical Manifestations

Addison's disease is characterized by muscle weakness; anorexia; GI symptoms; fatigue; emaciation; dark pigmentation of the mucous membranes and the skin, especially of the knuckles, knees, and elbows; hypotension; and low blood glucose, low serum sodium, and high serum potassium levels. Mental status changes such as depression, emotional lability, apathy, and confusion are present in 60% to 80% of patients. In severe cases, the disturbance of sodium and potassium metabolism may be marked by depletion of sodium and water and severe, chronic dehydration.

With disease progression and acute hypotension, **addisonian crisis** develops. This condition is characterized by cyanosis and the classic signs of circulatory shock: pallor, apprehension, rapid and weak pulse, rapid respirations, and low blood pressure. In addition, the patient may complain of headache, nausea, abdominal pain, and diarrhea and may show signs of confusion and restlessness. Even slight overexertion, exposure to cold, acute infection, or a decrease in salt intake may lead to circulatory collapse, shock, and death if untreated. The stress of surgery or dehydration resulting from preparation for diagnostic tests or surgery may precipitate an addisonian or hypotensive crisis.

Assessment and Diagnostic Findings

Although the clinical manifestations presented appear specific, the onset of Addison's disease usually occurs with nonspecific symptoms. The diagnosis is confirmed by laboratory test results. Combined measurements of early-morning

serum cortisol and plasma ACTH are performed to differentiate primary adrenal insufficiency from secondary adrenal insufficiency and from normal adrenal function. Patients with primary insufficiency have a greatly increased plasma ACTH level (more than 22.0 pmol/L) and a serum cortisol concentration lower than the normal range (less than 165 nmol/L) or in the low-normal range. Other laboratory findings include decreased levels of blood glucose (hypoglycemia) and sodium (hyponatremia), an increased serum potassium concentration (hyperkalemia), and an increased white blood cell count (leukocytosis).

The diagnosis is confirmed by low levels of adrenocortical hormones in the blood or urine and decreased serum cortisol levels. If the adrenal cortex is destroyed, baseline values are low, and ACTH administration fails to cause the normal increase in plasma cortisol and urinary 17-hydroxycorticosteroids. If the adrenal gland is normal but not stimulated properly by the pituitary, a normal response to repeated doses of exogenous ACTH is seen, but no response occurs after the administration of metyrapone (Metopirone), which stimulates endogenous ACTH.

Medical Management

Immediate treatment is directed toward combating circulatory shock: restoring blood circulation, administering fluids and corticosteroids, monitoring vital signs, and placing the patient in a recumbent position with the legs elevated. Hydrocortisone (Solu-Cortef) is administered by IV, followed by 5% dextrose in normal saline. Vasopressor amines may be required if hypotension persists.

Antibiotics may be administered if infection has precipitated adrenal crisis in a patient with chronic adrenal insufficiency. In addition, the patient is assessed closely to identify other factors, stressors, or illnesses that led to the acute episode.

Oral intake may be initiated as soon as tolerated. IV fluids are gradually decreased after oral fluid intake is adequate to prevent hypovolemia. If the adrenal gland does not regain function, the patient needs lifelong replacement of corticosteroids and mineralocorticoids to prevent recurrence of adrenal insufficiency. During stressful procedures or significant illnesses, additional supplementary therapy with glucocorticoids is required to prevent addisonian crisis. In addition, the patient may need to supplement dietary intake with added salt during gastrointestinal losses of fluids through vomiting and diarrhea.

Nursing Management

Assessing the Patient

The health history and examination focus on the presence of symptoms of fluid imbalance and on the patient's level of stress. The nurse should monitor the blood pressure and pulse rate as the patient moves from a lying, sitting, and standing position to assess for inadequate fluid volume. A decrease in systolic pressure (20 mm Hg or more) may indicate depletion of fluid volume, especially if accompanied by symptoms. The skin should be assessed for changes in color and turgor, which could indicate chronic adrenal insufficiency and hypovolemia. The patient is assessed for change in weight, muscle weakness, fatigue, and any illness or stress that may have precipitated the acute crisis.

Monitoring and Managing Addisonian Crisis

The patient at risk is monitored for signs and symptoms indicative of addisonian crisis, which can include shock; hypotension; rapid, weak pulse; rapid respiratory rate; pallor; and extreme weakness (see Chapter 15). Physical and psychological stressors such as cold exposure, overexertion, infection, and emotional distress should be avoided.

The patient with addisonian crisis requires immediate treatment with IV administration of fluid, glucose, and electrolytes, especially sodium; replacement of missing steroid hormones; and vasopressors. The nurse anticipates and meets the patient's needs to promote return to a precrisis state.

Restoring Fluid Balance

The nurse encourages the patient to consume foods and fluids that assist in restoring and maintaining fluid and electrolyte balance. Along with the dietitian, the nurse helps the patient select foods high in sodium during GI disturbances and in very hot weather.

The nurse instructs the patient and family to administer hormone replacement as prescribed and to modify the dosage during illness and other stressful situations. Written and verbal instructions are provided about the administration of mineralocorticoid (Florinef) or corticosteroid (prednisone) as prescribed.

Improving Activity Tolerance

Until the patient's condition is stabilized, the nurse takes precautions to avoid unnecessary activity and stress that could precipitate another hypotensive episode. Efforts are made to detect signs of infection or the presence of other

stressors. Explaining the rationale for minimizing stress during the acute crisis assists the patient to increase activity gradually.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Because of the need for lifelong replacement of adrenal cortex hormones to prevent addisonian crises, the patient and family members receive explicit verbal and written instructions about the rationale for replacement therapy and proper dosage. In addition, they are instructed about how to modify the medication dosage and increase salt intake in times of illness, very hot weather, and other stressful situations. The patient also learns how to modify diet and fluid intake to help maintain fluid and electrolyte balance.

The patient and family are frequently prescribed preloaded, single-injection syringes of corticosteroid for use in emergencies. Specific instructions about how and when to use the injection are also provided. It is important to instruct the patient to inform other health care providers, such as dentists, about the use of corticosteroids; to wear a medical alert bracelet; and to carry information at all times about the need for corticosteroids. If the patient with Addison's disease requires surgery, careful administration of fluids and corticosteroids is necessary before, during, and after surgery to prevent addisonian crisis.

The patient and family need to know the signs of excessive or insufficient hormone replacement. The development of edema or weight gain may signify too high a dose of hormone; postural hypotension and weight loss frequently signify too low a dose (Chart 42-11).

CHART 42-11 HOME CARE CHECKLIST The Patient With Adrenal Insufficiency (Addison's Disease)

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State present and potential effects of adrenal insufficiency on the body.	✓	✓
• State warning signs of adrenal crisis and need for emergency care.	✓	✓
• Explain components of an emergency kit and indications for their use; demonstrate how to use them.	✓	✓
• State strategies for dealing with stress and avoiding adrenal crisis.	✓	✓
• State the purpose, dose, route, schedule, side effects, and precautions of prescribed medications (corticosteroid replacement).	✓	✓
• State that compliance with medical regimen is lifelong.	✓	✓
• State importance of regular follow-up visits with health care provider.	✓	✓
• Recognize the need for dosage adjustment during times of stress.	✓	✓
• State need to wear medical alert identification and carry medical information card.	✓	✓
• State need to notify health care providers about disease before treatment or procedure.	✓	✓
• State need to avoid strenuous activity in hot, humid weather.	✓	✓
• State need for increased fluid intake and salt with excessive perspiration.	✓	✓
• State need for high-carbohydrate, high-protein diet with adequate sodium intake.	✓	✓
• Identify needed activity limitations and impact on lifestyle.	✓	✓

Continuing Care

Although most patients can return to their job and family responsibilities soon after hospital discharge, others cannot do so because of concurrent illnesses or incomplete recovery from the episode of adrenal insufficiency. In these circumstances, a referral for home care enables the home care nurse to assess the patient's recovery, monitor hormone replacement, and evaluate stress in the home. The nurse assesses the patient's and family's knowledge about medication therapy and dietary modifications. A home visit also allows the nurse to assess the patient's plans for follow-up visits to the clinic or physician's office. The nurse reminds the patient and family about the importance of participating in health promotion activities and health screening.

CUSHING'S SYNDROME

Cushing's syndrome results from excessive, rather than deficient, adrenocortical activity (Porth & Matfin, 2009). Cushing's syndrome is commonly caused by use of corticosteroid medications and is infrequently the result of excessive corticosteroid production secondary to hyperplasia of the adrenal cortex. However, overproduction of endogenous corticosteroids may be caused by several mechanisms, including a tumor of the pituitary gland that produces ACTH and stimulates the adrenal cortex to increase its hormone secretion despite production of adequate amounts. Primary hyperplasia of the adrenal glands in the absence of a pituitary tumor is less common. Another less common cause of Cushing's syndrome is the ectopic production of ACTH by malignancies; bronchogenic carcinoma is the most common type. Regardless of the cause, the normal feedback mechanisms that control the function of the adrenal cortex become ineffective, and the usual diurnal pattern of cortisol is lost. The signs and symptoms of Cushing's syndrome are primarily a result of oversecretion of glucocorticoids and androgens (sex hormones), although mineralocorticoid secretion also may be affected (Porth & Matfin, 2009).

Clinical Manifestations

When overproduction of the adrenal cortical hormone occurs, arrest of growth, obesity, and musculoskeletal changes occur along with glucose intolerance. The classic picture of Cushing's syndrome in the adult is that of central-type obesity, with a fatty "buffalo hump" in the neck and supraclavicular areas, a heavy trunk, and relatively thin extremities. The skin is thin, fragile, and easily traumatized; ecchymoses (bruises) and striae develop. The patient complains of weakness and lassitude. Sleep is disturbed because of altered diurnal secretion of cortisol.

Excessive protein catabolism occurs, producing muscle wasting and osteoporosis. Kyphosis, backache, and compression fractures of the vertebrae may result. Retention of sodium and water occurs as a result of increased mineralocorticoid activity, producing hypertension and heart failure.

The patient develops a "moon-faced" appearance and may experience increased oiliness of the skin and acne. There is increased susceptibility to infection. Hyperglycemia or overt diabetes may develop. The patient may also report weight gain, slow healing of minor cuts, and bruises.

Women between the ages of 20 and 40 years are five times more likely than men to develop Cushing's syndrome. In females of all ages, virilization may occur as a result of excess androgens. Virilization is characterized by the appearance of masculine traits and the recession of feminine traits. There is an excessive growth of hair on the face (hirsutism), the breasts atrophy, menses cease, the clitoris enlarges, and the voice deepens. Libido is lost in men and women.

Changes occur in mood and mental activity, and psychosis may develop. Distress and depression are common and are increased by the severity of the physical changes that occur with this syndrome. If Cushing's syndrome is a consequence of pituitary tumor, visual disturbances may occur because of pressure of the growing tumor on the optic chiasm. Chart 42-12 summarizes the changes associated with Cushing's syndrome.

Assessment and Diagnostic Findings

An overnight dexamethasone suppression test is the most widely used and most sensitive screening test for diagnosis of pituitary and adrenal causes of Cushing's syndrome. It can be performed on an outpatient basis. Dexamethasone (1 mg) is administered orally at 11 PM, and a plasma cortisol level is obtained at 8 AM the next morning. Suppression of cortisol to less than 5 mg/dL indicates that the hypothalamic-pituitary-adrenal axis is functioning properly. Stress, obesity, depression, and medications such as antiseizure agents, estrogen (during pregnancy or as oral medications), and rifampin (Rifadin) can falsely elevate cortisol levels. Nighttime salivary cortisol levels show promise in screening for Cushing's syndrome (Gross, Mindea, Pick, et al., 2007).

Indicators of Cushing's syndrome include an increase in serum sodium and blood glucose levels and a decrease in serum potassium, a reduction in the number of blood eosinophils, and disappearance of lymphoid tissue. Measurements of plasma and urinary cortisol levels are obtained. Several blood samples may be collected to determine whether the normal diurnal variation in plasma levels is present; this variation is frequently absent in adrenal dysfunction. If several blood samples are required, they must be collected at the times specified, and the time of collection must be noted on the requisition slip. Other diagnostic studies include a 24-hour urinary free cortisol level and a low-dose dexamethasone suppression test. Low-dose suppression tests are similar to the overnight test but vary in dosage and timing.

Measurement of plasma ACTH by radioimmunoassay is used in conjunction with the high-dose suppression test to distinguish pituitary tumors from ectopic sites of ACTH production as the cause of Cushing's syndrome. Elevation of both ACTH and cortisol indicates pituitary or hypothalamic disease. A low ACTH with a high cortisol level indicates adrenal disease. CT, ultrasound, or MRI may be performed to localize adrenal tissue and detect tumors of the adrenal gland.

Medical Management

If Cushing's syndrome is caused by pituitary tumors rather than tumors of the adrenal cortex, treatment is directed at the pituitary gland. Surgical removal of the tumor by transsphenoidal hypophysectomy (see Chapter 61) is the

Chart 42-12 • Clinical Manifestations of Cushing's Syndrome

Ophthalmic	Skeletal

This woman with Cushing's syndrome has several classic signs, including facial hair, buffalo hump, and moon face. From Rubin, E. & Farber, J. L. (2005). *Pathology* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

treatment of choice and has an 80% success rate. Radiation of the pituitary gland also has been successful, although it may take several months for control of symptoms. Adrenalectomy is the treatment of choice in patients with primary adrenal hypertrophy.

Postoperatively, symptoms of adrenal insufficiency may begin to appear 12 to 48 hours after surgery because of reduction of the high levels of circulating adrenal hormones. Temporary replacement therapy with hydrocortisone may

be necessary for several months, until the adrenal glands begin to respond normally to the body's needs. If both adrenal glands have been removed (bilateral adrenalectomy), lifetime replacement of adrenal cortex hormones is necessary.

Adrenal enzyme inhibitors (eg, metyrapone [Metopirone], aminoglutethimide [Cytadren], mitotane [Lysodren], and ketoconazole [Nizoral]) may be used to reduce hyperadrenalism if the syndrome is caused by ectopic ACTH secretion by a tumor that cannot be eradicated. Close monitoring is necessary, because symptoms of inadequate adrenal function may result and side effects of the medications may occur.

If Cushing's syndrome is a result of the administration of corticosteroids, an attempt is made to reduce or taper the medication to the minimum dosage needed to treat the underlying disease process (eg, autoimmune or allergic disease, rejection of a transplanted organ). Frequently, alternate-day therapy decreases the symptoms of Cushing's syndrome and allows recovery of the adrenal glands' responsiveness to ACTH.

NURSING PROCESS

THE PATIENT WITH CUSHING'S SYNDROME

Assessment

The health history and examination focus on the effects on the body of high concentrations of adrenal cortex hormones and on the inability of the adrenal cortex to respond to changes in cortisol and aldosterone levels.

The history includes information about the patient's level of activity and ability to carry out routine and self-care activities. The skin is observed and assessed for trauma, infection, breakdown, bruising, and edema. Changes in physical appearance are noted, and the patient's responses to these changes are elicited. The nurse assesses the patient's mental function, including mood, responses to questions, awareness of environment, and level of depression. The family is often a good source of information about gradual changes in the patient's physical appearance as well as emotional status.

Diagnosis

Nursing Diagnoses

Based on all the assessment data, the major nursing diagnoses of the patient with Cushing's syndrome include the following:

- Risk for injury related to weakness
- Risk for infection related to altered protein metabolism and inflammatory response
- Self-care deficit related to weakness, fatigue, muscle wasting, and altered sleep patterns
- Impaired skin integrity related to edema, impaired healing, and thin and fragile skin
- Disturbed body image related to altered physical appearance, impaired sexual functioning, and decreased activity level
- Disturbed thought processes related to mood swings, irritability, and depression

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Addisonian crisis
- Adverse effects of adrenocortical activity

Planning and Goals

The major goals for the patient include decreased risk of injury, decreased risk of infection, increased ability to carry out self-care activities, improved skin integrity, improved body image, improved mental function, and absence of complications.

Nursing Interventions**Decreasing Risk of Injury**

Establishing a protective environment helps prevent falls, fractures, and other injuries to bones and soft tissues. The patient who is very weak may require assistance from the nurse in ambulating to avoid falling or bumping into sharp corners of furniture. Foods high in protein, calcium, and vitamin D are recommended to minimize muscle wasting and osteoporosis. Referral to a dietitian may assist the patient in selecting appropriate foods that are also low in sodium and calories.

Decreasing Risk of Infection

The patient should avoid unnecessary exposure to others with infections. The nurse frequently assesses the patient for subtle signs of infection, because the anti-inflammatory effects of corticosteroids may mask the common signs of inflammation and infection.

Preparing the Patient for Surgery

The patient is prepared for adrenalectomy, if indicated, and the postoperative course (see later discussion). If Cushing's syndrome is a result of a pituitary tumor, a transsphenoidal hypophysectomy may be performed (see Chapter 61). Diabetes mellitus and peptic ulcer are common in patients with Cushing's syndrome. Therefore, insulin therapy and medication to treat peptic ulcer are initiated if needed. Before, during, and after surgery, blood glucose monitoring and assessment of stools for blood are carried out to monitor for these complications. If the patient has other symptoms of Cushing's syndrome, these are considered in the preoperative preparation. For example, if the patient has experienced weight gain, special instruction is given about postoperative breathing exercises.

Encouraging Rest and Activity

Although the patient with Cushing's syndrome experiences insomnia, weakness, fatigue, and muscle wasting, the nurse should encourage moderate activity to prevent complications of immobility and promote increased self-esteem. It is important to help the patient plan and space rest periods throughout the day and promote a relaxing, quiet environment for rest and sleep.

Promoting Skin Integrity

Meticulous skin care is necessary to avoid traumatizing the patient's fragile skin. Use of adhesive tape is avoided, because it can irritate the skin and tear the fragile tissue when the

tape is removed. The nurse frequently assesses the skin and bony prominences and encourages and assists the patient to change positions frequently to prevent skin breakdown.

Improving Body Image

If treated successfully, the major physical changes associated with Cushing's syndrome disappear in time. The patient may benefit from discussion of the effect the changes have had on his or her self-concept and relationships with others. Weight gain and edema may be modified by a low-carbohydrate, low-sodium diet, and a high protein intake may reduce some of the other bothersome symptoms.

Improving Thought Processes

Explanations to the patient and family members about the cause of emotional instability are important in helping them cope with the mood swings, irritability, and depression that may occur. Psychotic behavior may occur in a few patients and should be reported. The nurse encourages the patient and family members to verbalize their feelings and concerns.

Monitoring and Managing Potential Complications

ADDISONIAN CRISIS. The patient with Cushing's syndrome whose symptoms are treated by withdrawal of corticosteroids, by adrenalectomy, or by removal of a pituitary tumor is at risk for adrenal hypofunction and Addisonian crisis. If high levels of circulating adrenal hormones have suppressed the function of the adrenal cortex, atrophy of the adrenal cortex is likely. If the circulating hormone level is decreased rapidly because of surgery or abrupt cessation of corticosteroid agents, manifestations of adrenal hypofunction and Addisonian crisis may develop. Therefore, the patient with Cushing's syndrome should be assessed for signs and symptoms of Addisonian crisis as previously discussed. If Addisonian crisis occurs, the patient is treated for circulatory collapse and shock (see Chapter 15).

ADVERSE EFFECTS OF ADRENOCORTICAL ACTIVITY. The nurse assesses fluid and electrolyte status by monitoring laboratory values and daily weights. Because of the increased risk of glucose intolerance and hyperglycemia, blood glucose monitoring is initiated. The nurse reports elevated blood glucose levels to the physician so that treatment can be prescribed if indicated.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient and family should be informed that acute adrenal insufficiency and underlying symptoms will recur if corticosteroid therapy is stopped abruptly without medical supervision. The patient should be instructed to always have an adequate supply of the corticosteroid medication to avoid running out (see Therapeutic Uses of Corticosteroids).

The nurse stresses the need for dietary modifications to ensure adequate calcium intake without increasing the risks for hypertension, hyperglycemia, and weight gain. The patient and family can be taught to monitor blood pressure, blood glucose levels, and weight. Patients should be advised to wear a medical alert bracelet and to notify other health care providers (eg, dentist) about their condition (Chart 42-13).

CHART
42-13

HOME CARE CHECKLIST

The Patient With Cushing's Syndrome

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State present and potential effects of Cushing's syndrome on the body.	✓	✓
• Identify signs and symptoms of excessive and insufficient adrenal hormone.	✓	✓
• State the relationship between adrenal hormones, emotional state, and stress.	✓	✓
• Identify methods for managing labile emotions.	✓	✓
• Describe protective skin care measures and use of protective devices and practices.	✓	✓
• State the importance of regular follow-up visits with primary health care provider.	✓	✓
• State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications (adrenocortical inhibitors).	✓	✓
• Identify need to wear medical alert identification and carry medical information card.	✓	✓
• State importance of compliance with medical regimen.	✓	✓
• State the need to contact health care provider before taking over-the-counter medications.	✓	✓
• Identify foods high in potassium and low in sodium, calories, and carbohydrates.	✓	✓
• Identify areas of activity limitations and impact on lifestyle.	✓	✓

CONTINUING CARE. The need for follow-up depends on the origin and duration of the disease and its management. The patient who has been treated by adrenalectomy or removal of a pituitary tumor requires close monitoring to ensure that adrenal function has returned to normal and to ensure adequacy of circulating adrenal hormones. The patient who requires continued corticosteroid therapy is monitored to ensure understanding of the medications and the need for a dosage that treats the underlying disorder while minimizing the side effects. Home care referral may be indicated to ensure a safe environment that minimizes stress and risk of falls and other side effects. The home care nurse assesses the patient's physical and psychological status and reports changes to the physician. The nurse also assesses the patient's understanding of the medication regimen and his or her compliance with the regimen and reinforces previous teaching about the medications and the importance of taking them as prescribed. The nurse emphasizes the importance of regular medical follow-up, the side effects and toxic effects of medications, and the need to wear medical identification with Addison's and Cushing's disease. In addition, the nurse reminds the patient and family about the importance of health promotion activities and recommended health screening, including bone mineral density testing.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Decreases risk of injury
 - a. Is free of fractures or soft tissue injuries
 - b. Is free of ecchymotic areas
2. Decreases risk of infection
 - a. Experiences no temperature elevation, redness, pain, or other signs of infection or inflammation
 - b. Avoids contact with others who have infections

3. Increases participation in self-care activities
 - a. Plans activities and exercises to allow alternating periods of rest and activity
 - b. Reports improved well-being
 - c. Is free of complications of immobility
4. Attains/maintains skin integrity
 - a. Has intact skin, without evidence of breakdown or infection
 - b. Exhibits decreased edema in extremities and trunk
 - c. Changes position frequently and inspects bony prominences daily
5. Achieves improved body image
 - a. Verbalizes feelings about changes in appearance, sexual function, and activity level
 - b. States that physical changes are a result of excessive corticosteroids
6. Exhibits improved mental functioning
7. Exhibits absence of complications
 - a. Exhibits normal vital signs and weight and is free of symptoms of Addisonian crisis
 - b. Identifies signs and symptoms of adrenocortical hypofunction that should be reported and measures to take in case of severe illness and stress
 - c. Identifies strategies to minimize complications of Cushing's syndrome
 - d. Complies with recommendations for follow-up appointments and health screening

PRIMARY ALDOSTERONISM

The principal action of aldosterone is to conserve body sodium. Under the influence of this hormone, the kidneys excrete less sodium and more potassium and hydrogen. Excessive production of aldosterone, which occurs in some patients with functioning tumors of the adrenal gland, causes a distinctive pattern of biochemical changes and a corresponding

set of clinical manifestations that are diagnostic of this condition.

Clinical Manifestations

Patients with aldosteronism exhibit a profound decline in the serum levels of potassium (hypokalemia) and hydrogen ions (alkalosis), as demonstrated by an increase in pH and serum bicarbonate concentration. The serum sodium level is normal or elevated, depending on the amount of water reabsorbed with the sodium. Hypertension is the most prominent and almost universal sign of aldosteronism and is present in up to 10% of individuals with hypertension (Mulatero, Dluhy, Giacchetti, et al., 2005).

Hypokalemia is responsible for the variable muscle weakness, cramping, and fatigue in patients with aldosteronism, as well as an inability on the part of the kidneys to acidify or concentrate the urine. Accordingly, the urine volume is excessive, leading to polyuria. Serum, by contrast, becomes abnormally concentrated, contributing to excessive thirst (polydipsia) and arterial hypertension. A secondary increase in blood volume and possible direct effects of aldosterone on nerve receptors, such as the carotid sinus, are other factors that result in hypertension.

Hypokalemic alkalosis may decrease the ionized serum calcium level and predispose the patient to tetany and paresthesias. Trousseau's and Chvostek's signs may be used to assess neuromuscular irritability before overt paresthesia and tetany occur. Glucose intolerance may occur, because hypokalemia interferes with insulin secretion from the pancreas.

Assessment and Diagnostic Findings

In addition to a high or normal serum sodium level and a low serum potassium level, diagnostic studies indicate high serum aldosterone and low serum renin levels. The measurement of the aldosterone excretion rate after salt loading is a useful diagnostic test for primary aldosteronism. The renin-aldosterone stimulation test and bilateral adrenal venous sampling are useful in differentiating the cause of primary aldosteronism. Antihypertensive medication may be discontinued up to 2 weeks before testing.

Medical Management

Treatment of primary aldosteronism usually involves surgical removal of the adrenal tumor through adrenalectomy. Hypokalemia resolves for all patients after surgery, but

hypertension may persist. Spironolactone (Aldactone) may be prescribed to control hypertension.

Adrenalectomy is performed through an incision in the flank or the abdomen. In general, the postoperative care resembles that for other abdominal surgery. However, the patient is susceptible to fluctuations in adrenocortical hormones and requires administration of corticosteroids, fluids, and other agents to maintain blood pressure and prevent acute complications. If the adrenalectomy is bilateral, replacement of corticosteroids will be lifelong; if one adrenal gland is removed, replacement therapy may be temporarily necessary because of suppression of the remaining adrenal gland by high levels of adrenal hormones. A normal serum glucose level is maintained with insulin, appropriate IV fluids, and dietary modifications.

Nursing Management

Nursing management in the postoperative period includes frequent assessment of vital signs to detect early signs and symptoms of adrenal insufficiency and crisis or hemorrhage. Explaining all treatments and procedures, providing comfort measures, and providing rest periods can reduce the patient's stress and anxiety level.

Corticosteroid Therapy

Corticosteroids are used extensively for adrenal insufficiency and are also widely used in suppressing inflammation and autoimmune reactions, controlling allergic reactions, and reducing the rejection process in transplantation. Commonly used corticosteroid preparations are listed in Table 42-5. Their anti-inflammatory and antiallergy actions make corticosteroids effective in treating rheumatic or connective tissue diseases, such as rheumatoid arthritis and systemic lupus erythematosus. They are also frequently used in the treatment of asthma, multiple sclerosis, and other autoimmune disorders.

High doses appear to allow patients to tolerate high degrees of stress. Such antistress action may be caused by the ability of corticosteroids to aid circulating vasopressor substances in keeping the blood pressure elevated; other effects, such as maintenance of the serum glucose level, also may keep blood pressure elevated.

Table 42-5 COMMONLY USED CORTICOSTEROID PREPARATIONS

Generic Names	Trade Names
Hydrocortisone	Cortisol, Cortef, Hydrocortone, Solu-Cortef
Cortisone	Cortone, Cortate, Cortogen
Dexamethasone	Decadron, Dexameth, Deronil, Delalone, Dexasone, Dexone, Hexadrol
Prednisone	Meticorten, Deltasone, Orasone, Panasol, Novo-prednisone
Prednisolone	Meticortelone, Delta-Cortef, Prelone, Predalone
Methylprednisolone	Medrol, Solu-Medrol, Meprolone
Triamcinolone	Aristocort, Kenacort, Kenalog, Cenocort, Azmacort, Aristospan
Beclomethasone	Beconase, Beclovent, Vanceril, Vancenase, Propaderm
Betamethasone	Celestone, Betameth, Betnesol, Betnelan

Side Effects

Although the synthetic corticosteroids are safer for some patients because of relative freedom from mineralocorticoid activity, most natural and synthetic corticosteroids produce similar kinds of side effects. The dose required for anti-inflammatory and antiallergy effects also produces metabolic effects, pituitary and adrenal gland suppression, and changes in the function of the central nervous system. Therefore, although corticosteroids are highly effective therapeutically, they may also be very dangerous. Dosages of these medications are frequently altered to allow high concentrations when necessary and then tapered in an attempt to avoid undesirable effects. This requires that patients be observed closely for side effects and that the dose be reduced when high doses are no longer required. Suppression of the adrenal cortex may persist up to 1 year after a course of corticosteroids of only 2 weeks' duration.

Therapeutic Uses of Corticosteroids

The dosage of corticosteroids is determined by the nature and chronicity of the illness as well as the patient's other medical conditions. Rheumatoid arthritis, bronchial asthma, and multiple sclerosis are chronic disorders that corticosteroids do not cure; however, these medications may be useful when other measures do not provide adequate control of symptoms. In addition, corticosteroids may be used to treat acute exacerbations of these disorders.

In such situations, the adverse effects of corticosteroids are weighed against the patient's current condition. These medications may be used for a period but then are gradually reduced or tapered as the symptoms subside. The nurse plays an important role in providing encouragement and understanding during times when the patient is experiencing (or is apprehensive about experiencing) recurrence of symptoms while taking smaller doses.

Treatment of Acute Conditions

Acute flare-ups and crises are treated with large doses of corticosteroids. Examples include emergency treatment for bronchial obstruction in status asthmaticus and for septic shock from septicemia caused by gram-negative bacteria. Other measures, such as anti-infective agents or medications, are also used with corticosteroids to treat shock and other major symptoms. At times, corticosteroids are continued past the acute flare-up stage to prevent serious complications.

Ophthalmologic Treatment

Outer eye infections can be treated by topical application of corticosteroid eye drops, because the agents do not cause systemic toxicity. However, long-term application can cause an increase in intraocular pressure, which leads to glaucoma in some patients. In addition, prolonged use of corticosteroids can sometimes lead to cataract formation.

Dermatologic Disorders

Topical administration of corticosteroids in the form of creams, ointments, lotions, and aerosols is especially effective in many dermatologic disorders. It may be more effective in some conditions to use occlusive dressings around the affected part to achieve maximum absorption of the medication. Penetration and absorption are also increased if the medication is applied when the skin is hydrated or moist (eg, immediately after bathing).

Absorption of topical agents varies with body location. For example, absorption is greater through the layers of skin on the scalp, face, and genital area than on the forearm; as a result, use of topical agents on these sites increases the risk of side effects. The availability of over-the-counter topical corticosteroids increases the risk of side effects in patients who are unaware of their potential risks. Excessive use of these agents, especially on large surface areas of inflamed skin, can lead to decreased therapeutic effects and increased side effects.

Dosage

Attempts have been made to determine the best time to administer pharmacologic doses of steroids. If symptoms have been controlled on a 6-hour or 8-hour program, a once-daily or every-other-day schedule may be implemented. In keeping with the natural secretion of cortisol, the best time of day for the total corticosteroid dose is in the early morning, between 7 AM and 8 AM. Large-dose therapy at 8 AM, when the adrenal gland is most active, produces maximal suppression of the gland. A large 8 AM dose is more physiologic because it allows the body to escape effects of the steroids from 4 PM to 6 AM, when serum levels are normally low, hence minimizing cushingoid effects. If symptoms of the disorder being treated are suppressed, alternate-day therapy is helpful in reducing pituitary-adrenal suppression in patients requiring prolonged therapy. Some patients report discomfort associated with symptoms of their primary illness on the second day; therefore, it is important to explain to patients that this regimen is necessary to minimize side effects and suppression of adrenal function.

Tapering

Corticosteroid dosages are reduced gradually (tapered) to allow normal adrenal function to return and to prevent steroid-induced adrenal insufficiency. Up to 1 year or longer after use of corticosteroids, the patient is still at risk for adrenal insufficiency in times of stress. For example, if surgery for any reason is necessary, the patient is likely to require IV corticosteroids during and after surgery to reduce the risk of acute adrenal crisis. Patients receiving corticosteroids must have an adequate supply of medication on hand, so that they do not miss a scheduled dose and increase their risk of adrenal insufficiency. Table 42-6 provides an overview of the effects of corticosteroid therapy and their nursing implications.

Table 42-6

SIDE EFFECTS OF CORTICOSTEROID THERAPY AND IMPLICATIONS FOR NURSING PRACTICE

Side Effects	Collaborative Interventions
Cardiovascular Effects Hypertension Thrombophlebitis Thromboembolism Accelerated atherosclerosis	Monitor for elevated blood pressure. Assess for signs and symptoms of deep venous thrombosis: redness, warmth, tenderness, and edema of an extremity. Remind patient to avoid positions and situations that restrict blood flow (eg, crossing legs, prolonged sitting in same position). Encourage foot and leg exercises when recumbent. Encourage low sodium intake. Encourage limited intake of fat.
Immunologic Effects Increased risk of infection and masking of signs of infection	Assess for subtle signs of infection and inflammation. Encourage patient to avoid exposure to others with upper respiratory infection. Monitor patient for fungal infections. Encourage hand washing.
Ophthalmologic Changes Glaucoma Corneal lesions	Encourage frequent eye examinations. Refer patient to ophthalmologist if changes in visual acuity are detected.
Musculoskeletal Effects Muscle wasting Poor wound healing Osteoporosis with vertebral compression fractures, pathologic fractures of long bones, aseptic necrosis of head of the femur	Encourage high protein intake. Encourage high protein intake and vitamin C supplementation. Encourage diet high in calcium and vitamin D or calcium and vitamin D supplementation if indicated. Take measures to avoid falls and other trauma. Use caution in moving and turning patient. Encourage postmenopausal women on corticosteroids to consider bone mineral density testing and treatment, if indicated. Instruct patient to rise slowly from bed or chair to avoid falling due to postural hypotension.
Metabolic Effects Alterations in glucose metabolism Steroid withdrawal syndrome	Monitor blood glucose levels at periodic intervals. Instruct patient about medications, diet, and exercise prescribed to control blood glucose level. Report signs of adrenal insufficiency. Administer corticosteroids and mineralocorticoids as prescribed. Monitor fluid and electrolyte balance. Administer fluids and electrolytes as prescribed. Instruct patient about importance of taking corticosteroids as prescribed without abruptly stopping therapy. Encourage patient to obtain and wear a medical identification bracelet. Advise patient to notify all health care providers (eg, dentist) about need for corticosteroid therapy.
Changes in Appearance Moon face Weight gain Acne	Encourage low-calorie, low-sodium diet. Assure patient that most changes in appearance are temporary and will disappear if and when corticosteroid therapy is no longer necessary.

CRITICAL THINKING EXERCISES

1 A 72-year-old man has been diagnosed with hyperparathyroidism. He is scheduled for a minimally invasive parathyroidectomy in 1 week. How would you explain this disorder to the patient? Describe what he and his family can expect postoperatively. Describe the nursing role preoperatively and postoperatively. Discuss the importance of nutrition and activity as related to this disorder.

2 A 40-year-old woman is seen in the emergency department for severe nausea, vomiting, tachycardia, and agitation. Her eyes appear to bulge. She is diagnosed with severe hyperthyroidism and thyroid storm. What factors could have precipitated her condition? What is the significance of the bulging eyes? What nursing precautions should be taken? How would you explain this condition to the patient, and what information would you provide

to the family to assist them in understanding her symptoms? What diagnostic tests are likely to be performed? Describe the treatment for this condition.

EBP 3 A 50-year-old woman of Japanese descent is undergoing testing for thyroid disease because of symptoms of hyperthyroidism. Her physician has suggested that she receive treatment with radioactive iodine (RAI). Information the patient found on the Internet has convinced her that RAI is not safe or necessary to treat her disorder. Her grandparents lived in Nagasaki during World War II, and she recalls stories of horrible effects of the radiation on her grandfather and other relatives. Only her grandmother survived the atomic blast.

If untreated, the patient's condition can lead to serious complications. How would you address this patient's concerns and assist her in making an informed decision about treatment? What sources of information would you

use, and how would you evaluate the available evidence about the effectiveness and possible adverse effects of RAI?

4 A 50-year-old woman is recovering from acute adrenal insufficiency. Corticosteroid therapy has been prescribed, and she will be required to take it for the rest of her life. What instructions should you provide regarding precautions to take related to corticosteroid therapy? How can the patient and family prevent a reoccurrence of this disorder?

5 A 24-year-old man is scheduled for diagnostic testing for possible pheochromocytoma. Identify the major signs and symptoms of pheochromocytoma and their cause. If pheochromocytoma is diagnosed and the patient is scheduled for an adrenalectomy, what preoperative and postoperative nursing care would you anticipate? What teaching, if any, would you provide to the patient's family?

RESOURCES

Urinary Tract Function

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Involuntary Urine Loss During Physical Exertion and Ineffective Bladder Emptying

Mrs. Lopez is a 38-year-old woman with no significant past medical history. She has three children. During her annual physical examination, she tells the women's health nurse practitioner that when she jogs, coughs, or sneezes, she experiences an involuntary loss of small amounts of urine. The patient's urinalysis is normal. On physical examination, the nurse finds that Mrs. Lopez has a moderate cystocele and that her bladder feels mildly distended, although she had just voided to provide a urine sample. The nurse catheterizes Mrs. Lopez to check for postvoid residual urine and obtains 120 mL of clear urine.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
STRESS URINARY INCONTINENCE — Loss of less than 50 mL of urine occurring with increased abdominal pressure	PELVIC MUSCLE EXERCISES — Strengthening and training the levator ani and urogenital muscles through voluntary, repetitive contraction to decrease stress, urge, or mixed types of urinary incontinence	SYMPTOM CONTROL —Personal actions to minimize perceived changes in physical and emotional functioning
URINARY RETENTION —Incomplete emptying of the bladder	URINARY BLADDER TRAINING — Improving bladder function for those with urge incontinence by increasing the bladder's ability to hold urine and the patient's ability to suppress urination	URINARY CONTINENCE —Control of elimination of urine from the bladder
RISK FOR INFECTION —At increased risk for being invaded by pathogenic organisms	URINARY CATHETERIZATION: INTERMITTENT —Regular periodic use of a catheter to empty the bladder INFECTION PROTECTION — Prevention and early detection of infection in a patient at risk	INFECTION SEVERITY —Severity of infection and associated symptoms

chapter 43

Assessment of Renal and Urinary Tract Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the anatomy and physiology of the renal and urinary systems.
- 2 Discuss the role of the kidneys in regulating fluid and electrolyte balance, acid–base balance, and blood pressure.
- 3 Describe the diagnostic studies used to determine upper and lower urinary tract function.
- 4 Identify the assessment parameters used for determining the status of upper and lower urinary tract function.
- 5 Initiate education and preparation for patients undergoing assessment of the urinary system.

GLOSSARY

- aldosterone:** hormone synthesized and released by the adrenal cortex; causes the kidneys to reabsorb sodium
- antidiuretic hormone:** hormone secreted by the posterior pituitary gland; causes the kidneys to reabsorb more water; also called vasopressin
- anuria:** total urine output less than 50 mL in 24 hours
- bacteriuria:** bacteria in the urine; bacterial count higher than 100,000 colonies/mL
- creatinine:** endogenous waste product of muscle energy metabolism
- diuresis:** increased formation and secretion of urine
- dysuria:** painful or difficult urination
- frequency:** voiding more frequently than every 3 hours
- glomerular filtration:** plasma filtered at the glomerulus into the kidney tubules
- glomerulus:** tuft of capillaries forming part of the nephron through which filtration occurs
- hematuria:** red blood cells in the urine
- micturition:** urination or voiding
- nephron:** structural and functional unit of the kidney responsible for urine formation
- nocturia:** awakening at night to urinate
- oliguria:** total urine output less than 500 mL in 24 hours
- proteinuria:** protein in the urine
- pyuria:** white blood cells in the urine
- renal clearance:** volume of plasma that the kidneys can clear of a specific solute (eg, creatinine); expressed in milliliters per minute
- renal glycosuria:** recurring or persistent excretion of glucose in the urine
- specific gravity:** reflects the weight of particles dissolved in the urine; expression of the degree of concentration of the urine
- tubular reabsorption:** movement of a substance from the kidney tubule into the blood in the peritubular capillaries or vasa recta
- tubular secretion:** movement of a substance from the blood in the peritubular capillaries or vasa recta into the kidney tubule
- urea nitrogen:** nitrogenous end product of protein metabolism

Chart 43-1 • Functions of the Kidney

- Urine formation
- Excretion of waste products
- Regulation of electrolytes
- Regulation of acid–base balance
- Control of water balance
- Control of blood pressure
- Renal clearance
- Regulation of red blood cell production
- Synthesis of vitamin D to active form
- Secretion of prostaglandins
- Regulates calcium and phosphorus balance

Function of the renal and urinary systems is essential to life. The primary purpose of the renal and urinary systems is to maintain the body's state of homeostasis by carefully regulating fluid and electrolytes, removing wastes, and providing other functions (Chart 43-1). Dysfunction of the kidneys and lower urinary tract is common and may occur at any age and with varying degrees of severity. Assessment of upper and lower urinary tract function is part of every health examination and necessitates an understanding of the anatomy and physiology of the urinary system as well as the effects of changes in the system on other physiologic functions.

Anatomic and Physiologic Overview**Anatomy of the Renal and Urinary Tract Systems**

The renal and urinary systems include the kidneys, ureters, bladder, and urethra. Urine is formed by the kidney and flows through the other structures to be eliminated from the body.

Kidneys

The kidneys are a pair of bean-shaped, brownish-red structures located retroperitoneally (behind and outside the peritoneal cavity) on the posterior wall of the abdomen—from the 12th thoracic vertebra to the third lumbar vertebra in the adult (Fig. 43-1A). The average adult kidney weighs approximately 113 to 170 g (about 4.5 oz) and is 10 to 12 cm long, 6 cm wide, and 2.5 cm thick (Porth & Matfin, 2009). The right kidney is slightly lower than the left due to the location of the liver.

Externally, the kidneys are well protected by the ribs and by the muscles of the abdomen and back. Internally, fat deposits surround each kidney, providing protection against jarring. The kidneys and surrounding fat are suspended from the abdominal wall by renal fascia made of connective tissue. The fibrous connective tissue, blood vessels, and lymphatics surrounding each kidney are known as the renal capsule. An adrenal gland lies on top of each kidney. The kidneys and adrenals are independent in function, blood supply, and innervation.

The renal parenchyma is divided into two parts: the cortex and the medulla (Fig. 43-1B). The medulla, which is approximately 5 cm wide, is the inner portion of the kidney. It contains the loops of Henle, the vasa recta, and the collecting ducts of the juxtamedullary nephrons. The collecting ducts from both the juxtamedullary and the cortical nephrons connect to the renal pyramids, which are triangular and are situated with the base facing the concave surface of the kidney and the point (papilla) facing the hilum, or pelvis. Each kidney contains approximately 8 to 18 pyramids. The pyramids drain into minor calices, which drain into major calices that open directly into the renal pelvis. The renal pelvis is the beginning of the collecting system and is composed of structures that are designed to collect and transport urine. Once the urine leaves the renal pelvis, the composition or amount of urine does not change.

The cortex, which is approximately 1 cm wide, is located farthest from the center of the kidney and around the

Figure 43-1 A, Kidneys, ureters, and bladder. B, Internal structure of the kidney. Redrawn from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health status* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

outermost edges. It contains the **nephrons** (the functional units of the kidney), which are discussed below.

Blood Supply to the Kidneys

The hilum is the concave portion of the kidney through which the renal artery enters and the ureters and renal vein exit. The kidneys receive 20% to 25% of the total cardiac output, which means that all of the body's blood circulates through the kidneys approximately 12 times per hour. The renal artery (arising from the abdominal aorta) divides into smaller and smaller vessels, eventually forming the afferent arterioles. Each afferent arteriole branches to form a **glomerulus**, which is the capillary bed responsible for glomerular filtration. Blood leaves the glomerulus through the efferent arteriole and flows back to the inferior vena cava through a network of capillaries and veins.

Nephrons

Each kidney has 1 million nephrons that are located within the renal parenchyma and are responsible for the initial formation of urine. The large number of nephrons allows for adequate renal function even if the opposite kidney is damaged or becomes nonfunctional. If the total number of functioning nephrons is less than 20% of normal, renal replacement therapy needs to be considered.

There are two types of nephrons. The cortical nephrons, which make up 80% to 85% of the total number, are located in the outermost part of the cortex, and the juxtamedullary nephrons, which make up the remaining 15% to 20%, are located deeper in the cortex. The juxtamedullary nephrons are distinguished by long loops of Henle and are surrounded by long capillary loops called vasa recta that dip into the medulla of the kidney. The length of the tubular component of the nephron is directly related to its ability to concentrate urine.

Nephrons are made up of two basic components: a filtering element composed of an enclosed capillary network (the glomerulus) and the attached tubule (Fig. 43-2). The glomerulus is a unique network of capillaries suspended between the afferent and efferent blood vessels, which are enclosed in an epithelial structure called Bowman's capsule. The glomerular membrane is composed of three filtering layers: the capillary endothelium, the basement membrane, and the epithelium. This membrane normally allows filtration of fluid and small molecules yet limits passage of larger molecules, such as blood cells and albumin. Pressure changes and the permeability of the glomerular membrane of Bowman's capsule facilitate the passage of fluids and various substances from the blood vessels, filling the space within Bowman's capsule with this filtered solution.

The tubular component of the nephron begins in the Bowman's capsule. The filtrate created in the Bowman's capsule travels first into the proximal tubule, then the loop of Henle, the distal tubule, and either the cortical or medullary collecting ducts. The structural arrangement of the tubule allows the distal tubule to lie in close proximity to where the afferent and efferent arteriole respectively enter and leave the glomerulus. The distal tubular cells located in this area, known as the macula densa, function with the adjacent afferent arteriole and create what is known as the juxtaglomerular apparatus. This is the site of

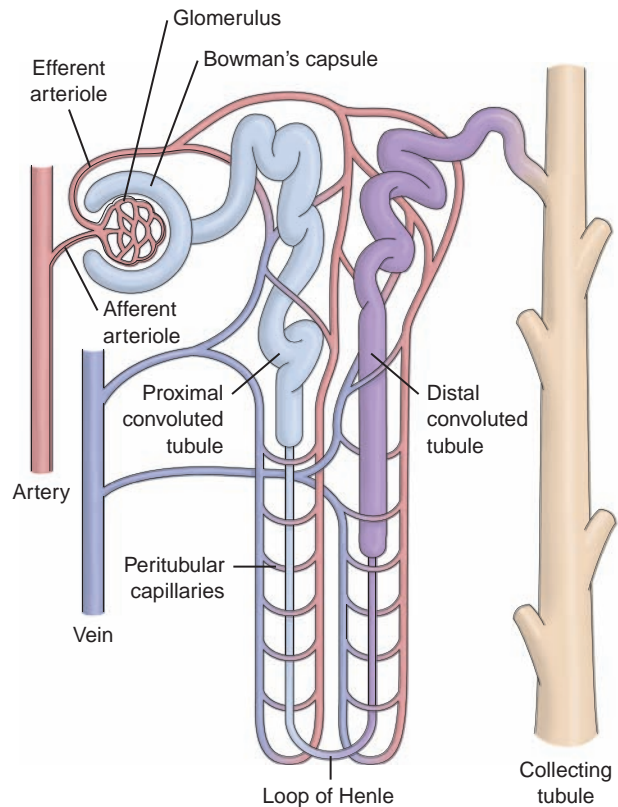

Figure 43-2 Representation of a nephron. Each kidney has about 1 million nephrons of two types: cortical and juxtamedullary. Cortical nephrons are located in the cortex of the kidney; juxtamedullary nephrons are adjacent to the medulla.

renin production. Renin is a hormone directly involved in the control of arterial blood pressure; it is essential for proper functioning of the glomerulus (see later discussion).

The tubular component consists of the Bowman's capsule, the proximal tubule, the descending and ascending limbs of the loop of Henle, and the cortical and medullary collecting ducts. This portion of the nephron is responsible for making adjustments in the filtrate based on the body's needs. Changes are continually made as the filtrate travels through the tubules until it enters the collecting system and is expelled from the body (see Fig. 43-2).

Ureters, Bladder, and Urethra

The urine formed in the nephrons flows into the renal pelvis and then into the ureters, which are long fibromuscular tubes that connect each kidney to the bladder. These narrow tubes, each 24 to 30 cm long, originate at the lower portion of the renal pelvis and terminate in the trigone of the bladder wall.

The left ureter is slightly shorter than the right ureter. The lining of the ureters is made up of transitional cell epithelium called urothelium. The urothelium prevents reabsorption of urine. The movement of urine from each renal pelvis through the ureter into the bladder is facilitated by peristaltic contraction of the smooth muscles in the ureter wall. There are three narrowed areas of each ureter: the ureteropelvic junction, the ureteral segment near the sacroiliac junction,

and the ureterovesical junction. These three areas of the ureters have a propensity for obstruction by renal calculi (kidney stones) or stricture. Obstruction of the ureteropelvic junction is the most serious because of its close proximity to the kidney and the risk of associated kidney dysfunction.

The urinary bladder is a muscular, hollow sac located just behind the pubic bone. The capacity of the adult bladder is 400 to 500 mL (Bickley, 2007). The bladder is characterized by its central, hollow area, called the vesicle, which has two inlets (the ureters) and one outlet (the urethra). The area surrounding the bladder neck is called the urethrovesical junction. The angling of the ureterovesical junction is the primary means of providing antegrade, or downward, movement of urine, also referred to as efflux of urine. This angling prevents vesicoureteral reflux (retrograde, or backward, movement of urine) from the bladder, up the ureter, toward the kidney.

The wall of the bladder contains four layers. The outermost layer is the adventitia, which is made up of connective tissue. Immediately beneath the adventitia is a smooth muscle layer known as the detrusor. Beneath the detrusor is a submucosal layer of loose connective tissue that serves as an interface between the detrusor and the innermost layer, a mucosal lining. The inner layer contains specialized transitional cell epithelium, a membrane that is impermeable to water and prevents reabsorption of urine stored in the bladder. The bladder neck contains bundles of involuntary smooth muscle that form a portion of the urethral sphincter known as the internal sphincter. An important portion of the sphincteric mechanism that helps maintain continence is the external urinary sphincter at the anterior urethra, the segment most distal from the bladder (Porth & Matfin, 2009). During voiding (**micturition**), increased intravesical pressure keeps the ureterovesical junction closed and keeps urine within the ureters. As soon as micturition is completed, intravesical pressure returns to its normal low baseline value, allowing efflux of urine to resume. Therefore, the only time that the bladder is completely empty is in the last seconds of micturition, before efflux of urine resumes.

The urethra arises from the base of the bladder: In the male, it passes through the penis; in the female, it opens just anterior to the vagina. In the male, the prostate gland, which lies just below the bladder neck, surrounds the urethra posteriorly and laterally.

Function of the Renal and Urinary Tract Systems

Urine Formation

The healthy human body is composed of approximately 60% water. Water balance is regulated by the kidneys and results in the formation of urine. Urine is formed in the nephrons through a complex three-step process: **glomerular filtration**, **tubular reabsorption**, and **tubular secretion** (Fig. 43-3). The various substances normally filtered by the glomerulus, reabsorbed by the tubules, and excreted in the urine include sodium, chloride, bicarbonate, potassium, glucose, urea, creatinine, and uric acid. Within the tubule, some of these substances are selectively reabsorbed into the blood. Others are secreted from the blood into the filtrate as it travels down the tubule.

Physiology Pathophysiology

Figure 43-3 Urine is formed in the nephrons in a three-step process: filtration, reabsorption, and excretion. Water, electrolytes, and other substances, such as glucose and creatinine, are filtered by the glomerulus; varying amounts of these substances are reabsorbed in the renal tubule or excreted in the urine. Approximate normal volumes of these substances during the steps of urine formation are shown at the top. Wide variations may occur in these values depending on diet.

Amino acids and glucose are usually filtered at the level of the glomerulus and reabsorbed so that neither is excreted in the urine. Normally, glucose does not appear in the urine. However, **renal glycosuria** (recurring or persistent excretion of glucose in the urine) occurs if the amount of glucose in the blood and glomerular filtrate exceeds the amount that the tubules are able to reabsorb. Renal glycosuria occurs in diabetes, the most common condition that causes the blood glucose level to exceed the kidney's reabsorption capacity. Renal glycosuria is also common in pregnancy.

Protein molecules also are not usually found in the urine; however, low-molecular-weight proteins (globulins and albumin) may periodically be excreted in small amounts. Protein in the urine is referred to as **proteinuria**.

Glomerular Filtration

The normal blood flow through the kidneys is about 1200 mL/min. As blood flows into the glomerulus from an afferent arteriole, filtration occurs. The filtered fluid, also known as filtrate or ultrafiltrate, then enters the renal tubules. Under normal conditions, about 20% of the blood passing through the glomeruli is filtered into the nephron, amounting to about 180 L/day of filtrate. The filtrate normally consists of water, electrolytes, and other small molecules, because water and small molecules are allowed to pass, whereas larger molecules stay in the bloodstream. Efficient filtration depends on adequate blood flow that maintains a consistent pressure through the glomerulus. Many factors can alter this blood flow and pressure, including hypotension, decreased oncotic pressure in the blood, and increased pressure in the renal tubules from an obstruction.

Tubular Reabsorption and Tubular Secretion

The second and third steps of urine formation occur in the renal tubules. In tubular reabsorption, a substance moves from the filtrate back into the peritubular capillaries or vasa recta. In tubular secretion, a substance moves from the peritubular capillaries or vasa recta into tubular filtrate. Of the 180 L (45 gallons) of filtrate that the kidneys produce each day, 99% is reabsorbed into the bloodstream, resulting in the formation of 1 L to 2 L of urine each day. Although most reabsorption occurs in the proximal tubule, reabsorption occurs along the entire tubule. Reabsorption and secretion in the tubule frequently involve passive and active transport and may require the use of energy. Filtrate becomes concentrated in the distal tubule and collecting ducts under hormonal influence and becomes urine, which then enters the renal pelvis.

Antidiuretic Hormone

Antidiuretic hormone (ADH), also known as vasopressin, is a hormone that is secreted by the posterior portion of the pituitary gland in response to changes in osmolality of the blood. With decreased water intake, blood osmolality tends to increase, stimulating ADH release. ADH then acts on the kidney, increasing reabsorption of water and thereby returning the osmolality of the blood to normal. With excess water intake, the secretion of ADH by the pituitary is suppressed; therefore, less water is reabsorbed by the kidney tubule. This latter situation leads to increased urine volume (**diuresis**).

A dilute urine with a fixed specific gravity (about 1.010) or fixed osmolality (about 300 mOsm/L) indicates an inability to concentrate and dilute the urine, a common early sign of kidney disease.

Osmolarity and Osmolality

Osmolarity refers to the ratio of solute to water. The regulation of salt and water is paramount for control of the extracellular volume and both serum and urine osmolality. Controlling either the amount of water or the amount of solute can change osmolality. Osmolarity and ionic composition are maintained by the body within very narrow limits. As little as a 1% to 2% change in the serum osmolality can cause a conscious desire to drink and conservation of water by the kidneys (Goertz, 2006).

The degree of dilution or concentration of the urine is also measured in terms of osmolality, the number of osmoles (the standard unit of osmotic pressure) dissolved per kilogram of solution. The filtrate in the glomerular capillary normally has the same osmolality as the blood, 280 to 300 mOsm/kg. Serum and urine osmolality and osmolarity are discussed in more detail in Chapter 14.

Regulation of Water Excretion

Regulation of the amount of water excreted is an important function of the kidney. With high fluid intake, a large volume of dilute urine is excreted. Conversely, with a low fluid intake, a small volume of concentrated urine is excreted. A person normally ingests about 1300 mL of oral liquids and 1000 mL of water in food per day. Of the fluid ingested, approximately 900 mL is lost through the skin and lungs (called insensible loss), 50 mL through sweat, and 200 mL

through feces. It is important to consider all fluid gained and lost when evaluating total fluid status. Daily weight measurements are a reliable means of determining overall fluid status. One pound equals approximately 500 mL, so a weight change of as little as 1 lb could suggest an overall fluid gain or loss of 500 mL.

Regulation of Electrolyte Excretion

When the kidneys are functioning normally, the volume of electrolytes excreted per day is equal to the amount ingested. For example, the average American daily diet contains 6 to 8 g each of sodium chloride (salt) and potassium chloride, and approximately the same amounts are excreted in the urine.

The regulation of sodium volume excreted depends on **aldosterone**, a hormone synthesized and released from the adrenal cortex. With increased aldosterone in the blood, less sodium is excreted in the urine, because aldosterone fosters renal reabsorption of sodium. Release of aldosterone from the adrenal cortex is largely under the control of angiotensin II. Angiotensin II levels are in turn controlled by renin, an enzyme that is released from specialized cells in the kidneys (Fig. 43-4). This complex system is activated when pressure in the renal arterioles falls below normal levels, as occurs with shock, dehydration, or decreased sodium chloride delivery to the tubules. Activation of this system increases the retention of water and expansion of the intravascular fluid volume, thereby maintaining enough pressure within the glomerulus to ensure adequate filtration.

The regulation of serum sodium and potassium are discussed in detail in Chapter 14.

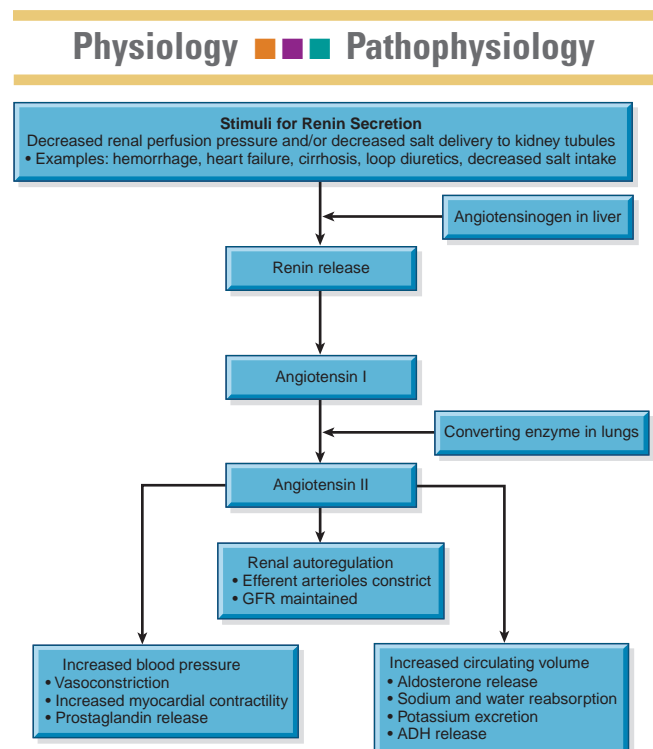

Figure 43-4 The renin–angiotensin system. ADH, antidiuretic hormone; GFR, glomerular filtration rate.

Regulation of Acid–Base Balance

The normal serum pH is about 7.35 to 7.45 and must be maintained within this narrow range for optimal physiologic function. The kidney performs two major functions to assist in this balance. The first is to reabsorb and return to the body's circulation any bicarbonate from the urinary filtrate; the second is to excrete acid in the urine. Because bicarbonate is a small ion, it is freely filtered at the glomerulus. The renal tubules actively reabsorb most of the bicarbonate in the urinary filtrate. To replace any lost bicarbonate, the renal tubular cells generate new bicarbonate through a variety of chemical reactions. This newly generated bicarbonate is then reabsorbed by the tubules and returned to the body.

The body's acid production is the result of catabolism, or breakdown, of proteins, which produces acid compounds, in particular phosphoric and sulfuric acids. The normal daily diet also includes a certain amount of acid materials. Unlike carbon dioxide (CO₂), phosphoric and sulfuric acids cannot be eliminated by the lungs. Because accumulation of these acids in the blood lowers pH (making the blood more acidic) and inhibits cell function, they must be excreted in the urine. A person with normal kidney function excretes about 70 mEq of acid each day. The kidney is able to excrete some of this acid directly into the urine until the urine pH reaches 4.5, which is 1000 times more acidic than blood.

However, more acid usually needs to be eliminated from the body than can be secreted directly as free acid in the urine. These excess acids are bound to chemical buffers so that they can be excreted in the urine. Two important chemical buffers are phosphate ions and ammonia (NH₃). When buffered with acid, ammonia becomes ammonium (NH₄⁺). Phosphate is present in the glomerular filtrate, and ammonia is produced by the cells of the renal tubules and secreted into the tubular fluid. Through the buffering process, the kidney is able to excrete large quantities of acid in a bound form, without further lowering the pH of the urine.

Autoregulation of Blood Pressure

Regulation of blood pressure is an important function of the kidney. Specialized vessels of the kidney, called the vasa recta, constantly monitor blood pressure as blood begins its passage into the kidney. When the vasa recta detect a decrease in blood pressure, specialized juxtaglomerular cells called *macula densa* cells, near the afferent arteriole, distal tubule, and efferent arteriole secrete the hormone renin. Renin converts angiotensinogen to angiotensin I, which is then converted to angiotensin II, the most powerful vasoconstrictor known; angiotensin II causes the blood pressure to increase (Goshorn, 2005). The adrenal cortex secretes aldosterone in response to stimulation by the pituitary gland, which occurs in response to poor perfusion or increasing serum osmolality. The result is an increase in blood pressure. When the vasa recta recognize the increase in blood pressure, renin secretion stops. Failure of this feedback mechanism is one of the primary causes of hypertension (see Fig. 43-4).

Renal Clearance

Renal clearance refers to the ability of the kidneys to clear solutes from the plasma. A 24-hour collection of urine is the primary test of renal clearance used to evaluate how well

the kidney performs this important excretory function. Renal clearance depends on several factors: how quickly the substance is filtered across the glomerulus, how much of the substance is reabsorbed along the tubules, and how much of the substance is secreted into the tubules. It is possible to measure the renal clearance of any substance, but the one measure that is particularly useful is the creatinine clearance.

Creatinine is an endogenous waste product of skeletal muscle that is filtered at the glomerulus, passed through the tubules with minimal change, and excreted in the urine. Hence, creatinine clearance is a good measure of the glomerular filtration rate (GFR). To calculate creatinine clearance, a 24-hour urine specimen is collected. Midway through the collection, the serum creatinine level is measured. The following formula is then used to calculate the creatinine clearance:

$$\frac{(\text{Volume of urine [mL/min]} \times \text{urine creatinine [mL/dL]})}{\text{Serum creatinine (mg/dL)}}$$

The adult GFR can vary from a normal of approximately 125 mL/min (1.67 to 2.0 mL/sec) to a high of 200 mL/min (Porth & Matfin, 2009). Creatinine clearance is an excellent measure of renal function; as renal function declines, creatinine clearance decreases.

Regulation of Red Blood Cell Production

When the kidneys detect a decrease in the oxygen tension in renal blood flow, they release erythropoietin. Erythropoietin is a glycoprotein from the kidney that stimulates the bone marrow to produce red blood cells (RBCs) that carry oxygen throughout the body.

Vitamin D Synthesis

The kidneys are also responsible for the final conversion of inactive vitamin D to its active form, 1,25-dihydroxycholecalciferol. Vitamin D is necessary for maintaining normal calcium balance in the body.

Secretion of Prostaglandins

The kidneys also produce prostaglandin E and prostacyclin, which have a vasodilatory effect and are important in maintaining renal blood flow.

Excretion of Waste Products

The kidneys eliminate the body's metabolic waste products. The major waste product of protein metabolism is urea, of which about 25 to 30 g are produced and excreted daily. All of this urea must be excreted in the urine; otherwise, it accumulates in body tissues. Other waste products of metabolism that must be excreted are creatinine, phosphates, and sulfates. Uric acid, formed as a waste product of purine metabolism, is also eliminated in the urine. The kidneys serve as the primary mechanism for excreting drug metabolites.

Urine Storage

The bladder is the reservoir for urine. Both filling and emptying of the bladder are mediated by coordinated sympathetic and parasympathetic nervous system control mechanisms involving the detrusor muscle and the bladder outlet.

Conscious awareness of bladder filling occurs as a result of sympathetic neuronal pathways that travel via the spinal cord to the level of T10 through T12, where peripheral, hypogastric nerve innervation allows for continued bladder filling. As bladder filling continues, stretch receptors in the bladder wall are activated, coupled with the desire to void. This information from the detrusor muscle is relayed back to the cerebral cortex via the parasympathetic pelvic nerves at the level of S1 through S4 (Porth & Matfin, 2009). Overall bladder pressure remains low due to the bladder's compliance (ability to expand or collapse) as urine volume changes.

Bladder compliance is due in part to the smooth muscle lining of the bladder and collagen deposits within the wall of the bladder, as well as to neuronal mechanisms that inhibit the detrusor muscle from contracting (specifically, adrenergic receptors that mediate relaxation). To maintain adequate kidney filtration rates, bladder pressure during filling must remain lower than 40 cm H₂O. This low pressure allows the urine to freely leave the renal pelvis and enter the ureters. The sensation of bladder fullness is transmitted to the central nervous system when the bladder has reached about 150 to 200 mL in adults, and an initial desire to void occurs. A marked sense of fullness and discomfort with a strong desire to void usually occurs when the bladder reaches its functional capacity 300 mL to 500 mL of urine (Bickley, 2007). Neurologic changes to the bladder at the level of the supraspinal nerves, the spinal nerves, or the bladder wall itself can cause abnormally high volumes (up to 2000 mL) of urine to be stored due to a decreased or absent urge to void.

Under normal circumstances with average fluid intake of approximately 1 to 2 L/day, the bladder should be able to store urine for periods of 2 to 4 hours at a time during the day. At night, the release of vasopressin in response to decreased fluid intake causes a decrease in the production of urine and makes it more concentrated. This phenomenon usually allows the bladder to continue filling for periods of 6 to 8 hours in adolescents and adults, making them able to sleep for longer periods before needing to void. In older people, decreasing bladder compliance and decreased vasopressin levels often cause **nocturia** (the need to wake up during the night to urinate).

Bladder Emptying

Micturition (voiding) normally occurs approximately eight times in a 24-hour period. It is activated via the micturition reflex arc within the sympathetic and parasympathetic nervous systems, which causes a coordinated sequence of events. Initiation of voiding occurs when the efferent pelvic nerve, which originates in the S1 to S4 area, stimulates the bladder to contract, resulting in complete relaxation of the striated urethral sphincter. This is followed by a decrease in urethral pressure, contraction of the detrusor muscle, opening of the vesicle neck and proximal urethra, and flow of urine. This coordinated effort by the parasympathetic system is mediated by muscarinic and, to a lesser extent, cholinergic receptors within the detrusor muscle. The pressure generated in the bladder during micturition is about 20 to 40 cm H₂O in females. It is somewhat higher and more variable in males 45 years of age and older due to the normal hyperplasia of the cells of the middle lobes of the

prostate gland, which surround the proximal urethra. Any obstruction of the bladder outlet, such as in advanced benign prostatic hyperplasia (BPH), results in a high voiding pressure. High voiding pressures make it more difficult to start urine flow and maintain it.

If the spinal pathways from the brain to the urinary system are destroyed (eg, after a spinal cord injury), reflex contraction of the bladder is maintained, but voluntary control over the process is lost. In both situations, the detrusor muscle can contract and expel urine, but the contractions are generally insufficient to empty the bladder completely, so residual urine (urine left in the bladder after voiding) remains. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult.

Gerontologic Considerations

Upper and lower urinary tract function changes with age (Stanley, Blair & Beare, 2005). The GFR decreases, starting between 35 and 40 years of age, and a yearly decline of about 1 mL/min continues thereafter. The elderly are more susceptible to acute and chronic renal failure due to the structural and functional changes in the kidney. Examples include sclerosis of the glomerulus and renal vasculature, decreased blood flow, decreased GFR, altered tubular function, and acid–base imbalance. Although renal function usually remains adequate, renal reserve is decreased and may reduce the kidneys' ability to respond effectively to drastic or sudden physiologic changes. This steady decrease in glomerular filtration, combined with the use of multiple medications in which metabolites are cleared by the kidneys, puts the older person at higher risk for adverse drug effects and drug–drug interactions (Stanley, et al., 2005).

The elderly are more prone to develop hypernatremia and fluid volume deficit, because increasing age is also associated with diminished osmotic stimulation of thirst (Stanley, et al., 2005). Thirst is defined as one's awareness of the desire to drink. The sense of thirst is so protective that hypernatremia almost never occurs in adults younger than 60 years of age.

Structural or functional abnormalities that occur with aging may also prevent complete emptying of the bladder. This may be due to decreased bladder wall contractility; secondary to myogenic or neurogenic factors; or related to bladder outlet obstruction, such as in BPH or after prostatectomy (Ostaszkiwicz, 2007). Vaginal and urethral tissues atrophy (become thinner) in aging women due to decreased estrogen levels. This causes decreased blood supply to the urogenital tissues, resulting in urethral and vaginal irritation and urinary incontinence.

Urinary incontinence is the most common reason for admission to skilled nursing facilities. Many older people and their families are unaware that urinary incontinence stems from many causes. The nurse needs to inform the patient and family that, with appropriate evaluation, urinary incontinence can often be managed at home, and in many cases it can be eliminated. Many treatments are available for urinary incontinence in the elderly, including noninvasive, behavioral interventions that the patient or caregiver can carry out (Palmer & Newman, 2007). Treatment

modalities for urinary incontinence are described in further detail in Chapter 45.

Preparation of the elderly patient for diagnostic tests must be managed carefully to prevent dehydration, which might precipitate renal failure in a patient with marginal renal function. Limitations in mobility may affect an elderly patient's ability to void adequately or to consume an adequate volume of fluids. The patient may limit fluid intake to minimize the frequency of voiding or the risk of incontinence. Teaching the patient and family about the dangers of an inadequate fluid intake is an important role of the nurse caring for the elderly incontinent patient.

Assessment of the Renal and Urinary Tract Systems

Health History

Obtaining a urologic health history requires excellent communication skills, because many patients are embarrassed or uncomfortable discussing genitourinary function or symptoms (Bickley, 2007; Weber & Kelley, 2007). It is important to use language the patient can understand and to avoid medical jargon. It is also important to review risk factors, particularly for those patients who are at high risk. For example, the nurse needs to be aware that multiparous women delivering their children vaginally have a high risk for stress urinary incontinence, which, if severe enough, can also lead to urge incontinence. Elderly women and people with neurologic disorders such as diabetic neuropathy, multiple sclerosis (MS), or Parkinson's disease often have incomplete emptying of the bladder and urinary stasis, which may result in urinary tract infection or increasing bladder pressure, leading to overflow incontinence, hydronephrosis, pyelonephritis, or chronic kidney disease (Burrrows-Hudson, 2005). Risk factors for specific disorders and kidney and lower urinary tract dysfunction are summarized in Table 43-1 and discussed in Chapters 44 and 45.

When obtaining the health history, the nurse should inquire about the following:

- The patient's chief concern or reason for seeking health care, the onset of the problem, and its effect on the patient's quality of life
- The location, character, and duration of pain, if present, and its relationship to voiding; factors that precipitate pain, and those that relieve it
- History of urinary tract infections, including past treatment or hospitalization for urinary tract infection
- Fever or chills
- Previous renal or urinary diagnostic tests or use of indwelling urinary catheters
- **Dysuria** and when during voiding (ie, at initiation or at termination of voiding) it occurs
- Hesitancy, straining, or pain during or after urination
- Urinary incontinence (stress incontinence, urge incontinence, overflow incontinence, or functional incontinence)
- Hematuria or change in color or volume of urine
- Nocturia and its date of onset
- Renal calculi (kidney stones), passage of stones or gravel in urine

Table 43-1 RISK FACTORS FOR SELECTED RENAL OR UROLOGIC DISORDERS

Risk Factor	Possible Renal or Urologic Disorder
Childhood diseases: "strep throat" impetigo, nephrotic syndrome	Chronic kidney disease
Advanced age	Incomplete emptying of bladder, leading to urinary tract infection
Instrumentation of urinary tract, cystoscopy, catheterization	Urinary tract infection, incontinence
Immobilization	Kidney stone formation
Occupational, recreational, or environmental exposure to chemicals (plastics, pitch, tar, rubber)	Acute renal failure
Diabetes mellitus	Chronic kidney disease, neurogenic bladder
Hypertension	Renal insufficiency, chronic renal failure
Multiple sclerosis	Incontinence, neurogenic bladder
Parkinson's disease	Incontinence
Systemic lupus erythematosus	Nephritis, chronic kidney disease
Gout, hyperparathyroidism, Crohn's disease, ileostomy	Kidney stone formation
Sickle cell anemia, multiple myeloma	Chronic kidney disease
Benign prostatic hyperplasia	Obstruction to urine flow, leading to frequency, oliguria, anuria
Radiation therapy to pelvis	Cystitis, fibrosis of ureter, or fistula in urinary tract
Recent pelvic surgery	Inadvertent trauma to ureters or bladder
Pregnancy	Proteinuria, frequent voiding
Obstetric injury, tumors	Incontinence
Spinal cord injury	Neurogenic bladder, urinary tract infection, incontinence

- Female patients: number and type (vaginal or cesarean) of deliveries; use of forceps; vaginal infection, discharge, or irritation; contraceptive practices
- History of **anuria** (decreased urine production) or other renal problem
- Presence or history of genital lesions or sexually transmitted diseases
- Use of tobacco, alcohol, or recreational drugs
- Any prescription and over-the-counter medications (including those prescribed for renal or urinary problems)

Common Symptoms

Dysfunction of the kidney can produce a complex array of symptoms throughout the body. Pain, changes in voiding, and gastrointestinal symptoms are particularly suggestive of urinary tract disease.

Pain

Genitourinary pain is usually caused by distention of some portion of the urinary tract as a result of obstructed urine flow or inflammation and swelling of tissues. Severity of pain is related to the sudden onset rather than the extent of distention.

Table 43-2 lists the various types of genitourinary pain, characteristics of the pain, associated signs and symptoms,

Table 43-2 IDENTIFYING CHARACTERISTICS OF GENITOURINARY PAIN

Type	Location	Character	Associated Signs and Symptoms	Possible Etiology
Kidney	Costovertebral angle, may extend to umbilicus	Dull constant ache; if sudden distention of capsule, pain is severe, sharp, stabbing, and colicky in nature	Nausea and vomiting, diaphoresis, pallor, signs of shock	Acute obstruction, kidney stone, blood clot, acute pyelonephritis, trauma
Bladder	Suprapubic area	Dull, continuous pain, may be intense with voiding, may be severe if bladder full	Urgency, pain at end of voiding, painful straining	Overdistended bladder, infection, interstitial cystitis; tumor
Ureteral	Costovertebral angle, flank, lower abdominal area, testis, or labium	Severe, sharp, stabbing pain, colicky in nature	Nausea and vomiting, paralytic ileus	Ureteral stone, edema or stricture, blood clot
Prostatic	Perineum and rectum	Vague discomfort, feeling of fullness in perineum, vague back pain	Suprapubic tenderness, obstruction to urine flow; frequency, urgency, dysuria, nocturia	Prostatic cancer, acute or chronic prostatitis
Urethral	Male: along penis to meatus; female: urethra to meatus	Pain variable, most severe during and immediately after voiding	Frequency, urgency, dysuria, nocturia, urethral discharge	Irritation of bladder neck, infection of urethra, trauma, foreign body in lower urinary tract

and possible causes. However, kidney disease does not always involve pain. It tends to be diagnosed because of other symptoms that cause a patient to seek health care, such as pedal edema, shortness of breath, and changes in urine elimination (Stanley, et al., 2005).

Changes in Voiding

Micturition is normally a painless function that occurs approximately eight times in a 24-hour period. The average person voids 1 to 2 L of urine in 24 hours, although this amount

varies depending on fluid intake, sweating, environmental temperature, vomiting, or diarrhea. Common problems associated with voiding include **frequency**, urgency, dysuria, hesitancy, incontinence, enuresis, polyuria, **oliguria**, and hematuria. These problems and others are described in Table 43-3. Increased urinary urgency and frequency coupled with decreasing urine volumes strongly suggest urine retention. Depending on the acuity of the onset of these symptoms, immediate bladder emptying via catheterization and evaluation may be necessary to prevent kidney dysfunction.

Table 43-3 PROBLEMS ASSOCIATED WITH CHANGES IN VOIDING

Problem	Definition	Possible Etiology
Frequency	Frequent voiding—more than every 3 h	Infection, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretics, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy
Urgency	Strong desire to void	Infection, chronic prostatitis, urethritis, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretics, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy
Dysuria	Painful or difficult voiding	Lower urinary tract infection, inflammation of bladder or urethra, acute prostatitis, stones, foreign bodies, tumors in bladder
Hesitancy	Delay, difficulty in initiating voiding	Benign prostatic hyperplasia, compression of urethra, outlet obstruction, neurogenic bladder
Nocturia	Excessive urination at night	Decreased renal concentrating ability, heart failure, diabetes mellitus, incomplete bladder emptying, excessive fluid intake at bedtime, nephrotic syndrome, cirrhosis with ascites
Incontinence	Involuntary loss of urine	External urinary sphincter injury, obstetric injury, lesions of bladder neck, detrusor dysfunction, infection, neurogenic bladder, medications, neurologic abnormalities
Enuresis	Involuntary voiding during sleep	Delay in functional maturation of central nervous system (bladder control usually achieved by 5 y of age), obstructive disease of lower urinary tract, genetic factors, failure to concentrate urine, urinary tract infection, psychological stress
Polyuria	Increased volume of urine voided	Diabetes mellitus, diabetes insipidus, use of diuretics, excess fluid intake, lithium toxicity, some forms of kidney disease (hypercalcemic and hypokalemic nephropathy)
Oliguria	Urine output less than 500 mL/day	Acute or chronic renal failure (see Chapter 44), inadequate fluid intake
Anuria	Urine output less than 50 mL/day	Acute or chronic renal failure (see Chapter 44), complete obstruction
Hematuria	Red blood cells in the urine	Cancer of genitourinary tract, acute glomerulonephritis, renal stones, renal tuberculosis, blood dyscrasia, trauma, extreme exercise, rheumatic fever, hemophilia, leukemia, sickle cell trait or disease
Proteinuria	Abnormal amounts of protein in the urine	Acute and chronic renal disease, nephrotic syndrome, vigorous exercise, heat stroke, severe heart failure, diabetic nephropathy, multiple myeloma

Gastrointestinal Symptoms

Gastrointestinal signs and symptoms are often associated with urologic conditions because of shared autonomic and sensory innervation and reointestinal reflexes (see Table 43-3). The proximity of the right kidney to the colon, duodenum, head of the pancreas, common bile duct, liver, and gallbladder may cause gastrointestinal disturbances. The proximity of the left kidney to the colon (splenic flexure), stomach, pancreas, and spleen may also result in intestinal symptoms. The most common signs and symptoms are nausea, vomiting, diarrhea, abdominal discomfort, and abdominal distention. Urologic symptoms can mimic such disorders as appendicitis, peptic ulcer disease, and cholecystitis; this can make diagnosis difficult, especially in the elderly, who have decreased neurologic innervation to this area (Goshorn, 2005).

Unexplained Anemia

Gradual kidney dysfunction can be insidious in its presentation, although fatigue is a common symptom. Fatigue, shortness of breath, and exercise intolerance all result from the condition known as “anemia of chronic disease.” Although historically hematocrit has been the blood test of choice when assessing a patient for anemia, use of the hemoglobin level rather than hematocrit is currently recommended, because that measurement is a better assessment of the oxygen transport ability of the blood.

Past Health, Family, and Social History

Data collection about previous health problems or diseases provides the health care team with useful information for evaluating the patient’s current urinary status. People with diabetes who have consistent hypertension and those with primary hypertension are at risk for renal dysfunction. Older men are at risk for prostatic enlargement, which causes urethral obstruction and can result in urinary tract infections and renal failure. People with a family history of urinary tract problems are at increased risk for renal disorders. Genetics may also influence renal conditions (Chart 43-2).

It is also important to assess the patient’s psychosocial status, level of anxiety, perceived threats to body image, available support systems, and sociocultural patterns.

Physical Assessment

Several body systems can affect upper and lower urinary tract dysfunction, and conversely that dysfunction can affect several end organs; therefore, a head-to-toe assessment is indicated. Areas of emphasis include the abdomen, suprapubic region, genitalia, lower back, and lower extremities.

The kidneys are not usually palpable. However, palpation of the kidneys may detect an enlargement that could prove to be very important (Bickley, 2007). The correct technique for palpation is illustrated in Figure 43-5. It

GENETICS IN NURSING PRACTICE Renal and Urinary Tract Disorders

Various conditions that affect the renal system and urinary tract function are influenced by genetic factors. Some examples of these genetic disorders are:

- Alport syndrome
- Congenital absence of the vas deferens (caused by *CFTR* gene mutation for cystic fibrosis)
- Cystic, dysplastic kidneys
- Fabry disease
- Familial Wilms’ tumor
- Focal and segmental glomerulosis
- Horseshoe kidney
- Polycystic kidney (autosomal dominant gene)
- Nephrosis of later onset
- Renal cystic disease in tuberous sclerosis complex

Nursing Assessments

Family History

- Inquire about other family members with renal and/or urinary tract malformations.
- Ask about family history of kidney disease with onset in third to fifth decade (polycystic kidney, autosomal dominant gene).
- Identify family history of male infertility and cystic fibrosis (congenital absence of vas deferens).
- Be alert for family members with history of early-onset renal (Wilms’ tumor) or other cancers.

Physical Assessment

- Be alert for signs and symptoms of renal disease at an early age (hematuria, hypertension, abdominal mass).

- Assess for clinical findings suggesting that renal disease is a component of a genetic syndrome (eg, seizures, mental retardation, skin involvement).

Management Issues Specific to Genetics

- Inquire whether DNA mutation or other genetic testing has been performed on an affected family member.
- If indicated, refer for genetic counseling and evaluation so that the family can discuss concerns regarding inheritance, risks to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetics information and resources (eg, Genetic Alliance Web site).
- Provide support to families newly diagnosed with gene-related renal and/or kidney disease.

Figure 43-5 Technique for palpating the right kidney (*top*). Place one hand under the patient's back with the fingers under the lower rib. Place the palm of the other hand anterior to the kidney with fingers above the umbilicus. Push the hand on top forward as the patient inhales deeply. The left kidney (*bottom*) is palpated similarly by reaching over to the patient's left side and placing the right hand beneath the patient's lower left rib. From Weber, J. & Kelley, J. (2007). *Health assessment in nursing* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.

may be possible to palpate the smooth, rounded lower pole of the kidney between the hands. The right kidney is easier to detect, because it is somewhat lower than the left one. In obese patients, palpation of the kidneys is more difficult.

Renal dysfunction may produce tenderness over the costovertebral angle, which is the angle formed by the lower border of the 12th, or bottom, rib and the spine (Fig. 43-6). The abdomen (just slightly to the right and left of the midline in both upper quadrants) is auscultated to assess for bruits (low-pitched murmurs that indicate renal artery stenosis or an aortic aneurysm). The abdomen is also assessed for the presence of ascites (accumulation of fluid in the peritoneal cavity), which may occur with kidney as well as liver dysfunction.

To check for residual urine, the bladder should be percussed after the patient voids. Percussion of the bladder begins at the midline just above the umbilicus and proceeds downward. The sound changes from tympanic to dull when percussing over the bladder. The bladder, which can be palpated only if it is moderately distended, feels like a smooth,

Figure 43-6 Location of the costovertebral angle.

firm, round mass rising out of the abdomen, usually at midline (Fig. 43-7). Dullness to percussion of the bladder after voiding indicates incomplete bladder emptying (Bickley, 2007; Weber & Kelley, 2007).

In older men, BPH or prostatitis can cause difficulty with urination (Stanley, et al., 2005). Because the signs and symptoms of prostate cancer can mimic those of

Figure 43-7 Palpation of the bladder.

BPH, the prostate gland is palpated by digital rectal examination (DRE) as part of the yearly physical examination in men 40 years of age and older (see Chapter 49). In addition, a blood specimen is obtained to test the prostate-specific antigen (PSA) level annually; the results of the DRE and PSA are then correlated. Blood is drawn for PSA before the DRE, because manipulation of the prostate can cause the PSA level to increase temporarily. The inguinal area is examined for enlarged nodes, an inguinal or femoral hernia, and varicocele (varicose veins of the spermatic cord).

In women, the vulva, urethral meatus, and vagina are examined (Bickley, 2007; Weber & Kelley, 2007). The urethra is palpated for diverticula, and the vagina is assessed for adequate estrogen effect and any of five types of herniation. Urethrocele is the bulging of the anterior vaginal wall into the urethra. Cystocele is the herniation of the bladder wall into the vaginal vault. Pelvic prolapse is bulging of the cervix into the vaginal vault. Enterocoele is herniation of the bowel into the posterior vaginal wall. Rectocele is herniation of the rectum into the vaginal wall. These prolapses are graded depending on the degree of herniation (see Chapter 47 for more information).

The woman is asked to cough and perform a Valsalva maneuver to assess the urethra's system of muscular and ligament support. If urine leakage occurs, the index and middle fingers of the examiner's gloved hand are used to support either side of the urethra as the woman is asked to repeat the Valsalva maneuver; this is called the Marshall-Boney maneuver. If this produces urinary leakage, referral is suggested.

The patient is assessed for edema and changes in body weight. Edema may be observed, particularly in the face and dependent parts of the body, such as the ankles and sacral areas, and suggests fluid retention. An increase in body weight commonly accompanies edema. A 1-kg weight gain equals approximately 1000 mL of fluid (1 lb is approximately 500 mL).

The deep tendon reflexes of the knee are examined for quality and symmetry. This is an important part of testing for neurologic causes of bladder dysfunction, because the sacral area, which innervates the lower extremities, is the same peripheral nerve area responsible for urinary continence. The gait pattern of the person with bladder dysfunction is also noted, as well as the patient's ability to walk toe-to-heel. These tests evaluate possible supraspinal causes for urinary incontinence.

Diagnostic Evaluation

A comprehensive health history is used to determine the appropriate laboratory and diagnostic tests. The following sections review some of the tests that might be used.

Most patients undergoing urologic testing or imaging studies are apprehensive, even those who have had these tests in the past. Patients frequently feel discomfort and embarrassment about such a private and personal function as voiding. Voiding in the presence of others can frequently

cause guarding, a natural reflex that inhibits voiding due to situational anxiety. Because the outcomes of these studies determine the plan of care, the nurse must help the patient relax by providing as much privacy and explanation about the procedure as possible (Chart 43-3). In addition, Chart 43-4 provides a plan of care for patients undergoing diagnostic testing.

Urinalysis and Urine Culture

The urinalysis provides important clinical information about kidney function and helps diagnose other diseases, such as diabetes. The urine culture determines whether bacteria are present in the urine, as well as their strains and concentration. Urine culture and sensitivity also identify the antimicrobial therapy that is best suited for the particular strains identified, taking into consideration the antibiotics that have the best rate of resolution in that particular geographic region. Appropriate evaluation of any abnormality can assist in detecting serious underlying diseases.

Components

Urine examination includes the following:

- Urine color (Table 43-4)
- Urine clarity and odor
- Urine pH and specific gravity
- Tests to detect protein, glucose, and ketone bodies in the urine (proteinuria, renal glycosuria, and ketonuria, respectively)
- Microscopic examination of the urine sediment after centrifugation to detect RBCs (**hematuria**), white blood cells (**pyuria**), casts (cylindruria), crystals (crystalluria), and bacteria (**bacteriuria**)

Researchers are working on additional noninvasive tests that can be performed on urine to detect conditions such as bladder cancer. For example, urine telomerase activity levels have been found to be sensitive and specific to detect bladder cancer in men (Sanchini, Gunelli, Nanni, et al., 2005). More research is needed before these tests are acceptable for routine use in patients.

Significance of Findings

Several abnormalities, such as hematuria and proteinuria, produce no symptoms but may be detected during a routine urinalysis using a dipstick. Normally, about 1 million RBCs pass into the urine daily, which is equivalent to one to three RBCs per high-power field. Hematuria (more than three RBCs per high-power field) can develop from an abnormality anywhere along the genitourinary tract and is more common in women than in men. Common causes include acute infection (cystitis, urethritis, or prostatitis), renal calculi, and neoplasm. Other causes include systemic disorders, such as bleeding disorders; malignant lesions; and medications, such as warfarin (Coumadin) and heparin (Heparin Sodium). Although hematuria may initially be detected using a dipstick test, further microscopic evaluation is necessary (Tierney & Henderson, 2005).

Proteinuria may be a benign finding, or it may signify serious disease (Burrows-Hudson, 2005). Occasional loss of

CHART
43-3

PATIENT EDUCATION

Before and After Urodynamic Testing

- A physician or nurse will conduct an in-depth interview. Questions related to your urologic symptoms and voiding habits will be asked.
- You will be asked to describe sensations felt during the procedure.
- During the procedure, you might be asked to change positions (eg, from supine to sitting or standing).
- You may be asked to cough or perform the Valsalva maneuver (bear down) during the procedure.
- You will probably need to have one or two urethral catheters inserted so that bladder pressure and bladder filling can be measured. Another catheter may be placed in the rectum or vagina to measure abdominal pressure.
- You may also have electrodes (surface, wire, or needle) placed in the perianal area for electromyography (EMG). This may be uncomfortable initially during insertion and later during position changes.
- Your bladder will be filled through the urethral catheter one or more times during the procedure.
- After the procedure, you may experience urinary frequency, urgency, or dysuria from the urethral catheters. Avoid caffeinated, carbonated, and alcoholic beverages after the procedure because these can further irritate the bladder. These symptoms usually decrease or subside by the day after the procedure.
- You might notice a slight hematuria (blood-tinged urine) right after the procedure (especially in men with benign prostatic hyperplasia). Drinking fluids will help to clear the hematuria.
- If the urinary meatus is irritated, a warm sitz bath may be helpful.
- Be alert for signs of a urinary tract infection after the procedure. Contact your physician if you experience fever, chills, lower back pain, or continued dysuria and hematuria.
- If you receive an antibiotic medication before the procedure, you should continue taking the complete course of medication after the procedure. This is a measure to prevent infection.

up to 150 mg/day of protein in the urine, primarily albumin and Tamm-Horsfall protein (also known as uromodulin), is considered normal and usually does not require further evaluation. A dipstick examination, which can detect from 30 to 1000 mg/dL of protein, should be used as a screening test only, because urine concentration, pH, hematuria, and radiocontrast materials all affect the results. Because dipstick analysis does not detect protein concentrations of less than 30 mg/dL, the test cannot be used for early detection of diabetic nephropathy. Microalbuminuria (excretion of 20 to 200 mg/dL of protein in the urine) is an early sign of diabetic nephropathy. Common benign causes of transient proteinuria are fever, strenuous exercise, and prolonged standing.

Causes of persistent proteinuria include glomerular diseases, malignancies, collagen diseases, diabetes mellitus, preeclampsia, hypothyroidism, heart failure, exposure to heavy metals, and use of medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors (Karch, 2008).

Specific Gravity

Specific gravity measures the density of a solution compared to the density of water, which is 1.000. Specific gravity is altered by the presence of blood, protein, and casts in the urine. The normal range of urine specific gravity is 1.010 to 1.025.

Methods for determination of specific gravity include the following:

- Multiple-test dipstick (most common method), with a specific reagent area for specific gravity
- Urinometer (least accurate method), in which urine is placed in a small cylinder and the urinometer is floated in the urine; a specific gravity reading is obtained at the meniscus level of the urine

- Refractometer, an instrument used in a laboratory setting, which measures differences in the speed of light passing through air and the urine sample

Urine specific gravity depends largely on hydration status. When fluid intake decreases, specific gravity normally increases. With high fluid intake, specific gravity decreases. In patients with kidney disease, urine specific gravity does not vary with fluid intake, and the patient's urine is said to have a fixed specific gravity. Disorders or conditions that cause decreased urine specific gravity include diabetes insipidus, glomerulonephritis, and severe renal damage. Those that can cause increased specific gravity include diabetes mellitus, nephritis, and fluid deficit.

Osmolality

Osmolality is the most accurate measurement of the kidney's ability to dilute and concentrate urine. It measures the number of solute particles in a kilogram of water. Serum and urine osmolality are measured simultaneously to assess the body's fluid status. In healthy adults serum osmolality is 280 to 300 mOsm/kg, and normal urine osmolality is 200 to 800 mOsm/kg (Goertz, 2006). For a 24-hour urine sample, the normal value is 300 to 900 mOsm/kg.

Renal Function Tests

Renal function tests are used to evaluate the severity of kidney disease and to assess the status of the patient's kidney function. These tests also provide information about the effectiveness of the kidney in carrying out its excretory function. Renal function test results may be within normal limits until the GFR is reduced to less than 50% of normal. Renal function can be assessed most accurately if several tests are performed and their results are analyzed together. Common tests of renal function include renal concentration tests, creatinine clearance, and

CHART
43-4

PLAN OF NURSING CARE

*Care of the Patient Undergoing Diagnostic Testing of the Renal–Urologic System***NURSING DIAGNOSIS:** Deficient knowledge about procedures and diagnostic tests**GOAL:** Patient demonstrates increased understanding of the procedure and tests and expected behaviors

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess patient's level of understanding of planned diagnostic tests. 2. Provide a description of tests in language the patient can understand. 3. Assess patient's understanding of test results after their completion. 4. Reinforce information provided to patient about test results and implications for follow-up care. 	<ol style="list-style-type: none"> 1. Provides basis for teaching and gives indication of patient's perception of tests 2. Understanding what is expected enhances patient compliance and cooperation. 3. Apprehension may interfere with patient's ability to understand information and results provided by health care team. 4. Provides opportunity for patient to clarify information and anticipate follow-up care. 	<ul style="list-style-type: none"> • States rationale for planned diagnostic tests and what tasks and behaviors are expected during the procedure • Complies with urine collection, fluid modifications, or other procedures required for diagnostic evaluation • Restates in own words results of diagnostic tests • Asks for clarification of terms and procedures • Explains rationale for follow-up care • Participates in follow-up care

NURSING DIAGNOSIS: Acute pain related to infection, edema, obstruction, or bleeding along urinary tract or related to invasive diagnostic tests**GOAL:** Patient reports decrease in pain and absence of discomfort

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess level of pain: dysuria, burning on urination, abdominal or flank pain, bladder spasm. 2. Encourage fluid intake (unless contraindicated). 3. Encourage warm sitz baths. 4. Report increased pain to physician. 5. Administer analgesic and antispasmodic agents for pain and spasm as prescribed. 6. Assess voiding patterns and hygiene practices and provide instructions about recommended voiding patterns and hygienic practices. 	<ol style="list-style-type: none"> 1. Provides baseline for evaluation of pain relief strategies and progression of dysfunction 2. Promotes dilute urine and flushing of the lower urinary tract 3. Relieves local discomfort and promotes relaxation 4. May indicate progression or untoward signs (eg, bleeding, calculi) 5. Prescribed to relieve pain or spasm 6. Delayed emptying of the bladder and poor hygiene may contribute to pain secondary to renal or urinary tract dysfunction. 	<ul style="list-style-type: none"> • Reports decreasing levels of pain • Reports absence of local symptoms • States ability to start and stop urinary stream without discomfort • Consumes increased fluid intake if indicated • Uses sitz bath as indicated • Identifies signs and symptoms to be reported to the health care provider • Takes medications as prescribed • Does not delay in emptying bladder • Uses appropriate hygienic measures, avoids use of bubble bath, uses appropriate hygiene after bowel movements

NURSING DIAGNOSIS: Fear related to potential alteration in renal function and embarrassment secondary to discussion of urinary function and invasion of genitalia**GOAL:** Patient appears relaxed and reports decreased fear and anxiety

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess patient's level of fear and apprehension. 2. Explain all procedures and tests to patient. 3. Provide privacy and respect patient's modesty by closing doors and keeping patient covered. Keep urinal and bedpan covered and out of sight. 4. Use correct terminology in a factual manner when questioning patient about urinary tract dysfunction. 5. Assess patient's fears about perceived changes associated with tests and other procedures. 6. Instruct patient in relaxation techniques. 	<ol style="list-style-type: none"> 1. A high level of fear or apprehension can interfere with learning and cooperation. 2. Knowledge about what is expected helps reduce fear and apprehension. 3. Communicates that you are aware of and accept patient's need for privacy and modesty 4. Conveys that you are comfortable discussing patient's urinary dysfunction and symptoms with patient 5. May uncover fears and misconceptions of the patient that can be alleviated by correct understanding 6. Promotes relaxation and assists patient in coping with uncertainty about outcomes 	<ul style="list-style-type: none"> • Appears relaxed with a low level of fear or apprehension • States rationale for tests and procedures in a calm, relaxed manner • Maintains usual privacy and modesty • Discusses own urinary tract dysfunction using correct terminology without overt indications of embarrassment or discomfort • Relates fears and concerns • Demonstrates correct understanding of procedures and possible outcomes • Appears relaxed with low level of fear and apprehension

Urine Color	Possible Cause
Colorless to pale yellow	Dilute urine due to diuretics, alcohol consumption, diabetes insipidus, glycosuria, excess fluid intake, renal disease
Yellow to milky white	Pyuria, infection, vaginal cream
Bright yellow	Multiple vitamin preparations
Pink to red	Hemoglobin breakdown, red blood cells, gross blood, menses, bladder or prostate surgery, beets, blackberries, medications (phenytoin, [Dilantin], rifampin [Rifadin], phenothiazine [Mellaril], cascara [Sagrada], senna products)
Blue, blue green	Dyes, methylene blue, <i>Pseudomonas</i> species organisms, medications (amitriptyline [Amitriptyline HCL], triamterine [Dyrenium])
Orange to amber	Concentrated urine due to dehydration, fever, bile, excess bilirubin or carotene, medications (pyridium [Phenazopyridium HCL], nitrofurantoin [Furadantin])
Brown to black	Old red blood cells, urobilinogen, bilirubin, melanin, porphyrin, extremely concentrated urine due to dehydration, medications (cascara, metronidazole [Flagyl], iron preparations, quinine [Quinine Sulfate], senna products, methyl dopa [Aldomet], nitrofurantoin)

serum creatinine and blood **urea nitrogen** levels. Table 43-5 describes the purpose and gives the normal range for each test. Other tests for evaluating renal function that may be helpful include serum electrolyte levels (see Chapter 14).

Diagnostic Imaging

Kidney, Ureter, and Bladder Studies

An x-ray study of the abdomen or kidneys, ureters, and bladder (KUB) may be performed to delineate the size, shape, and position of the kidneys and to reveal urinary system abnormalities (Labus, 2008).

General Ultrasonography

Ultrasonography is a noninvasive procedure that uses sound waves passed into the body through a transducer to detect abnormalities of internal tissues and organs. Abnormalities such as fluid accumulation, masses, congenital malformations, changes in organ size, and obstructions can be identified. During the test, the lower abdomen and genitalia may need to be exposed. Ultrasonography requires a full bladder; therefore, fluid intake should be encouraged before the procedure. Because of its sensitivity, ultrasonography has replaced many other tests as the initial diagnostic procedure (Burrows-Hudson, 2005).

Bladder Ultrasonography

Bladder ultrasonography is a noninvasive method of measuring urine volume in the bladder. It may be indicated for urinary frequency, inability to void after removal of an indwelling urinary catheter, measurement of postvoiding residual urine volume, inability to void postoperatively, or assessment of the need for catheterization during the initial stages of an intermittent catheterization training program. Portable, battery-operated devices are available for bedside use. The scan head is placed on the patient's abdomen and

Test	Purpose	Normal Values																					
Renal Concentration Tests																							
Specific gravity	Evaluates ability of kidneys to concentrate solutes in urine.	1.010–1.025																					
Urine osmolality	Concentrating ability is lost early in kidney disease; hence, these test findings may disclose early defects in renal function.	300–900 mOsm/kg/24 h, 50–1200 mOsm/kg random sample																					
24-Hour Urine Test																							
Creatinine clearance	Detects and evaluates progression of renal disease. Test measures volume of blood cleared of endogenous creatinine in 1 min, which provides an approximation of the glomerular filtration rate. Sensitive indicator of renal disease used to follow progression of renal disease.	Measured in mL/min/1.73 m ² <table border="1"> <thead> <tr> <th>Age</th> <th>Male</th> <th>Female</th> </tr> </thead> <tbody> <tr> <td>Under 30</td> <td>88–146</td> <td>81–134</td> </tr> <tr> <td>30–40</td> <td>82–140</td> <td>75–128</td> </tr> <tr> <td>40–50</td> <td>75–133</td> <td>69–122</td> </tr> <tr> <td>50–60</td> <td>68–126</td> <td>64–116</td> </tr> <tr> <td>60–70</td> <td>61–120</td> <td>58–110</td> </tr> <tr> <td>70–80</td> <td>55–113</td> <td>52–105</td> </tr> </tbody> </table>	Age	Male	Female	Under 30	88–146	81–134	30–40	82–140	75–128	40–50	75–133	69–122	50–60	68–126	64–116	60–70	61–120	58–110	70–80	55–113	52–105
Age	Male	Female																					
Under 30	88–146	81–134																					
30–40	82–140	75–128																					
40–50	75–133	69–122																					
50–60	68–126	64–116																					
60–70	61–120	58–110																					
70–80	55–113	52–105																					
Serum Tests																							
Creatinine level	Measures effectiveness of renal function. Creatinine is end product of muscle energy metabolism. In normal function, level of creatinine, which is regulated and excreted by the kidneys, remains fairly constant in body.	0.6–1.2 mg/dL (50–110 mmol/L)																					
Urea nitrogen (blood urea nitrogen [BUN])	Serves as index of renal function. Urea is nitrogenous end product of protein metabolism. Test values are affected by protein intake, tissue breakdown, and fluid volume changes.	7–18 mg/dL Patients >60 yrs: 8–20 mg/dL																					
BUN-to-creatinine ratio	Evaluates hydration status. An elevated ratio is seen in hypovolemia; a normal ratio with an elevated BUN and creatinine is seen with intrinsic renal disease.	About 10:1																					

directed toward the bladder. The device automatically calculates and displays urine volume.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) scans and magnetic resonance imaging (MRI) are noninvasive techniques that provide excellent cross-sectional views of the anatomy of the kidney and urinary tract (Labus, 2008). They are used to evaluate genitourinary masses, nephrolithiasis, chronic renal infections, renal or urinary tract trauma, metastatic disease, and soft tissue abnormalities. Occasionally, an oral or intravenous (IV) radiopaque contrast agent is used in CT scanning to enhance visualization.

Preparation for Magnetic Resonance Imaging

Patient preparation should include teaching relaxation techniques and informing the patient that he or she will be able to communicate with the staff by means of a microphone located inside the scanner. Many MRI suites provide headphones so that patients can listen to the music of their choice during the procedure. Nursing care guidelines for patient preparation and test precautions for any imaging procedure that requires a contrast agent (contrast medium) are explained in Chart 43-5.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) are removed. This includes

medication patches (eg, nicotine and nitroglycerine) that have a metal backing, which can cause burns if they are not removed. No metal objects (eg, oxygen tanks, ventilators, stethoscopes) may be brought into the MRI room. The magnetic field is so strong that any metal-containing items will be pulled toward the magnet, causing severe injury and possible death. A patient history is obtained to determine the presence of any metal objects (eg, aneurysm clips, orthopedic hardware, pacemakers, artificial heart valves, intrauterine devices). These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants are inactivated by MRI; therefore, other imaging procedures are considered. A sedative may be prescribed, because claustrophobia is a problem for some patients.

Prior to MRI of the urinary system the patient needs to be informed to avoid alcohol, caffeine-containing beverages, and smoking for at least 2 hours and food for at least 1 hour prior to the scan. Patients should continue taking their usual medication, except for iron supplements, which can interfere with the imaging (Labus, 2008).

Nuclear Scans

Nuclear scans require injection of a radioisotope (a technetium 99m–labeled compound or iodine 123 [¹²³I] hippurate) into the circulatory system; the isotope is then monitored as it moves through the blood vessels of the kidneys. A scintillation camera is placed behind the kidney with the patient in a supine, prone, or seated position. Hypersensitivity to the radioisotope is rare. The technetium scan provides information about kidney perfusion. The ¹²³I-hippurate renal scan provides information about kidney function, such as GFR.

Nuclear scans are used to evaluate acute and chronic renal failure, renal masses, and blood flow before and after kidney transplantation. The radioisotope is injected at a specified time to achieve the proper concentration in the kidneys. After the procedure is completed, the patient is encouraged to drink fluids to promote excretion of the radioisotope by the kidneys.

Intravenous Urography

IV urography includes various tests such as excretory urography, intravenous pyelography (IVP), and infusion drip pyelography. A radiopaque contrast agent is administered by IV. An IVP shows the kidneys, ureter, and bladder via x-ray imaging as the dye moves through the upper and then the lower urinary system. A nephrotomogram may be carried out as part of the study to visualize different layers of the kidney and the diffuse structures within each layer and to differentiate solid masses or lesions from cysts in the kidneys or urinary tract.

IV urography may be used as the initial assessment of many suspected urologic conditions, especially lesions in the kidneys and ureters. It also provides an approximate estimate of renal function. After the contrast agent (sodium diatrizoate or meglumine diatrizoate) is administered by IV, multiple x-rays are obtained to visualize drainage structures in the upper and lower urinary systems.

Infusion drip pyelography requires IV infusion of a large volume of a dilute contrast agent to opacify the renal

Chart 43-5 • Patient Care During Urologic Testing With Contrast Agents

For some patients, contrast agents are nephrotoxic and allergenic. The following guidelines can help the nurse and other health care providers respond quickly in the event of a problem.

Nursing Actions for Room Preparation

- Have emergency equipment and medications available in case the patient has an anaphylactic reaction to the contrast agent. Emergency supplies include epinephrine, corticosteroids, vasopressors, oxygen, and airway and suction equipment.

Nursing Actions for Patient Preparation

- Obtain the patient's allergy history with emphasis on allergy to iodine, shellfish, and other seafood, because many contrast agents contain iodine.
- Notify physician and radiologist if the patient is allergic or suspected to be allergic to iodine.
- Obtain health history. Contrast agents should be used with caution in older patients and patients who have diabetes mellitus, multiple myeloma, renal insufficiency, or volume depletion.
- Inform the patient that he or she may experience a temporary feeling of warmth, flushing of the face, and an unusual flavor (similar to that of seafood) in the mouth when the contrast agent is infused.
- Monitor patient closely for allergic reaction and monitor urine output.

parenchyma and fill the urinary tract. This examination method is useful when prolonged opacification of the drainage structures is desired so that tomograms (body-section radiography) can be made. Images are obtained at specified intervals after the start of the infusion. These images show the filled and distended collecting system. The patient preparation is the same as for excretory urography, except that fluids are not restricted.

Retrograde Pyelography

In retrograde pyelography, catheters are advanced through the ureters into the renal pelvis by means of cystoscopy. A contrast agent is then injected. Retrograde pyelography is usually performed if IV urography provides inadequate visualization of the collecting systems. It may also be used before extracorporeal shock wave lithotripsy and in patients with urologic cancer who need follow-up and have an allergy to IV contrast agents. Possible complications include infection, hematuria, and perforation of the ureter. Retrograde pyelography is used infrequently because of improved techniques in excretory urography.

Cystography

Cystography aids in evaluating vesicoureteral reflux (back-flow of urine from the bladder into one or both ureters) and in assessing for bladder injury. A catheter is inserted into the bladder, and a contrast agent is instilled to outline the bladder wall. The contrast agent may leak through a small bladder perforation stemming from bladder injury, but such leakage is usually harmless. Cystography can also be performed with simultaneous pressure recordings inside the bladder.

Voiding Cystourethrography

Voiding cystourethrography uses fluoroscopy to visualize the lower urinary tract and assess urine storage in the bladder. It is commonly used as a diagnostic tool to identify vesicoureteral reflux. A urethral catheter is inserted, and a contrast agent is instilled into the bladder. When the bladder is full and the patient feels the urge to void, the catheter is removed, and the patient voids.

Renal Angiography

A renal angiogram, or renal arteriogram, provides an image of the renal arteries. The femoral (or axillary) artery is pierced with a needle, and a catheter is threaded up through the femoral and iliac arteries into the aorta or renal artery. A contrast agent is injected to opacify the renal arterial supply. Angiography is used to evaluate renal blood flow in suspected renal trauma, to differentiate renal cysts from tumors, and to evaluate hypertension. It is used preoperatively for renal transplantation. Before the procedure, a laxative may be prescribed to evacuate the colon so that unobstructed x-rays can be obtained. Injection sites (groin for femoral approach or axilla for axillary approach) may be shaved. The peripheral pulse sites (radial, femoral, and dorsalis pedis) are marked for easy access during postprocedural assessment. The patient is informed that there may be a brief sensation of warmth along the course of the vessel when the contrast agent is injected.

After the procedure, vital signs are monitored until stable. If the axillary artery was the injection site, blood pressure measurements are taken on the opposite arm. The injection site is examined for swelling and hematoma. Peripheral pulses are palpated, and the color and temperature of the involved extremity are noted and compared with those of the uninvolved extremity. Cold compresses may be applied to the injection site to decrease edema and pain. Possible complications include hematoma formation, arterial thrombosis or dissection, false aneurysm formation, and altered renal function.

Urologic Endoscopic Procedures

Endourology, or urologic endoscopic procedures, can be performed in one of two ways: using a cystoscope inserted into the urethra, or percutaneously, through a small incision.

The cystoscopic examination is used to directly visualize the urethra and bladder. The cystoscope, which is inserted through the urethra into the bladder, has an optical lens system that provides a magnified, illuminated view of the bladder (Fig. 43-8). The use of a high-intensity light and interchangeable lenses allows excellent visualization and permits still and motion pictures to be taken. The cystoscope is manipulated to allow complete visualization of the urethra and bladder as well as the ureteral orifices and prostatic urethra. Small ureteral catheters can be passed through the cystoscope for assessment of the ureters and the pelvis of each kidney.

The cystoscope also allows the urologist to obtain a urine specimen from each kidney to evaluate its function. Cup forceps can be inserted through the cystoscope for biopsy. Calculi may be removed from the urethra, bladder, and ureter using cystoscopy. If a lower tract cystoscopy is performed, the patient is usually conscious, and the procedure is usually no more uncomfortable than a catheterization. To

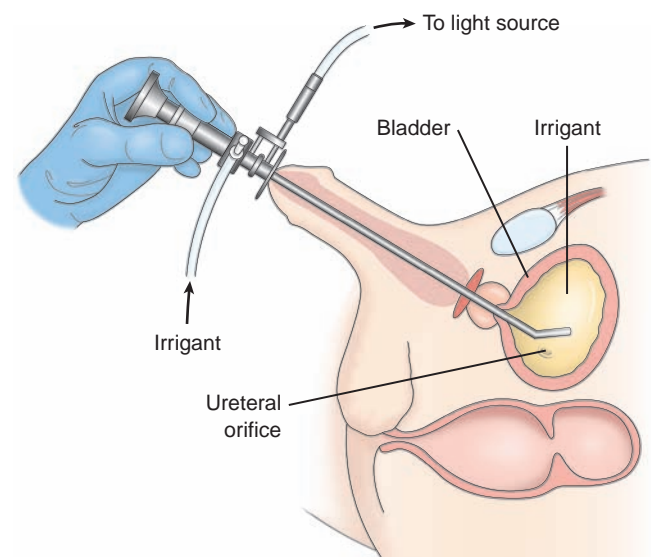

Figure 43-8 Cystoscopic examination. A rigid or semirigid cystoscope is introduced into the bladder. The upper cord is an electric line for the light at the distal end of the cystoscope. The lower tubing leads from a reservoir of sterile irrigant that is used to inflate the bladder.

minimize posttest urethral discomfort, viscous lidocaine is administered several minutes before the study. If the cystoscopy includes examination of the upper tracts, a sedative may be administered before the procedure. General anesthesia is usually administered to ensure that there are no involuntary muscle spasms when the scope is being passed through the ureters or kidney.

The nurse describes the procedure to the patient and family to prepare them and to allay their fears. If an upper cystoscopy is to be performed, the patient is usually restricted to nothing by mouth (NPO) for several hours beforehand.

Postprocedural management is directed at relieving any discomfort resulting from the examination. Some burning on voiding, blood-tinged urine, and urinary frequency from trauma to the mucous membranes can be expected. Moist heat to the lower abdomen and warm sitz baths are helpful in relieving pain and relaxing the muscles.

After a cystoscopic examination, the patient with obstructive pathology may experience urine retention if the instruments used during the examination caused edema. The nurse carefully monitors the patient with prostatic hyperplasia for urine retention. Warm sitz baths and antispasmodic medication, such as flavoxate (Urispas), may be prescribed to relieve temporary urine retention caused by poor relaxation of the urinary sphincter; however, intermittent catheterization may be necessary for a few hours after the examination. The nurse monitors the patient for signs and symptoms of urinary tract infection. Because edema of the urethra secondary to local trauma may obstruct urine flow, the patient is also monitored for signs and symptoms of obstruction.

Biopsy

Renal and Ureteral Brush Biopsy

Brush biopsy techniques provide specific information when abnormal x-ray findings of the ureter or renal pelvis raise questions about whether a defect is a tumor, a stone, a blood clot, or an artifact. First, a cystoscopic examination is conducted. Then, a ureteral catheter is introduced, followed by a biopsy brush that is passed through the catheter. The suspected lesion is brushed back and forth to obtain cells and surface tissue fragments for histologic analysis.

After the procedure, IV fluids may be administered to help clear the kidneys and prevent clot formation. Urine may contain blood (usually clearing in 24 to 48 hours) from oozing at the brushing site. Postoperative renal colic occasionally occurs and responds to analgesic agents.

Kidney Biopsy

Biopsy of the kidney is used to help diagnose and evaluate the extent of kidney disease. Indications for biopsy include unexplained acute renal failure, persistent proteinuria or hematuria, transplant rejection, and glomerulopathies. A small section of renal cortex is obtained either percutaneously (needle biopsy) or by open biopsy through a small flank incision. Before the biopsy is carried out, coagulation studies are conducted to identify any risk of postbiopsy bleeding. Contraindications to kidney biopsy include bleed-

ing tendencies, uncontrolled hypertension, a solitary kidney, and morbid obesity (Morton, Fontaine, Hudak, et al., 2005).

Procedure

The patient may be prescribed a fasting regimen 6 to 8 hours before the test. An IV line is established. A urine specimen is obtained and saved for comparison with the postbiopsy specimen.

If a needle biopsy is to be performed, the patient is instructed to breathe in and hold that breath (to prevent the kidney from moving) while the needle is being inserted. The sedated patient is placed in a prone position with a sandbag under the abdomen. The skin at the biopsy site is infiltrated with a local anesthetic agent. The biopsy needle is introduced just inside the renal capsule of the outer quadrant of the kidney. The location of the needle may be confirmed by fluoroscopy or by ultrasound, in which case a special probe is used.

With open biopsy, a small incision is made over the kidney, allowing direct visualization. Preparation for an open biopsy is similar to that for any major abdominal surgery.

CRITICAL THINKING EXERCISES

EBP 1 Two days after major surgery your patient complains of lower abdominal pain. Describe the assessment techniques appropriate to evaluate the pain. Review the possible causes, describe the actions you would take and the rationale for each action, and identify the evidence base that supports the actions. What criteria would you use to evaluate the strength of the evidence?

2 A 46-year-old patient with a history of smoking is admitted to the hospital for evaluation of urinary dysfunction and is scheduled for a urinary system MRI. Explain why the MRI is indicated for this patient and what, if any, precautions must be taken because the patient is trying to stop smoking. What nursing observations and assessments are indicated because of the history of smoking? What patient teaching is appropriate before the MRI?

EBP 3 You make a home visit to an elderly female patient who is incontinent. Identify assessments and possible interventions you would use to evaluate and manage the incontinence. Identify the evidence for the assessments and nursing interventions you chose and the strength of that evidence.

Management of Patients With Renal Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the key factors associated with the development of renal disorders.
- 2 Differentiate between the causes of chronic kidney disease and acute and chronic renal failure.
- 3 Compare and contrast the pathophysiology, clinical manifestations, medical management, and nursing management for patients with renal disorders.
- 4 Describe the nursing management of patients with acute and chronic renal failure.
- 5 Compare and contrast the renal replacement therapies including hemodialysis, peritoneal dialysis, and kidney transplantation.
- 6 Describe the nursing management of the hospitalized patient on dialysis.
- 7 Develop a postoperative plan of nursing care and teaching plan for the patient undergoing kidney surgery and transplantation.

GLOSSARY

- acute nephritic syndrome:** type of renal failure with glomerular inflammation
- acute renal failure:** sudden rapid deterioration of kidney function that is sometimes reversible
- acute tubular necrosis:** type of acute renal failure in which there is actual damage to the kidney tubules
- anuria:** total urine output less than 50 mL in 24 hours
- arteriovenous fistula:** type of vascular access for dialysis; created by surgically connecting an artery to a vein
- arteriovenous graft:** type of surgically created vascular access for dialysis by which a piece of biologic, semibiologic, or synthetic graft material connects the patient's artery to a vein
- azotemia:** abnormal concentration of nitrogenous wastes in the blood
- chronic kidney disease:** chronic progressive and irreversible diseases of the kidneys
- continuous ambulatory peritoneal dialysis:** method of peritoneal dialysis whereby a patient manually performs four or five complete exchanges or cycles throughout the day

GLOSSARY (Continued)

- continuous cyclic peritoneal dialysis:** method of peritoneal dialysis in which a peritoneal dialysis machine (cycler) automatically performs exchanges, usually while the patient sleeps
- continuous renal replacement therapy:** variety of methods used to replace normal kidney function by circulating the patient's blood through a filter and returning it to the patient
- dialysate:** solution that circulates through the dialyzer in hemodialysis and through the peritoneal membrane in peritoneal dialysis
- dialyzer:** "artificial kidney" or dialysis machine; contains a semipermeable membrane through which particles of a certain size can pass
- diffusion:** movement of solutes (waste products) from an area of higher concentration to an area of lower concentration
- effluent:** term used to describe the drained fluid from a peritoneal dialysis exchange
- end-stage renal disease:** final stage of renal failure that results in retention of uremic waste products and the need for renal replacement therapies
- exchange (peritoneal dialysis):** complete cycle of peritoneal dialysis includes fill, dwell, and drain phases
- glomerulonephritis:** inflammation of the glomerular capillaries
- hemodialysis:** procedure during which a patient's blood is circulated through a dialyzer to remove waste products and excess fluid
- interstitial nephritis:** inflammation within the renal tissue
- nephrosclerosis:** hardening of the renal arteries
- nephrotic syndrome:** type of renal failure with increased glomerular permeability and massive proteinuria
- nephrotoxic:** any substance, medication, or action that destroys kidney tissue
- osmosis:** movement of water through a semipermeable membrane from an area of lower solute concentration to an area of higher solute concentration
- peritoneal dialysis:** procedure that uses the lining of the patient's peritoneal cavity as the semipermeable membrane for exchange of fluid and solutes
- peritonitis:** inflammation of the peritoneal membrane (lining of the peritoneal cavity)
- pyelonephritis:** inflammation of the renal pelvis
- ultrafiltration:** process whereby water is removed from the blood by means of a pressure gradient between the patient's blood and the dialysate
- uremia:** an excess of urea and other nitrogenous wastes in the blood
- urinary casts:** proteins secreted by damaged kidney tubules

The renal system helps regulate the body's internal environment and is essential for the maintenance of life. Nurses working in any clinical setting may encounter patients with various renal disorders and thus need to be knowledgeable about these disorders. This chapter provides an overview of electrolyte imbalances that are common in patients with renal disorders. The main causes of kidney disease are discussed, together with management strategies to prevent damage and preserve renal function. Chronic kidney disease and acute and chronic renal failure are discussed, as is the care of patients with other renal conditions who require dialysis, transplantation, and kidney surgery.

FLUID AND ELECTROLYTE IMBALANCES IN RENAL DISORDERS

Patients with renal disorders commonly experience fluid and electrolyte imbalances and require careful assessment and close monitoring for signs of potential problems. The patient whose fluid intake exceeds the ability of the kidneys to excrete fluid is said to have fluid overload. If fluid intake is inadequate, the patient is said to be volume depleted and

may show signs and symptoms of fluid volume deficit. The fluid intake and output (I&O) record, a key monitoring tool, is used to document important fluid parameters, including the amount of fluid taken in (orally or parenterally), the volume of urine excreted, and other fluid losses (diarrhea, vomiting, diaphoresis). Patient weight is also important, and documenting trends in weight is a key assessment strategy essential for determining the daily fluid allowance and indicating signs of fluid overload or deficit.

NURSING ALERT

The most accurate indicator of fluid loss or gain in an acutely ill patient is weight. An accurate daily weight must be obtained and recorded. A 1-kg weight gain is equal to 1000 mL of retained fluid.

Clinical Manifestations

The signs and symptoms of common fluid and electrolyte disturbances that can occur in patients with renal disorders and their general management strategies are listed in Table 44-1. The nurse continually assesses, monitors, and informs appro-

Table 44-1 COMMON FLUID AND ELECTROLYTE DISTURBANCES IN RENAL DISORDERS

Disturbance	Manifestations	General Management Strategies
Fluid volume deficit	Acute weight loss $\geq 5\%$, decreased skin turgor, dry mucous membranes, oliguria or anuria, increased hematocrit, blood urea nitrogen (BUN) level increased out of proportion to creatinine level, hypothermia	Fluid challenge, fluid replacement orally or parenterally
Fluid volume excess	Acute weight gain $\geq 5\%$, edema, crackles, shortness of breath, decreased BUN, decreased hematocrit, distended neck veins	Fluid and sodium restriction, diuretics, dialysis
Sodium deficit	Nausea, malaise, lethargy, headache, abdominal cramps, apprehension, seizures	Diet, normal saline or hypertonic saline solutions
Sodium excess	Dry, sticky mucous membranes, thirst, rough dry tongue, fever, restlessness, weakness, disorientation	Fluids, diuretics, dietary restriction
Potassium deficit	Anorexia, abdominal distention, paralytic ileus, muscle weakness, ECG changes, dysrhythmias	Diet, oral or parenteral potassium replacement therapy
Potassium excess	Diarrhea, colic, nausea, irritability, muscle weakness, ECG changes	Dietary restriction, diuretics, IV glucose, insulin and sodium bicarbonate, cation-exchange resin, calcium gluconate, dialysis
Calcium deficit	Abdominal and muscle cramps, stridor, carpopedal spasm, hyperactive reflexes, tetany, positive Chvostek's or Trousseau's sign, tingling of fingers and around mouth, ECG changes	Diet, oral or parenteral calcium salt replacement
Calcium excess	Deep bone pain, flank pain, muscle weakness, depressed deep tendon reflexes, constipation, nausea and vomiting, confusion, impaired memory, polyuria, polydipsia, ECG changes	Fluid replacement, etidronate, pamidronate, mithramycin, calcitonin, glucocorticoids, phosphate salts
Bicarbonate deficit	Headache, confusion, drowsiness, increased respiratory rate and depth, nausea and vomiting, warm flushed skin	Bicarbonate replacement, dialysis
Bicarbonate excess	Depressed respirations, muscle hypertonicity, dizziness, tingling of fingers and toes	Fluid replacement if volume depleted; ensure adequate chloride
Protein deficit	Chronic weight loss, emotional depression, pallor, fatigue, soft flabby muscles	Diet, dietary supplements, hyperalimentation, albumin
Magnesium deficit	Dysphagia, muscle cramps, hyperactive reflexes, tetany, positive Chvostek's or Trousseau's sign, tingling of fingers, dysrhythmias, vertigo	Diet, oral or parenteral magnesium replacement therapy
Magnesium excess	Facial flushing, nausea and vomiting, sensation of warmth, drowsiness, depressed deep tendon reflexes, muscle weakness, respiratory depression, cardiac arrest	Calcium gluconate, mechanical ventilation, dialysis
Phosphorus deficit	Deep bone pain, flank pain, muscle weakness and pain, paresthesia, apprehension, confusion, seizures	Diet, oral or parenteral phosphorus supplementation therapy
Phosphorus excess	Tetany, tingling of fingers and around mouth, muscle spasms, soft tissue calcification	Diet restriction, phosphate binders, normal saline solution, IV dextrose solution, and insulin

priate members of the health care team if the patient exhibits any of these signs. Management strategies for fluid and electrolyte disturbances in renal disease are discussed in greater depth later in this chapter (see also Chapter 14).

Gerontologic Considerations

With aging, the kidney is less able to respond to acute fluid and electrolyte changes. Elderly patients may develop atypical and nonspecific signs and symptoms of disturbed renal function and fluid and electrolyte imbalances. A fluid balance deficit in the elderly can lead to constipation, falls, medication toxicity, urinary tract and respiratory tract infections, delirium, seizures, electrolyte imbalances, hyperthermia, and delayed wound healing (Mentes, 2006). Recognition of acute changes in fluid and electrolytes is further hampered by their association with preexisting disorders and the misconception that they are normal changes of aging.

RENAL DISORDERS

Chronic Kidney Disease

Chronic kidney disease (CKD) is an umbrella term that describes kidney damage or a decrease in the glomerular filtration rate (GFR) for 3 or more months (Thomas-Hawkins & Zazworsky, 2005). CKD is associated with decreased quality of life, increased health care expenditures, and premature death. Untreated CKD can result in **end-stage renal disease (ESRD)** and necessitate renal replacement therapy (dialysis or kidney transplantation). Risk factors include cardiovascular disease, diabetes, hypertension, and obesity. Recent research reported that 16.8% of the U.S. population aged 20 years and older have CKD (Centers for Disease Control and Prevention [CDC], 2007).

Diabetes is the primary cause of CKD. Between 25% and 40% of patients with type 1 diabetes and 5% to 40% of those with type 2 diabetes develop kidney damage (Thomas & Atkins, 2006). Diabetes is the leading cause of renal failure in patients starting renal replacement therapy. The second leading cause is hypertension, followed by glomerulonephritis and **pyelonephritis**; polycystic, hereditary, or congenital disorders; and renal cancers (U.S. Renal Data System [USRDS], 2007).

Pathophysiology

In the early stages of CKD there can be significant damage to the kidneys without signs or symptoms. The pathophysiology of CKD is not yet clearly understood, but the damage to the kidneys is thought to be caused by prolonged acute inflammation that is not organ specific and thus has subtle systemic manifestations.

Stages of Chronic Kidney Disease

CKD has been classified into five stages by the National Kidney Foundation (NKF) (Chart 44-1). Stage 5 results when the kidneys cannot remove the body's metabolic wastes or perform their regulatory functions and renal replacement therapies are required to sustain life. Screening

Chart 44-1 • Stages of Chronic Kidney Disease

Stages are based on the glomerular filtration rate (GFR). The normal GFR is 125 mL/min/1.73 m².

Stage 1

GFR \geq 90 mL/min/1.73 m²
Kidney damage with normal or increased GFR

Stage 2

GFR = 60–89 mL/min/1.73 m²
Mild decrease in GFR

Stage 3

GFR = 30–59 mL/min/1.73 m²
Moderate decrease in GFR

Stage 4

GFR = 15–29 mL/min/1.73 m²
Severe decrease in GFR

Stage 5

GFR < 15 mL/min/1.73 m²
Kidney failure (end-stage renal disease [ESRD])

and early intervention are important, as not all patients progress to stage 5 CKD. Patients with CKD are at increased risk for cardiovascular disease, the leading cause of morbidity and mortality (Thomas & Atkins, 2006). Treatment of hypertension, anemia, and hyperglycemia and detection of proteinuria all help to slow disease progression and improve patient outcomes (Compton, 2007).

Clinical Manifestations

Elevated serum creatinine levels indicate underlying kidney disease; as the creatinine level increases, symptoms of chronic kidney disease begin. Anemia, due to decreased erythropoietin production by the kidney; metabolic acidosis; and abnormalities in calcium and phosphorus herald the development of CKD. Fluid retention, evidenced by both edema and congestive heart failure, develops. As the disease progresses, abnormalities in electrolytes occur, heart failure worsens, and hypertension becomes more difficult to control.

Assessment and Diagnostic Findings

The GFR is the amount of plasma filtered through the glomeruli per unit of time. Creatinine clearance is a measure of the amount of creatinine the kidneys are able to clear in a 24-hour period. Normal values differ in men and women. Calculation of GFR, an important assessment perimeter in CKD, is discussed in Chapter 43.

Medical Management

The management of patients with CKD includes treatment of the underlying causes. Regular clinical and laboratory assessment is important to keep the blood pressure (BP) below 130/80 mm Hg. Medical management also includes early referral for initiation of renal replacement therapies as indicated by the patient's renal status. Prevention of

complications is accomplished by controlling cardiovascular risk factors; treating hyperglycemia; treating anemia; smoking cessation, weight loss, and exercise programs as needed; and reduction in salt and alcohol intake.

Gerontologic Considerations

Changes in kidney function with normal aging increase the susceptibility of elderly patients to kidney dysfunction and renal failure (Miller, 2009). In addition, the incidence of systemic diseases, such as atherosclerosis, hypertension, heart failure, diabetes, and cancer, increases with advancing age, predisposing older adults to renal disease associated with these disorders. Therefore, acute problems need to be prevented if possible or recognized and treated quickly to avoid kidney damage. Thus, nurses in all settings need to be alert for signs and symptoms of renal dysfunction in elderly patients.

Elderly patients frequently take multiple prescription and over-the-counter medications. Because alterations in renal blood flow, glomerular filtration, and renal clearance increase the risk for medication-associated changes in renal function, precautions are indicated with all medications. When elderly patients undergo extensive diagnostic tests or when new medications (eg, diuretic agents) are added, precautions must be taken to prevent dehydration, which can compromise marginal renal function and lead to renal failure (Mentes, 2006).

Nephrosclerosis

Nephrosclerosis (hardening of the renal arteries) is most often due to prolonged hypertension and diabetes. Nephrosclerosis is a major cause of CKD and ESRD secondary to many disorders.

Pathophysiology

There are two forms of nephrosclerosis: malignant (accelerated) and benign. Malignant nephrosclerosis is often associated with significant hypertension (diastolic blood pressure higher than 130 mm Hg). It usually occurs in young adults and twice as often in men compared to women. Damage is caused by decreased blood flow to the kidney resulting in patchy necrosis of the renal parenchyma. Over time, fibrosis occurs and glomeruli are destroyed.

The disease process progresses rapidly. Without dialysis, more than half of patients die from **uremia** (an excess of urea and other nitrogenous wastes in the blood) in a few years. Benign nephrosclerosis can be found in older adults, associated with atherosclerosis and hypertension.

Assessment and Diagnostic Findings

Symptoms are rare early in the disease, even though the urine usually contains protein and occasional casts. Renal insufficiency and associated signs and symptoms occur late in the disease.

Medical Management

Treatment of nephrosclerosis is aggressive antihypertensive therapy. An angiotensin-converting enzyme (ACE) inhibitor, alone or in combination with other antihyperten-

sive medications, significantly reduces its incidence (Munar & Singh, 2007). See Chapter 32 for additional information on hypertension.

Primary Glomerular Diseases

Diseases that destroy the glomerulus of the kidney are the third most common cause of stage 5 CKD. In these disorders, the glomerular capillaries are primarily involved. Antigen–antibody complexes form in the blood and become trapped in the glomerular capillaries (the filtering portion of the kidney), inducing an inflammatory response. Immunoglobulin G (IgG), the major immunoglobulin (antibody) found in the blood, can be detected in the glomerular capillary walls. The major clinical manifestations of glomerular injury include proteinuria, hematuria, decreased GFR, decreased excretion of sodium, edema, and hypertension (Chart 44-2).

ACUTE NEPHRITIC SYNDROME

The **acute nephritic syndrome** is the clinical manifestation of glomerular inflammation (Porth & Matfin, 2009). **Glomerulonephritis** is an inflammation of the glomerular capillaries that can occur in acute and chronic forms.

Pathophysiology

Primary glomerular diseases include postinfectious glomerulonephritis, rapidly progressive glomerulonephritis, membrane proliferative glomerulonephritis, and membranous glomerulonephritis. Postinfectious causes are group A beta-hemolytic streptococcal infection of the throat that precedes the onset of glomerulonephritis by 2 to 3 weeks (Fig. 44-1). It may also follow impetigo (infection of the skin) and acute viral infections (upper respiratory tract infections, mumps, varicella zoster virus, Epstein-Barr virus, hepatitis B, and human immunodeficiency virus [HIV] infection). In some patients, antigens outside the body (eg, medications, foreign serum) initiate the process, resulting in antigen–antibody complexes being deposited in the glomeruli. In other patients, the kidney tissue itself serves as the inciting antigen.

Chart 44-2 • Terms Typically Used When Describing Glomerular Disease

Primary:	Disease is mainly in glomeruli
Secondary:	Glomerular diseases that are the consequence of systemic disease
Idiopathic:	Cause is unknown
Acute:	Occurs over days or weeks
Chronic:	Occurs over months or years
Rapidly progressing:	Constant loss of renal function with minimal chance of recovery
Diffuse:	Involves all glomeruli
Focal:	Involves some glomeruli
Segmental:	Involves portions of individual glomeruli
Membranous:	Evidence of thickened glomerular capillary walls
Proliferative:	Number of glomerular cells involved is increasing

Physiology ■ ■ ■ Pathophysiology

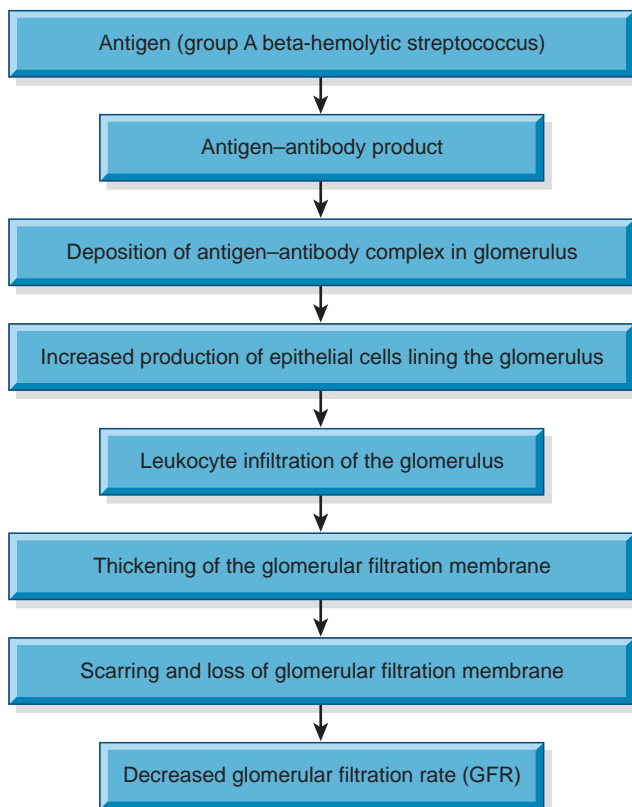

Figure 44-1 Sequence of events in acute nephritic syndrome.

Clinical Manifestations

The primary presenting features of an acute glomerular inflammation are hematuria, edema, **azotemia**, an abnormal concentration of nitrogenous wastes in the blood, and proteinuria or excess protein in the urine (Porth & Matfin, 2009). The hematuria may be microscopic (identifiable only through microscopic examination) or macroscopic (visible to the eye). The urine may appear cola-colored because of red blood cells (RBCs) and protein plugs or casts; RBC casts indicate glomerular injury. Glomerulonephritis may be mild and the hematuria discovered incidentally through a routine urinalysis, or the disease may be severe, with acute renal failure (ARF) and oliguria.

Some degree of edema and hypertension is present in most patients. Marked proteinuria due to the increased permeability of the glomerular membrane may also occur, with associated pitting edema, hypoalbuminemia, hyperlipidemia, and fatty casts in the urine. Blood urea nitrogen (BUN) and serum creatinine levels may increase as urine output decreases. In addition, anemia may be present.

In the more severe form of the disease, patients also complain of headache, malaise, and flank pain. Elderly patients may experience circulatory overload with dyspnea, engorged neck veins, cardiomegaly, and pulmonary edema. Atypical symptoms include confusion, somnolence, and

seizures, which are often confused with the symptoms of a primary neurologic disorder.

Assessment and Diagnostic Findings

In acute nephritic syndrome, the kidneys become large, edematous, and congested. All renal tissues including the glomeruli, tubules, and blood vessels are affected to varying degrees. Patients with an IgA nephropathy have an elevated serum IgA and low to normal complement levels. Electron microscopy and immunofluorescent analysis help identify the nature of the lesion; however, a kidney biopsy may be needed for definitive diagnosis. (See Chapter 43 for discussion of kidney biopsy.)

If the patient improves, the amount of urine increases and the urinary protein and sediment diminish. The percentage of adults who recover is unknown. Some patients develop severe uremia (an excess of urea and other nitrogenous wastes in the blood) within weeks and require dialysis for survival. Others, after a period of apparent recovery, insidiously develop chronic glomerulonephritis.

Complications

Complications of acute glomerulonephritis include hypertensive encephalopathy, heart failure, and pulmonary edema. Hypertensive encephalopathy is a medical emergency, and therapy is directed toward reducing the blood pressure without impairing renal function. This can occur in acute nephritic syndrome or preeclampsia with chronic hypertension of greater than 140/90 mm Hg. Rapidly progressive glomerulonephritis is characterized by a rapid decline in renal function. Without treatment, ESRD develops in a matter of weeks or months. Signs and symptoms are similar to those of acute glomerulonephritis (hematuria and proteinuria), but the course of the disease is more severe and rapid. Crescent-shaped cells accumulate in Bowman's space, disrupting the filtering surface. Plasma exchange (plasmapheresis) and treatment with high-dose corticosteroids and cytotoxic agents have been used to reduce the inflammatory response. Dialysis is initiated in acute glomerulonephritis if signs and symptoms of uremia are severe. The prognosis for patients with acute nephritic syndrome is excellent and rarely causes CKD (Porth & Matfin, 2009).

Medical Management

Management consists primarily of treating symptoms, attempting to preserve kidney function, and treating complications promptly. Treatment may include corticosteroids, managing hypertension, and controlling proteinuria (Glick, 2007). Pharmacologic therapy depends on the cause of acute glomerulonephritis. If residual streptococcal infection is suspected, penicillin is the agent of choice; however, other antibiotic agents may be prescribed. Dietary protein is restricted when renal insufficiency and nitrogen retention (elevated BUN) develop. Sodium is restricted when the patient has hypertension, edema, and heart failure.

Nursing Management

Although most patients with acute uncomplicated glomerulonephritis are cared for as outpatients, nursing care is important in every setting.

Providing Care in the Hospital

In a hospital setting, carbohydrates are given liberally to provide energy and reduce the catabolism of protein. I&O are carefully measured and recorded. Fluids are given based on the patient's fluid losses and daily body weight. Insensible fluid loss through the lungs (300 mL) and skin (600 mL) is considered when estimating fluid loss (see Chapter 14). If treatment is effective, diuresis will begin, resulting in decreased edema and blood pressure. Proteinuria and microscopic hematuria may persist for many months; in fact, 20% of patients have some degree of persistent proteinuria or decreased GFR 1 year after presentation (Porth & Matfin, 2009). Other nursing interventions focus on patient education about the disease process, explanations of laboratory and other diagnostic tests, and preparation for safe and effective self-care at home (Hughes, 2008).

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Patient education is directed toward symptom management and monitoring for complications. Fluid and diet restrictions must be reviewed with the patient to avoid worsening of edema and hypertension. The patient is instructed verbally and in writing to notify the physician if symptoms of renal failure occur (eg, fatigue, nausea, vomiting, diminishing urine output) or at the first sign of any infection.

Continuing Care

The importance of follow-up evaluations of blood pressure, urinalysis for protein, and BUN and serum creatinine levels to determine if the disease has progressed is stressed to the patient. A referral for home care may be indicated; a visit from a home care nurse provides an opportunity for careful assessment of the patient's progress and detection of early signs and symptoms of renal insufficiency. If corticosteroids, immunosuppressant agents, or antibiotic medications are prescribed, the home care nurse or nurse in the outpatient setting uses the opportunity to review the dosage, desired actions, and adverse effects of medications and the precautions to be taken.

CHRONIC GLOMERULONEPHRITIS

Chronic glomerulonephritis may be due to repeated episodes of acute nephritic syndrome, hypertensive nephrosclerosis, hyperlipidemia, chronic tubulointerstitial injury, or hemodynamically mediated glomerular sclerosis. Secondary glomerular diseases that can have systemic effects include lupus erythematosus, Goodpasture's syndrome (caused by antibodies to the glomerular basement membrane), diabetic glomerulosclerosis, and amyloidosis.

Pathophysiology

The kidneys are reduced to as little as one-fifth their normal size (consisting largely of fibrous tissue). The cortex layer shrinks to 1 to 2 mm in thickness or less. Bands of scar tissue distort the remaining cortex, making the surface of the kidney rough and irregular. Numerous glomeruli and their tubules become scarred, and the branches of the renal artery are thickened. The resulting severe glomerular damage can

progress to stage 5 CKD and require renal replacement therapies.

Clinical Manifestations

The symptoms of chronic glomerulonephritis vary. Some patients with severe disease have no symptoms at all for many years (Porth & Matfin, 2009). The condition may be discovered when hypertension or elevated BUN and serum creatinine levels are detected. Most patients report general symptoms, such as loss of weight and strength, increasing irritability, and an increased need to urinate at night (nocturia). Headaches, dizziness, and digestive disturbances are also common.

As chronic glomerulonephritis progresses, signs and symptoms of CKD and chronic renal failure may develop. The patient appears poorly nourished, with a yellow-gray pigmentation of the skin and periorbital and peripheral (dependent) edema. Blood pressure may be normal or severely elevated. Retinal findings include hemorrhage, exudate, narrowed tortuous arterioles, and papilledema. Anemia causes pale mucous membranes. Cardiomegaly, a gallop rhythm, distended neck veins, and other signs and symptoms of heart failure may be present. Crackles can be heard in the bases of the lungs.

Peripheral neuropathy with diminished deep tendon reflexes and neurosensory changes occur late in the disease. The patient becomes confused and demonstrates a limited attention span. An additional late finding includes evidence of pericarditis with a pericardial friction rub and pulsus paradoxus (difference in blood pressure during inspiration and expiration of greater than 10 mm Hg).

Assessment and Diagnostic Findings

A number of laboratory abnormalities occur. Urinalysis reveals a fixed specific gravity of about 1.010, variable proteinuria, and **urinary casts** (proteins secreted by damaged kidney tubules). As renal failure progresses and the GFR falls below 50 mL/min, the following changes occur:

- Hyperkalemia due to decreased potassium excretion, acidosis, catabolism, and excessive potassium intake from food and medications
- Metabolic acidosis from decreased acid secretion by the kidney and inability to regenerate bicarbonate
- Anemia secondary to decreased erythropoiesis (production of RBCs)
- Hypoalbuminemia with edema secondary to protein loss through the damaged glomerular membrane
- Increased serum phosphorus level due to decreased renal excretion of phosphorus
- Decreased serum calcium level (calcium binds to phosphorus to compensate for elevated serum phosphorus levels)
- Mental status changes
- Impaired nerve conduction due to electrolyte abnormalities and uremia

Chest x-rays may show cardiac enlargement and pulmonary edema. The electrocardiogram (ECG) may be normal or may indicate left ventricular hypertrophy associated with hypertension and signs of electrolyte disturbances, such as tall, tented (or peaked) T waves associated with hyperkalemia. Computed tomography (CT) and magnetic

resonance imaging (MRI) scans show a decrease in the size of the renal cortex.

Medical Management

Management of symptoms guides the treatment. If the patient has hypertension, efforts are made to reduce the blood pressure with sodium and water restriction, antihypertensive agents, or both. Weight is monitored daily, and diuretic medications are prescribed to treat fluid overload. Proteins of high biologic value (dairy products, eggs, meats) are provided to promote good nutritional status. Adequate calories are provided to spare protein for tissue growth and repair. Urinary tract infections (UTIs) must be treated promptly to prevent further renal damage.

Dialysis is initiated early in the course of the disease to keep the patient in optimal physical condition, prevent fluid and electrolyte imbalances, and minimize the risk of complications of renal failure. The course of dialysis is smoother if treatment begins before the patient develops complications.

Nursing Management

Whether the patient is hospitalized or cared for in the home, the nurse observes the patient for common fluid and electrolyte disturbances in renal disease (see Table 44-1). Changes in fluid and electrolyte status and in cardiac and neurologic status are reported promptly to the physician. Anxiety levels are often extremely high for both the patient and family. Throughout the course of the disease and treatment, the nurse gives emotional support by providing opportunities for the patient and family to verbalize their concerns, have their questions answered, and explore their options.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The nurse has a major role in teaching the patient and family about the prescribed treatment plan and the risks associated with noncompliance. Instructions to the patient include explanations and scheduling for follow-up evaluations: blood pressure, urinalysis for protein and casts, and laboratory studies of BUN and serum creatinine levels. If long-term dialysis is needed, the nurse teaches the patient and family about the procedure, how to care for the access site, dietary restrictions, and other necessary lifestyle modifications. These topics are discussed later in this chapter.

Periodic hospitalization, visits to the outpatient clinic or office, and home care referrals provide the nurse in each setting with the opportunity for careful assessment of the patient's progress and continued education about changes to report to the primary health care provider (worsening signs and symptoms of renal failure, such as nausea, vomiting, and diminished urine output). Specific teaching may include explanations about recommended diet and fluid modifications and medications (purpose, desired effects, adverse effects, dosage, and administration schedule).

Continuing Care

Periodic laboratory evaluations of creatinine clearance and BUN and serum creatinine levels are carried out to assess residual renal function and the need for dialysis or trans-

plantation. If dialysis is initiated, the patient and family require considerable assistance and support in dealing with therapy and its long-term implications. The patient and family are reminded of the importance of participation in health promotion activities, including health screening. The patient is instructed to inform all health care providers about the diagnosis of glomerulonephritis so that all medical management, including pharmacologic therapy, is based on altered renal function.

NEPHROTIC SYNDROME

Nephrotic syndrome is a type of renal failure characterized by increased glomerular permeability and is manifested by massive proteinuria (Porth & Matfin, 2009). Clinical findings include a marked increase in protein (particularly albumin) in the urine (proteinuria), a decrease in albumin in the blood (hypoalbuminemia), diffuse edema, high serum cholesterol, and low-density lipoproteins (hyperlipidemia).

The syndrome is apparent in any condition that seriously damages the glomerular capillary membrane and results in increased glomerular permeability to plasma proteins. Although the liver is capable of increasing the production of albumin, it cannot keep up with the daily loss of albumin through the kidneys. Thus, hypoalbuminemia results (Fig. 44-2).

Pathophysiology

Nephrotic syndrome occurs with many intrinsic renal diseases and systemic diseases that cause glomerular damage. It is not a specific glomerular disease but a constellation of clinical findings that result from the glomerular damage (Porth & Matfin, 2009).

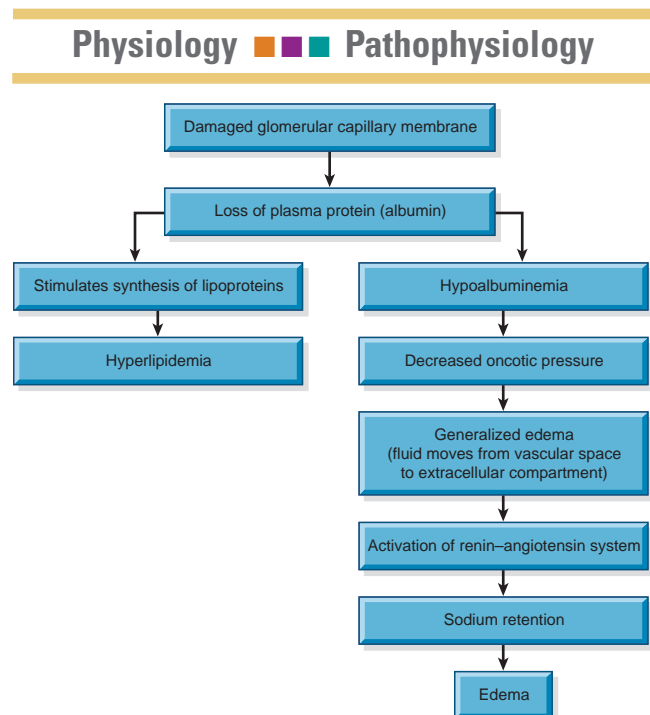

Figure 44-2 Sequence of events in nephrotic syndrome.

Clinical Manifestations

The major manifestation of nephrotic syndrome is edema. It is usually soft and pitting and commonly occurs around the eyes (periorbital), in dependent areas (sacrum, ankles, and hands), and in the abdomen (ascites). Patients may also exhibit irritability, headache, and malaise.

Assessment and Diagnostic Findings

Proteinuria (predominately albumin) exceeding 3.5 g/day is the hallmark of the diagnosis of nephrotic syndrome (Porth & Matfin, 2009). Protein electrophoresis and immunoelectrophoresis may be performed on the urine to categorize the type of proteinuria. The urine may also contain increased white blood cells (WBCs) as well as granular and epithelial casts. A needle biopsy of the kidney may be performed for histologic examination of renal tissue to confirm the diagnosis.

Complications

Complications of nephrotic syndrome include infection (due to a deficient immune response), thromboembolism (especially of the renal vein), pulmonary emboli, ARF (due to hypovolemia), and accelerated atherosclerosis (due to hyperlipidemia).

Medical Management

Treatment is focused on treating the underlying disease state causing proteinuria, slowing progression of CKD, and relieving symptoms. Typical treatment includes diuretics for edema, ACE inhibitors to reduce proteinuria, and lipid-lowering agents for hyperlipidemia.

Nursing Management

In the early stages of nephrotic syndrome, nursing management is similar to that of the patient with acute glomerulonephritis, but as the condition worsens, management is similar to that of the patient with ESRD (see the following section).

Patients with nephrotic syndrome need adequate instruction about the importance of following all medication and dietary regimens so that their condition can remain stable as long as possible. Patients must be made aware of the importance of communicating any health-related change to their health care providers as soon as possible so that appropriate medication and dietary changes can be made before further changes occur within the glomeruli.

Polycystic Kidney Disease

Pathophysiology

Polycystic kidney disease (PKD) is a genetic disorder characterized by the growth of numerous cysts in the kidneys. When cysts form in the kidneys, they are filled with fluid, destroying the nephrons. PKD cysts can profoundly enlarge the kidneys while replacing much of the normal structure, resulting in reduced kidney function and leading to kidney failure.

PKD can also cause cysts in the liver and problems in other organs, such as blood vessels in the brain and heart. The number of cysts as well as the complications they cause help distinguish PKD from the usually harmless “simple” cysts that can form in the kidneys in later years of life. In the United

States, PKD and cystic diseases are the fifth leading cause of kidney failure. Two major inherited forms of PKD exist:

- *Autosomal dominant PKD* is the most common inherited form. Symptoms usually develop between the ages of 30 and 40, but they can begin earlier, even in childhood. About 90% of all PKD cases are autosomal dominant PKD.
- *Autosomal recessive PKD* is a rare inherited form. Symptoms of autosomal recessive PKD begin in the earliest months of life or in utero.

When autosomal dominant PKD causes kidneys to fail, which usually happens after many years, the patient requires dialysis or kidney transplantation. About one half of people with the most common type of PKD progress to CKD stage 5, requiring renal replacement.

Clinical Manifestations

Signs and symptoms of PKD result from loss of renal function and the increasing size of the kidneys as the cysts grow. Renal damage can result in hematuria, polyuria (large amounts of urine), hypertension, development of renal calculi and associated urinary tract infections, and proteinuria. The growing cysts are noted with reports of abdominal fullness and flank pain (back and lower sides).

Assessment and Diagnostic Findings

Since PKD is a genetic disease, careful evaluation of family history is necessary. Palpation of the abdomen will often reveal enlarged cystic kidneys. Diagnosis is usually made with ultrasound imaging of the kidney (Porth & Matfin, 2009).

Medical Management

PKD has no cure and treatment is largely supportive including blood pressure control, pain control, and antibiotics to resolve infections. Once the kidneys fail, renal replacement therapy is indicated. Genetic testing and counseling may be indicated.

RENAL CANCER

Renal cancer accounts for about 3% of all cancers in adult men and 2% in adult woman in the United States (American Cancer Society, 2009). In the United States, the incidence of renal cancer at all stages has increased in the past two decades. The incidence of renal cell carcinoma is higher in both men and women with an increased body mass index. Tobacco use continues to be a significant risk factor for renal carcinoma (Chart 44-3).

CHART

44-3

Risk Factors for Renal Cancer

- Gender: Affects men more than women
- Tobacco use
- Occupational exposure to industrial chemicals, such as petroleum products, heavy metals, and asbestos
- Obesity
- Unopposed estrogen therapy
- Polycystic kidney disease

The most common type of renal carcinoma arises from the renal epithelium and accounts for more than 85% of all kidney tumors. These tumors may metastasize early to the lungs, bone, liver, brain, and contralateral kidney. One quarter of patients have metastatic disease at the time of diagnosis. Although enhanced imaging techniques account for improved detection of early-stage kidney cancer, it is unknown why the rate of late-stage kidney cancers is high (Cohen & McGovern, 2005).

Clinical Manifestations

Many renal tumors produce no symptoms and are discovered on a routine physical examination as a palpable abdominal mass. The classic signs and symptoms, which occur in only 10% of patients, include hematuria, pain, and a mass in the flank (Cohen & McGovern, 2005). The usual sign that first calls attention to the tumor is painless hematuria, which may be either intermittent and microscopic or continuous and gross. There may be a dull pain in the back from the pressure produced by compression of the ureter, extension of the tumor into the perirenal area, or hemorrhage into the kidney tissue. Colicky pains occur if a clot or mass of tumor cells passes down the ureter. Symptoms from metastasis may be the first manifestations of renal tumor and may include unexplained weight loss, increasing weakness, and anemia.

Assessment and Diagnostic Findings

The diagnosis of a renal tumor may require intravenous (IV) urography, cystoscopic examination, nephrotomograms, renal angiograms, ultrasonography, or a CT scan. These tests may be exhausting for patients already debilitated by the systemic effects of a tumor as well as for elderly patients and those who are anxious about the diagnosis and outcome. The nurse assists the patient to prepare physically and psychologically for these procedures and monitors carefully for signs and symptoms of dehydration and exhaustion.

Medical Management

The goal of management is to eradicate the tumor before metastasis occurs.

Surgical Management

Nephrectomy

A radical nephrectomy is the preferred treatment if the tumor can be removed. This includes removal of the kidney (and tumor), adrenal gland, surrounding perinephric fat and Gerota's fascia, and lymph nodes. Laparoscopic nephrectomy can be performed for removal of the kidney with a small tumor. This procedure incurs less morbidity and a shorter recovery time. Radiation therapy, hormonal therapy, or chemotherapy may be used along with surgery. Immunotherapy may also be helpful. For patients with bilateral tumors or cancer of a functional single kidney, nephron-sparing surgery (partial nephrectomy) may be considered. Favorable results have been achieved in patients with small local tumors and a normal contralateral kidney (Cohen & McGovern, 2005).

Nephron-sparing surgery is increasingly being used to treat patients with solid renal lesions. The technical success

rate of nephron-sparing surgery is excellent, and operative morbidity and mortality are low.

Patients with upper tract transitional cell carcinoma may benefit from laparoscopic nephroureterectomy. Although it is a lengthier surgical procedure, it has the same efficacy and is better tolerated by patients than open nephroureterectomy.

Renal Artery Embolization

In patients with metastatic renal carcinoma, the renal artery may be occluded to impede the blood supply to the tumor and thus kill the tumor cells. After angiographic studies are completed, a catheter is advanced into the renal artery, and embolizing materials (eg, Gelfoam, autologous blood clot, steel coils) are injected into the artery and carried with the arterial blood flow to occlude the tumor vessels mechanically. This decreases the local blood supply, making removal of the kidney (nephrectomy) easier. It also stimulates an immune response because infarction of the renal cell carcinoma releases tumor-associated antigens that enhance the patient's response to metastatic lesions. The procedure may also reduce the number of tumor cells entering the venous circulation during surgical manipulation.

After renal artery embolization and tumor infarction, a characteristic symptom complex called postinfarction syndrome occurs, lasting 2 to 3 days. The patient has pain localized to the flank and abdomen, elevated temperature, and gastrointestinal (GI) symptoms. Pain is treated with parenteral analgesic agents, and acetaminophen (Tylenol) is administered to control fever. Antiemetic medications, restriction of oral intake, and IV fluids are used to treat the GI symptoms.

Pharmacologic Therapy

Currently, no pharmacologic agents are in widespread use for treatment of renal cell carcinoma, which is refractory to most chemotherapeutic agents. However, depending on the stage of the tumor, percutaneous partial or radical nephrectomy may be followed by treatment with chemotherapeutic agents. Radiation therapy may be used for palliation in patients who are not candidates for surgery.

Treatment with biologic response modifiers such as interleukin-2 (IL-2) is effective. IL-2, a protein that regulates cell growth, is used alone or in combination with lymphokine-activated killer cells (WBCs that have been stimulated by IL-2 to increase their ability to kill cancer cells). Interferon, another biologic response modifier, appears to have a direct antiproliferative effect on renal tumors. Temsirolimus (Torisel) is administered by IV infusion on a weekly basis to treat advanced renal cell carcinoma (Aschenbrenner, 2007).

Another promising experimental approach to renal cell carcinoma is a vaccination to stimulate immune response, with autologous tumor cells with IL-2-, granulocyte-macrophage stimulating factor-, and dendritic cell-type vaccines. If patients with renal cancer do not respond to immunotherapy, allogeneic stem cell transplantation may be indicated (Cohen & McGovern, 2005).

Nursing Management

The patient with a renal tumor usually undergoes extensive diagnostic and therapeutic procedures. Treatment includes surgery, radiation therapy, and medications. After surgery,

the patient usually has catheters and drains in place to maintain a patent urinary tract, to remove drainage, and to permit accurate measurement of urine output. Because of the location of the surgical incision, the patient's position during surgery, and the nature of the surgical procedure, pain and muscle soreness are common. Pharmacologic management often includes immunosuppressant agents; therefore, patients are monitored for infection (Aschenbrenner, 2007).

The patient requires frequent analgesia during the postoperative period and assistance with turning, coughing, use of incentive spirometry, and deep breathing to prevent atelectasis and other pulmonary complications. The patient and family require assistance and support to cope with the diagnosis and uncertain prognosis. (See this chapter for discussion of postoperative care of the patient undergoing kidney surgery and Chapter 16 for discussion of care of the patient with cancer.)

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The nurse teaches the patient to inspect and care for the incision and perform other general postoperative care including activity and lifting restrictions, driving, and pain management. Instructions are provided about when to notify the physician about problems (eg, fever, breathing difficulty, wound drainage, blood in the urine, pain or swelling of the legs).

The nurse encourages the patient to eat a healthy diet and to drink adequate liquids to avoid constipation and to maintain an adequate urine volume. Education and emotional support are provided related to the diagnosis, treatment, and continuing care because many patients are concerned about the loss of the other kidney, the possible need for dialysis, or the recurrence of cancer.

Continuing Care

Follow-up care is essential to detect signs of metastases and to reassure the patient and family about the patient's status and well-being. The patient who has had surgery for renal carcinoma should have a yearly physical examination and chest x-ray, because late metastases are not uncommon. All subsequent symptoms should be evaluated with possible metastases in mind.

If follow-up chemotherapy is necessary, the patient and family are informed about the treatment plan or chemotherapy protocol, what to expect with each visit, and when to notify the physician. Evaluation of remaining renal function (creatinine clearance, BUN and serum creatinine levels) may also be carried out periodically. A home care nurse may monitor the patient's physical status and psychological well-being and coordinate other indicated services and resources.

RENAL FAILURE

Renal failure results when the kidneys cannot remove the body's metabolic wastes or perform their regulatory functions. The substances normally eliminated in the urine ac-

cumulate in the body fluids as a result of impaired renal excretion, affecting endocrine and metabolic functions as well as fluid, electrolyte, and acid-base disturbances. Renal failure is a systemic disease and is a final common pathway of many different kidney and urinary tract diseases. Each year, the number of deaths from irreversible renal failure increases (USRDS, 2007).

Acute Renal Failure

Acute renal failure (ARF) is a rapid loss of renal function due to damage to the kidneys. Depending on the duration and severity of ARF, a wide range of potentially life-threatening metabolic complications can occur, including metabolic acidosis as well as fluid and electrolyte imbalances. Treatment is aimed at replacing renal function temporarily to minimize potentially lethal complications and reduce potential causes of increased renal injury with the goal of minimizing long-term loss of renal function. ARF is a problem seen in hospitalized patients and those in outpatient settings. A widely accepted criterion for ARF is a 50% or greater increase in serum creatinine above baseline (normal creatinine is less than 1.0 mg/dL) (Best & Counselman, 2008). Urine volume may be normal, or changes may occur. Possible changes include oliguria (less than 500 mL/day), nonoliguria (greater than 800 mL/day), or **anuria** (less than 50 mL/day) (Counts, 2008).

Pathophysiology

Although the pathogenesis of ARF and oliguria is not always known, many times there is a specific underlying problem. Some of the factors may be reversible if identified and treated promptly, before kidney function is impaired. This is true of the following conditions that reduce blood flow to the kidney and impair kidney function: (1) hypovolemia; (2) hypotension; (3) reduced cardiac output and heart failure; (4) obstruction of the kidney or lower urinary tract by tumor, blood clot, or kidney stone; and (5) bilateral obstruction of the renal arteries or veins. If these conditions are treated and corrected before the kidneys are permanently damaged, the increased BUN and creatinine levels, oliguria, and other signs may be reversed.

Although renal stones are not a common cause of ARF, some types may increase the risk for ARF. Some hereditary stone diseases (see Chapter 45), primary struvite stones, and infection-related urolithiasis associated with anatomic and functional urinary tract anomalies and spinal cord injury may cause recurrent bouts of obstruction as well as crystal-specific damage to tubular epithelial cells and interstitial renal cells.

Categories of Acute Renal Failure

The major categories of ARF are prerenal (hypoperfusion of kidney), intrarenal (actual damage to kidney tissue), and postrenal (obstruction to urine flow). Prerenal ARF, which occurs in 60% to 70% of cases, is the result of impaired blood flow that leads to hypoperfusion of the kidney and a decrease in the GFR. Intrarenal ARF is the result of actual

parenchymal damage to the glomeruli or kidney tubules. **Acute tubular necrosis (ATN)** is the most common type of intrinsic ARF. Characteristics of ATN are intratubular obstruction, tubular back leak (abnormal reabsorption of filtrate and decreased urine flow through the tubule), vasoconstriction, and changes in glomerular permeability. These processes result in a decrease of GFR, progressive azotemia, and fluid and electrolyte imbalances. CKD, diabetes, heart failure, hypertension, and cirrhosis can lead to ATN (Bednarski, Castner & Douglas, 2008). Postrenal ARF usually results from obstruction distal to the kidney. Pressure rises in the kidney tubules and eventually, the GFR decreases. Common causes of each type of ARF are summarized in Chart 44-4.

Chart 44-4 • Causes of Acute Renal Failure

Prerenal Failure

- Volume depletion resulting from:
 - Hemorrhage
 - Renal losses (diuretics, osmotic diuresis)
 - Gastrointestinal losses (vomiting, diarrhea, nasogastric suction)
- Impaired cardiac efficiency resulting from:
 - Myocardial infarction
 - Heart failure
 - Dysrhythmias
 - Cardiogenic shock
- Vasodilation resulting from:
 - Sepsis
 - Anaphylaxis
 - Antihypertensive medications or other medications that cause vasodilation

Intrarenal Failure

- Prolonged renal ischemia resulting from:
 - Pigment nephropathy (associated with the breakdown of blood cells containing pigments that in turn occlude kidney structures)
 - Myoglobinuria (trauma, crush injuries, burns)
 - Hemoglobinuria (transfusion reaction, hemolytic anemia)
- Nephrotoxic agents such as:
 - Aminoglycoside antibiotics (gentamicin, tobramycin)
 - Radiopaque contrast agents
 - Heavy metals (lead, mercury)
 - Solvents and chemicals (ethylene glycol, carbon tetrachloride, arsenic)
 - Nonsteroidal anti-inflammatory drugs (NSAIDs)
 - Angiotensin-converting enzyme inhibitors (ACE inhibitors)
- Infectious processes such as:
 - Acute pyelonephritis
 - Acute glomerulonephritis

Postrenal Failure

- Urinary tract obstruction, including:
 - Calculi (stones)
 - Tumors
 - Benign prostatic hyperplasia
 - Strictures
 - Blood clots

Phases of Acute Renal Failure

There are four phases of ARF: initiation, oliguria, diuresis, and recovery.

- The initiation period begins with the initial insult and ends when oliguria develops.
- The oliguria period is accompanied by an increase in the serum concentration of substances usually excreted by the kidneys (urea, creatinine, uric acid, organic acids, and the intracellular cations [potassium and magnesium]). The minimum amount of urine needed to rid the body of normal metabolic waste products is 400 mL. In this phase uremic symptoms first appear and life-threatening conditions such as hyperkalemia develop.

Some patients have decreased renal function with increasing nitrogen retention, yet actually excrete normal amounts of urine (2 L/day or more). This is the nonoliguric form of renal failure and occurs predominantly after exposure of the patient to nephrotoxic agents, burns, traumatic injury, and the use of halogenated anesthetic agents.

- The diuresis period is marked by a gradual increase in urine output, which signals that glomerular filtration has started to recover. Laboratory values stabilize and eventually decrease. Although the volume of urinary output may reach normal or elevated levels, renal function may still be markedly abnormal. Because uremic symptoms may still be present, the need for expert medical and nursing management continues. The patient must be observed closely for dehydration during this phase; if dehydration occurs, the uremic symptoms are likely to increase.
- The recovery period signals the improvement of renal function and may take 3 to 12 months. Laboratory values return to the patient's normal level. Although a permanent 1% to 3% reduction in the GFR is common, it is not clinically significant.

Clinical Manifestations

Almost every system of the body is affected with failure of the normal renal regulatory mechanisms. The patient may appear critically ill and lethargic. The skin and mucous membranes are dry from dehydration. Central nervous system signs and symptoms include drowsiness, headache, muscle twitching, and seizures. Table 44-2 summarizes common clinical characteristics in all three categories of ARF.

Assessment and Diagnostic Findings

Assessment of the patient with ARF includes evaluation for changes in the urine, diagnostic tests that evaluate the kidney contour, and a variety of laboratory values. See Chapter 43 for information about the normal characteristics of urine, diagnostic findings, and laboratory values in the renal system.

In ARF, urine output varies from scanty to a normal volume, hematuria may be present, and the urine has a low specific gravity (compared with a normal value of 1.010 to 1.025). One of the earliest manifestations of tubular damage is the inability to concentrate the urine (Porth & Matfin, 2009). Patients with prerenal azotemia have a decreased amount of sodium in the urine (less than 20 mEq/L) and

Table 44-2 COMPARING CLINICAL CHARACTERISTICS OF ACUTE RENAL FAILURE

Characteristics	Categories		
	Prerenal	Intrarenal	Postrenal
Etiology	Hypoperfusion	Parenchymal damage	Obstruction
Blood urea nitrogen value	Increased (out of normal 20:1 proportion to creatinine)	Increased	Increased
Creatinine	Increased	Increased	Increased
Urine output	Decreased	Varies, often decreased	Varies, may be decreased, or sudden anuria
Urine sodium	Decreased to <20 mEq/L	Increased to >40 mEq/L	Varies, often decreased to 20 mEq/L or less
Urinary sediment	Normal, few hyaline casts	Abnormal casts and debris	Usually normal
Urine osmolality	Increased to 500 mOsm	About 350 mOsm similar to serum	Varies, increased or equal to serum
Urine specific gravity	Increased	Low normal	Varies

normal urinary sediment. Patients with intrarenal azotemia usually have urinary sodium levels greater than 40 mEq/L with urinary casts and other cellular debris.

Ultrasonography is a critical component of the evaluation of patients with renal failure. A renal sonogram or a CT or MRI scan may show evidence of anatomic changes.

The BUN level increases steadily at a rate dependent on the degree of catabolism (breakdown of protein), renal perfusion, and protein intake. Serum creatinine levels are useful in monitoring kidney function and disease progression and increase with glomerular damage.

With a decline in the GFR, oliguria, and anuria, patients are at high risk for hyperkalemia. Protein catabolism results in the release of cellular potassium into the body fluids, causing severe hyperkalemia (high serum potassium levels). Hyperkalemia may lead to dysrhythmias, such as ventricular tachycardia and cardiac arrest. Sources of potassium include normal tissue catabolism, dietary intake, blood in the GI tract, or blood transfusion and other sources (eg, IV infusions, potassium penicillin, and extracellular shift in response to metabolic acidosis).

Progressive metabolic acidosis occurs in renal failure because patients cannot eliminate the daily metabolic load of acid-type substances produced by the normal metabolic processes. In addition, normal renal buffering mechanisms fail. This is reflected by a decrease in the serum CO_2 -combining power and blood pH.

There may be an increase in blood phosphate concentrations; calcium levels may be low due to decreased absorption of calcium from the intestine and as a compensatory mechanism for the elevated blood phosphate levels. Anemia is another common laboratory finding in ARF, as a result of reduced erythropoietin production, uremic GI lesions, reduced RBC lifespan, and blood loss from the GI tract.

Prevention

ARF has a high mortality rate that ranges from 25% to 90%. Factors that influence mortality include increased age, comorbid conditions, and preexisting renal and vascular diseases (Dirkes & Hodge, 2007). Therefore, prevention of ARF is essential (Chart 44-5).

A careful history is obtained to identify exposure to nephrotoxic agents or environmental toxins. The kidneys

are susceptible to the adverse effects of medications because the kidneys are repeatedly exposed to substances in the blood. Patients taking nephrotoxic medications (eg, aminoglycosides, gentamicin, tobramycin, colistimethate, polymyxin B, amphotericin B, vancomycin, amikacin, cyclosporine) should be monitored closely for changes in renal function. BUN and serum creatinine levels should be obtained at baseline within 24 hours after initiation of these medications and at least twice a week while the patient is receiving them.

Chart 44-5 • Preventing Acute Renal Failure

1. Provide adequate hydration to patients at risk for dehydration including:
 - Before, during, and after surgery
 - Patients undergoing intensive diagnostic studies requiring fluid restriction and contrast agents (eg, barium enema, intravenous pyelograms), especially elderly patients who may have marginal renal reserve
 - Patients with neoplastic disorders or disorders of metabolism (eg, gout) and those receiving chemotherapy
2. Prevent and treat shock promptly with blood and fluid replacement.
3. Monitor central venous and arterial pressures and hourly urine output of critically ill patients to detect the onset of renal failure as early as possible.
4. Treat hypotension promptly.
5. Continually assess renal function (urine output, laboratory values) when appropriate.
6. Take precautions to ensure that the appropriate blood is administered to the correct patient in order to avoid severe transfusion reactions, which can precipitate renal failure.
7. Prevent and treat infections promptly. Infections can produce progressive renal damage.
8. Pay special attention to wounds, burns, and other precursors of sepsis.
9. To prevent infections from ascending in the urinary tract, give meticulous care to patients with indwelling catheters. Remove catheters as soon as possible.
10. To prevent toxic drug effects, closely monitor dosage, duration of use, and blood levels of all medications metabolized or excreted by the kidneys.

Any agent that reduces renal blood flow (eg, long-term analgesic use) may cause renal insufficiency. Chronic use of analgesic agents, particularly nonsteroidal anti-inflammatory drugs (NSAIDs), may cause **interstitial nephritis** (inflammation within the renal tissue) and papillary necrosis. Patients with heart failure or cirrhosis with ascites are at particular risk for NSAID-induced renal failure. Increased age, preexisting renal disease, and the simultaneous administration of several nephrotoxic agents increase the risk for kidney damage.

Radiocontrast-induced nephropathy (CIN) is a major cause of hospital-acquired ARF. Patients undergo more than 1 million radiocontrast studies in the United States annually; of these approximately 150,000 will experience CIN, and at least 1% of these will require dialysis and experience a prolonged hospital stay (Barreto, 2007). This is a potentially preventable condition. Baseline levels of creatinine greater than 2 mg/dL identify patients at high risk. Limiting the patient's exposure to contrast agents and nephrotoxic medications will reduce the risk of CIN (Steward, 2007). Administration of *N*-acetylcysteine and sodium bicarbonate before and during procedures reduces risk, but prehydration with saline is considered the most effective method to prevent CIN (Barreto, 2007).

Gerontologic Considerations

About half of all patients who develop ARF during hospitalization are older than 60 years. The etiology of ARF in older adults includes prerenal causes such as dehydration, intrarenal causes such as **nephrotoxic** agents (eg, medications, contrast agents), and complications of major surgery (Steward, 2007). Suppression of thirst, enforced bed rest, lack of access to drinking water, and confusion all contribute to the older patient's failure to consume adequate fluids and may lead to dehydration, further compromising already decreased renal function.

ARF in the elderly is also often seen in the community setting. Nurses in the ambulatory setting need to be aware of the risk. All medications need to be monitored for potential side effects that could result in damage to the kidney either through reduced circulation or nephrotoxicity. Outpatient procedures that require fasting or a bowel preparation may cause dehydration and therefore require careful monitoring.

Medical Management

The kidneys have a remarkable ability to recover from insult. The objectives of treatment of ARF are to restore normal chemical balance and prevent complications until repair of renal tissue and restoration of renal function can occur. Management includes eliminating the underlying cause; maintaining fluid balance; avoiding fluid excesses; and, when indicated, providing renal replacement therapy. Prerenal azotemia is treated by optimizing renal perfusion, whereas postrenal failure is treated by relieving the obstruction. Intrarenal azotemia is treated with supportive therapy, with removal of causative agents, aggressive management of prerenal and postrenal failure, and avoidance of associated risk factors. Shock and infection, if present, are treated promptly (see Chapter 15).

Maintenance of fluid balance is based on daily body weight, serial measurements of central venous pressure, serum and urine concentrations, fluid losses, blood pressure, and the clinical status of the patient. The parenteral and oral intake and the output of urine, gastric drainage, stools, wound drainage, and perspiration are calculated and are used as the basis for fluid replacement. The insensible fluid produced through the normal metabolic processes and lost through the skin and lungs is also considered in fluid management.

Fluid excesses can be detected by the clinical findings of dyspnea, tachycardia, and distended neck veins. The patient's lungs are auscultated for moist crackles. Because pulmonary edema may be caused by excessive administration of parenteral fluids, extreme caution must be used to prevent fluid overload. The development of generalized edema is assessed by examining the presacral and pretibial areas several times daily. Mannitol (Osmitol), furosemide (Lasix), or ethacrynic acid (Edecrin) may be prescribed to initiate diuresis.

Adequate renal blood flow in patients with prerenal causes of ARF may be restored by IV fluids or transfusions of blood products. If ARF is caused by hypovolemia secondary to hypoproteinemia, an infusion of albumin may be prescribed. Dialysis may be initiated to prevent complications of ARF, such as hyperkalemia, metabolic acidosis, pericarditis, and pulmonary edema. Dialysis corrects many biochemical abnormalities; allows for liberalization of fluid, protein, and sodium intake; diminishes bleeding tendencies; and promotes wound healing. **Hemodialysis** (a procedure that circulates the patient's blood through a dialyzer to remove waste products and excess fluid), **peritoneal dialysis** (PD) (a procedure that uses the patient's peritoneal membrane [the lining of the peritoneal cavity] as the semipermeable membrane to exchange fluid and solutes), or a variety of **continuous renal replacement therapies** (CRRTs) (methods used to replace normal kidney function by circulating the patient's blood through a hemofilter) may be performed. These and other treatment modalities for patients with renal dysfunction are discussed later in this chapter.

Pharmacologic Therapy

Hyperkalemia is the most life-threatening of the fluid and electrolyte changes that occur in patients with renal disturbances. Therefore, the patient is monitored for hyperkalemia through serial serum electrolyte levels (potassium value greater than 5.0 mEq/L [5 mmol/L]), ECG changes (tall, tented, or peaked T waves), and changes in clinical status (see Chapter 14). Other symptoms of hyperkalemia include irritability, abdominal cramping, diarrhea, paresthesia, and generalized muscle weakness. Muscle weakness may present as slurred speech, difficulty breathing, paresthesia, and paralysis. As the potassium level increases, both cardiac and other muscular function declines, making this a true medical emergency (Counts, 2008).

The elevated potassium levels may be reduced by administering cation-exchange resins (sodium polystyrene sulfonate [Kayexalate]) orally or by retention enema. Kayexalate works by exchanging sodium ions for potassium ions in the intestinal tract. Sorbitol may be administered in combination with Kayexalate to induce a diarrhea-type effect

(it induces water loss in the GI tract). If a Kayexalate retention enema is administered (the colon is the major site of potassium exchange), a rectal catheter with a balloon may be used to facilitate retention if necessary. The patient should retain the Kayexalate for 30 to 45 minutes to promote potassium removal. Afterward, a cleansing enema may be prescribed to remove remaining medication as a precaution against fecal impaction.

If the patient is hemodynamically unstable (low blood pressure, changes in mental status, dysrhythmia), IV dextrose 50%, insulin, and calcium replacement may be administered to shift potassium back into the cells. Albuterol sulfate (Ventolin HFA) by nebulizer can lower plasma potassium concentration by 0.5 to 1.5 mEq/L (Best & Counselman, 2008). The shift of potassium into the intracellular space is temporary, so arrangements for dialysis need to be made on an emergent basis.

Since many medications are eliminated through the kidneys, dosages must be reduced when a patient has ARF. Examples of commonly used agents that require adjustment are antibiotic medications (especially aminoglycosides), digoxin, ACE inhibitors, and magnesium-containing agents.

In addition, many medications have been used in patients with ARF in an attempt to improve patient outcomes. Diuretic agents are often used to control fluid volume, but they have not been shown to improve recovery from ARF (Dirkes & Hodge, 2007).

In patients with severe acidosis, the arterial blood gases and serum bicarbonate levels (CO_2 -combining power) must be monitored because the patient may require sodium bicarbonate therapy or dialysis. If respiratory problems develop, appropriate ventilatory measures must be instituted. The elevated serum phosphate level may be controlled with phosphate-binding agents (eg, calcium or lanthanum carbonate) that help prevent a continuing rise in serum phosphate levels by decreasing the absorption of phosphate from the intestinal tract.

Nutritional Therapy

ARF causes severe nutritional imbalances (because nausea and vomiting contribute to inadequate dietary intake), impaired glucose use and protein synthesis, and increased tissue catabolism. The patient is weighed daily and loses 0.2 to 0.5 kg (0.5 to 1 lb) daily if the nitrogen balance is negative (ie, caloric intake falls below caloric requirements). If the patient gains or does not lose weight or develops hypertension, fluid retention should be suspected.

Nutritional support is based on the underlying cause of ARF, the catabolic response, the type and frequency of renal replacement therapy, comorbidities, and nutritional status. Replacement of dietary proteins is individualized to provide the maximum benefit and minimize uremic symptoms. Caloric requirements are met with high-carbohydrate meals, because carbohydrates have a protein-sparing effect (ie, in a high-carbohydrate diet, protein is not used for meeting energy requirements but is “spared” for growth and tissue healing). Foods and fluids containing potassium or phosphorus (eg, bananas, citrus fruits and juices, coffee) are restricted.

The oliguric phase of ARF may last 10 to 20 days and is followed by the diuretic phase, at which time urine output

begins to increase, signaling that kidney function is returning. Results of blood chemistry tests are used to determine the amounts of sodium, potassium, and water needed for replacement, along with assessment for overhydration or underhydration. Following the diuretic phase, the patient is placed on a high-protein, high-calorie diet and is encouraged to resume activities gradually.

Nursing Management

The nurse has an important role in caring for the patient with ARF. The nurse monitors for complications, participates in emergency treatment of fluid and electrolyte imbalances, assesses the patient’s progress and response to treatment, and provides physical and emotional support. Additionally, the nurse keeps family members informed about the patient’s condition, helps them understand the treatments, and provides psychological support. Although the development of ARF may be the most serious problem, the nurse continues to provide nursing care indicated for the primary disorder (eg, burns, shock, trauma, obstruction of the urinary tract).

Monitoring Fluid and Electrolyte Balance

Because of the serious fluid and electrolyte imbalances that can occur with ARF, the nurse monitors the patient’s serum electrolyte levels and physical indicators of these complications during all phases of the disorder. Hyperkalemia is the most immediate life-threatening imbalance seen in ARF. Parenteral fluids, all oral intake, and all medications are screened carefully to ensure that hidden sources of potassium are not inadvertently administered or consumed. IV solutions must be carefully selected based on the patient’s fluid and electrolyte status. The patient’s cardiac function and musculoskeletal status are monitored closely for signs of hyperkalemia.

The nurse monitors fluid status by paying careful attention to fluid intake (IV medications should be administered in the smallest volume possible), urine output, apparent edema, distention of the jugular veins, alterations in heart sounds and breath sounds, and increasing difficulty in breathing. Accurate daily weights, as well as I&O records, are essential. Indicators of deteriorating fluid and electrolyte status are reported immediately to the physician, and preparation is made for emergency treatment. Severe fluid and electrolyte disturbances may be treated with hemodialysis, PD, or CRRT.

Reducing Metabolic Rate

The nurse takes steps to reduce the patient’s metabolic rate. Bed rest may be indicated to reduce exertion and the metabolic rate during the most acute stage of the disorder. Fever and infection, both of which increase the metabolic rate and catabolism, are prevented or treated promptly.

Promoting Pulmonary Function

Attention is given to pulmonary function, and the patient is assisted to turn, cough, and take deep breaths frequently to prevent atelectasis and respiratory tract infection. Drowsiness and lethargy may prevent the patient from moving and turning without encouragement and assistance.

Preventing Infection

Asepsis is essential with invasive lines and catheters to minimize the risk of infection and increased metabolism. An indwelling urinary catheter is avoided whenever possible due to the high risk of UTI associated with its use but may be required to provide ongoing data required to monitor fluid I&O.

Providing Skin Care

The skin may be dry or susceptible to breakdown as a result of edema; therefore, meticulous skin care is important. Additionally, excoriation and itching of the skin may result from the deposit of irritating toxins in the patient's tissues. Bathing the patient with cool water, frequent turning, and keeping the skin clean and well moisturized and the fingernails trimmed to avoid excoriation are often comforting and prevent skin breakdown.

Providing Psychosocial Support

The patient with ARF may require treatment with hemodialysis, PD, or CRRT. The length of time that these treatments are necessary varies with the cause and extent of damage to the kidneys. The patient and family need assistance, explanation, and support during this period. The purpose of the treatment is explained to the patient and family by the physician. However, high levels of anxiety and fear may necessitate repeated explanation and clarification by the nurse. The family members may initially be afraid to touch and talk to the patient during these procedures but should be encouraged and assisted to do so.

In an intensive care setting, many of the nurse's functions are devoted to the technical aspects of patient care; however, it is essential that the psychological needs and other concerns of the patient and family be addressed. Continued assessment of the patient for complications of ARF and precipitating causes is essential.

Chronic Renal Failure (End-Stage Renal Disease)

When a patient has sustained enough kidney damage to require renal replacement therapy on a permanent basis, the patient has moved into the fifth or final stage of CKD, also referred to as chronic renal failure (CRF) or ESRD.

Pathophysiology

As renal function declines, the end products of protein metabolism (normally excreted in urine) accumulate in the blood. Uremia develops and adversely affects every system in the body. The greater the buildup of waste products, the more pronounced the symptoms are.

The rate of decline in renal function and progression of ESRD is related to the underlying disorder, the urinary excretion of protein, and the presence of hypertension. The disease tends to progress more rapidly in patients who excrete significant amounts of protein or have elevated blood pressure than in those without these conditions.

Clinical Manifestations

Because virtually every body system is affected in ESRD, patients exhibit a number of signs and symptoms (Broscious & Castagnola, 2006). The severity of these signs and symptoms depends in part on the degree of renal impairment, other underlying conditions, and the patient's age. Cardiovascular disease is the predominant cause of death in patients with ESRD (Burrows & Muller, 2007). Peripheral neuropathy, a disorder of the peripheral nervous system, is present in some patients. Patients complain of severe pain and discomfort. Restless leg syndrome and burning feet can occur in the early stage of uremic peripheral neuropathy (Phillips & Ryr, 2005; Slack & Landis, 2006). The precise mechanisms for many of these systemic signs and symptoms have not been identified. However, it is generally thought that the accumulation of uremic waste products is the probable cause. Chart 44-6 summarizes the systemic signs and symptoms.

Assessment and Diagnostic Findings

Glomerular Filtration Rate

As the GFR decreases (due to nonfunctioning glomeruli), the creatinine clearance decreases, while the serum creatinine and BUN levels increase. Serum creatinine is a more sensitive indicator of renal function than BUN. The BUN is affected not only by renal disease but also by protein intake in the diet, catabolism (tissue and RBC breakdown), parenteral nutrition, and medications such as corticosteroids.

Sodium and Water Retention

The kidney cannot concentrate or dilute the urine normally in ESRD. Appropriate responses by the kidney to changes in the daily intake of water and electrolytes, therefore, do not occur. Some patients retain sodium and water, increasing the risk for edema, heart failure, and hypertension. Hypertension may also result from activation of the renin-angiotensin-aldosterone axis and the concomitant increased aldosterone secretion. Other patients have a tendency to lose sodium and run the risk of developing hypotension and hypovolemia. Vomiting and diarrhea may cause sodium and water depletion, which worsens the uremic state.

Acidosis

Metabolic acidosis occurs in ESRD because the kidneys are unable to excrete increased loads of acid. Decreased acid secretion results from the inability of the kidney tubules to excrete ammonia (NH_3^-) and to reabsorb sodium bicarbonate (HCO_3^-). There is also decreased excretion of phosphates and other organic acids.

Anemia

Anemia develops as a result of inadequate erythropoietin production, the shortened lifespan of RBCs, nutritional deficiencies, and the patient's tendency to bleed, particularly from the GI tract. Erythropoietin, a substance normally produced by the kidneys, stimulates bone marrow to produce RBCs (Brattich, 2007). In ESRD, erythropoietin production decreases and profound anemia results, producing fatigue, angina, and shortness of breath.

Chart 44-6 • Assessing for End-stage Renal Disease

Be alert for the following signs and symptoms:

Neurologic

- Weakness and fatigue
- Confusion
- Inability to concentrate
- Disorientation
- Tremors
- Seizures
- Asterixis
- Restlessness of legs
- Burning of soles of feet
- Behavior changes

Integumentary

- Gray-bronze skin color
- Dry, flaky skin
- Pruritus
- Ecchymosis
- Purpura
- Thin, brittle nails
- Coarse, thinning hair

Cardiovascular

- Hypertension
- Pitting edema (feet, hands, sacrum)
- Periorbital edema
- Pericardial friction rub
- Engorged neck veins
- Pericarditis
- Pericardial effusion
- Pericardial tamponade
- Hyperkalemia
- Hyperlipidemia

Pulmonary

- Crackles
- Thick, tenacious sputum
- Depressed cough reflex
- Pleuritic pain
- Shortness of breath
- Tachypnea
- Kussmaul-type respirations
- Uremic pneumonitis

Gastrointestinal

- Ammonia odor to breath (“uremic fetor”)
- Metallic taste
- Mouth ulcerations and bleeding
- Anorexia, nausea, and vomiting
- Hiccups
- Constipation or diarrhea
- Bleeding from gastrointestinal tract

Hematologic

- Anemia
- Thrombocytopenia

Reproductive

- Amenorrhea
- Testicular atrophy
- Infertility
- Decreased libido

Musculoskeletal

- Muscle cramps
- Loss of muscle strength
- Renal osteodystrophy
- Bone pain
- Bone fractures
- Foot drop

Calcium and Phosphorus Imbalance

Another abnormality seen in ESRD is a disorder in calcium and phosphorus metabolism (McCarley & Arjomand, 2008). Serum calcium and phosphate levels have a reciprocal relationship in the body: As one increases, the other decreases. With a decrease in filtration through the glomerulus of the kidney, there is an increase in the serum phosphate level and a reciprocal or corresponding decrease in the serum calcium level. The decreased serum calcium level causes increased secretion of parathormone from the parathyroid glands. However, in renal failure, the body does not respond normally to the increased secretion of parathormone; as a result, calcium leaves the bone, often producing bone changes and bone disease as well as calcification of major blood vessels in the body. In addition, the active metabolite of vitamin D (1,25-dihydroxycholecalciferol) normally manufactured by the kidney decreases as renal failure progresses (Gesek & Desmond, 2008). Uremic bone disease, often called renal osteodystrophy, develops from the complex changes in calcium, phosphate, and parathormone balance. There is also evidence of calcification of blood vessels.

Complications

Potential complications of chronic renal failure that concern the nurse and necessitate a collaborative approach to care include the following:

- Hyperkalemia due to decreased excretion, metabolic acidosis, catabolism, and excessive intake (diet, medications, fluids)
- Pericarditis, pericardial effusion, and pericardial tamponade due to retention of uremic waste products and inadequate dialysis
- Hypertension due to sodium and water retention and malfunction of the renin–angiotensin–aldosterone system
- Anemia due to decreased erythropoietin production, decreased RBC lifespan, bleeding in the GI tract from irritating toxins and ulcer formation, and blood loss during hemodialysis
- Bone disease and metastatic and vascular calcifications due to retention of phosphorus, low serum calcium levels, abnormal vitamin D metabolism, and elevated aluminum levels

Medical Management

The goal of management is to maintain kidney function and homeostasis for as long as possible. All factors that contribute to ESRD and all factors that are reversible (eg, obstruction) are identified and treated. Management is accomplished primarily with medications and diet therapy, although dialysis may also be needed to decrease the level of uremic waste products in the blood and to control electrolyte balance.

Pharmacologic Therapy

Complications can be prevented or delayed by administering prescribed phosphate-binding agents, calcium supplements, antihypertensive and cardiac medications, anti-seizure medications, and erythropoietin (Epogen).

Calcium and Phosphorus Binders

Hyperphosphatemia and hypocalcemia are treated with medications that bind dietary phosphorus in the GI tract. Binders such as calcium carbonate (Os-Cal) or calcium acetate (PhosLo) are prescribed, but there is a risk of hypercalcemia. If calcium is high or the calcium-phosphorus product exceeds 55 mg/dL, a polymeric phosphate binder such as sevelamer hydrochloride (Renagel) may be prescribed (Zonderman & Doyle, 2006). These medications bind dietary phosphorus in the intestinal tract. All binding agents must be administered with food to be effective. Magnesium-based antacids are avoided to prevent magnesium toxicity.

Antihypertensive and Cardiovascular Agents

Hypertension is managed by intravascular volume control and a variety of antihypertensive agents. Heart failure and pulmonary edema may also require treatment with fluid restriction, low-sodium diets, diuretic agents, inotropic agents such as digoxin (Lanoxin) or dobutamine (Dobutrex), and dialysis. The metabolic acidosis of ESRD usually produces no symptoms and requires no treatment; however, sodium bicarbonate supplements or dialysis may be needed to correct the acidosis if it causes symptoms (Molzahn & Butera, 2006).

Antiseizure Agents

Neurologic abnormalities may occur, so the patient must be observed for early evidence of slight twitching, headache, delirium, or seizure activity. If seizures occur, the onset of the seizure is recorded along with the type, duration, and general effect on the patient. The physician is notified immediately. IV diazepam (Valium) or phenytoin (Dilantin) is usually administered to control seizures. The side rails of the bed should be raised and padded to protect the patient. The nursing management of the patient with seizures is discussed in Chapter 61.

Erythropoietin

Anemia associated with ESRD is treated with recombinant human erythropoietin (Epogen). Patients with anemia (hematocrit less than 30%) present with nonspecific symptoms, such as malaise, general fatigability, and decreased activity tolerance. Erythropoietin therapy is initiated to achieve a hematocrit of 33% to 38% and a target hemoglo-

bin of 12 g/dL, which generally alleviates the symptoms of anemia (Brattich, 2007).

Erythropoietin is administered intravenously or subcutaneously three times a week in ESRD. It may take 2 to 6 weeks for the hematocrit to increase; therefore, the medication is not indicated for patients who need immediate correction of severe anemia. Adverse effects seen with erythropoietin therapy include hypertension (especially during early stages of treatment), increased clotting of vascular access sites, seizures, and depletion of body iron stores (Zonderman & Doyle, 2006).

Management involves adjustment of heparin to prevent clotting of the lines during hemodialysis treatments, frequent monitoring of hemoglobin and hematocrit, and periodic assessment of serum iron and transferrin levels. Because adequate stores of iron are necessary for an adequate response to erythropoietin, supplementary iron may be prescribed. Common iron supplements include iron sucrose (Venofer) and ferric gluconate (Ferrlecit). In addition, the patient's blood pressure and serum potassium level are monitored to detect hypertension and increasing serum potassium levels, which may occur with therapy and the increasing RBC mass. The occurrence of hypertension requires initiation or adjustment of the patient's antihypertensive therapy. Hypertension that cannot be controlled is a contraindication to recombinant erythropoietin therapy.

Patients who have received erythropoietin therapy have reported decreased levels of fatigue, increased feelings of well-being, better tolerance of dialysis, higher energy levels, and improved exercise tolerance. Additionally, this therapy has decreased the need for transfusion and its associated risks, including bloodborne infectious disease, antibody formation, and iron overload.

Nutritional Therapy

Dietary intervention is necessary with deterioration of renal function and includes careful regulation of protein intake, fluid intake to balance fluid losses, sodium intake to balance sodium losses, and some restriction of potassium. At the same time, adequate caloric intake and vitamin supplementation must be ensured. Protein is restricted because urea, uric acid, and organic acids—the breakdown products of dietary and tissue proteins—accumulate rapidly in the blood when there is impaired renal clearance. The allowed protein must be of high biologic value (dairy products, eggs, meats). High-biologic-value proteins are those that are complete proteins and supply the essential amino acids necessary for growth and cell repair.

Usually, the fluid allowance per day is 500 mL to 600 mL more than the previous day's 24-hour urine output. Calories are supplied by carbohydrates and fat to prevent wasting. Vitamin supplementation is necessary because a protein-restricted diet does not provide the necessary complement of vitamins. Additionally, the patient on dialysis may lose water-soluble vitamins during the dialysis treatment.

Hyperkalemia is usually prevented by ensuring adequate dialysis treatments with potassium removal and careful monitoring of diet, medications, and fluids for their potassium content. Sodium polystyrene sulfonate (Kayexalate), a cation-exchange resin, may be needed for acute hyperkalemia.

Dialysis

The patient with increasing symptoms of renal failure is referred to a dialysis and transplantation center early in the course of progressive renal disease. Dialysis is usually initiated when the patient cannot maintain a reasonable lifestyle with conservative treatment.

Nursing Management

The patient with ESRD requires astute nursing care to avoid the complications of reduced renal function and the stresses and anxieties of dealing with a life-threatening illness.

Nursing care is directed toward assessing fluid status and identifying potential sources of imbalance, implementing a dietary program to ensure proper nutritional intake within the limits of the treatment regimen, and promoting positive feelings by encouraging increased self-care and greater independence. It is extremely important to provide explanations and information to the patient and family concerning ESRD, treatment options, and potential complications. A great deal of emotional support is needed by the patient and family because of the numerous changes experienced. Specific interventions, along with rationale and evaluation criteria, are presented in more detail in the plan of nursing care for the patient with chronic renal failure (Chart 44-7).

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The nurse plays an important role in teaching the patient with ESRD. Because of the extensive teaching needed, the home care nurse, dialysis nurse, and nurses in the hospital and outpatient settings all provide ongoing education and reinforcement while monitoring the patient's progress and compliance with the treatment regimen.

A referral to a nutritionist is made because of the dietary changes required. The patient is taught how to check the vascular access device for patency and appropriate precautions, such as avoiding venipuncture and blood pressure measurements on the arm with the access device.

Additionally, the patient and family need to know what problems to report to the health care provider. These include the following:

- Worsening signs and symptoms of renal failure (nausea, vomiting, change in usual urine output [if any], ammonia odor on breath)
- Signs and symptoms of hyperkalemia (muscle weakness, diarrhea, abdominal cramps)
- Signs and symptoms of access problems (clotted fistula or graft, infection)

These signs and symptoms of decreasing renal function, in addition to increasing BUN and serum creatinine levels, may indicate a need to alter the dialysis prescription. The dialysis nurses also provide ongoing education and support at each treatment visit.

Continuing Care

The importance of follow-up examinations and treatment is stressed to the patient and family because of changing physical status, renal function, and dialysis requirements. Referral for home care provides the home care nurse with the op-

portunity to assess the patient's environment and emotional status and the coping strategies used by the patient and family to deal with the changes in family roles often associated with chronic illness.

The home care nurse also assesses the patient for further deterioration of renal function and signs and symptoms of complications resulting from the primary renal disorder, the resulting renal failure, and effects of treatment strategies (eg, dialysis, medications, dietary restrictions). Patients need education and reinforcement of the dietary restrictions required, including fluid, sodium, potassium, and protein restriction. Reminders about the need for health promotion activities and health screening are an important part of nursing care for the patient with renal failure.

Gerontologic Considerations

Diabetes, hypertension, chronic glomerulonephritis, interstitial nephritis, and urinary tract obstruction are the causes of ESRD in the elderly. The signs and symptoms of renal disease in the elderly are often nonspecific. The occurrence of symptoms of other disorders (heart failure, dementia) can mask the symptoms of renal disease and delay or prevent diagnosis and treatment. Patients often develop signs and symptoms of nephrotic syndrome, such as edema and proteinuria.

Hemodialysis and PD are used effectively in treating elderly patients. The number of elderly patients initiating dialysis has dramatically increased in the past decade (Kurella, Covinsky, Collins, et al., 2007). Although there is no specific age limitation for renal transplantation, concomitant disorders (eg, coronary artery disease, peripheral vascular disease) have made it a less common treatment for the elderly. However, the outcome is comparable to that of younger patients. Some elderly patients elect not to undergo dialysis or transplantation. Conservative management, including nutritional therapy, fluid control, and medications such as phosphate binders, may be considered in patients who are not suitable for or elect not to have dialysis or transplantation.

RENAL REPLACEMENT THERAPIES

The use of renal replacement therapies becomes necessary when the kidneys can no longer remove wastes, maintain electrolytes, and regulate fluid balance. This can occur rapidly or over a long period of time and the need for replacement therapy can be acute (short term) or chronic (long term). The main renal replacement therapies include the various types of dialysis and kidney transplantation.

Dialysis

Types of dialysis include hemodialysis, CRRT, and PD. Acute dialysis is indicated when there is a high and increasing level of serum potassium, fluid overload, or impending pulmonary edema, increasing acidosis, pericarditis, and severe confusion. It may also be used to remove medications or toxins (poisoning or medication overdose) from

PLAN OF NURSING CARE
The Patient With Chronic Renal Failure

NURSING DIAGNOSIS: Excess fluid volume related to decreased urine output, dietary excesses, and retention of sodium and water
GOAL: Maintenance of ideal body weight without excess fluid

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess fluid status: <ol style="list-style-type: none"> a. Daily weight b. Intake and output balance c. Skin turgor and presence of edema d. Distention of neck veins e. Blood pressure, pulse rate, and rhythm f. Respiratory rate and effort 2. Limit fluid intake to prescribed volume. 3. Identify potential sources of fluid: <ol style="list-style-type: none"> a. Medications and fluids used to take or administer medications: oral and intravenous b. Foods 4. Explain to patient and family rationale for fluid restriction. 5. Assist patient to cope with the discomforts resulting from fluid restriction. 6. Provide or encourage frequent oral hygiene. 	<ol style="list-style-type: none"> 1. Assessment provides baseline and ongoing database for monitoring changes and evaluating interventions. 2. Fluid restriction will be determined on basis of weight, urine output, and response to therapy. 3. Unrecognized sources of excess fluids may be identified. 4. Understanding promotes patient and family cooperation with fluid restriction. 5. Increasing patient comfort promotes compliance with dietary restrictions. 6. Oral hygiene minimizes dryness of oral mucous membranes. 	<ul style="list-style-type: none"> • Demonstrates no rapid weight changes • Maintains dietary and fluid restrictions • Exhibits normal skin turgor without edema • Exhibits normal vital signs • Exhibits no neck vein distention • Reports no difficulty breathing or shortness of breath • Performs oral hygiene frequently • Reports decreased thirst • Reports decreased dryness of oral mucous membranes

NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements related to anorexia, nausea, vomiting, dietary restrictions, and altered oral mucous membranes
GOAL: Maintenance of adequate nutritional intake

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess nutritional status: <ol style="list-style-type: none"> a. Weight changes b. Laboratory values (serum electrolyte, BUN, creatinine, protein, transferrin, and iron levels) 2. Assess patient's nutritional dietary patterns: <ol style="list-style-type: none"> a. Diet history b. Food preferences c. Calorie counts 3. Assess for factors contributing to altered nutritional intake: <ol style="list-style-type: none"> a. Anorexia, nausea, or vomiting b. Diet unpalatable to patient c. Depression d. Lack of understanding of dietary restrictions e. Stomatitis 4. Provide patient's food preferences within dietary restrictions. 5. Promote intake of high-biologic-value protein foods: eggs, dairy products, meats. 	<ol style="list-style-type: none"> 1. Baseline data allow for monitoring of changes and evaluating effectiveness of interventions. 2. Past and present dietary patterns are considered in planning meals. 3. Information about other factors that may be altered or eliminated to promote adequate dietary intake is provided. 4. Increased dietary intake is encouraged. 5. Complete proteins are provided for positive nitrogen balance needed for growth and healing. 	<ul style="list-style-type: none"> • Consumes protein of high biologic value • Chooses foods within dietary restrictions that are appealing • Consumes high-calorie foods within dietary restrictions • Explains in own words rationale for dietary restrictions and relationship to urea and creatinine levels • Takes medications on schedule that does not produce anorexia or feeling of fullness • Consults written lists of acceptable foods • Reports increased appetite at meals • Exhibits no rapid increases or decreases in weight • Demonstrates normal skin turgor without edema; wound healing and acceptable plasma albumin levels

PLAN OF NURSING CARE
The Patient With Chronic Renal Failure (Continued)

NURSING DIAGNOSIS: Activity intolerance related to fatigue, anemia, retention of waste products, and dialysis procedure
GOAL: Participation in activity within tolerance

Nursing Interventions

1. Assess factors contributing to activity intolerance:
 - a. Fatigue
 - b. Anemia
 - c. Fluid and electrolyte imbalances
 - d. Retention of waste products
 - e. Depression
2. Promote independence in self-care activities as tolerated; assist if fatigued.
3. Encourage alternating activity with rest.
4. Encourage patient to rest after dialysis treatments.

Rationale

1. Indicates factors contributing to severity of fatigue
2. Promotes improved self-esteem
3. Promotes activity and exercise within limits and adequate rest
4. Adequate rest is encouraged after dialysis treatments, which are exhausting to many patients.

Expected Outcomes

- Participates in increasing levels of activity and exercise
- Reports increased sense of well-being
- Alternates rest and activity
- Participates in selected self-care activities

NURSING DIAGNOSIS: Risk for situational low self-esteem related to dependency, role changes, change in body image, and change in sexual function
GOAL: Improved self-esteem

Nursing Interventions

1. Assess patient's and family's responses and reactions to illness and treatment.
2. Assess relationship of patient and significant family members.
3. Assess usual coping patterns of patient and family members.
4. Encourage open discussion of concerns about changes produced by disease and treatment:
 - a. Role changes
 - b. Changes in lifestyle
 - c. Changes in occupation
 - d. Sexual changes
 - e. Dependence on health care team
5. Explore alternate ways of sexual expression other than sexual intercourse.
6. Discuss role of giving and receiving love, warmth, and affection.

Rationale

1. Provides data about problems encountered by patient and family in coping with changes in life
2. Identifies strengths and supports of patient and family
3. Coping patterns that may have been effective in past may be harmful in view of restrictions imposed by disease and treatment.
4. Encourages patient to identify concerns and steps necessary to deal with them
5. Alternative forms of sexual expression may be acceptable.
6. Sexuality means different things to different people, depending on stage of maturity.

Expected Outcomes

- Identifies previously used coping styles that have been effective and those no longer possible due to disease and treatment (alcohol or drug use; extreme physical exertion)
- Patient and family identify and verbalize feelings and reactions to disease and necessary changes in their lives
- Seeks professional counseling, if necessary, to cope with changes resulting from renal failure
- Reports satisfaction with method of sexual expression

COLLABORATIVE PROBLEMS: Hyperkalemia; pericarditis, pericardial effusion, and pericardial tamponade; hypertension; anemia; bone disease and metastatic calcifications
GOAL: Absence of complications

Nursing Interventions**Hyperkalemia**

1. Monitor serum potassium levels. Notify physician if level greater than 5.5 mEq/L, and prepare to treat hyperkalemia.
2. Assess patient for muscle weakness, diarrhea, ECG changes (tall-tented T waves and widened QRS).

Rationale

1. Hyperkalemia causes potentially life-threatening changes in the body.
2. Cardiovascular signs and symptoms are characteristic of hyperkalemia.

Expected Outcomes

- Patient has normal potassium level
- Experiences no muscle weakness or diarrhea
- Exhibits normal ECG pattern
- Vital signs are within normal limits

PLAN OF NURSING CARE
The Patient With Chronic Renal Failure (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p>Pericarditis, Pericardial Effusion, and Pericardial Tamponade</p> <ol style="list-style-type: none"> 1. Assess patient for fever, chest pain, and a pericardial friction rub (signs of pericarditis) and, if present, notify physician. 2. If patient has pericarditis, assess for the following every 4 hours: <ol style="list-style-type: none"> a. Paradoxical pulse >10 mm Hg b. Extreme hypotension c. Weak or absent peripheral pulses d. Altered level of consciousness e. Bulging neck veins 3. Prepare patient for cardiac ultrasound to aid in diagnosis of pericardial effusion and cardiac tamponade. 4. If cardiac tamponade develops, prepare patient for emergency pericardiocentesis. 	<ol style="list-style-type: none"> 1. About 30%–50% of patients with chronic renal failure develop pericarditis due to uremia; fever, chest pain, and a pericardial friction rub are classic signs. 2. Pericardial effusion is a common fatal sequela of pericarditis. Signs of an effusion include a paradoxical pulse (>10 mm Hg drop in blood pressure during inspiration) and signs of shock due to compression of the heart by a large effusion. Cardiac tamponade exists when the patient is severely compromised hemodynamically. 3. Cardiac ultrasound is useful in visualizing pericardial effusions and cardiac tamponade. 4. Cardiac tamponade is a life-threatening condition, with a high mortality rate. Immediate aspiration of fluid from the pericardial space is essential. 	<ul style="list-style-type: none"> • Has strong and equal peripheral pulses • Absence of a paradoxical pulse • Absence of pericardial effusion or tamponade on cardiac ultrasound • Patient has normal heart sounds
<p>Hypertension</p> <ol style="list-style-type: none"> 1. Monitor and record blood pressure as indicated. 2. Administer antihypertensive medications as prescribed. 3. Encourage compliance with dietary and fluid restriction therapy. 4. Teach patient to report signs of fluid overload, vision changes, headaches, edema, or seizures. 	<ol style="list-style-type: none"> 1. Provides objective data for monitoring. Elevated levels may indicate nonadherence to the treatment regimen. 2. Antihypertensive medications play a key role in treatment of hypertension associated with chronic renal failure. 3. Adherence to diet and fluid restrictions and dialysis schedule prevents excess fluid and sodium accumulation. 4. These are indications of inadequate control of hypertension and the need to alter therapy. 	<ul style="list-style-type: none"> • Blood pressure within normal limits • Reports no headaches, visual problems, or seizures • Edema is absent • Demonstrates compliance with dietary and fluid restrictions
<p>Anemia</p> <ol style="list-style-type: none"> 1. Monitor RBC count, hemoglobin, and hematocrit levels as indicated. 2. Administer medications as prescribed, including iron and folic acid supplements, Epogen, and multivitamins. 3. Avoid drawing unnecessary blood specimens. 4. Teach patient to prevent bleeding: avoid vigorous nose blowing and contact sports, and use a soft toothbrush. 5. Administer blood component therapy as indicated. 	<ol style="list-style-type: none"> 1. Provides assessment of degree of anemia 2. RBCs need iron, folic acid, and vitamins to be produced. Epogen stimulates the bone marrow to produce RBC. 3. Anemia is worsened by drawing numerous specimens. 4. Bleeding from anywhere in the body worsens anemia. 5. Blood component therapy may be needed if the patient has symptoms. 	<ul style="list-style-type: none"> • Patient has a normal skin color without pallor • Exhibits hematology values within acceptable limits • Experiences no bleeding from any site

PLAN OF NURSING CARE

The Patient With Chronic Renal Failure (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p>Bone Disease and Metastatic Calcifications</p> <ol style="list-style-type: none"> Administer the following medications as prescribed: phosphate binders, calcium supplements, vitamin D supplements. Monitor serum lab values as indicated (calcium, phosphorus, aluminum levels) and report abnormal findings to physician. Assist patient with an exercise program. 	<ol style="list-style-type: none"> Chronic renal failure causes numerous physiologic changes affecting calcium, phosphorus, and vitamin D metabolism. Hyperphosphatemia, hypocalcemia, and excess aluminum accumulation are common in chronic renal failure. Bone demineralization increases with immobility. 	<ul style="list-style-type: none"> Exhibits serum calcium, phosphorus, and aluminum levels within acceptable ranges Exhibits no symptoms of hypocalcemia Has no bone demineralization on bone scan Discusses importance of maintaining activity level and exercise program

the blood or for edema that does not respond to other treatment, hepatic coma, hyperkalemia, hypercalcemia, hypertension, and uremia (Mosenkis, Kirk & Berns, 2006).

Chronic or maintenance dialysis is indicated in advanced CKD and ESRD in the following instances: the presence of uremic signs and symptoms affecting all body systems (nausea and vomiting, severe anorexia, increasing lethargy, mental confusion), hyperkalemia, fluid overload not responsive to diuretics and fluid restriction, and a general lack of well-being. An urgent indication for dialysis in patients with renal failure is pericardial friction rub.

The decision to initiate dialysis should be reached only after thoughtful discussion among the patient, family, physician, and others as appropriate. Many potentially life-threatening issues are associated with the need for dialysis. The nurse can assist the patient and family by answering their questions, clarifying the information provided, and supporting their decision.

Successful kidney transplantation eliminates the need for dialysis. Not only is the quality of life much improved in patients with ESRD who undergo transplantation, but physiologic function is improved as well. Patients who undergo renal transplantation from living donors before dialysis is initiated generally have longer survival of the transplanted kidney than patients who receive transplantation after dialysis treatment is initiated.

HEMODIALYSIS

Hemodialysis is used for patients who are acutely ill and require short-term dialysis (days to weeks) and for patients with advanced CKD and ESRD who require long-term or permanent renal replacement therapy. Hemodialysis prevents death but does not cure renal disease and does not compensate for the loss of endocrine or metabolic activities of the kidneys. More than 90% of patients requiring long-term renal replacement therapy are on chronic hemodialysis (USRDS, 2007). Most patients receive intermittent hemodialysis that involves treatments three times a week with the average treatment duration of 3 to 4 hours in an outpatient setting. Hemodialysis can also be performed at home by the patient and a caregiver. With home dialysis, treatment time and frequency can be adjusted to meet optimal patient needs.

The objectives of hemodialysis are to extract toxic nitrogenous substances from the blood and to remove excess water. A **dialyzer** (also referred to as an artificial kidney) serves as a synthetic semipermeable membrane, replacing the renal glomeruli and tubules as the filter for the impaired kidneys. In hemodialysis, the blood, laden with toxins and nitrogenous wastes, is diverted from the patient to a machine, a dialyzer, where toxins are filtered out and removed and the blood is returned to the patient.

Diffusion, osmosis, and ultrafiltration are the principles on which hemodialysis is based (see Chapter 14). The toxins and wastes in the blood are removed by **diffusion**—that is, they move from an area of higher concentration in the blood to an area of lower concentration in the **dialysate**. The dialysate is a solution made up of all the important electrolytes in their ideal extracellular concentrations. The electrolyte level in the patient's blood can be brought under control by properly adjusting the dialysate bath. The semipermeable membrane impedes the diffusion of large molecules, such as RBCs and proteins.

Excess water is removed from the blood by **osmosis**, in which water moves from an area of low concentration potential (the blood) to an area of high concentration potential (the dialysate bath). In **ultrafiltration**, water moves under high pressure to an area of lower pressure. This process is much more efficient than osmosis at water removal and is accomplished by applying negative pressure or a suctioning force to the dialysis membrane. Because patients with renal disease usually cannot excrete water, this force is necessary to remove fluid to achieve fluid balance.

The body's buffer system is maintained using a dialysate bath made up of bicarbonate (most common) or acetate, which is metabolized to form bicarbonate. The anticoagulant heparin is administered to keep blood from clotting in the dialysis circuit. Cleansed blood is returned to the body. By the end of the dialysis treatment, many waste products have been removed, the electrolyte balance has been restored to normal, and the buffer system has been replenished.

Dialyzers

Dialyzers are hollow-fiber devices containing thousands of tiny strawlike tubes that carry the blood through the dialyzer. The tubes are porous and act as a semipermeable membrane

Figure 44-3 Hemodialysis system. **A**, Blood from an artery is pumped into **(B)** a dialyzer where it flows through the cellophane tubes, which act as the semipermeable membrane (*inset*). The dialysate, which has the same chemical composition as the blood except for urea and waste products, flows in around the tubules. The waste products in the blood diffuse through the semipermeable membrane into the dialysate.

allowing toxins, fluid, and electrolytes to pass through. The constant flow of the solution maintains the concentration gradient to facilitate the exchange of wastes from the blood through the semipermeable membrane into the dialysate solution, where they are removed and discarded (Fig. 44-3).

Dialyzers have undergone many technologic changes in performance and biocompatibility. High-flux dialysis uses highly permeable membranes to increase the clearance of low- and mid-molecular-weight molecules. These special membranes are used with higher than traditional rates of flow for the blood entering and exiting the dialyzer (500 to 550 mL/min). High-flux dialysis increases the efficiency of treatments while shortening their duration and reducing the need for heparin.

Vascular Access

Access to the patient's vascular system must be established to allow blood to be removed, cleansed, and returned to the patient's vascular system at rates between 300 and 800 mL/min. Several types of access are available.

Vascular Access Devices

Immediate access to the patient's circulation for acute hemodialysis is achieved by inserting a double-lumen, non-cuffed, large-bore catheter into the subclavian, internal

jugular, or femoral vein by the physician (Fig. 44-4). This method of vascular access involves some risk (eg, hematoma, pneumothorax, infection, thrombosis of the subclavian vein, inadequate flow). The catheter is removed when no longer needed (eg, because the patient's condition has improved or another type of access has been established). Double-lumen, cuffed catheters may also be inserted, usually by either a surgeon or interventional radiologist, into the internal jugular vein of the patient. Since these catheters have cuffs under the skin, the insertion site heals, sealing the wound and reducing the risk for ascending infection. This feature makes these catheters safe for longer-term use. Infection rates, however, remain high and septicemia continues to be a common cause for hospital admission.

Arteriovenous Fistula

The preferred method of permanent access is an **arteriovenous fistula (AVF)** that is created surgically (usually in the forearm) by joining (anastomosing) an artery to a vein, either side to side or end to side (Fig. 44-5A). Needles are inserted into the vessel to obtain blood flow adequate to pass through the dialyzer. The arterial segment of the fistula is used for arterial flow to the dialyzer and the venous segment for reinfusion of the dialyzed blood. This

Figure 44-4 Double-lumen, cuffed hemodialysis catheter used in acute hemodialysis. The red adapter is attached to a blood line through which blood is pumped from the patient to the dialyzer. After the blood passes through the dialyzer (artificial kidney), it returns to the patient through the blue adapter.

access will need time, (2 to 3 months) to “mature” before it can be used. As the AVF matures, the venous segment dilates due to the increased blood flow coming directly from the artery. Once sufficiently dilated it will then accommodate two large-bore (14-, 15-, or 16-gauge) needles that are inserted for each dialysis treatment. The patient is encouraged to perform hand exercises to increase the size of these vessels (ie, squeezing a rubber ball for forearm fistulas) to accommodate the large-bore needles. Once established, this access has the longest useful life and thus is the best option for vascular access for the chronic hemodialysis patient.

Arteriovenous Graft

An **arteriovenous graft** can be created by subcutaneously interposing a biologic, semibiologic, or synthetic graft material between an artery and vein (Fig. 44-5B). Usually a graft is created when the patient’s vessels are not suitable for creation of an AV fistula. Patients with compromised vascular systems (eg, from diabetes) will require a graft because their native vessels are not suitable for creation of an AV Fistula. Grafts are usually placed in the arm but may be placed in the thigh or chest area. Stenosis, infection, and thrombosis are the most common complications that result in loss of this access. It is not at all uncommon to see a dialysis patient with numerous “old” or “nonfunctioning” accesses present on their arms. The patient is asked to identify which is the current access in use and it is checked carefully for the presence of a bruit and thrill.

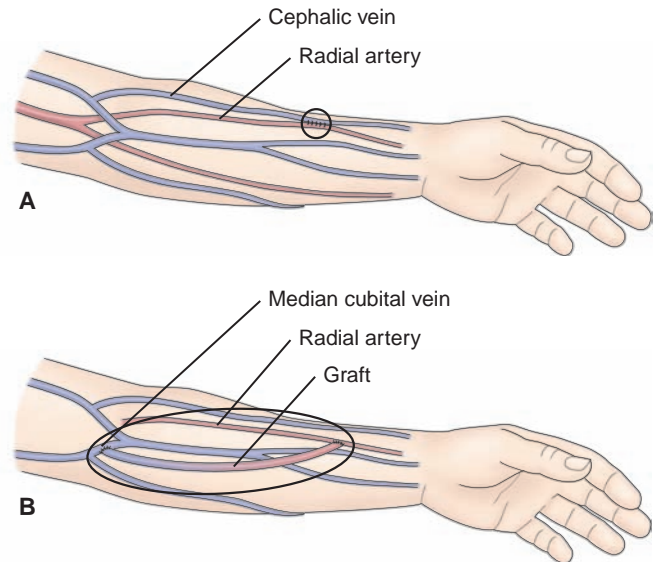

Figure 44-5 **A**, Arteriovenous fistulas are created by anastomosing a patient’s vein to an artery. This illustrates a side-to-side anastomosis. **B**, Arteriovenous grafts are established by placing synthetic tubing between the artery and vein.

NURSING ALERT

Failure of the permanent dialysis access (fistula or graft) accounts for most hospital admissions of patients undergoing chronic hemodialysis. Thus, protection of the access is of high priority.

Complications

While hemodialysis can prolong life indefinitely, it does not alter the natural course of the underlying CKD, nor does it completely replace kidney function. The CKD complications previously discussed will continue to worsen and require more aggressive treatment. With the initiation of dialysis, disturbances of lipid metabolism (hypertriglyceridemia) are accentuated and contribute to cardiovascular complications. Heart failure, coronary heart disease, angina, stroke, and peripheral vascular insufficiency may occur and can incapacitate the patient. Cardiovascular disease remains the leading cause of death in patients receiving dialysis (Burrows & Muller, 2007).

Anemia is compounded by blood lost during hemodialysis. Gastric ulcers may result from the physiologic stress of chronic illness, medication, and preexisting medical conditions (eg, diabetes). Patients with uremia report a metallic taste and nausea when they require dialysis. Vomiting may occur during the hemodialysis treatment when rapid fluid shifts and hypotension occur. These contribute to the malnutrition seen in patients on dialysis. Worsening calcium metabolism and renal osteodystrophy can result in bone pain and fractures, interfering with mobility. As time on dialysis continues, calcification of major blood vessels has been reported and linked to hypertension and other vascular complications. Phosphorus deposits in the skin can occur and cause itching.

Up to 85% of people undergoing hemodialysis experience major sleep problems that further complicate their overall health status (Phillips & Ryr, 2005). Early-morning or late-afternoon dialysis may be a risk factor for developing sleep disturbances.

Other complications of dialysis treatment may include the following:

- Episodes of shortness of breath often occur as fluid accumulates between dialysis treatments.
- Hypotension may occur during the treatment as fluid is removed. Nausea and vomiting, diaphoresis, tachycardia, and dizziness are common signs of hypotension.
- Painful muscle cramping may occur, usually late in dialysis as fluid and electrolytes rapidly leave the extracellular space.
- Exsanguination may occur if blood lines separate or dialysis needles become dislodged.
- Dysrhythmias may result from electrolyte and pH changes or from removal of antiarrhythmic medications during dialysis.
- Air embolism is rare but can occur if air enters the vascular system.
- Chest pain may occur in patients with anemia or arteriosclerotic heart disease.
- Dialysis disequilibrium results from cerebral fluid shifts. Signs and symptoms include headache, nausea and vomiting, restlessness, decreased level of consciousness, and seizures. It is more likely to occur in acute renal failure or when blood urea nitrogen levels are very high (exceeding 150 mg/dL).

Nursing Management

The nurse in the dialysis unit has an important role in monitoring, supporting, assessing, and educating the patient. During dialysis, the patient, the dialyzer, and the dialysate bath require constant monitoring because numerous complications are possible, including clotting of the circuit, air embolism, inadequate or excessive ultrafiltration hypotension, cramping, vomiting, blood leaks, contamination, and access complications. Nursing care of the patient and maintenance of the vascular access device are especially important and are discussed later in this chapter in the section titled Special Considerations: Nursing Management of the Hospitalized Patient on Dialysis.

Promoting Pharmacologic Therapy

Many medications are removed from the blood during hemodialysis; therefore, dosage or timing of the medication administration may require adjustment. Medications that are water soluble are readily removed during hemodialysis treatment and those that are fat soluble or adhere to other substances (like albumin) are not dialyzed out very well. This is the reason some drug overdoses are treated with emergency hemodialysis and others are not.

Patients undergoing hemodialysis who require medications (eg, cardiac glycosides, antibiotic agents, antiarrhythmic medications, antihypertensive agents) are monitored closely to ensure that blood and tissue levels of these medications are maintained without toxic accumulation. Antihypertensive therapy, often part of the regimen of patients

on dialysis, is one example when communication, teaching, and evaluation can make a difference in patient outcomes. The patient must know when and when not to take the medication. For example, if an antihypertensive agent is taken on a dialysis day, hypotension may occur during dialysis, causing dangerously low blood pressure. Many medications that are taken once daily can be held until after the dialysis treatment.

Promoting Nutritional and Fluid Therapy

Diet is important for patients on hemodialysis because of the effects of uremia. Goals of nutritional therapy are to minimize uremic symptoms and fluid and electrolyte imbalances; to maintain good nutritional status through adequate protein, calorie, vitamin, and mineral intake; and to enable the patient to eat a palatable and enjoyable diet. Restricting dietary protein decreases the accumulation of nitrogenous wastes, reduces uremic symptoms, and may even postpone the initiation of dialysis for a few months. Restriction of fluid is also part of the dietary prescription because fluid accumulation may occur, leading to weight gain, heart failure, and pulmonary edema.

With the initiation of hemodialysis, the patient usually requires some restriction of dietary protein, sodium, potassium, and fluid intake. Protein intake is restricted to about 1.2 to 1.3 g/kg ideal body weight per day; therefore, protein must be of high biologic quality. Sodium is usually restricted to 2 to 3 g/day; fluids are restricted to an amount equal to the daily urine output plus 500 mL/day. The goal for patients on hemodialysis is to keep their interdialytic (between dialysis treatments) weight gain under 1.5 kg (Welch & Perkins, 2006). Potassium restriction depends on the amount of residual renal function and the frequency of dialysis. Dietary restriction is an unwelcome change in lifestyle for many patients with chronic renal failure. Patients can feel stigmatized in social situations because there may be few food choices available for their diet. If the restrictions are ignored, life-threatening complications, such as hyperkalemia and pulmonary edema, may result. Thus, the patient may feel punished for responding to basic human drives to eat and drink. The nurse who cares for a patient with symptoms or complications resulting from dietary indiscretion must avoid harsh, judgmental, or punitive tones when communicating with him or her. Regular education with reinforcement is needed to achieve this difficult change in life style (Welch & Perkins, 2006) (Chart 44-8).

Meeting Psychosocial Needs

Patients requiring long-term hemodialysis are often concerned about the unpredictability of the illness and the disruption of their lives. They often have financial problems, difficulty holding a job, waning sexual desire and impotence, depression from being chronically ill, and fear of dying. Younger patients worry about marriage, having children, and the burden that they bring to their families. The regimented lifestyle that frequent dialysis treatments and restrictions in food and fluid intake impose is often demoralizing to the patient and family.

Dialysis alters the lifestyle of the patient and family. The amount of time required for dialysis and physician visits and being chronically ill can create conflict, frustration, guilt,

Hemodialysis and Nonadherence

Belguzar, K., Kayser, C. & Kilic, S. (2007). Nonadherence with diet and fluid restrictions and perceived social support in patients receiving hemodialysis. *Journal of Nursing Scholarship*, 39(3), 243–248.

Purpose

Nonadherence to diet and fluid restrictions has adverse consequences for patients receiving hemodialysis. The purpose of this study was to describe nonadherence with diet and fluid restrictions and the level of perceived social support in hemodialysis patients. Nonadherence often occurs when a person's behavior conflicts with medical advice regarding taking medications, following diets, or other lifestyle changes.

Design

This descriptive study surveyed 160 patients on hemodialysis in three centers in Turkey. Participants were asked about personal characteristics, and data were collected using the Dialysis Diet and Fluid Nonadherence Questionnaire (DDFQ) and Multidimensional Scale of Perceived Social Support (MSP). Data were collected during the patient's regularly scheduled dialysis session. The DDFQ is a four-item self-report

questionnaire that assesses the frequency of nonadherence to diet and fluid restrictions for the previous 14 days. The MSP is a 12-item scale used to assess emotional support and the degree of satisfaction with perceived social support from family, friends, and significant others.

Findings

Adherence to fluid restriction is a difficult and stressful aspect of hemodialysis treatment, and most patients in this study showed some degree of nonadherence to fluid restrictions (68%) and diet (58%). Participants perceived total social support as low. Nonadherence was most common with younger patients, those who were married, and those with lower levels of perceived social support.

Nursing Implications

Nurses working in hemodialysis centers need to consider social support and how it affects adherence in patients receiving hemodialysis. The results of this study suggest that younger, married patients may require assistance to develop the levels of social support needed to adhere to fluid and diet restrictions between hemodialysis sessions.

and depression. It may be difficult for the patient, spouse, and family to express anger and negative feelings.

The nurse needs to give the patient and family the opportunity to express feelings of anger and concern about the limitations that the disease and treatment impose, possible financial problems, and job insecurity. If anger is not expressed, it may be directed inward and lead to depression, despair, and attempts at suicide (suicide is more prevalent in patients on dialysis); however, if anger is projected outward to other people, it may destroy already threatened family relationships.

Although these feelings are normal in this situation, they are often profound and overwhelming. Counseling and psychotherapy may be necessary. Depression may require treatment with antidepressant agents. Referring the patient and family to a mental health provider with expertise in the care of patients receiving dialysis may also be helpful. Clinical nurse specialists, psychologists, and social workers may be helpful in assisting the patient and family to cope with the changes brought about by renal failure and its treatment.

The "sense of loss" that the patient experiences cannot be underestimated because every aspect of a "normal life" is disrupted. Some patients use denial to deal with the overwhelming array of medical problems (eg, infections, hypertension, anemia, neuropathy). Staff who are tempted to label the patient as noncompliant must consider the impact of renal failure and its treatment on the patient and family and the coping strategies that they may use.

Palliative care principles that focus on symptom control are becoming increasingly important as greater attention is focused on quality-of-life issues (Cohen, Moss, Weisord, et al., 2006). Patients and their families should be encouraged to discuss end-of-life options and have developed advanced directives or living wills.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Preparing a patient for hemodialysis is challenging. Often the patient does not fully comprehend the impact of dialysis, and learning needs may go unrecognized. Good communication between dialysis staff and home care nurses is essential.

Assessment helps identify the learning needs of the patient and family members. In many cases, the patient is discharged home before learning needs and readiness to learn can be thoroughly evaluated; therefore, hospital-based nurses, dialysis staff, and home care nurses must work together to provide appropriate teaching that meets the patient's and family's changing needs and readiness to learn.

The diagnosis of chronic renal failure and the need for dialysis often overwhelm the patient and family. In addition, many patients with ESRD have depressed mentation, a shortened attention span, a decreased level of concentration, and altered perception. Therefore, teaching must occur in brief, 10- to 15-minute sessions, with time added for clarification, repetition, reinforcement, and questions from the patient and family. The nurse needs to convey a nonjudgmental attitude to enable the patient and family to discuss options and their feelings about those options. Team conferences are helpful for sharing information and providing every team member the opportunity to discuss the needs of the patient and family.

Home Hemodialysis

Most patients who undergo hemodialysis do so in an outpatient setting, but home hemodialysis is an option for some. Home hemodialysis requires a highly motivated patient who is willing to take responsibility for the procedure and is able to adjust each treatment to meet the body's changing

needs. It also requires the commitment and cooperation of a caregiver to assist the patient. However, many patients are not comfortable imposing on others this way and do not wish to subject family members to the feeling that their home is being turned into a clinic. The health care team never forces a patient to use home hemodialysis because this treatment requires significant changes in the home and family. Home hemodialysis must be the patient's and family's decision (American Nephrology Nurses Association, 2007a).

The patient undergoing home hemodialysis and the caregiver assisting that patient must be trained to prepare, operate, and disassemble the dialysis machine; maintain and clean the equipment; administer medications (eg, heparin) into the machine lines; and handle emergency problems (hemodialysis dialyzer rupture, electrical or mechanical problems, hypotension, shock, and seizures). Because home hemodialysis places primary responsibility for the treatment on the patient and the family member, they must understand and be capable of performing all aspects of the hemodialysis procedure (Chart 44-9).

Before home hemodialysis is initiated, the home environment, household and community resources, and ability and willingness of the patient and family to carry out this treatment are assessed. The home is surveyed to see if electrical outlets, plumbing facilities, and storage space are adequate. Modifications may be needed to enable the patient and assistant to perform dialysis safely and to deal with emergencies.

Once home hemodialysis is initiated, the home care nurse must visit periodically to evaluate compliance with

the recommended techniques, to assess the patient for complications, to reinforce previous teaching, and to provide reassurance.

Continuing Care

The health care team's goal in treating patients with chronic renal failure is to maximize their vocational potential, functional status, and quality of life. To facilitate renal rehabilitation, appropriate follow-up and monitoring by members of the health care team (physicians, dialysis nurses, social worker, psychologist, home care nurses, and others as appropriate) are essential to identify and resolve problems early on. Many patients with chronic renal failure can resume relatively normal lives, doing the things that are important to them: traveling, exercising, working, or actively participating in family activities. If appropriate interventions are available early in the course of dialysis, the potential for better health improves, and the patient can remain active in family and community life. Outcome goals for renal rehabilitation include employment for those able to work, improved physical functioning of all patients, improved understanding about adaptation and options for living well, increased control over the effects of kidney disease and dialysis, and resumption of activities enjoyed before dialysis.

CONTINUOUS RENAL REPLACEMENT THERAPIES

Continuous renal replacement therapies (CRRTs) may be indicated for patients with acute or chronic renal failure who are too clinically unstable for traditional hemodialysis,

CHART
44-9

HOME CARE CHECKLIST Hemodialysis

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Discuss renal failure and its effects on the body.	✓	✓
• Describe the cause of renal failure and why hemodialysis is necessary.	✓	✓
• Describe the basic principles of hemodialysis.	✓	✓
• Discuss common problems that may occur during hemodialysis and their prevention and management.	✓	✓
• Demonstrate knowledge about prescribed medications and the reason for their use, potential side effects, guidelines on when to notify physician, and the schedule of medications on dialysis and nondialysis days.	✓	✓
• Acknowledge dietary and fluid restrictions, rationale, and consequences of noncompliance.	✓	✓
• Describe commonly measured laboratory values, results, and implications.	✓	✓
• List guidelines for prevention and detection of fluid overload, meaning of "dry" weight, and how to weigh self.	✓	✓
• Demonstrate vascular access care, how to check patency, signs and symptoms of infection, and prevention of complications.	✓	✓
• Discuss strategies for detection, management, and relief of pruritus, neuropathy, and other complications of renal failure.	✓	✓
• Develop strategies to manage or reduce anxiety and maintain independence.	✓	✓
• Coordinate financial arrangements for dialysis and strategies to identify and obtain resources.	✓	✓

Figure 44-6 Devices for administering continuous renal replacement therapy (CRRT) offer an integrated fluid warmer for the heating of infusion and dialysate fluids, a weighing system to reduce the possibility of error in assessing fluid balance, and a battery backup that allows treatments to continue when the patient is moved. **A**, Diapact CRRT System, B-Braun Medical, Inc., Bethlehem, PA. **B**, PRISMA, Gambro Corporation, Lakewood, CO.

for patients with fluid overload secondary to oliguric (low urine output) renal failure, and for patients whose kidneys cannot handle their acutely high metabolic or nutritional needs. CRRT does not produce rapid fluid shifts, does not require dialysis machines or dialysis personnel to carry out the procedures, and can be initiated quickly. Several types of CRRT are available and widely used in critical care units (Fig. 44-6). The methods are similar as they require access to the circulation and blood to pass through an artificial filter. A hemofilter (an extremely porous blood filter containing a semipermeable membrane) is used in all types.

Continuous Venovenous Hemofiltration

Continuous venovenous hemofiltration (CVVH) is used to manage acute renal failure. Blood from a double-lumen venous catheter is pumped (using a small blood pump) through a hemofilter and then returned to the patient through the same catheter. CVVH provides continuous slow fluid removal (ultrafiltration); therefore, hemodynamic effects are mild and better tolerated by patients with unstable conditions. CVVH does not require arterial access, and critical care nurses can set up, initiate, maintain, and terminate the system.

Continuous Venovenous Hemodialysis

Continuous venovenous hemodialysis (CVVHD) is similar to CVVH. Blood is pumped from a double-lumen venous catheter through a hemofilter and returned to the patient through the same catheter. In addition to the benefits of ultrafiltration, CVVHD uses a concentration gradient to facilitate the removal of uremic toxins and fluid. No arterial access is required, hemodynamic effects are usually mild,

and critical care nurses can set up, initiate, maintain, and terminate the system (Martin & Jurschak, 2007).

Examples of less frequently used CRRT include slow continuous ultrafiltration (SCUF), continuous arteriovenous hemofiltration (CAVH), and continuous arteriovenous hemodialysis (CAVHD) (Martin & Jurschak, 2007).

PERITONEAL DIALYSIS

The goals of PD are to remove toxic substances and metabolic wastes and to reestablish normal fluid and electrolyte balance. PD may be the treatment of choice for patients with renal failure who are unable or unwilling to undergo hemodialysis or renal transplantation. Patients who are susceptible to the rapid fluid, electrolyte, and metabolic changes that occur during hemodialysis experience fewer of these problems with the slower rate of PD. Therefore, patients with diabetes or cardiovascular disease, many older patients, and those who may be at risk for adverse effects of systemic heparin are likely candidates for PD. Additionally, severe hypertension, heart failure, and pulmonary edema not responsive to usual treatment regimens have been successfully treated with PD. Less than 8% of patients with ESRD receive PD as their treatment modality (USRDS, 2007).

In PD, the peritoneal membrane that covers the abdominal organs and lines the abdominal wall serves as the semipermeable membrane. Sterile dialysate fluid is introduced into the peritoneal cavity through an abdominal catheter at intervals (Fig. 44-7). Once the sterile solution is in the peritoneal cavity, uremic toxins such as urea and creatinine begin to be cleared from the blood. Diffusion and osmosis occur as waste products move from an area of higher concentration (the blood stream) to an area of lesser

Figure 44-7 In peritoneal dialysis and in acute intermittent peritoneal dialysis, dialysate is infused into the peritoneal cavity by gravity, after which the clamp on the infusion line is closed. After a dwell time (when the dialysate is in the peritoneal cavity), the drainage tube is unclamped and the fluid drains from the peritoneal cavity, again by gravity. A new container of dialysate is infused as soon as drainage is complete. The duration of the dwell time depends on the type of peritoneal dialysis.

concentration (the dialysate fluid) through a semipermeable membrane (the peritoneum). This movement of solute from the blood into the dialysate fluid is called clearance. Since substances cross the peritoneal membrane at different rates, adjustments in dwell time and amount of fluid used are made to facilitate the process. Ultrafiltration (water removal) occurs in PD through an osmotic gradient created by using a dialysate fluid with a higher glucose concentration. PD usually takes 36 to 48 hours to achieve what hemodialysis accomplishes in 6 to 8 hours.

Procedure

As with other forms of treatment, the decision to begin PD is made by the patient and family in consultation with the physician. The patient may be acutely ill, thus requiring short-term treatment to correct severe disturbances in fluid and electrolyte status, or may have ESRD and need to receive ongoing treatments.

Preparing the Patient

The nurse's preparation of the patient and family for PD depends on the patient's physical and psychological status, level of alertness, previous experience with dialysis, and understanding of and familiarity with the procedure.

The nurse explains the procedure to the patient and assists in obtaining signed consent. Baseline vital signs, weight, and serum electrolyte levels are recorded. Evaluation of the abdomen for placement of the catheter is done to facilitate self-care. Typically the catheter is placed on the nondominant side to allow the patient easier access to the

catheter connection site when exchanges are done. The patient is encouraged to empty the bladder and bowel to reduce the risk of puncture of internal organs during the insertion procedure. Broad-spectrum antibiotic agents may be administered to prevent infection. The peritoneal catheter can be inserted in interventional radiology, in the operating room, or at the bedside. Depending on the situation, this will need to be explained to the patient and family.

Preparing the Equipment

In addition to assembling the equipment for PD, the nurse consults with the physician to determine the concentration of dialysate to be used and the medications to be added to it. Heparin may be added to prevent fibrin formation and resultant occlusion of the peritoneal catheter. Potassium chloride may be prescribed to prevent hypokalemia. Antibiotics may be added to treat **peritonitis** (inflammation of the peritoneal membrane) caused by infection. Regular insulin may be added for patients with diabetes. Aseptic technique is imperative whenever medications are added.

Before medications are added, the dialysate is warmed to body temperature to prevent patient discomfort and abdominal pain and to dilate the vessels of the peritoneum to increase urea clearance. Solutions that are too cold cause pain, cramping, and vasoconstriction and reduce clearance. Dry heating (heating cabinet, incubator, or heating pad) is recommended. Methods not recommended include soaking the bags of solution in warm water (can introduce bacteria to the exterior of the bags of solution and increase the chance of peritonitis) and use of a microwave to heat the fluid (increases the danger of burning the peritoneum).

Immediately before initiating dialysis, using aseptic technique, the nurse assembles the administration set and tubing. The tubing is filled with the prepared dialysate to reduce the amount of air entering the catheter and peritoneal cavity, which could increase abdominal discomfort and interfere with instillation and drainage of the fluid.

Inserting the Catheter

Ideally, the peritoneal catheter is inserted in the operating room or radiology suite to maintain surgical asepsis and minimize the risk of contamination. However, in some circumstances, the physician may insert the rigid stylet catheter at the bedside using strict asepsis. Whenever a rigid catheter is used, careful securing and close observation for bowel perforation is essential to minimize complications.

Catheters for long-term use (eg, Tenckhoff, Swan, or Cruz) are usually soft and flexible and made of silicone with a radiopaque strip to permit visualization on x-ray. These catheters have three sections: (1) an intraperitoneal section, with numerous openings and an open tip to let dialysate flow freely; (2) a subcutaneous section that passes from the peritoneal membrane and tunnels through muscle and subcutaneous fat to the skin; and (3) an external section for connection to the dialysate system. Most of these catheters have two cuffs, which are made of Dacron polyester. The cuffs stabilize the catheter, limit movement, prevent leaks, and provide a barrier against microorganisms. One cuff is placed just distal to the peritoneum, and the other cuff is placed subcutaneously. The subcutaneous tunnel (5 to 10 cm long) further protects against bacterial infection (Fig. 44-8).

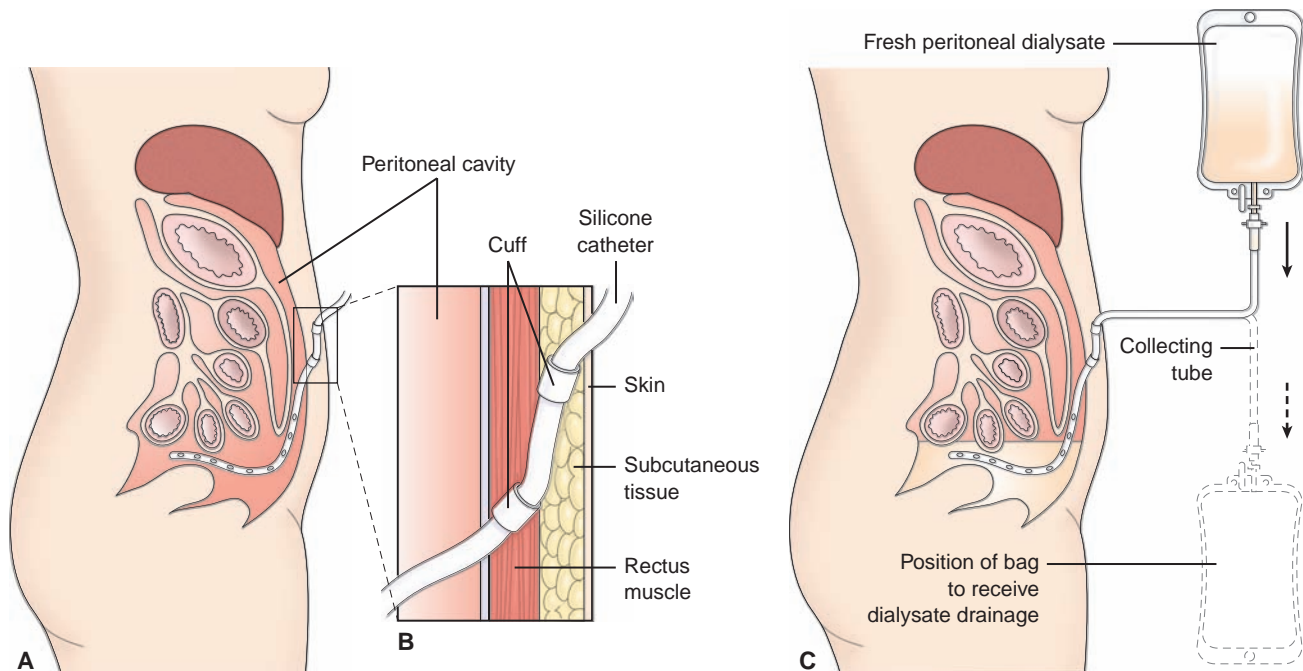

Figure 44-8 Continuous ambulatory peritoneal dialysis. **A**, The peritoneal catheter is implanted through the abdominal wall. **B**, Dacron cuffs and a subcutaneous tunnel provide protection against bacterial infection. **C**, Dialysate flows by gravity through the peritoneal catheter into the peritoneal cavity. After a prescribed period of time, the fluid is drained by gravity and discarded. New solution is then infused into the peritoneal cavity until the next drainage period. Dialysis thus continues on a 24-hour-a-day basis, during which the patient is free to move around and engage in his or her usual activities.

Performing the Exchange

PD involves a series of exchanges or cycles. An **exchange** is defined as the infusion (fill), dwell, and drainage of the dialysate. This cycle is repeated throughout the course of the dialysis. The dialysate is infused by gravity into the peritoneal cavity. A period of about 5 to 10 minutes is usually required to infuse 2 to 3 L of fluid. The prescribed dwell, or equilibration, time allows diffusion and osmosis to occur. At the end of the dwell time, the drainage portion of the exchange begins. The tube is unclamped and the solution drains from the peritoneal cavity by gravity through a closed system. Drainage is usually completed in 10 to 20 minutes. The drainage fluid is normally colorless or straw-colored and should not be cloudy. Bloody drainage may be seen in the first few exchanges after insertion of a new catheter but should not occur after that time. The number of cycles or exchanges and their frequency are prescribed based on monthly laboratory values and presence of uremic symptoms.

The removal of excess water during PD occurs because dialysate has a high dextrose concentration, making it hypertonic. An osmotic gradient is created between the blood and the dialysate solution. Dextrose solutions of 1.5%, 2.5%, and 4.25% are available in several volumes, from 1000 mL to 3000 mL. The higher the dextrose concentration, the greater the osmotic gradient and the more water will be removed. Selection of the appropriate solution is based on the patient's fluid status.

Complications

Most complications of PD are minor, but several, if unattended, can have serious consequences.

Acute Complications

Peritonitis

Peritonitis is the most common and serious complication of PD. The first sign of peritonitis is cloudy dialysate drainage fluid. Diffuse abdominal pain and rebound tenderness occur much later. Hypotension and other signs of shock may also occur with advancing infection. The patient with peritonitis may be treated as an inpatient or outpatient (most common), depending on the severity of the infection and the patient's clinical status. Drainage fluid is examined for cell count; Gram stain and culture are used to identify the organism and guide treatment. Antibiotic agents (aminoglycosides or cephalosporins) are usually added to subsequent exchanges until Gram stain or culture results are available for appropriate antibiotic determination. Intraperitoneal administration of antibiotics is as effective as IV administration and therefore most often used. Antibiotic therapy continues for 10 to 14 days. Careful selection and calculation of the antibiotic dosage are needed to prevent nephrotoxicity and further compromise of residual renal function.

Regardless of which organism causes peritonitis, the patient with peritonitis loses large amounts of protein through the peritoneum. Acute malnutrition and delayed healing may result. Therefore, attention must be given to detecting and promptly treating peritonitis.

Leakage

Leakage of dialysate through the catheter site may occur immediately after the catheter is inserted. Usually, the leak stops spontaneously if dialysis is withheld for several days,

giving the tissue surrounding the cuffs located on the abdominal catheter a chance to infiltrate the Dacron and seal the insertion tunnel. It also allows the exit site time to heal. During this time, it is important to reduce factors that might delay healing, such as undue abdominal muscle activity and straining during bowel movement. In many cases, leakage can be avoided by using small volumes (500 mL) of dialysate, gradually increasing the volume up to 2000 to 3000 mL.

Bleeding

A bloody **effluent** (drainage) may be observed occasionally, especially in young, menstruating women. (The hypertonic fluid pulls blood from the uterus, through the opening in the fallopian tubes, and into the peritoneal cavity.) Bleeding is also common during the first few exchanges after a new catheter insertion because some blood enters the abdominal cavity following insertion. In many cases, no cause can be found for the bleeding, although catheter displacement from the pelvis has occasionally been associated with bleeding. Some patients have had bloody effluent after an enema or from minor trauma. Invariably, bleeding stops in 1 to 2 days and requires no specific intervention. More frequent exchanges and the addition of heparin to the dialysate during this time may be necessary to prevent blood clots from obstructing the catheter.

Long-Term Complications

Hypertriglyceridemia is common in patients undergoing long-term PD, suggesting that the therapy may accelerate atherogenesis. Despite this, the use of cardioprotective medications is relatively uncommon, and many patients have suboptimal blood pressure control. Given the high burden of disease in these patients, beta-blockers and ACE inhibitors should be used to control hypertension or protect the heart, and the use of aspirin and statins should be considered.

Other complications that may occur with long-term PD include abdominal hernias (incisional, inguinal, diaphragmatic, and umbilical), probably resulting from continuously increased intra-abdominal pressure. The persistently elevated intra-abdominal pressure also aggravates symptoms of hiatal hernia and hemorrhoids. Low back pain and anorexia from fluid in the abdomen and a constant sweet taste related to glucose absorption may also occur.

Mechanical problems occasionally occur and may interfere with instillation or drainage of the dialysate. Formation of clots in the peritoneal catheter and constipation are factors that may contribute to these problems.

Approaches

PD can be performed using several different approaches: acute intermittent peritoneal dialysis, **continuous ambulatory peritoneal dialysis (CAPD)**, and **continuous cyclic peritoneal dialysis (CCPD)**.

Acute Intermittent Peritoneal Dialysis

Indications for acute intermittent PD, a variation of PD, include uremic signs and symptoms (nausea, vomiting, fatigue, altered mental status), fluid overload, acidosis, and hyperkalemia. Although PD is not as efficient as hemodial-

ysis in removing solute and fluid, it permits a more gradual change in the patient's fluid volume status and in waste product removal. Therefore, it may be the treatment of choice for the hemodynamically unstable patient. It can be carried out manually (the nurse warms, spikes, and hangs each container of dialysate) or by a cycler machine. Exchange times range from 30 minutes to 2 hours. A common routine is hourly exchanges consisting of a 10-minute infusion, a 30-minute dwell time, and a 20-minute drain time.

Maintaining the PD cycle is a nursing responsibility. Strict aseptic technique is maintained when changing solution containers and emptying drainage containers. Vital signs, weight, I&O, laboratory values, and patient status are frequently monitored. The nurse uses a flow sheet to document each exchange and records vital signs, dialysate concentration, medications added, exchange volume, dwell time, dialysate fluid balance for each exchange (fluid lost or gained), and cumulative fluid balance. The nurse also carefully assesses skin turgor and mucous membranes to evaluate fluid status and monitor the patient for edema.

If the peritoneal fluid does not drain properly, the nurse can facilitate drainage by turning the patient from side to side or raising the head of the bed. The catheter should never be pushed further into the peritoneal cavity. Other measures to promote drainage include checking the patency of the catheter by inspecting for kinks, closed clamps, or an air lock. The nurse monitors for complications, including peritonitis, bleeding, respiratory difficulty, and leakage of peritoneal fluid. Abdominal girth may be measured periodically to determine if the patient is retaining large amounts of dialysis solution. Additionally, the nurse must ensure that the PD catheter remains secure and that the dressing remains dry. Physical comfort measures, frequent turning, and skin care are provided. The patient and family are educated about the procedure and are kept informed about progress (fluid loss, weight loss, laboratory values). Emotional support and encouragement are given to the patient and family during this stressful and uncertain time.

Continuous Ambulatory Peritoneal Dialysis

CAPD is the second most common form of dialysis for patients with ESRD to be started on (USRDS, 2007). CAPD is performed at home by the patient or a trained caregiver who is usually a family member. The procedure allows the patient reasonable freedom and control of daily activities but requires a serious commitment to be successful. Chart 44-10 discusses suitability for CAPD.

CAPD works on the same principles as other forms of PD: diffusion and osmosis. Less extreme fluctuations in the patient's laboratory values occur with CAPD than with intermittent PD or hemodialysis because the dialysis is constantly in progress. The serum electrolyte levels usually remain in the normal range.

Procedure

The patient performs exchanges four or five times a day, 24 hours a day, 7 days a week, at intervals scheduled throughout the day. Different manufacturers supply different equipment. Most commonly used is a Y-shaped system, in which a bag containing dialysate solution comes connected to one branch of the "Y" and a sterile empty

Chart 44-10 • Considerations in CAPD

Although CAPD is not suitable for all patients with end-stage renal disease (ESRD), it is a viable therapy for those who can perform self-care and exchanges and who can fit therapy into their own routines. Often, patients report having more energy and feeling healthier once they begin CAPD. Nurses can be instrumental in helping patients with ESRD find the dialysis therapy that best suits their lifestyle. Those considering CAPD need to understand the advantages and disadvantages along with the indications and contraindications for this form of therapy.

Advantages

- Freedom from a dialysis machine
- Control over daily activities
- Opportunities to avoid dietary restrictions, increase fluid intake, raise serum hematocrit values, improve blood pressure control, avoid venipuncture, and gain a sense of well-being

Disadvantages

- Continuous dialysis 24 hours a day, 7 days a week

Indications

- Patient's willingness, motivation, and ability to perform dialysis at home
- Strong family or community support system (essential for success), particularly if the patient is an older adult

- Special problems with long-term hemodialysis, such as dysfunctional or failing vascular access devices, excessive thirst, severe hypertension, postdialysis headaches, and severe anemia requiring frequent transfusion
- Interim therapy while awaiting kidney transplantation
- ESRD secondary to diabetes because hypertension, uremia, and hyperglycemia are easier to manage with CAPD than with hemodialysis

Contraindications

- Adhesions from previous surgery (adhesions reduce clearance of solutes) or systemic inflammatory disease
- Chronic backache and preexisting disk disease, which could be aggravated by the continuous pressure of dialysis fluid in the abdomen
- Risk of complications, for example, in patients receiving immunosuppressive medications, which impede healing of the catheter site, and in patients with a colostomy, ileostomy, nephrostomy, or ileal conduit because of the risk of peritonitis. The risk for complications is not an absolute contraindication for CAPD therapy.
- Diverticulitis because CAPD has been associated with rupture of the diverticulum
- Severe arthritis or poor hand strength necessitating assistance in performing the exchange. However, blind or partially blind patients and those with other physical limitations can learn to perform CAPD.

bag is connected to the second branch. This leaves the third part of the "Y" open and available for connection to the transfer set on the PD catheter. To perform an exchange, the patient (or person doing the exchange) washes his or her hands, dons a mask, and then removes the cap from the transfer set while maintaining sterility. The open end of the "Y" set is connected to the end of the transfer set and the dialysate infused where it will dwell. After the dialysate is infused, the patient clamps off the transfer set and the tubing set, disconnects the tubing set, and applies a new cap to the transfer set, making it a closed system. The patient drains the fluid (effluent) from the peritoneal cavity through the catheter (over about 20 to 30 minutes) into an empty bag. Once the effluent has been fully drained, fresh fluid is instilled into the peritoneal cavity.

The longer the dwell time, the better the clearance of uremic toxins is. If dwell time is excessive, the patient will absorb some of the effluent back into the body simply because the osmotic gradient is lost. Once equilibrium is reached, the movement of fluid and toxins stops.

Complications

To reduce the risk of peritonitis, the patient (and all caregivers) must use meticulous care to avoid contaminating the catheter, fluid, or tubing and to avoid accidentally disconnecting the catheter from the tubing. Whenever a connection/disconnection is made, hands must be washed and a mask worn by anyone within 6 feet of the area to avoid contamination with airborne bacteria. Excess manipulation

should be avoided and meticulous care of the catheter entry site is provided using a standardized protocol.

Continuous Cyclic Peritoneal Dialysis

CCPD uses a machine called a cyclor to provide the exchanges. It is programmed as to how much fluid to use and how long and how many exchanges need to be done. Since it is programmed, it also keeps track of the total amounts removed and will sound an alarm if limits are not met. It requires that a person set up and break down the system for use, which typically takes about 15 minutes.

CCPD combines overnight intermittent PD with a prolonged dwell time during the day. The peritoneal catheter is connected to a cyclor machine every evening, usually just before the patient goes to sleep for the night. Because the machine is very quiet, the patient can sleep, and the extra-long tubing allows the patient to move and turn normally during sleep.

In the morning, the patient disconnects from the cyclor. Sometimes dialysate is left in the abdominal cavity for a longer day dwell cycle. This day exchange is drained during the day either by using a "Y" set or reattaching to the cyclor. This process is done every day to achieve the effects of dialysis required.

CCPD has a lower infection rate than other forms of PD because there are fewer opportunities for contamination with bag changes and tubing disconnections. It also allows the patient to be free from exchanges throughout the day, making it possible to engage in work and activities of daily living more freely.

Nursing Management

Meeting Psychosocial Needs

In addition to the complications of PD previously described, patients who elect to do PD may experience altered body image because of the presence of the abdominal catheter, bag, tubing, andycler. Waist size increases from 1 to 2 inches (or more) with fluid in the abdomen. This affects clothing selection and may make the patient feel “fat.” Body image may be so altered that patients do not want to look at or care for the catheter for days or weeks. The nurse may arrange for the patient to talk with other patients who have adapted well to PD. Although some patients have no psychological problems with the catheter—they think of it as their lifeline and as a life-sustaining device—other patients feel they are doing exchanges all day long and have no free time, particularly in the beginning. They may experience depression because they feel overwhelmed with the responsibility of self-care.

Patients undergoing PD may also experience altered sexuality patterns and sexual dysfunction. The patient and partner may be reluctant to engage in sexual activities, partly because of the catheter being psychologically “in the way” of sexual performance. The peritoneal catheter,

drainage bag, and about 2 L of dialysate may interfere with the patient’s sexual function and body image as well. In patients on CCPD, the presence of the dialysis cycler in the bedroom and the continual connection during the sleeping hours can also cause interference with intimacy. Although these problems may resolve with time, some problems may warrant special counseling. Questions by the nurse about concerns related to sexuality and sexual function often provide the patient with a welcome opportunity to discuss these issues and a first step toward their resolution.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Patients are taught as inpatients or outpatients to perform PD once their condition is medically stable. Training usually takes 5 days to 2 weeks. Patients are taught according to their own learning ability and knowledge level and only as much at one time as they can handle without feeling uncomfortable or becoming overwhelmed. Education topics for the patient and family who will be performing PD at home are described in Chart 44-11. The use of an adult learning theory-based curriculum may decrease peritonitis and exit site infection rates.

CHART
44-11  HOME CARE CHECKLIST
Peritoneal Dialysis (CAPD or CCPD)

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Discuss basic information about normal kidney function.	✓	✓
• Discuss basic information about the disease process.	✓	✓
• Discuss the basic principles of peritoneal dialysis.	✓	✓
• Demonstrate catheter and exit site care.	✓	✓
• Demonstrate measurement of vital signs and weight measurement.	✓	✓
• Discuss monitoring and management of fluid balance.	✓	✓
• Discuss basic principles of aseptic technique.	✓	✓
• Demonstrate the CAPD exchange procedure using aseptic technique (CCPD patients should also demonstrate exchange procedure in case of failure or unavailability of cycling machine).	✓	✓
• Demonstrate cycler set-up procedure and maintenance if on CCPD.	✓	✓
• Discuss complications of peritoneal dialysis; prevention, recognition, and management of complications.	✓	✓
• Demonstrate procedure for adding medications to the dialysis solution.	✓	✓
• Demonstrate procedure for obtaining sterile dialysis fluid samples.	✓	✓
• Discuss routine laboratory tests needed and implications of results.	✓	✓
• Discuss dietary restrictions.		
• Discuss medications: name of medications, their actions, potential side effects, and when to contact physician.	✓	✓
• Discuss ordering, storage, and inventory of dialysis supplies.	✓	✓
• Describe plan for follow-up care.	✓	✓
• Demonstrate maintenance of home dialysis records.	✓	✓
• Describe actions in case of emergency.	✓	✓

Because of protein loss with continuous PD, the patient is instructed to eat a high-protein, well-balanced diet. The patient is also encouraged to increase his or her daily fiber intake to help prevent constipation, which can impede the flow of dialysate into or out of the peritoneal cavity. Many patients gain 3 to 5 lb within a month of initiating PD, so they may be asked to limit their carbohydrate intake to avoid excessive weight gain. Potassium, sodium, and fluid restrictions are not usually needed. Patients commonly lose about 2 to 3 L of fluid over and above the volume of dialysate infused into the abdomen during a 24-hour period, permitting a normal fluid intake even in an anephric patient (a patient without kidneys).

Continuing Care

Follow-up care through phone calls, visits to the outpatient department, and continuing home care assists patients in the transition to home and promotes their active participation in their own health care. Patients often depend on checking with the nurse to see if they are making the correct choices about dialysate or control of blood pressure, or simply to discuss a problem.

Patients may be seen by the PD team as outpatients once a month or more often if needed. The exchange procedure is evaluated at that time to see that strict aseptic technique is being used. Blood chemistry values are followed closely to make certain the therapy is adequate for the patient.

If a referral is made for home care, the home care nurse assesses the home environment and suggests modifications to accommodate the equipment and facilities needed to carry out PD. In addition, the nurse assesses the patient's and family's understanding of PD and evaluates their technique in performing PD. Assessments include checking for changes related to renal disease, complications such as peritonitis, and treatment-related problems such as heart failure, inadequate drainage, and weight gain or loss. The nurse continues to reinforce and clarify teaching about PD and renal disease and assesses the patient's and family's progress in coping with the procedure. This is also an opportunity to remind patients about the need to participate in appropriate health promotion activities and health screening (eg, gynecologic examinations, colonoscopy).

Because of the projected high numbers of elderly patients who will develop ESRD, the nursing home or extended care facility is likely to become an increasingly important site for both rehabilitation and long-term management of patients with renal failure.

SPECIAL CONSIDERATIONS: NURSING MANAGEMENT OF THE HOSPITALIZED PATIENT ON DIALYSIS

Whether undergoing hemodialysis or PD, the patient may be hospitalized for treatment of complications related to the dialysis treatment, the underlying renal disorder, or health problems not related to renal dysfunction or its treatment.

Protecting Vascular Access

When the patient undergoing hemodialysis is hospitalized for any reason, care must be taken to protect the vascular access. The nurse assesses the vascular access for patency

and takes precautions to ensure that the extremity with the vascular access is not used for measuring blood pressure or for obtaining blood specimens; tight dressings, restraints, or jewelry over the vascular access must be avoided as well.

The bruit, or "thrill," over the venous access site must be evaluated at least every 8 hours. Absence of a palpable thrill or audible bruit may indicate blockage or clotting in the vascular access. Clotting can occur if the patient has an infection anywhere in the body (serum viscosity increases) or if the blood pressure has dropped. When blood flow is reduced through the access for any reason (hypotension, application of blood pressure cuff or tourniquet), the access can clot. If a patient has a hemodialysis catheter or implanted hemodialysis access device, the nurse must observe for signs and symptoms of infection such as redness, swelling, drainage from the exit site, fever, and chills. The nurse must assess the integrity of the dressing and change it as needed. Patients with renal disease are more prone to infection; therefore, infection control measures must be used for all procedures.

Taking Precautions During Intravenous Therapy

When the patient needs IV therapy, the rate of administration must be as slow as possible and should be strictly controlled by a volumetric infusion pump. Because patients on dialysis cannot excrete water, rapid or excessive administration of IV fluid can result in pulmonary edema. Accurate intake and output records are essential.

Monitoring Symptoms of Uremia

As metabolic end products accumulate, symptoms of uremia worsen. Patients whose metabolic rate accelerates (those receiving corticosteroid medications or parenteral nutrition, those with infections or bleeding disorders, those undergoing surgery) accumulate waste products more quickly and may require daily dialysis. These same patients are more likely than other patients receiving dialysis to experience complications.

Detecting Cardiac and Respiratory Complications

Cardiac and respiratory assessment must be conducted frequently. As fluid builds up, fluid overload, heart failure, and pulmonary edema develop. Crackles in the bases of the lungs may indicate pulmonary edema.

Pericarditis may result from the accumulation of uremic toxins. If not detected and treated promptly, this serious complication may progress to pericardial effusion and cardiac tamponade. Pericarditis is detected by the patient's report of substernal chest pain (if the patient can communicate), low-grade fever (often overlooked), and pericardial friction rub. A pulsus paradoxus (a decrease in blood pressure of more than 10 mm Hg during inspiration) is often present. When pericarditis progresses to effusion, the friction rub disappears, heart sounds become distant and muffled, ECG waves show very low voltage, and the pulsus paradoxus worsens.

The effusion may progress to life-threatening cardiac tamponade, noted by narrowing of the pulse pressure in

addition to muffled or inaudible heart sounds, crushing chest pain, dyspnea, and hypotension. Although pericarditis, pericardial effusion, and cardiac tamponade can be detected by chest x-ray, they should also be detected through astute nursing assessment. Because of their clinical significance, assessment of the patient for these complications is a priority.

Controlling Electrolyte Levels and Diet

Electrolyte alterations are common, and potassium changes can be life-threatening. All IV solutions and medications to be administered are evaluated for their electrolyte content. Serum laboratory values are assessed daily. If blood transfusions are required, they may be administered during hemodialysis, if possible, so that excess potassium can be removed. Dietary intake must also be monitored. The patient's frustrations related to dietary restrictions typically increase if the hospital food is unappetizing. The nurse needs to recognize that this may lead to dietary indiscretion and hyperkalemia.

Hypoalbuminemia is an indicator of malnutrition in patients undergoing long-term or maintenance dialysis. Although some patients can be treated with adequate nutrition alone, some patients remain hypoalbuminemic for reasons that are poorly understood.

Managing Discomfort and Pain

Complications such as pruritus and pain secondary to neuropathy must be managed. Antihistamine agents, such as diphenhydramine hydrochloride (Benadryl), are commonly used, and analgesic medications may be prescribed. However, because elimination of the metabolites of medications occurs through dialysis rather than through renal excretion, medication dosages may need to be adjusted. Keeping the skin clean and well moisturized using bath oils, superfatted soap, and creams or lotions helps promote comfort and reduce itching. Teaching the patient to keep the nails trimmed to avoid scratching and excoriation also promotes comfort.

Monitoring Blood Pressure

Hypertension in renal failure is common. It is usually the result of fluid overload and, in part, oversecretion of renin. Many patients undergoing dialysis receive some form of antihypertensive therapy and require ongoing teaching about its purpose and adverse effects. The trial-and-error approach that may be necessary to identify the most effective antihypertensive agent and dosage may confuse the patient if no explanation is provided. Antihypertensive agents must be withheld before dialysis to avoid hypotension due to the combined effect of the dialysis and the medication.

Typically these patients require single or multiple antihypertensive agents to achieve normal blood pressure, thus adding to the total number of medications needed on an ongoing basis.

Preventing Infection

Patients with ESRD commonly have low WBC counts (and decreased phagocytic ability), low RBC counts (anemia), and impaired platelet function. Together, these pose a high risk for infection and potential for bleeding after even minor trauma. Preventing and controlling infection are essential because the incidence of infection is high. Infection of the vascular access site and pneumonia are common.

Caring for the Catheter Site

Patients receiving CAPD usually know how to care for the catheter site; however, the hospital stay is an opportunity to assess catheter care technique and correct misperceptions or deviations from recommended technique. Recommended daily or three-or-four-times-weekly routine catheter site care is typically performed during showering or bathing. The exit site should not be submerged in bath water. The most common cleaning method is soap and water; liquid soap is recommended. During care, the nurse and patient need to make sure that the catheter remains secure to avoid tension and trauma. The patient may wear a gauze or semi-transparent dressing over the exit site.

Administering Medications

All medications and the dosage prescribed for any patient on dialysis must be closely monitored to avoid those that are toxic to the kidneys and may threaten remaining renal function. Medications are also scrutinized for potassium and magnesium content, because medications containing potassium or magnesium must be avoided. Care must be taken to evaluate all problems and symptoms that the patient reports without automatically attributing them to renal failure or to dialysis therapy.

Providing Psychological Support

Patients undergoing dialysis for a while may begin to reevaluate their status, the treatment modality, their satisfaction with life, and the impact of these factors on their families and support systems. Nurses must provide opportunities for these patients to express their feelings and reactions and to explore options. The decision to begin dialysis does not require that dialysis be continued indefinitely, and it is not uncommon for patients to consider discontinuing treatment. These feelings and reactions must be taken seriously, and the patient should have the opportunity to discuss them with the dialysis team as well as with a psychologist, psychiatrist, psychiatric nurse, trusted friend, or spiritual advisor. The patient's informed decision about discontinuing treatment, after thoughtful deliberation, should be respected.

KIDNEY SURGERY

A patient may undergo surgery to remove obstructions that affect the kidney (tumors or calculi), to insert a tube for draining the kidney (nephrostomy, ureterostomy), or to remove the kidney involved in unilateral kidney disease, renal carcinoma, or kidney transplantation.

Management of Patients Undergoing Kidney Surgery

Preoperative Considerations

Surgery is performed only after a thorough evaluation of renal function. Patient preparation to ensure that optimal renal function is maintained is essential. Fluids are encouraged to promote increased excretion of waste products

before surgery unless contraindicated because of preexisting renal or cardiac dysfunction. If kidney infection is present preoperatively, broad-spectrum antimicrobial agents may be prescribed to prevent bacteremia. Antibiotic agents must be given with extreme care because many are toxic to the kidneys. Coagulation studies (prothrombin time, partial thromboplastin time, platelet count) may be indicated if the patient has a history of bruising and bleeding. The preoperative preparation is similar to that described in Chapter 18.

Because many patients facing kidney surgery are apprehensive, the nurse encourages the patient to recognize and verbalize concerns. Confidence is reinforced by establishing a relationship of trust and by providing expert care. Patients faced with the prospect of losing a kidney may think that they will be dependent on dialysis for the rest of their lives. It is important to teach the patient and family that normal function may be maintained by a single healthy kidney.

Perioperative Concerns

Renal surgery requires various patient positions to expose the surgical site adequately. Three surgical approaches are common: flank, lumbar, and thoracoabdominal (Fig. 44-9). During surgery, plans are carried out for managing altered urinary drainage. These may include inserting a nephrostomy or other drainage tube.

Postoperative Management

Because the kidney is a highly vascular organ, hemorrhage and shock are the chief complications of renal surgery. Fluid and blood component replacement is frequently necessary in the immediate postoperative period to treat intraoperative blood loss.

Abdominal distention and paralytic ileus are fairly common after renal and ureteral surgery and are thought to be due to a reflex paralysis of intestinal peristalsis and manipulation of the colon or duodenum during surgery. Abdominal distention is relieved by decompression through a nasogastric tube (see Chapter 38 for treatment of paralytic ileus). Oral fluids are permitted when the passage of flatus is noted.

If infection occurs, antibiotics are prescribed after a culture reveals the causative organism. The toxic effects that antibiotic agents have on the kidneys (nephrotoxicity) must be kept in mind when assessing the patient. Low-dose heparin therapy may be initiated postoperatively to prevent thromboembolism in patients who had any type of urologic surgery.

Nursing Management

In addition to those interventions listed in this section, Chart 44-12 provides a plan of nursing care for the patient undergoing kidney surgery.

Providing Immediate Postoperative Care

Immediate postoperative care of the patient who has undergone surgery of the kidney includes assessment of all body systems. Respiratory and circulatory status, pain level, fluid and electrolyte status, and patency and adequacy of urinary drainage systems are assessed.

Respiratory Status

As with any surgery, the use of anesthesia increases the risk for respiratory complications. Noting the location of the surgical incision assists the nurse in anticipating respiratory problems and pain. Respiratory status is assessed by monitoring the rate, depth, and pattern of respirations. The location of the incision frequently causes pain on inspiration and coughing; therefore, the patient tends to splint the chest wall and take shallow respirations. Auscultation is performed to assess normal and adventitious breath sounds.

Circulatory Status and Blood Loss

The patient's vital signs and arterial or central venous pressure are monitored. Skin color and temperature and urine output provide information about circulatory status. The surgical incision and drainage tubes are observed frequently to help detect unexpected blood loss and hemorrhage.

Pain

Postoperative pain is a major problem for the patient because of the location of the surgical incision and patient's

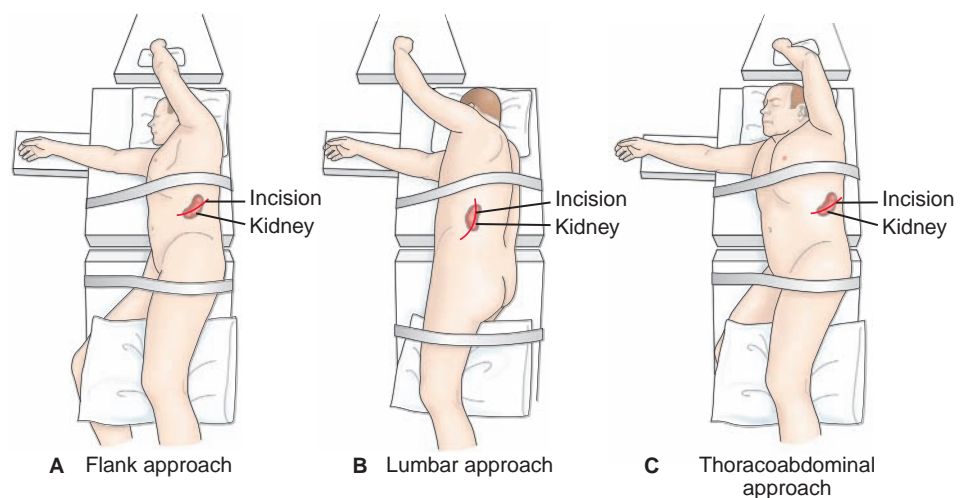

Figure 44-9 Patient positioning and incisional approaches (A, flank; B, lumbar; C, thoracoabdominal) for kidney surgery are associated with significant postoperative discomfort.

 CHART
44-12

PLAN OF NURSING CARE
Care of Patient Undergoing Kidney Surgery

NURSING DIAGNOSIS: Ineffective airway clearance related to pain of high abdominal or flank incision, abdominal discomfort, and immobility; risk for ineffective breathing pattern related to high abdominal incision

GOAL: Improved airway clearance

Nursing Interventions

1. Administer analgesic agent as prescribed.
2. Splint incision with hands or pillow to assist patient in coughing.
3. Assist patient to change positions frequently.
4. Encourage use of incentive spirometer if indicated or prescribed.
5. Assist with and encourage early ambulation.

Rationale

1. Enables patient to take deep breaths and cough
2. Splints incision and promotes adequate cough and prevention of atelectasis
3. Promotes drainage and inflation of all lobes of the lungs
4. Encourages adequate deep breaths
5. Mobilizes pulmonary secretions

Expected Outcomes

- Takes deep breaths and coughs adequately when encouraged and assisted
- Exhibits respiratory rate of 12–18 breaths/min
- Exhibits normal breath sounds without adventitious sounds
- Exhibits full thoracic excursion without shallow respirations
- Uses incentive spirometer with encouragement
- Splints incision while taking deep breaths and coughing
- Reports progressively less pain and discomfort with coughing and deep breaths
- Exhibits normal blood gas levels and chest x-ray
- Exhibits normal body temperature with no signs of atelectasis or pneumonia on assessment

NURSING DIAGNOSIS: Acute pain and discomfort related to surgical incision, positioning, and stretching of muscles during kidney surgery

GOAL: Relief of pain and discomfort

Nursing Interventions

1. Assess level of pain.
2. Administer analgesic agents as prescribed.
3. Splint incision with hands or pillow during movement or deep breathing and coughing exercises.
4. Assist and encourage early ambulation.

Rationale

1. Provides baseline for later evaluation of pain relief strategies
2. Promotes pain relief
3. Minimizes sensation of pulling or tension on incision and provides sense of support to the patient
4. Promotes resumption of muscle activity exercise

Expected Outcomes

- Reports relief of severe pain and discomfort
- Takes analgesia as prescribed
- Exercises aching muscles within recommendations
- Uses distraction, relaxation exercises, and imagery to relieve pain
- Exhibits no behavioral manifestations of pain and discomfort (eg, restlessness, perspiration, verbal expressions of pain)
- Participates in deep-breathing and coughing exercises
- Gradually increases physical activity and exercise

NURSING DIAGNOSIS: Fear and anxiety related to diagnosis, outcome of surgery, and alteration in urinary function

GOAL: Reduction of fear and anxiety

Nursing Interventions

1. Assess patient's anxiety and fear before surgery if possible.
2. Assess patient's knowledge about procedure and expected surgical outcome preoperatively.
3. Evaluate the meaning of alterations resulting from surgical procedure for the patient and family or partner.
4. Encourage patient to verbalize reactions, feelings, and fears.

Rationale

1. Provides a baseline for postoperative assessment
2. Provides a basis for further teaching
3. Enables understanding of patient's reactions and responses to expected and unexpected results of surgery
4. Affirms patient's understanding of and ultimate resolution of feelings and fears

Expected Outcomes

- Verbalizes reactions and feelings to staff
- Shares reactions and feelings with family or partner
- Grieves appropriately for self and for changes in role and function
- Identifies information needed to promote own adaptation and coping
- Participates in activities and events in immediate environment

PLAN OF NURSING CARE

Care of Patient Undergoing Kidney Surgery (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 5. Encourage patient to share feelings with spouse or partner. 6. Offer and arrange for visit from member of support group (eg, ostomy group, if indicated). 	<ol style="list-style-type: none"> 5. Enables patient and partner to receive mutual support and reduces sense of isolation from each other 6. Provides support from another person who has encountered the same or a similar surgical procedure and an example of how others have coped with the alteration 	<ul style="list-style-type: none"> • Accepts visit from ostomy group if indicated • Identifies support person or support group
<p>NURSING DIAGNOSIS: Impaired urinary elimination related to urinary drainage; risk for infection related to altered urinary drainage</p> <p>GOAL: Maintenance of urinary elimination; infection-free urinary tract</p>		
Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess urinary drainage system immediately. 2. Assess adequacy of urinary output and patency of drainage system. 3. Use asepsis and hand hygiene when providing care and manipulating drainage system. 4. Maintain closed urinary drainage system. 5. If irrigation of the drainage system is necessary, use sterile gloves and sterile irrigating solution and a closed drainage and irrigation system. 6. If irrigation is necessary and prescribed, perform it gently with sterile saline and the prescribed amount of irrigating fluid. 7. Assist patient in turning and moving in bed and when ambulating to prevent displacement or inadvertent removal of urinary stent or ureteral catheters if in place. 8. Observe urine color, volume, odor, and components. 9. Minimize trauma and manipulation of catheter, drainage system, and urethra. 10. Clean catheter gently with soap during bath, avoiding any to-and-fro movement of catheter. 11. Anchor drainage tube. 12. Maintain adequate fluid intake. 13. Assist with and encourage early ambulation while ensuring placement of urinary drainage system. 14. If patient is to be discharged with urinary drainage system (catheter) in place or a urinary diversion, instruct patient and family member in care. 	<ol style="list-style-type: none"> 1. Provides basis for further assessment and action 2. Provides baseline 3. Prevents or reduces risk of contamination of urinary drainage system 4. Reduces risk of bacterial contamination and infection 5. Permits irrigation when necessary while maintaining closed drainage system, minimizing risk of infection 6. Maintains patency of the catheter or drainage system and prevents sudden increases in pressure in the urinary tract that may cause trauma, pressure on sutures or urinary tract structures, and pain 7. Prevents trauma from accidental displacement of urinary stent or ureteral catheter necessitating repeated instrumentation of the urinary tract (eg, cystoscopy) to replace them 8. Provides information about adequacy of urine output, condition and patency of drainage system, and debris in urine 9. Reduces risk of contamination of drainage system and eliminates site of bacterial invasion 10. Removes debris and encrustations without causing trauma to or contamination of urethra 11. Prevents movement or slipping of drainage tube, minimizing trauma to and contamination of urethra or catheter 12. Promotes adequate urine output and prevents urinary stasis 13. Minimizes cardiovascular and pulmonary complications while preventing loss, dislodging, or disruption of drainage system 14. Knowledge and understanding of the drainage system or urinary diversion are essential to prevent infection and other complications. 	<ul style="list-style-type: none"> • Exhibits adequate urinary output and patent drainage system • Exhibits urinary output consistent with fluid intake • Demonstrates normal laboratory values: BUN, serum creatinine levels, urine specific gravity, and osmolality • Exhibits sterile urine on urine culture • Exhibits clear, dilute urine without debris or encrustation in the drainage system • States rationale for avoiding manipulation of catheter, drainage, or irrigation system • Exhibits normal placement of urinary stent or ureteral catheters until removed by physician • Maintains closed urinary drainage system • Exhibits normal body temperature without signs or symptoms of urinary tract infection • Cleans catheter with soap and water • Consumes adequate fluid intake (6 to 8 glasses of water or more per day, unless contraindicated) • Urinary drainage system remains in place until physician removes or discontinues it • Maintains urinary drainage system without infection or obstruction • Maintains urinary diversion as instructed • Maintains self-care so that environment is odor-free • States rationale for close follow-up and maintains recommended schedule of appointments with health care providers

CHART
44-12

PLAN OF NURSING CARE

Care of Patient Undergoing Kidney Surgery (Continued)

NURSING DIAGNOSIS: Risk for imbalanced fluid volume related to surgical fluid loss, altered urinary output, parenteral fluid administration

GOAL: Normal fluid balance will be maintained

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Weigh patient daily. 2. Take accurate intake and output measurements. 3. Place all parenteral therapy on an infusion pump. 4. Monitor amount and characteristics of urine. 5. Monitor vital signs: temperature, pulse, respirations, and blood pressure. 6. Auscultate heart and lungs every shift. 	<ol style="list-style-type: none"> 1. Daily weight is the most sensitive indicator of fluid loss or gain. 2. Detects fluid retention due to poor cardiac or renal output 3. Ensures that the patient does not receive excess or insufficient intravenous fluids 4. Assists in early detection of possible complications of surgery or tube insertion 5. When fluid volume or cardiac output is altered, vital signs are affected. 6. When fluid volume is increased because of poor cardiac or renal output, fluid accumulates in the lungs. Also, heart sounds change as heart failure develops; frequent auscultation ensures early detection. 	<ul style="list-style-type: none"> • Patient's weight will be within 2–3 lb of patient's baseline. • Intake that exceeds output will be detected early. • The exact amount of solution is infused with no adverse effects resulting from overinfusion or underinfusion. • Urine is clear and absent of blood, pus, or any foreign substances. • Temperature, pulse, respiration, and blood pressure are normal. • Normal heart and lung sounds are present.

position on the operating table to permit access to the kidney. The location and severity of pain are assessed before and after analgesic medications are administered. Abdominal distention, which increases discomfort, is also noted.

Urinary Drainage

Urine output and drainage from tubes inserted during surgery are monitored for amount, color, and type or characteristics. Decreased or absent drainage is promptly reported to the physician because it may indicate obstruction that could cause pain, infection, and disruption of the suture lines.

Monitoring and Managing Potential Complications

Bleeding is a major complication of kidney surgery. If undetected and untreated it can result in hypovolemia and hemorrhagic shock. The nurse's role is to observe for these complications, to report their signs and symptoms, and to administer prescribed parenteral fluids and blood and blood components. Monitoring of vital signs, skin condition, the urinary drainage system, the surgical incision, and the level of consciousness is necessary to detect evidence of bleeding, decreased circulating blood, and fluid volume and cardiac output. Frequent monitoring of vital signs (initially monitored at least at hourly intervals) and urinary output is necessary for early detection of these complications.

If bleeding goes undetected or is not detected promptly, the patient may lose significant amounts of blood and may experience hypoxemia. In addition to hypovolemic shock due to hemorrhage, this type of blood loss may precipitate a myocardial infarction or transient ischemic attack. Bleeding may be suspected when the patient experiences fatigue and when urine output is less than 30 mL/h. As bleeding

persists, late signs of hypovolemia occur, such as cool skin, flat neck veins, and change in level of consciousness or responsiveness. Transfusions of blood components are indicated, along with surgical repair of the bleeding vessel.

Pneumonia may be prevented through use of an incentive spirometer, adequate pain control, and early ambulation. Early signs of pneumonia include fever, increased heart and respiratory rates, and adventitious breath sounds.

Preventing infection is the rationale for using asepsis when changing dressings and handling and preparing catheters, other drainage tubes, central venous catheters, and IV catheters for administration of fluids. Insertion sites are monitored closely for signs and symptoms of inflammation: redness, drainage, heat, and pain. Special care must be taken to prevent urinary tract infection, which is associated with the use of indwelling urinary catheters. Catheters and other invasive tubes are removed as soon as they are no longer needed.

Antibiotics are commonly administered postoperatively to prevent infection. If antibiotic agents are prescribed, serum creatinine and BUN values must be monitored closely because many antibiotic agents are toxic to the kidney or can accumulate to toxic levels if renal function is decreased.

Preventing fluid imbalance is critical when caring for a patient undergoing kidney surgery, because both fluid loss and fluid excess are possible adverse effects of the surgery. Fluid loss may occur during surgery as a result of excessive urinary drainage when the obstruction is removed, or it may occur if diuretic agents are used. Such loss may also occur with GI losses, with diarrhea resulting from antibiotic use, or with nasogastric drainage. When postoperative IV therapy is inadequate to match the output or fluids lost, a fluid

deficit results. Fluid excess, or overload, may result from cardiac effects of anesthesia, administration of excessive amounts of fluids, or the patient's inability to excrete fluid because of changes in renal function. Decreased urine output may be an indication of fluid excess.

Astute assessment skills are needed to detect early signs of fluid excess (such as weight gain, pedal edema, urine output below 30 mL/h, and slightly elevated pulmonary wedge pressure, if available) before they become severe (appearance of adventitious breath sounds, shortness of breath).

Fluid excess may be treated with fluid restriction and administration of furosemide (Lasix) or other diuretic agents. If renal insufficiency is present, these medications may prove ineffective; therefore, dialysis may be necessary to prevent heart failure and pulmonary edema.

Deep venous thrombosis (DVT) may occur postoperatively because of surgical manipulation of the iliac vessels during surgery or prolonged immobility. Anti-embolism stockings are applied, and the patient is monitored closely for signs and symptoms of thrombosis and encouraged to exercise the legs. Heparin may be administered postoperatively to reduce the risk of thrombosis.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

If the patient has a drainage system in place, measures are taken to ensure that both the patient and family understand the importance of maintaining the system correctly at home and preventing infection. Verbal and written instructions and guidelines are provided to the patient and family at the time of hospital discharge. The patient may be asked to demonstrate management of the drainage system to ensure understanding. The importance of strategies to prevent postoperative complications (urinary tract infection and obstruction, DVT, atelectasis, and pneumonia) is stressed to the patient and family. Those signs, symptoms, problems, and questions that should be referred to the physician or other primary health care provider are reviewed by the nurse with the patient and family.

Continuing Care

The need for postoperative assessment and care after renal surgery continues regardless of the setting: the home, subacute care unit, outpatient clinic or office, or rehabilitation facility. Referral for home care is indicated for the patient going home with a urinary drainage system in place. During the home visit, the home care nurse reviews the instructions and guidelines given to the patient at hospital discharge. The nurse assesses the patient's ability to carry out the instructions in the home and answers questions that the patient or family has about management of the drainage system and the surgical incision.

Additionally, the home care nurse obtains vital signs and assesses the patient for signs and symptoms of urinary tract infection and obstruction. The nurse also ensures that pain is adequately controlled and that the patient is complying with recommendations. The home care nurse encourages adequate fluid intake and increased levels of activity. Together the nurse, patient, and family review the signs, symptoms, problems, and questions that should be referred to the

physician or other primary health care provider. If the patient has a drainage tube in place, the nurse assesses the site and the patency of the system and monitors the patient for complications, such as DVT, bleeding, or pneumonia.

Because it is easy for the patient, family, and health care team to focus on the patient's immediate disorder to the exclusion of other health issues, the nurse reminds the patient and family about the importance of participating in health promotion activities, including health screening.

Kidney Transplantation

Kidney transplantation has become the treatment of choice for most patients with ESRD. During the past 40 years, more than 400,000 kidney transplantations have been performed worldwide, and approximately 9000 are performed in the United States each year. In the United States, there are many more patients on the waiting list for kidney transplantation than there are organ donors (Danovitch, 2005). Patients choose kidney transplantation for various reasons, such as the desire to avoid dialysis or to improve their sense of well-being and the wish to lead a more normal life. Additionally, the cost of maintaining a successful transplantation is one-third the cost of dialysis treatment. Kidney transplantation is an elective procedure, not an emergency life-saving procedure. Therefore, patients should be in the best possible condition prior to transplantation.

Kidney transplantation involves transplanting a kidney from a living donor or deceased donor to a recipient who no longer has renal function (Chart 44-13). A living donor is a person who is alive at the time of donation and may or may not be related to the recipient. A deceased or cadaveric transplant comes from someone who has died and donated his or her organs. Transplantation from well-matched living donors who are related to the patient (those with compatible ABO and human leukocyte antigens) is slightly more successful than from cadaver donors. The success rate further increases if kidney transplantation from a living donor is performed before dialysis is initiated (Danovitch, 2005).

Prior to either receiving or donating an organ, an extensive medical evaluation is performed. Not everyone is suitable

Chart 44-13 • Kidney Donation

An inadequate number of available kidneys remains the greatest limitation to treating patients with end-stage renal disease successfully. For those interested in donating a kidney, the National Kidney Foundation provides written information describing the organ donation program and a card specifying the organs to be donated in the event of death.

The organ donation card is signed by the donor and two witnesses and should be carried by the donor at all times. Procurement of an adequate number of kidneys for potential recipients is still a major problem, despite national legislation that requires relatives of deceased patients or patients declared brain-dead to be asked if they would consider organ donation.

In some states in the United States, drivers can indicate their desire to be organ donors on their driver's license application or renewal.

for a kidney transplant. Contraindications include recent malignancy, active or chronic infection, severe irreversible extrarenal disease (eg, inoperable cardiac disease, chronic lung disease, severe peripheral vascular disease), active autoimmune disease (eg, HIV, hepatitis B and C), morbid obesity (body mass index greater than 35), current substance abuse, inability to give informed consent, and history of nonadherence to treatment regimens (Counts, 2008). Donors may be rejected for the same reasons or any condition that is determined to have an impact on the remaining kidney. Examples include hypertension and diabetes mellitus since both are known causes of renal disease. It is imperative when donors are evaluated that serious consideration be given to the overall long-term health of the donor. Every precaution must be taken to ensure that the remaining kidney in the donor will remain healthy. If these conditions are met, the donor should remain healthy after donation and have a normal lifespan. Since one kidney can easily handle the body's needs, no long-term adjustments will need to be made.

The patient's native kidneys are not usually removed. The transplanted kidney is placed in the patient's iliac fossa anterior to the iliac crest because it allows for easier access to the blood supply needed to perfuse the kidney. The ureter of the newly transplanted kidney is transplanted into the bladder or anastomosed to the ureter of the recipient (Fig. 44-10). Once the blood supply has been reestablished to the transplanted kidney in the operating room, urine should begin to flow. The production of urine at this stage is an important indicator of the overall success of the procedure and ultimate long-term outcome.

Preoperative Management

Preoperative management goals include bringing the patient's metabolic state to a level as close to normal as possible, making sure that the patient is free of infection, and preparing the patient for surgery and the postoperative course.

Medical Management

A complete physical examination is performed to detect and treat any conditions that could cause complications after transplantation. Tissue typing, blood typing, and antibody screening are performed to determine compatibility of the tissues and cells of the donor and recipient. Other diagnostic tests must be completed to identify conditions requiring treatment before transplantation. The lower urinary tract is studied to assess bladder neck function and to detect ureteral reflux.

The patient must be free of infection at the time of renal transplantation, because after surgery medications to prevent transplant rejection will be prescribed. These medications suppress the immune response, leaving the patient immunosuppressed and at risk for infection. Therefore, the patient is evaluated and treated for any infections, including gingival (gum) disease and dental caries.

A psychosocial evaluation is conducted to assess the patient's ability to adjust to the transplant, coping styles, social history, social support available, and financial resources. A history of psychiatric illness is important to obtain because psychiatric conditions are often aggravated by the corticosteroids needed for immunosuppression after transplantation. If a dialysis routine has been established, hemodialysis is often performed the day before the scheduled transplantation procedure to optimize the patient's physical status.

Nursing Management

The nursing aspects of preoperative care for the patient undergoing renal transplant are similar to those for patients undergoing other types of kidney or elective abdominal surgery. Preoperative teaching can be conducted in a variety of settings, including the outpatient preadmission area, the hospital, or the transplantation clinic during the preliminary workup phase. Patient teaching addresses postoperative pulmonary hygiene, pain management options, dietary

Figure 44-10 Renal transplantation: **1**, The transplanted kidney is placed in the iliac fossa. **2**, The renal artery of the donated kidney is sutured to the iliac artery, and the renal vein is sutured to the iliac vein. **3**, The ureter of the donated kidney is sutured to the bladder or to the patient's ureter.

restrictions, IV and arterial lines, tubes (indwelling catheter and possibly a nasogastric tube), and early ambulation. The patient who receives a kidney from a living related donor may be concerned about the donor and how the donor will tolerate the surgical procedure.

Most patients have been on dialysis for months or years before transplantation. Many have waited months to years for a kidney transplant and are anxious about the surgery, possible rejection, and the need to return to dialysis. Helping the patient to deal with these concerns is part of the nurse's role in preoperative management, as is teaching the patient about what to expect after surgery.

Postoperative Management

The goal of care is to maintain homeostasis until the transplanted kidney is functioning well. The patient whose kidney functions immediately has a more favorable prognosis than the patient whose kidney does not.

Medical Management

After a kidney transplant, rejection and failure can occur within 24 hours (hyperacute), within 3 to 14 days (acute), or after many years. The long-term survival of a transplanted kidney depends on how well it matches the recipient and how well the body's immune response is controlled. Since the body's immune system views the transplanted kidney as "foreign," it continually works to reject it. To overcome or minimize the body's defense mechanisms, immunosuppressive agents are administered. Optimally, medications modify the immune system enough to prevent rejection, but not enough to allow infections or malignancies to occur.

Combinations of glucocorticoids and medications specifically developed to affect the action of lymphocytes are used to minimize the body's reaction to the transplanted organ. Treatment with combinations of new agents has dramatically improved survival rates, and now 90% to 95% of transplanted kidneys still function after 1 year (American Nephrology Nurses Association, 2007b). Doses of immunosuppressive agents are often adjusted depending on the patient's immunologic response to the transplant. However, the patient will be required to take some form of immunosuppressive therapy for the entire time that he or she has the transplanted kidney.

The risks associated with taking these medications include nephrotoxicity, hypertension, hyperlipidemia, hirsutism, tremors, blood dyscrasias, cataracts, gingival hyperplasia, and several types of cancer (American Nephrology Nurses Association, 2006).

Nursing Management

Assessing the Patient for Transplant Rejection

After kidney transplantation, the nurse assesses the patient for signs and symptoms of transplant rejection: oliguria, edema, fever, increasing blood pressure, weight gain, and swelling or tenderness over the transplanted kidney or graft. Patients receiving cyclosporine may not exhibit the usual signs and symptoms of acute rejection. In these patients, the only sign may be an asymptomatic rise in the serum creatinine level (more than a 20% rise is considered acute rejection).

Preventing Infection

The results of blood chemistry tests and leukocyte and platelet counts are monitored closely because immunosuppression depresses the formation of leukocytes and platelets. The patient is closely monitored for infection because of susceptibility to impaired healing and infection related to immunosuppressive therapy and complications of renal failure. Clinical manifestations of infection include shaking chills, fever, rapid heartbeat (tachycardia), and respirations (tachypnea), as well as either an increase or a decrease in WBCs (leukocytosis or leukopenia).

Infection may be introduced through the urinary tract, the respiratory tract, the surgical site, or other sources. Urine cultures are performed frequently because of the high incidence of bacteriuria during early and late stages of transplantation. Any type of wound drainage should be viewed as a potential source of infection because drainage is an excellent culture medium for bacteria. Catheter and drain tips may be cultured when removed by cutting off the tip of the catheter or drain (using aseptic technique) and placing the tip in a sterile container to be taken to the laboratory for culture (Chart 44-14).

The nurse ensures that the patient is protected from exposure to infection by hospital staff, visitors, and other

Chart 44-14 • Renal Transplant Rejection and Infection

Renal graft rejection and failure may occur within 24 hours (hyperacute), within 3 to 14 days (acute), or after many years (chronic). It is not uncommon for rejection to occur during the first year after transplantation.

Detecting Rejection

Ultrasonography may be used to detect enlargement of the kidney; percutaneous renal biopsy (most reliable) and x-ray techniques are used to evaluate transplant rejection. If the body rejects the transplanted kidney, the patient needs to return to dialysis. The rejected kidney may or may not be removed, depending on when the rejection occurs (acute versus chronic) and the risk for infection if the kidney is left in place.

Potential Infection

About 75% of kidney transplant recipients have at least one episode of infection in the first year after transplantation because of immunosuppressant therapy. Immunosuppressants of the past made the transplant recipient more vulnerable to opportunistic infections (candidiasis, cytomegalovirus, *Pneumocystis pneumonia*) and infection with other relatively nonpathogenic viruses, fungi, and protozoa, which can be a major hazard. Cyclosporine therapy has reduced the incidence of opportunistic infections because it selectively exerts its effect, sparing T cells that protect the patient from life-threatening infections. In addition, combination immunosuppressant therapy and improved clinical care have produced 1-year patient survival rates approaching 100% and graft survival exceeding 90%. Infections, however, remain a major cause of death at all points in time for kidney transplant recipients (Danovitch, 2005).

patients with active infections. Attention to hand hygiene by all who come in contact with the patient is imperative.

Monitoring Urinary Function

A kidney from a living donor related to the patient usually begins to function immediately after surgery and may produce large quantities of dilute urine. A kidney from a cadaver donor may undergo acute tubular necrosis and therefore may not function for 2 or 3 weeks, during which time anuria, oliguria, or polyuria may be present. During this stage, the patient may experience significant changes in fluid and electrolyte status. Therefore, careful monitoring is indicated. The output from the urinary catheter (connected to a closed drainage system) is measured every hour. IV fluids are administered on the basis of urine volume and serum electrolyte levels and as prescribed by the physician. Hemodialysis may be necessary postoperatively to maintain homeostasis until the transplanted kidney is functioning well. It also may be required if fluid overload and hyperkalemia occur. After successful renal transplantation, the vascular access device may clot, possibly from improved coagulation with the return of renal function. The vascular access for hemodialysis is monitored to ensure patency and to evaluate for evidence of infection.

Addressing Psychological Concerns

The rejection of a transplanted kidney is of great concern to the patient, the family, and the health care team for many months. The fear of kidney rejection and the complications of immunosuppressive therapy (Cushing's syndrome, diabetes, capillary fragility, osteoporosis, glaucoma, cataracts, acne, nephrotoxicity) place tremendous psychological stress on the patient. Anxiety and uncertainty about the future and difficult posttransplantation adjustment are often sources of stress for the patient and family.

An important nursing function is the assessment of the patient's stress and coping. The nurse uses each visit with the patient to determine if the patient and family are coping effectively and the patient is adhering to the prescribed medication regimen. If indicated or requested, the nurse refers the patient for counseling.

Monitoring and Managing Potential Complications

The patient undergoing kidney transplantation is at risk for the postoperative complications that are associated with any surgical procedure. In addition, the patient's physical condition may be compromised because of the effects of long-standing renal failure and its treatment. Therefore, careful assessment for the complications related to renal failure and those associated with a major surgery are important aspects of nursing care. Breathing exercises, early ambulation, and care of the surgical incision are important aspects of postoperative care.

GI ulceration and corticosteroid-induced bleeding may occur. Fungal colonization of the GI tract (especially the mouth) and urinary bladder may occur secondary to corticosteroid and antibiotic therapy. Closely monitoring the patient and notifying the physician about the occurrence of these complications are important nursing interventions. In addition, the patient is monitored closely for signs and symptoms of adrenal insufficiency if the treatment has included use of corticosteroids.

Promoting Home and Community-Based Care

Teaching Patients Self-Care. The nurse works closely with the patient and family to be sure that they understand the need for continuing immunosuppressive therapy as prescribed. Additionally, the patient and family are instructed to assess for and report signs and symptoms of transplant rejection, infection, or significant adverse effects of the immunosuppressive regimen. These include decreased urine output; weight gain; malaise; fever; respiratory distress; tenderness over the transplanted kidney; anxiety; depression; changes in eating, drinking, or other habits; and changes in blood pressure. The patient is instructed to inform other health care providers (eg, dentist) about the kidney transplant and the use of immunosuppressive agents.

Continuing Care. The patient needs to know that follow-up care after transplantation is a lifelong necessity. Individual verbal and written instructions are provided concerning diet, medication, fluids, daily weight, daily measurement of urine, management of I&O, prevention of infection, resumption of activity, and avoidance of contact sports in which the transplanted kidney may be injured. Because of the risk for other potential complications, the patient is followed closely.

Cardiovascular disease is the major cause of morbidity and mortality after transplantation, due in part to the increasing age of patients with transplants. An additional problem is possible malignancy; patients receiving long-term immunosuppressive therapy are at higher risk for cancers than the general population. So the patient is reminded of the importance of health promotion and health screening.

The American Association of Kidney Patients (listed at the end of this chapter) is a nonprofit organization that serves the needs of those with kidney disease. It can provide many helpful suggestions for patients and family members learning to cope with dialysis and transplantation.

RENAL TRAUMA

The kidneys are protected by the rib cage and musculature of the back posteriorly and by a cushion of abdominal wall and viscera anteriorly. They are highly mobile and are fixed only at the renal pedicle (stem of renal blood vessels and the ureter). With traumatic injury, the kidneys can be thrust against the lower ribs, resulting in contusion and rupture. Rib fractures or fractures of the transverse process of the upper lumbar vertebrae may be associated with renal contusion or laceration. Failure to wear seat belts contributes to the incidence of renal trauma in motor vehicle crashes. Up to 80% of patients with renal trauma have associated injuries of other internal organs.

Injuries may be blunt (automobile and motorcycle crashes, falls, athletic injuries, assaults) or penetrating (gunshot wounds, stabbings). Blunt renal trauma accounts for 80% to 90% of all renal injuries; penetrating renal trauma accounts for the remaining 10% to 20%.

Blunt renal trauma is classified into one of four groups, as follows:

- Contusion: bruises or hemorrhages under the renal capsule; capsule and collecting system intact

- Minor laceration: superficial disruption of the cortex; renal medulla and collecting system are not involved
- Major laceration: parenchymal disruption extending into cortex and medulla, possibly involving the collecting system
- Vascular injury: tears of renal artery or vein

The most common renal injuries are contusions, lacerations, ruptures, and renal pedicle injuries or small internal lacerations of the kidney (Fig. 44-11). The kidneys receive half of the blood flow from the abdominal aorta; therefore, even a fairly small renal laceration can produce massive bleeding. About 70% of patients are in shock when admitted to the hospital. In some cases, there is an isolated renal artery thrombosis.

Clinical manifestations include pain, renal colic (due to blood clots or fragments obstructing the collecting system), hematuria, mass or swelling in the flank, ecchymoses, and lacerations or wounds of the lateral abdomen and flank. Hematuria is the most common manifestation of renal trauma; its presence after trauma suggests renal injury. There is no relationship between the degree of hematuria and the degree of injury. Hematuria may not occur, or it may be detectable only on microscopic examination. Signs and symptoms of hypovolemia and shock are likely with significant hemorrhage.

Medical Management

The goals of management in patients with renal trauma are to control hemorrhage, pain, and infection as well as to preserve and restore renal function. All urine is saved and sent to the laboratory for analysis to detect RBCs and to evaluate the course of bleeding. Hematocrit and hemoglobin levels are monitored closely; decreasing values indicate hemorrhage.

Figure 44-11 Types and pathophysiologic effects of renal injuries: contusions, lacerations, rupture, and pedicle injury.

The patient is monitored for oliguria and signs of hemorrhagic shock, because a pedicle injury or shattered kidney can lead to rapid exsanguination (lethal blood loss). An expanding hematoma may cause rupture of the kidney capsule. To detect hematoma, the area around the lower ribs, upper lumbar vertebrae, flank, and abdomen is palpated for tenderness. A palpable flank or abdominal mass with local tenderness, swelling, and ecchymosis suggests renal hemorrhage. The area of the original mass can be outlined with a marking pen so that the examiner can evaluate the area for change.

Renal trauma is often associated with other injuries to the abdominal organs (liver, colon, small intestines); therefore, the patient is assessed for skin abrasions, lacerations, and entry and exit wounds of the upper abdomen and lower thorax because these may be associated with renal injury.

With a contusion of the kidney, healing may take place with conservative measures. If the patient has microscopic hematuria and a normal IV urogram, outpatient management is possible. If gross hematuria or a minor laceration is present, the patient is hospitalized and kept on bed rest until the hematuria clears. Antimicrobial medications may be prescribed to prevent infection from perirenal hematoma or urinoma (a cyst containing urine). Patients with retroperitoneal hematomas may develop low-grade fever as absorption of the clot takes place.

Surgical Management

In renal trauma, any sudden change in the patient's condition suggests hemorrhage and requires rapid surgical intervention. Depending on the patient's condition and the nature of the injury, major lacerations may be treated through surgical intervention or conservatively (bed rest, no surgery). Vascular injuries require immediate exploratory surgery because of the high incidence of involvement of other organ systems and the serious complications that may result if these injuries are untreated. The patient is often in shock and requires aggressive fluid resuscitation. The damaged kidney may have to be removed (nephrectomy).

Early postoperative complications (within 6 months) include rebleeding, perinephritic abscess formation, sepsis, urine extravasation, and fistula formation. Other complications include stone formation, infection, cysts, vascular aneurysms, and loss of renal function. Hypertension can be a complication of any renal surgery but usually is a late complication of renal injury.

Nursing Management

The patient with renal trauma must be assessed frequently during the first few days after injury to detect flank and abdominal pain, muscle spasm, and swelling over the flank. During this time, the patient who has undergone surgery is instructed about care of the incision and the importance of an adequate fluid intake. In addition, instructions about changes that should be reported to the physician, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function, are provided. Guidelines for gradually increasing activity, lifting, and driving are also provided in accordance with the physician's prescription.

Follow-up nursing care includes monitoring the blood pressure to detect hypertension and advising the patient to

restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding. The patient should be advised to schedule periodic follow-up assessments of renal function (creatinine clearance, BUN and serum creatinine analyses). If a nephrectomy was necessary, the patient is advised to wear medical identification.

CRITICAL THINKING EXERCISES

1 You are a staff nurse in an outpatient dialysis facility. A 50-year-old woman with ESRD is scheduled to be seen in the clinic; it is anticipated that she will need dialysis in the near future. The patient lives alone and will require teaching about the dialysis options. Develop a teaching plan to explain the different types of dialysis, goals, and level of involvement on the part of the patient.

EBP 2 A 45-year-old married man visits the nephrology department to discuss options for dealing with his ESRD. His brother has begun the workup to donate one of his kidneys and the preliminary reports show that a match is possible. The patient states that he does not want his brother to go through the process of kidney donation if dialysis is possible. Identify the evidence for and the criteria used to evaluate the strength of the evidence for dialysis compared to kidney transplantation.

3 You are caring for a 35-year-old woman who has been recently diagnosed with renal cancer. Identify possible treatment options. What nursing assessment and interventions should you make at this time? What explanations would you give the patient about renal cancer?

4 A 55-year-old man who is blind has just had a catheter placed for PD. His wife, his primary caretaker, is deaf. Develop a teaching plan to explain peritoneal dialysis, goals, and level of involvement to the patient and family.

Management of Patients With Urinary Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify factors contributing to upper and lower urinary tract infections (UTIs).
- 2 Use the nursing process as a framework for care of the patient with a UTI.
- 3 Differentiate between the various adult dysfunctional voiding patterns.
- 4 Develop a patient education plan for a patient who has mixed (stress and urge) urinary incontinence.
- 5 Identify potential causes of an obstruction of the urinary tract and management of the patient with this condition.
- 6 Develop a teaching plan for the patient undergoing treatment for renal calculi (kidney stones).
- 7 Formulate preoperative and postoperative nursing diagnoses for the patient undergoing surgery for urinary diversion.

GLOSSARY

bacteriuria: more than 10^5 colonies of bacteria per milliliter of urine

cystectomy: removal of the urinary bladder

cystitis: inflammation of the urinary bladder

frequency: voiding more often than every 3 hours

ileal conduit: transplantation of the ureters to an isolated section of the terminal ileum, with one end of the ureters brought to the abdominal wall

interstitial cystitis: inflammation of the bladder wall that eventually causes disintegration of the lining and loss of bladder elasticity

micturition: voiding or urination

neurogenic bladder: bladder dysfunction that results from a disorder or dysfunction of the nervous system; may result in either urinary retention or bladder overactivity, resulting in urinary urgency and urge incontinence

nocturia: awakening at night to urinate

overflow incontinence: involuntary urine loss associated with overdistention of the bladder due to mechanical or anatomic bladder outlet obstruction

prostatitis: inflammation of the prostate gland

pyelonephritis: inflammation of the renal pelvis

pyuria: white blood cells in the urine

residual urine: urine that remains in the bladder after voiding

suprapubic catheter: a urinary catheter that is inserted through a suprapubic incision into the bladder

ureterosigmoidostomy: transplantation of the ureters into the sigmoid colon, allowing urine to flow through the colon and out the rectum

ureterovesical or vesicoureteral reflux: backward flow of urine from the bladder into one or both ureters

urethritis: inflammation of the urethra

urethrovesical reflux: backward flow of urine from the urethra into the bladder

urinary incontinence: involuntary or uncontrolled loss of urine from the bladder sufficient to cause a social or hygienic problem

urosepsis: sepsis resulting from infected urine, most often a UTI

The urinary system is responsible for providing the route for drainage of urine formed by the kidneys. Care of the patient with disorders of the urinary tract requires an understanding of the anatomy, physiology, diagnostic testing, nursing care, and rehabilitation of patients with the multiple processes that affect the urinary system. Nurses care for patients with urologic disorders in all settings. This chapter focuses on the nursing management of patients with common urinary dysfunctions, including infections, dysfunctional voiding patterns, urolithiasis, genitourinary trauma, cancer of the urinary tract, and urinary diversions.

INFECTIONS OF THE URINARY TRACT

Urinary tract infections (UTIs) are caused by pathogenic microorganisms in the urinary tract (the normal urinary tract is sterile above the urethra). UTIs are generally classified as infections involving the upper or lower urinary tract and further classified as uncomplicated or complicated, depending on other patient-related conditions (Chart 45-1).

Lower UTIs include bacterial **cystitis** (inflammation of the urinary bladder), bacterial **prostatitis** (inflammation of the prostate gland), and bacterial **urethritis** (inflammation of the urethra). There can be acute or chronic nonbacterial causes of inflammation in any of these areas that can be misdiagnosed as bacterial infections. Upper UTIs are much less common and include acute or chronic **pyelonephritis** (inflammation of the renal pelvis), interstitial nephritis (inflammation of the kidney), and renal abscesses. Upper and lower UTIs are further classified as uncomplicated or complicated, depending on whether the UTI is recurrent and the duration of the infection. Most uncomplicated UTIs are

community acquired. Complicated UTIs usually occur in people with urologic abnormalities or recent catheterization and are often acquired during hospitalization.

A UTI is the second most common infection in the body. Most cases occur in women; one out of every five women in the United States will develop a UTI during her lifetime. The urinary tract is the most common site of nosocomial infection, accounting for greater than 40% of the total number reported by hospitals and affecting about 600,000 patients each year. In most of these hospital-acquired UTIs, instrumentation of the urinary tract or catheterization is the precipitating cause. More than 250,000 cases of acute pyelonephritis occur in the United States each year, with 100,000 patients requiring hospitalization. Approximately 11.3 million women are diagnosed with UTIs in the United States annually, representing an expenditure of about \$1.6 billion in direct health care costs. This amount does not include the indirect costs associated with time lost from work and the negative impact on the person's lifestyle (National Kidney and Urologic Diseases Information Clearinghouse, 2005).

Lower Urinary Tract Infections

Several mechanisms maintain the sterility of the bladder: the physical barrier of the urethra, urine flow, ureterovesical junction competence, various antibacterial enzymes and antibodies, and antiadherent effects mediated by the mucosal cells of the bladder. Abnormalities or dysfunctions of these mechanisms are contributing risk factors for lower UTIs (Chart 45-2).

Pathophysiology

For infection to occur, bacteria must gain access to the bladder, attach to and colonize the epithelium of the urinary tract to avoid being washed out with voiding, evade host

Chart 45-1 • Classifying Urinary Tract Infections

Urinary tract infections (UTIs) are classified by location: the lower urinary tract (which includes the bladder and structures below the bladder) or the upper urinary tract (which includes the kidneys and ureters). They can also be classified as uncomplicated or complicated UTIs.

Lower UTIs

Cystitis, prostatitis, urethritis

Upper UTIs

Acute pyelonephritis, chronic pyelonephritis, renal abscess, interstitial nephritis, perirenal abscess

Uncomplicated Lower or Upper UTIs

Community-acquired infection; common in young women and not usually recurrent

Complicated Lower or Upper UTIs

Often nosocomial (acquired in the hospital) and related to catheterization; occur in patients with urologic abnormalities, pregnancy, immunosuppression, diabetes mellitus, and obstructions and are often recurrent

CHART
45-2

Risk Factors for Urinary Tract Infection

- Inability or failure to empty the bladder completely
- Obstructed urinary flow caused by:
 - Congenital abnormalities
 - Urethral strictures
 - Contracture of the bladder neck
 - Bladder tumors
 - Calculi (stones) in the ureters or kidneys
 - Compression of the ureters
- Decreased natural host defenses or immunosuppression
- Instrumentation of the urinary tract (eg, catheterization, cystoscopic procedures)
- Inflammation or abrasion of the urethral mucosa
- Contributing conditions such as:
 - Diabetes mellitus (increased urinary glucose levels create an infection-prone environment in the urinary tract)
 - Pregnancy
 - Neurologic disorders
 - Gout
 - Altered states caused by incomplete emptying of the bladder and urinary stasis

defense mechanisms, and initiate inflammation. Many UTIs result from fecal organisms ascending from the perineum to the urethra and the bladder and then adhering to the mucosal surfaces.

Bacterial Invasion of the Urinary Tract

By increasing the normal slow shedding of bladder epithelial cells (resulting in bacteria removal), the bladder can clear large numbers of bacteria. Glycosaminoglycan (GAG), a hydrophilic protein, normally exerts a nonadherent protective effect against various bacteria. The GAG molecule attracts water molecules, forming a water barrier that serves as a defensive layer between the bladder and the urine. GAG may be impaired by certain agents (cyclamate, saccharin, aspartame, and tryptophan metabolites). The normal bacterial flora of the vagina and urethral area also interfere with adherence of *Escherichia coli*. Urinary immunoglobulin A (IgA) in the urethra may also provide a barrier to bacteria.

Reflux

An obstruction to free-flowing urine is a condition known as **urethrovesical reflux**, which is the reflux (backward flow) of urine from the urethra into the bladder (Fig. 45-1). With coughing, sneezing, or straining, the bladder pressure increases, which may force urine from the bladder into the urethra. When the pressure returns to normal, the urine

Figure 45-1 Mechanisms of urethrovesical and ureterovesical reflux may cause urinary tract infection. **Urethrovesical reflux:** With coughing and straining, bladder pressure rises, which may force urine from the bladder into the urethra. **A**, When bladder pressure returns to normal, the urine flows back to the bladder (**B**), which introduces bacteria from the urethra to the bladder. **Ureterovesical reflux:** With failure of the ureterovesical valve, urine moves up the ureters during voiding (**C**) and flows into the bladder when voiding stops (**D**). This prevents complete emptying of the bladder. It also leads to urinary stasis and contamination of the ureters with bacteria-laden urine.

flows back into the bladder, bringing into the bladder bacteria from the anterior portions of the urethra. Urethrovesical reflux is also caused by dysfunction of the bladder neck or urethra. The urethrovesical angle and urethral closure pressure may be altered with menopause, increasing the incidence of infection in postmenopausal women. Reflux is most often noted in young children, and treatment is based on its severity.

Ureterovesical or vesicoureteral reflux refers to the backward flow of urine from the bladder into one or both ureters (see Fig. 45-1). Normally, the ureterovesical junction prevents urine from traveling back into the ureter. The ureters tunnel into the bladder wall so that the bladder musculature compresses a small portion of the ureter during normal voiding. When the ureterovesical valve is impaired by congenital causes or ureteral abnormalities, the bacteria may reach the kidneys and eventually destroy them.

Uropathogenic Bacteria

Bacteriuria is generally defined as more than 10^5 colonies of bacteria per milliliter of urine. Because urine samples (especially in women) are commonly contaminated by the bacteria normally present in the urethral area, a bacterial count exceeding 10^5 colonies/mL of clean-catch midstream urine is the measure that distinguishes true bacteriuria from contamination. In men, contamination of the collected urine sample occurs less frequently; hence, bacteriuria is defined as 10^4 colonies/mL urine. Community-acquired UTIs are among the most common bacterial infections in women (Porth & Matfin, 2009).

The organisms most frequently responsible for UTIs are those normally found in the lower gastrointestinal (GI) tract, usually *E. coli*. However, isolation of *E. coli* is decreasing compared with previous observations, especially in males and in patients with indwelling bladder catheters, who instead have higher rates of *Pseudomonas* and *Enterococcus* organisms than females and noncatheterized patients (Porth & Matfin, 2009).

Routes of Infection

Bacteria enter the urinary tract in three ways: by the transurethral route (ascending infection), through the bloodstream (hematogenous spread), or by means of a fistula from the intestine (direct extension).

The most common route of infection is transurethral, in which bacteria (often from fecal contamination) colonize the periurethral area and subsequently enter the bladder by means of the urethra. In women, the short urethra offers little resistance to the movement of uropathogenic bacteria. Sexual intercourse forces the bacteria from the urethra into the bladder. This accounts for the increased incidence of UTIs in sexually active women. Bacteria may also enter the urinary tract by means of the blood from a distant site of infection or through direct extension by way of a fistula from the intestinal tract.

Clinical Manifestations

A variety of signs and symptoms are associated with UTI. About half of all patients with bacteriuria have no symptoms. Signs and symptoms of an uncomplicated lower UTI

(cystitis) include burning on urination, **frequency** (voiding more than every 3 hours), urgency, **nocturia** (awakening at night to urinate), incontinence, and suprapubic or pelvic pain. Hematuria and back pain may also be present. In older people, these symptoms are less common (see Gerontologic Considerations).

In patients with complicated UTIs, manifestations can range from asymptomatic bacteriuria to gram-negative sepsis with shock. Complicated UTIs often are caused by a broader spectrum of organisms, have a lower response rate to treatment, and tend to recur. Many patients with catheter-associated UTIs are asymptomatic; however, any patient with a catheter who suddenly develops signs and symptoms of septic shock should be evaluated for **urosepsis** (sepsis resulting from infected urine).

Gerontologic Considerations

The incidence of bacteriuria in the elderly differs from that in younger adults. Bacteriuria increases with age and disability, and women are affected more frequently than men. UTI is the most common cause of acute bacterial sepsis in patients older than 65 years of age, in whom gram-negative sepsis carries a mortality rate exceeding 50%. Urologists see many asymptomatic patients with bacteriuria and 20% are women older than 65 years. In older patients who reside in nursing homes, 25% to 50% of females and 15% to 40% of males have chronic bacteriuria (Juthani-Mehta, 2007; Miller, 2009).

In the elderly population at large, structural abnormalities secondary to decreased bladder tone and neurogenic bladder (dysfunctional bladder) secondary to stroke or autonomic neuropathy of diabetes may prevent complete emptying of the bladder and increase the risk for UTI (Morton, Fontaine, Hudak, et al., 2005). When indwelling catheters are used, the risk of UTI increases dramatically. Elderly women often have incomplete emptying of the bladder and urinary stasis. In the absence of estrogen, postmenopausal women are susceptible to colonization and increased adherence of bacteria to the vagina and urethra. Oral or topical estrogen has been used to restore the glycogen content of vaginal epithelial cells and an acidic pH for some postmenopausal women with recurrent cystitis.

The antibacterial activity of prostatic secretions that protect men from bacterial colonization of the urethra and bladder decreases with aging. Although UTIs are rare in men, the prevalence of infection in men older than 50 years of age approaches that of women in the same age group. The increase of UTIs in men as they age is largely a result of prostatic hyperplasia or carcinoma, strictures of the urethra, and neuropathic bladder. The use of catheterization or cystoscopy in evaluation or treatment may also contribute to the higher incidence of UTIs in this group. The incidence of bacteriuria increases in men with confusion, dementia, or bowel or bladder incontinence. The most common cause of recurrent UTIs in elderly males is chronic bacterial prostatitis. Resection of the prostate gland may help reduce its incidence (see Chapter 49).

In institutionalized elderly patients, such as those in long-term care facilities, infecting pathogens are often resistant to many antibiotics. Chart 45-3 lists other factors that may contribute to UTI in elderly patients in these en-

CHART
45-3

GERONTOLOGIC CONSIDERATIONS Factors That Contribute to Urinary Tract Infection in Older Adults

- High incidence of multiple chronic medical conditions
- Frequent use of antimicrobial agents
- Presence of infected pressure ulcers
- Immunocompromise
- Cognitive impairment
- Immobility and incomplete emptying of bladder
- Use of a bedpan rather than a commode or toilet

vironments. Diligent hand hygiene, careful perineal care, and frequent toileting may decrease the incidence of UTIs.

The organisms responsible for UTIs in the institutionalized elderly may differ from those found in patients residing in the community; this is thought to result in part from the frequent use of antibiotic agents by patients in long-term care facilities. *E. coli* is the most common organism seen in elderly patients in the community or hospital. However, patients with indwelling catheters are more likely to be infected with *Proteus*, *Klebsiella*, *Pseudomonas*, or *Staphylococcus* species. Patients who have been previously treated with antibiotics may be infected with *Enterococcus* species. Frequent reinfections are common in older adults.

The most common subjective presenting symptom of UTI in older adults is generalized fatigue. The most common objective finding is a change in cognitive functioning, especially in those with dementia, because these patients usually exhibit even more profound cognitive changes with the onset of a UTI.

Controversy continues about the need for treatment of asymptomatic bacteriuria in institutionalized elderly patients, because resulting antibiotic-resistant organisms and sepsis may be greater threats to patients. Most experts now recommend withholding antibiotics unless symptoms develop. However, treatment regimens are generally the same as those for younger adults, although age-related changes in the intestinal absorption of medications and decreased renal function and hepatic flow may necessitate alterations in the antimicrobial regimen. Renal function must be monitored, and medication dosages should be altered accordingly.

NURSING ALERT

Elderly patients often lack the typical symptoms of UTI and sepsis. Although frequency and urgency may occur, nonspecific symptoms, such as altered sensorium, lethargy, anorexia, new incontinence, hyperventilation, and low-grade fever, may be the only clues.

Assessment and Diagnostic Findings

Results of various tests, such as bacterial colony counts, cellular studies, and urine cultures, help confirm the diagnosis of UTI. In an uncomplicated UTI, the strain of bacteria determines the antibiotic of choice.

Urine Cultures

Urine cultures are useful for documenting a UTI and identifying the specific organism present. UTI is diagnosed by bacteria in the urine culture. A colony count of at least 10^5

colony-forming units (CFU) per milliliter of urine on a clean-catch midstream or catheterized specimen is a major criterion for infection (Smythe, Moore & Goldsmith, 2006). However, UTI and subsequent sepsis have occurred with lower bacterial colony counts. About one third of women with symptoms of acute infections have negative midstream urine culture results and may go untreated if 10^5 CFU/mL is used as the criterion for infection. The presence of any bacteria in specimens obtained by suprapubic needle aspiration of the urinary bladder or catheterization (insertion of a tube into the urinary bladder) is considered indicative of infection.

The following groups of patients should have urine cultures obtained when bacteriuria is present:

- All men (because of the likelihood of structural or functional abnormalities)
- All children
- Women with a history of compromised immune function or renal problems
- Patients with diabetes mellitus
- Patients who have undergone recent instrumentation (including catheterization) of the urinary tract
- Patients who have been recently hospitalized or who live in long-term care facilities
- Patients with prolonged or persistent symptoms
- Patients with three or more UTIs in the previous year
- Pregnant women
- Postmenopausal women
- Women who are sexually active
- Women who have new sexual partners

Cellular Studies

Microscopic hematuria is present in about half of patients with an acute UTI (see Chapter 43). **Pyuria** (greater than 4 white blood cells [WBCs] per high-power field) occurs in all patients with UTI; however, it is not specific for bacterial infection. Pyuria can also be seen with kidney stones, interstitial nephritis, and renal tuberculosis.

Other Studies

A multiple-test dipstick often includes testing for WBCs, known as the leukocyte esterase test, and nitrite testing. Urine hydroxyproline, an amino acid found mainly in collagen, may be tested for in disorders characterized by bone resorption (Karpoff & Labus, 2008).

Tests for sexually transmitted diseases (STDs), also referred to as sexually transmitted infections (STIs), may be performed because acute urethritis caused by sexually transmitted organisms (ie, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, herpes simplex) or acute vaginitis infections (caused by *Trichomonas* or *Candida* species) may be responsible for symptoms similar to those of UTIs.

Diagnostic studies such as computed tomography (CT) and ultrasonography are useful diagnostic tools. A CT scan may detect pyelonephritis or abscesses, and ultrasonography is extremely sensitive for detecting obstruction, abscesses, tumors, and cysts. Transrectal ultrasonography (to assess the prostate and bladder) is the procedure of choice for men with recurrent or complicated UTIs. A cystourethroscopy may be indicated to visualize the ureters or to detect strictures, calculi, or tumors (Karpoff & Labus, 2008).

Medical Management

Management of UTIs typically involves pharmacologic therapy and patient education. The nurse teaches the patient about prescribed medication regimens and infection prevention measures.

Acute Pharmacologic Therapy

The ideal medication for treatment of UTI is an antibacterial agent that eradicates bacteria from the urinary tract with minimal effects on fecal and vaginal flora, thereby minimizing the incidence of vaginal yeast infections. (Yeast vaginitis occurs in as many as 25% of patients treated with antimicrobial agents that affect vaginal flora. Yeast vaginitis can cause more symptoms and be more difficult and costly to treat than the original UTI.) Additionally, the antibacterial agent should be affordable and should have few adverse effects and low resistance. Because the organism in initial, uncomplicated UTIs in women is most likely *E. coli* or other fecal flora, the agent should be effective against these organisms (Mehner-Kay, 2005). Various treatment regimens have been successful in treating uncomplicated lower UTIs in women: single-dose administration, short-course (3 to 4 days) regimens, or 7- to 10-day regimens. The trend is toward a shortened course of antibiotic therapy for uncomplicated UTIs, because most cases are cured after 3 days of treatment. Patients in institutional settings may require 7 to 10 days of medication for the treatment to be effective. Some of the medications commonly used to treat UTIs are listed in Table 45-1. Regardless of the regimen prescribed, the patient is instructed to take all the doses prescribed, even if relief of symptoms occurs promptly. Longer medication courses are indicated for men, pregnant women, and women with pyelonephritis and other types of complicated UTIs. Hospitalization and intravenous (IV) antibiotics are occasionally necessary (Karch, 2008).

Long-Term Pharmacologic Therapy

Although brief pharmacologic treatment of UTIs for 3 days is usually adequate in women, infection recurs in about 20% of women treated for uncomplicated UTIs. Infections that recur within 2 weeks of therapy do so because organisms of the original offending strain remain. Relapses suggest that the source of bacteriuria may be the upper urinary tract or that initial treatment was inadequate or administered for too short a time. Recurrent infections in men are usually caused by persistence of the same organism; further evaluation and treatment are indicated.

Reinfection with new bacteria is the reason for more than 90% of recurrent UTIs in women. If the diagnostic evaluation reveals no structural abnormalities in the urinary tract, the woman with recurrent UTIs may be instructed to begin treatment on her own whenever symptoms occur and to contact her health care provider only when symptoms persist, fever occurs, or the number of treatment episodes exceeds four in a 6-month period. The patient may be taught to use dip-slide culture devices to detect bacteria.

If infection recurs after completing antimicrobial therapy, another short course (3 to 4 days) of full-dose antimicrobial therapy followed by a regular bedtime dose of an antimicrobial agent may be prescribed. If there is no recurrence, medication is taken every other night for 6 to

Table 45-1  **EXAMPLES OF MEDICATIONS USED TO TREAT UTIs AND PYELONEPHRITIS**

Drug Classes	Generic (Brand) Name	Major Indications
Antibiotic Cephalosporin (first generation)	Cephalexin (Keflex)	Genitourinary infections
Antibiotic	Ampicillin (Principen)	UTI—not commonly used alone due to <i>Escherichia coli</i> resistance Pyelonephritis
Antibiotic	Amoxicillin (Amoxil)	UTI—not commonly used alone due to <i>E. coli</i> resistance
Trimethoprim-sulfamethoxazole combination	Cotrimoxazole (TMP-SMZ, Bactrim Septra)	UTI Pyelonephritis
Antibiotic Urinary tract anti-infective	Nitrofurantoin (Macrochantin, Furadantin)	UTI
Fluoroquinolone Antibiotic	Ciprofloxacin (Cipro)	UTI Pyelonephritis
Fluoroquinolone	Levofloxacin (Levaquin)	Uncomplicated UTI
Urinary analgesic agent	Phenazopyridine (Pyridium)	For relief of burning, burning, pain and other symptoms associated with UTI

UTI, urinary tract infection.

Compiled using information from Karch, A. (2008). 2008 *Lippincott's nursing drug guide*. Philadelphia: Lippincott Williams & Wilkins; and Mehnert-Kay, S. A. (2005). Diagnosis and management of uncomplicated urinary tract infections. *American Family Physician*, 72(3), 451–456.

7 months. Long-term use of antimicrobial agents decreases the risk of reinfection and may be indicated in patients with recurrent infections.

If recurrence is caused by persistent bacteria from preceding infections, the cause (ie, kidney stone, abscess), if known, must be treated. After treatment and sterilization of the urine, low-dose preventive therapy (trimethoprim with or without sulfamethoxazole) each night at bedtime is often prescribed.

Current evidence about the effectiveness of daily intake of cranberry juice to prevent UTIs is inconclusive (McMurdo, Bissett, Price, et al., 2005). Patients who like cranberry juice can be encouraged to include it in their increased fluid intake to help flush bacteria (Dudek, 2006).

NURSING PROCESS

THE PATIENT WITH A LOWER URINARY TRACT INFECTION

Nursing care of the patient with a lower UTI focuses on treating the underlying infection and preventing its recurrence.

Assessment

A history of signs and symptoms related to UTI is obtained from the patient with a suspected UTI. The presence of pain, frequency, urgency, hesitancy, and changes in urine are assessed, documented, and reported. The patient's usual pattern of voiding is assessed to detect factors that may predispose him or her to UTI. Infrequent emptying of the bladder, the association of symptoms of UTI with sexual intercourse, contraceptive practices, and personal hygiene are assessed. The patient's knowledge about prescribed antimicrobial medications and preventive health care measures is also assessed. Additionally, the urine is assessed for volume, color, concentration, cloudiness, and odor, all of which are altered by bacteria in the urinary tract.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the nursing diagnoses may include the following:

- Acute pain related to infection within the urinary tract
- Deficient knowledge about factors predisposing the patient to infection and recurrence, detection and prevention of recurrence, and pharmacologic therapy

Collaborative Problems/Potential Complications

Based on assessment data, the following complications may develop:

- Sepsis (urosepsis)
- Renal failure, which may occur as the long-term result of either an extensive infective or inflammatory process

Planning and Goals

Major goals for the patient may include relief of pain and discomfort, increased knowledge of preventive measures and treatment modalities, and absence of complications.

Nursing Interventions

Relieving Pain

The pain associated with UTI is quickly relieved once effective antimicrobial therapy is initiated. Antispasmodic agents may also be useful in relieving bladder irritability and pain. Analgesic agents and the application of heat to the perineum help relieve pain and spasm. The patient is encouraged to drink liberal amounts of fluids (water is the best choice) to promote renal blood flow and to flush the bacteria from the urinary tract. Urinary tract irritants (eg, coffee, tea, citrus, spices, colas, alcohol) are avoided. Frequent voiding (every 2 to 3 hours) is encouraged to empty the bladder completely because this can significantly lower urine bacterial counts, reduce urinary stasis, and prevent reinfection.

Monitoring and Managing Potential Complications

Early recognition of UTI and prompt treatment are essential to prevent recurrent infection and the possibility of complications, such as renal failure, sepsis (urosepsis), strictures, and obstructions. The goal of treatment is to prevent infection from progressing and causing permanent renal damage and renal failure. Thus, the patient must be taught to recognize early signs and symptoms, to test for bacteriuria, and to initiate treatment as prescribed. Appropriate antimicrobial therapy, liberal fluid intake, frequent voiding, and hygienic measures are commonly prescribed for managing UTIs. The patient is instructed to notify the primary health care provider if fatigue, nausea, vomiting, or pruritus occurs. Periodic monitoring of renal function and evaluation for strictures, obstructions, or stones may be indicated for patients with recurrent UTIs.

Patients with UTIs are at increased risk for gram-negative sepsis. Indwelling catheters should be avoided if possible and removed at the earliest opportunity. However, if an indwelling catheter is necessary, the following specific nursing interventions are initiated to prevent infection and urosepsis:

- Using strict aseptic technique during insertion of the smallest catheter possible
- Securing the catheter with tape to prevent movement
- Frequently inspecting urine color, odor, and consistency
- Performing meticulous daily perineal care with soap and water
- Maintaining a closed system
- Following the manufacturer's instructions when using the catheter port to obtain urine specimens

Careful assessment of vital signs and level of consciousness may alert the nurse to kidney involvement or impending sepsis. Positive blood cultures and elevated WBC counts must be reported immediately. At the same time, appropriate antibiotic therapy and increased fluid intake are prescribed (IV antibiotic therapy and fluids may be required). Aggressive early treatment is the key to reducing the

mortality rate associated with gram-negative sepsis, especially in elderly patients.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. In helping patients learn about and prevent or manage a recurrent UTI, the nurse implements teaching that meets the patient's needs. Health-related behaviors that help prevent recurrent UTIs include practicing careful personal hygiene, increasing fluid intake to promote voiding and dilution of urine, urinating regularly and more frequently, and adhering to the therapeutic regimen. For a detailed discussion of patient teaching, see Chart 45-4.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Experiences relief of pain
 - a. Reports absence of pain, urgency, frequency, nocturia, or hesitancy on voiding
 - b. Takes analgesic, antispasmodic, and antibiotic agents as prescribed
2. Explains UTIs and their treatment
 - a. Demonstrates knowledge of preventive measures and prescribed treatments
 - b. Drinks 8 to 10 glasses of fluids daily
 - c. Voids every 2 to 3 hours
 - d. Produces urine that is clear and odorless
3. Experiences no complications
 - a. Reports no symptoms of infection (fever, frequency)
 - b. Has normal renal function, negative urine and blood cultures
 - c. Exhibits normal vital signs and temperature; no signs or symptoms of sepsis (urosepsis)
 - d. Maintains adequate urine output more than 30 mL/h

CHART
45-4

PATIENT EDUCATION

Preventing Recurrent Urinary Tract Infections

Hygiene

- Shower rather than bathe in tub because bacteria in the bath water may enter the urethra.
- After each bowel movement, clean the perineum and urethral meatus from front to back. This will help reduce concentrations of pathogens at the urethral opening and, in women, the vaginal opening.

Fluid Intake

- Drink liberal amounts of fluids daily to flush out bacteria.
- Avoid coffee, tea, colas, alcohol, and other fluids that are urinary tract irritants.

Voiding Habits

- Void every 2 to 3 hours during the day and completely empty the bladder. This prevents overdistention of the bladder and compromised blood supply to the bladder wall. Both predispose the patient to UTI. Precautions

expressly for women include voiding immediately after sexual intercourse.

Therapy

- Take medication *exactly* as prescribed. Special timing of administration may be required.
- If bacteria continue to appear in the urine, long-term antimicrobial therapy may be required to prevent colonization of the periurethral area and recurrence of infection.
- For recurrent infection, consider acidification of the urine through ascorbic acid (vitamin C), 1000 mg daily, or cranberry juice.
- If prescribed, test urine for presence of bacteria following manufacturer's and health care provider's instructions.
- Notify the primary health care provider if fever occurs or if signs and symptoms persist.
- Consult the primary health care provider regularly for follow-up.

Upper Urinary Tract Infections

Pyelonephritis is a bacterial infection of the renal pelvis, tubules, and interstitial tissue of one or both kidneys. Causes involve either the upward spread of bacteria from the bladder or spread from systemic sources reaching the kidney via the bloodstream. Pathogenic bacteria from a bladder infection can ascend into the kidney, resulting in pyelonephritis. An incompetent ureterovesical valve or obstruction occurring in the urinary tract increases the susceptibility of the kidneys to infection (see Fig. 45-1), because static urine provides a good medium for bacterial growth. Bladder tumors, strictures, benign prostatic hyperplasia, and urinary stones are some potential causes of obstruction that can lead to infections. Systemic infections (such as tuberculosis) can spread to the kidneys and result in abscesses.

Pyelonephritis may be acute or chronic. Acute pyelonephritis is usually manifested by enlarged kidneys with interstitial infiltrations of inflammatory cells. Abscesses may be noted on or within the renal capsule and at the corticomedullary junction. Eventually, atrophy and destruction of tubules and the glomeruli may result. When pyelonephritis becomes chronic, the kidneys become scarred, contracted, and nonfunctioning. Chronic pyelonephritis is a cause of chronic kidney disease that can result in the need for renal replacement therapies such as transplantation or dialysis (Burrows-Hudson, 2005).

ACUTE PYELONEPHRITIS

Clinical Manifestations

The patient with acute pyelonephritis is acutely ill with chills, fever, leukocytosis, bacteriuria, and pyuria. Low back pain, flank pain, nausea and vomiting, headache, malaise, and painful urination are common findings. Physical examination reveals pain and tenderness in the area of the costovertebral angle (see Chapter 43, Fig. 43-6). In addition, symptoms of lower urinary tract involvement, such as urgency and frequency, are common.

Assessment and Diagnostic Findings

An ultrasound study or a CT scan may be performed to locate any obstruction in the urinary tract. Relief of obstruction is essential to prevent the complications and eventual kidney damage. An IV pyelogram may be indicated with pyelonephritis if functional and structural renal abnormalities are suspected (Karpoff & Labus, 2008). Radionuclide imaging with gallium citrate and indium-111 (^{111}In)-labeled WBCs may be useful to identify sites of infection that may not be visualized on CT scan or ultrasound. Urine culture and sensitivity tests are performed to determine the causative organism so that appropriate antimicrobial agents can be prescribed.

Medical Management

Patients with acute uncomplicated pyelonephritis are most often treated on an outpatient basis if they are not exhibiting dehydration, nausea or vomiting, or symptoms of sepsis. In addition, they must be responsible and reliable to ensure that all medications will be taken as prescribed. For outpa-

tients, a 2-week course of antibiotics is recommended because renal parenchymal disease is more difficult to eradicate than mucosal bladder infections. Commonly prescribed agents include some of the same medications prescribed for the treatment of UTIs (see Table 45-1).

Pregnant women may be hospitalized for 2 or 3 days of parenteral antibiotic therapy. Oral antibiotic agents may be prescribed once the patient is afebrile and showing clinical improvement.

A possible issue in acute pyelonephritis treatment is a chronic or recurring symptomless infection persisting for months or years. After the initial antibiotic regimen, the patient may need antibiotic therapy for up to 6 weeks if a relapse occurs. A follow-up urine culture is obtained 2 weeks after completion of antibiotic therapy to document clearing of the infection.

Hydration with oral or parenteral fluids is essential in all patients with UTIs when there is adequate kidney function. Hydration helps facilitate “flushing” of the urinary tract and reduces pain and discomfort.

CHRONIC PYELONEPHRITIS

Repeated bouts of acute pyelonephritis may lead to chronic pyelonephritis.

Clinical Manifestations

The patient with chronic pyelonephritis usually has no symptoms of infection unless an acute exacerbation occurs. Noticeable signs and symptoms may include fatigue, headache, poor appetite, polyuria, excessive thirst, and weight loss. Persistent and recurring infection may produce progressive scarring of the kidney, resulting in renal failure (see Chapter 44).

Assessment and Diagnostic Findings

The extent of the disease is assessed by an IV urogram and measurements of creatinine clearance, blood urea nitrogen, and creatinine levels. Bacteria, if detected in the urine, are eradicated if possible.

Complications

Complications of chronic pyelonephritis include end-stage renal disease (from progressive loss of nephrons secondary to chronic inflammation and scarring), hypertension, and formation of kidney stones (from chronic infection with urea-splitting organisms).

Medical Management

Long-term use of prophylactic antimicrobial therapy may help limit recurrence of infections and renal scarring. Impaired renal function alters the excretion of antimicrobial agents and necessitates careful monitoring of renal function, especially if the medications are potentially toxic to the kidneys.

Nursing Management

The patient may require hospitalization or may be treated as an outpatient. When the patient requires hospitalization, fluid intake and output are carefully measured and recorded. Unless contraindicated, 3 to 4 L of fluids per day is encouraged to

dilute the urine, decrease burning on urination, and prevent dehydration. The nurse assesses the patient's temperature every 4 hours and administers antipyretic and antibiotic agents as prescribed. Symptomatic patients are often more comfortable on bed rest.

Patient teaching focuses on prevention of further infection by consuming adequate fluids, emptying the bladder regularly, and performing recommended perineal hygiene. The importance of taking antimicrobial medications exactly as prescribed is stressed, as is the need for keeping follow-up appointments.

ADULT VOIDING DYSFUNCTION

Both neurogenic and non-neurogenic disorders can cause adult voiding dysfunction (Table 45-2). The **micturition** (voiding or urination) process involves several highly coordinated neurologic responses that mediate bladder function. A functional urinary system allows for appropriate bladder filling and complete bladder emptying (see Chapter 43). If voiding dysfunction goes undetected and untreated, the upper urinary system may be compromised. Chronic incomplete bladder emptying from poor detrusor pressure results in recurrent bladder infection. Incomplete bladder emptying due to bladder outlet obstruction (such as benign prostatic hyperplasia), causing high-pressure detrusor contractions, can result in hydronephrosis from the high detrusor pressure that radiates up the ureters to the renal pelvis.

Urinary Incontinence

More than 17 million adults in the United States are estimated to have **urinary incontinence** (involuntary loss of urine from the bladder), with most of them experiencing

overactive bladder syndrome, making this disorder more prevalent than diabetes or ulcer disease (Vinsnes, Harkless & Nyronning, 2007). Despite widespread media coverage, urinary incontinence remains underdiagnosed and underreported. Patients may be too embarrassed to seek help, causing them to ignore or conceal symptoms. Many patients resort to using absorbent pads or other devices without having their condition properly diagnosed and treated. Health care providers must be alert to subtle cues of urinary incontinence and stay informed about current management strategies.

The cost of urologic care in the United States is more than 11 billion dollars (Carson, 2007). The costs of care for patients with urinary incontinence include the expenses of absorbent products, medications, and surgical or nonsurgical treatment modalities, as well as psychosocial costs (ie, embarrassment, loss of self-esteem, and social isolation).

Although urinary incontinence is commonly regarded as a condition that occurs in older multiparous women, it can occur in young nulliparous women, especially during vigorous high-impact activity. Age, gender, and number of vaginal deliveries are established risk factors that explain, in part, the increased incidence in women (Chart 45-5). Urinary incontinence is a symptom of many possible disorders.

Types of Urinary Incontinence

This section provides some of the more common terms used to describe the many types of urinary incontinence (Miller, 2009; Muller, 2005).

Stress incontinence is the involuntary loss of urine through an intact urethra as a result of sneezing, coughing, or changing position (Miller, 2009). It predominantly affects women who have had vaginal deliveries and is thought to be the result of decreasing ligament and pelvic floor support of the urethra and decreasing or absent estrogen levels

Table 45-2 CONDITIONS CAUSING ADULT VOIDING DYSFUNCTION

Condition	Voiding Dysfunction	Treatment
Neurogenic Disorders		
Cerebellar ataxia	Incontinence or dyssynergia	Timed voiding; anticholinergic agents
Cerebrovascular accident	Retention or incontinence	Anticholinergic agents; bladder retraining
Dementia	Incontinence	Prompted voiding; anticholinergic agents
Diabetes mellitus	Incontinence and/or incomplete bladder emptying	Timed voiding; EMG/biofeedback; pelvic floor nerve stimulation; anticholinergic/antispasmodic agents; well-controlled blood glucose levels
Multiple sclerosis	Incontinence or incomplete bladder emptying	Timed voiding; EMG/biofeedback to learn pelvic muscle exercises and urge inhibition; pelvic floor nerve stimulation; antispasmodic agents
Parkinson's disease	Incontinence	Anticholinergic/antispasmodic agents
Spinal Cord Dysfunction		
Acute injury	Urinary retention	Indwelling catheter
Degenerative disease	Incontinence and/or incomplete bladder emptying	EMG/biofeedback; pelvic floor nerve stimulation; anticholinergic agents
Non-Neurogenic Disorders		
"Bashful bladder"	Inability to initiate voiding in public bathrooms	Relaxation therapy; EMG/biofeedback
Overactive bladder	Urgency, frequency, and/or urge incontinence	EMG/biofeedback; pelvic floor nerve stimulation; bladder drill (see Chart 45-8); anticholinergic agents
Post-general surgery	Acute urine retention	Catheterization
Postprostatectomy	Incontinence	<i>Mild:</i> biofeedback; bladder drill (see Chart 45-8); pelvic floor nerve stimulation <i>Moderate/severe:</i> surgery—artificial sphincter
Stress incontinence	Incontinence with cough, laugh, sneeze, position change	<i>Mild:</i> biofeedback; bladder drill (see Chart 45-8); periurethral bulking with collagen <i>Moderate/severe:</i> surgery

CHART
45-5**Risk Factors for
Urinary Incontinence**

- Pregnancy: vaginal delivery, episiotomy
- Menopause
- Genitourinary surgery
- Pelvic muscle weakness
- Incompetent urethra due to trauma or sphincter relaxation
- Immobility
- High-impact exercise
- Diabetes mellitus
- Stroke
- Age-related changes in the urinary tract
- Morbid obesity
- Cognitive disturbances: dementia, Parkinson's disease
- Medications: diuretics, sedatives, hypnotics, opioids
- Caregiver or toilet unavailable

within the urethral walls and bladder base. In men, stress incontinence is often experienced after a radical prostatectomy for prostate cancer because of the loss of urethral compression that the prostate had supplied before the surgery, and possibly bladder wall irritability.

Urge incontinence is the involuntary loss of urine associated with a strong urge to void that cannot be suppressed. The patient is aware of the need to void but is unable to reach a toilet in time (Miller, 2009). An uninhibited detrusor contraction is the precipitating factor. This can occur in a patient with neurologic dysfunction that impairs inhibition of bladder contraction or in a patient without overt neurologic dysfunction.

Functional incontinence refers to those instances in which lower urinary tract function is intact but other factors, such as severe cognitive impairment (eg, Alzheimer's dementia), make it difficult for the patient to identify the need to void

or physical impairments make it difficult or impossible for the patient to reach the toilet in time for voiding.

Latrogenic incontinence refers to the involuntary loss of urine due to extrinsic medical factors, predominantly medications. One such example is the use of alpha-adrenergic agents to decrease blood pressure. In some people with an intact urinary system, these agents adversely affect the alpha receptors responsible for bladder neck closing pressure; the bladder neck relaxes to the point of incontinence with a minimal increase in intra-abdominal pressure, thus mimicking stress incontinence. As soon as the medication is discontinued, the apparent incontinence resolves.

Mixed urinary incontinence, which encompasses several types of urinary incontinence, is involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing (Miller, 2009).

Only with appropriate recognition of the problem, assessment, and referral for diagnostic evaluation and treatment can the outcome of incontinence be determined. All people with incontinence should be considered for evaluation and treatment.

**Gerontologic Considerations**

Although urinary incontinence is not a normal consequence of aging, age-related changes in the urinary tract do predispose the older person to incontinence. However, if nurses and other health care providers accept incontinence as an inevitable part of illness or aging or consider it irreversible and untreatable, it cannot be treated successfully. Collaborative, interdisciplinary efforts are essential in assessing and effectively treating urinary incontinence (Specht, 2005). Chart 45-6 presents research about improving urinary incontinence in frail elderly patients. Urinary incontinence can decrease an elderly person's ability to maintain an independent lifestyle, which increases dependence on caregivers and may lead to institutionalization. Between 25% and 50% of all nursing home residents have urinary incontinence.

CHART
45-6**NURSING RESEARCH PROFILE****Improving Urinary Incontinence in Frail Elderly Patients**

Vinsnes, A. G., Harkless, G. E. & Nyronning, S. (2007). Unit-based intervention to improve urinary incontinence in frail elderly. *Journal of Nursing Research & Clinical Studies*, 27(3), 53–56.

Purpose

Of the many health challenges that frail elderly people face, urinary incontinence is one of the most common. The purpose of this study was to determine the effect of a unit-based educational program in a nursing home on urinary incontinence in frail elderly people.

Design

This quantitative study used a quasi-experimental design and involved 18 patients (16 women, 2 men) with a mean age of 83 years who were all experiencing urinary incontinence before the study began. The intervention was a systemic educational program for staff delivered over 14 weeks, which included regular coaching about caring for elders with urinary incontinence. Outcome measures were postvoid residual

urine volumes, urinary pad weights, oral fluid intake patterns, and urinary tract infections.

Findings

The education sessions were successful. Both the average and maximum incontinence pads weighed less following the intervention. Average postvoiding residual urine did not change, but the average minimum amount per resident decreased in volume. Daily fluid volume intake remained the same; however, more patients received drinks at night after the intervention with no subsequent increase in overall amount of incontinence.

Nursing Implications

This small study demonstrates the potential of using a unit-based educational program to improve care and change outcomes for patients. Future work is needed to expand the research to a larger, more diverse patient population; develop better tools and strategies for investigation; and enhance treatment and evaluation methods in the frail elderly population.

Many older people experience transient episodes of incontinence that tend to be abrupt in onset. When this occurs, the nurse should question the patient, as well as the family if possible, about the onset of symptoms and any signs or symptoms of a change in other organ systems. Acute UTI, infection elsewhere in the body, constipation, decreased fluid intake, and a change in a chronic disease pattern, such as elevated blood glucose levels in patients with diabetes or decreased estrogen levels in menopausal women, can provoke the onset of urinary incontinence. If the cause is identified and modified or eliminated early at the onset of incontinence, the incontinence itself may be eliminated. Although the bladder of the older person is more vulnerable to altered detrusor activity, age alone is not a risk factor for urinary incontinence (Vinsnes, et al., 2007).

Decreased bladder muscle tone is a normal age-related change found in the elderly. This leads to decreased bladder capacity, increased residual urine, and an increase in urgency (Miller, 2009).

Many medications affect urinary continence in addition to causing other unwanted or unexpected effects. All medications need to be assessed for potential interactions.

Assessment and Diagnostic Findings

Once incontinence is recognized, a thorough history is necessary. This includes a detailed description of the problem and a history of medication use. The patient's voiding history, a diary of fluid intake and output, and bedside tests (eg, residual urine, stress maneuvers) may be used to help determine the type of urinary incontinence involved. Extensive urodynamic tests may be performed (see Chapter 43). Urinalysis and urine culture are performed to identify infection.

Urinary incontinence may be transient or reversible if the underlying cause is successfully treated and the voiding pattern reverts to normal. Chart 45-7 provides causes of transient incontinence.

Medical Management

Management depends on the type of urinary incontinence and its causes. Management of urinary incontinence may be behavioral, pharmacologic, or surgical.

Behavioral Therapy

Behavioral therapies are the first choice to decrease or eliminate urinary incontinence (Chart 45-8). In using these

techniques, health care professionals help patients avoid potential adverse effects of pharmacologic or surgical interventions. Pelvic floor muscle exercises (sometimes called Kegel exercises) represent the cornerstone of behavioral intervention for addressing symptoms of stress, urge, and mixed incontinence. Other behavioral treatments include use of a voiding diary, biofeedback, verbal instruction (prompted voiding), and physical therapy (Miller, 2009).

Pharmacologic Therapy

Pharmacologic therapy works best when used as an adjunct to behavioral interventions. Anticholinergic agents inhibit bladder contraction and are considered first-line medications for urge incontinence. Several tricyclic antidepressant medications (eg, amitriptyline [Endep], amoxapine [Asendin]) can also decrease bladder contractions as well as increase bladder neck resistance (Karch, 2008). Pseudoephedrine sulfate (Sudafed), which acts on alpha-adrenergic receptors, causing urinary retention, may be used to treat stress incontinence; it needs to be used with caution in men with prostatic hyperplasia. Hormone therapy (eg, estrogen) taken orally, transdermally, or topically was once the treatment of choice for urinary incontinence in postmenopausal women because it restores the mucosal, vascular, and muscular integrity of the urethra. However, the results of the Women's Health Initiative showed that after 1 year of therapy, incontinence had increased, especially in women taking estrogen alone compared to placebo (Mennick, 2005). More research is needed in this area.

Surgical Management

Surgical correction may be indicated in patients who have not achieved continence using behavioral and pharmacologic therapy. Surgical options vary according to the underlying anatomy and the physiologic problem. Most procedures involve lifting and stabilizing the bladder or urethra to restore the normal urethrovesical angle or to lengthen the urethra.

Women with stress incontinence may undergo an anterior vaginal repair, retropubic suspension, or needle suspension to reposition the urethra. Procedures to compress the urethra and increase resistance to urine flow include sling procedures and placement of periurethral bulking agents such as artificial collagen.

Periurethral bulking is a semipermanent procedure in which small amounts of artificial collagen are placed within the walls of the urethra to enhance the closing pressure of the urethra. This procedure takes only 10 to 20 minutes and may be performed under local anesthesia or moderate sedation. A cystoscope is inserted into the urethra. An instrument is inserted through the cystoscope to deliver a small amount of collagen into the urethral wall at locations selected by the urologist. The patient is usually discharged home after voiding. There are no restrictions following the procedure, although occasionally more than one collagen bulking session may be necessary if the initial procedure did not halt stress incontinence. Collagen placement anywhere in the body is considered semipermanent because its durability averages between 12 and 24 months, until the body absorbs the material. Periurethral bulking with collagen offers an alternative to surgery, as in a frail, elderly person.

Delirium
Infection of urinary tract
Atrophic vaginitis, urethritis
Pharmacologic agents (anticholinergic agents, sedatives, alcohol, analgesic agents, diuretics, muscle relaxants, adrenergic agents)
Psychological factors (depression, regression)
Excessive urine production (increased intake, diabetes insipidus, diabetic ketoacidosis)
Restricted activity
Stool impaction

Chart 45-8 • Behavioral Interventions for Urinary Incontinence

Behavioral strategies are largely carried out, coordinated, and monitored by the nurse. These interventions may or may not be augmented by the use of medications.

Fluid Management

An adequate daily fluid intake of approximately 50 to 60 ounces (1500 to 1600 mL), taken as small increments between breakfast and the evening meal, helps to reduce urinary urgency related to concentrated urine production, decreases the risk of urinary tract infection, and maintains bowel functioning. (Constipation, resulting from inadequate daily fluid intake, can increase urinary urgency and urine retention.) The best fluid is water. Fluids containing caffeine, carbonation, alcohol, or artificial sweetener should be avoided because they irritate the bladder wall, thus resulting in urinary urgency. Some patients who have heart failure or end-stage renal disease need to discuss their daily fluid limit with their primary health care provider.

Standardized Voiding Frequency

After establishing a patient's natural voiding and urinary incontinence tendencies, voiding on a schedule can be very effective in those with and without cognitive impairment, although patients with cognitive impairment may require assistance with this technique from nursing personnel or family members. The object is to purposely empty the bladder before the bladder reaches the critical volume that would cause an urge or stress incontinence episode. This approach involves the following:

- **Timed voiding** involves establishing a set voiding frequency (such as every 2 hours if incontinent episodes tend to occur 2 or more hours after voiding). The individual chooses to "void by the clock" at the given interval while awake, rather than wait until a voiding urge occurs.
- **Prompted voiding** is timed voiding that is carried out by staff or family members when the individual has cognitive difficulties that make it difficult to remember to void at set intervals. The caregiver checks the patient to assess if he or she has remained dry and, if so, assists the patient to use the bathroom while providing positive reinforcement for remaining dry.
- **Habit retraining** is timed voiding at an interval that is more frequent than the individual would usually choose. This technique helps to restore the sensation of the need to void in individuals who are experiencing diminished sensation of bladder filling due to various medical conditions such as a mild cerebrovascular accident (CVA).
- **Bladder retraining**, also known as "bladder drill," incorporates a timed voiding schedule and urinary urge inhibition exercises to inhibit voiding, or leaking urine, in an attempt to remain dry for a set time. When the first timing interval is easily reached on a consistent basis without urinary urgency or incontinence, a new voiding interval, usually

10 to 15 minutes beyond the last, is established. Again, the individual practices urge inhibition exercises to delay voiding or avoid incontinence until the next preset interval arrives. When an acceptable voiding interval is reached, the patient continues that timed voiding sequence throughout the day.

Pelvic Muscle Exercise (PME)

Also known as Kegel exercises, PME aims to strengthen the voluntary muscles that assist in bladder and bowel continence in both men and women. Research shows that written or verbal instruction alone is usually inadequate to teach an individual how to identify and strengthen the pelvic floor for sufficient bladder and bowel control. Biofeedback-assisted PME uses either electromyography or manometry to help the individual identify the pelvic muscles as he or she attempts to learn which muscle group is involved when performing PME. The biofeedback method also allows assessment of the strength of this muscle area.

PME involves gently tightening the same muscles used to stop flatus or the stream of urine for 5- to 10-second increments, followed by 10-second resting phases. To be effective, these exercises need to be performed two or three times a day for at least 6 weeks. Depending on the strength of the pelvic musculature when initially evaluated, anywhere from 10 to 30 repetitions of PME are prescribed at each session. Elderly patients may need to exercise for an even longer time to strengthen the pelvic floor muscles. Pelvic muscle exercises are helpful for women with stress, urge, or mixed incontinence and for men who have undergone prostate surgery.

Vaginal Cone Retention Exercises

Vaginal cone retention exercises are an adjunct to the Kegel exercises. Vaginal cones of varying weight are inserted intravaginally twice a day. The patient tries to retain the cone for 15 minutes by contracting the pelvic muscles.

Transvaginal or Transrectal Electrical Stimulation

Commonly used to treat urinary incontinence, electrical stimulation is known to elicit a passive contraction of the pelvic floor musculature, thus re-educating these muscles to provide enhanced levels of continence. This modality is often used with biofeedback-assisted pelvic muscle exercise training and voiding schedules. At high frequencies, it is effective for stress incontinence. At low frequencies, electrical stimulation can also relieve symptoms of urinary urgency, frequency, and urge incontinence. Intermediate ranges are used for mixed incontinence.

Neuromodulation

Neuromodulation via transvaginal or transrectal nerve stimulation of the pelvic floor inhibits detrusor overactivity and hypersensory bladder signals and strengthens weak sphincter muscles.

It is also an option for people who are seeking help with stress incontinence who prefer to avoid surgery and who do not have access to behavioral therapies.

An artificial urinary sphincter can be used to close the urethra and promote continence. Two types of artificial sphincters are a periurethral cuff and a cuff inflation pump.

Men with overflow and stress incontinence may undergo a transurethral resection to relieve symptoms of prostatic enlargement. An artificial sphincter can be used after prostatic surgery for sphincter incompetence (Fig. 45-2). After surgery, periurethral bulking agents can be injected into the periurethral area to increase compression of the urethra.

Figure 45-2 Male artificial urinary sphincter. An inflatable cuff is inserted surgically around the urethra or neck of the bladder. To empty the bladder, the cuff is deflated by squeezing the control pump located in the scrotum.

Nursing Management

Nursing management is based on the premise that incontinence is not inevitable with illness or aging and that it is often reversible and treatable. The nursing interventions are determined in part by the type of treatment that is undertaken. For behavioral therapy to be effective, the nurse must provide support and encouragement, because it is easy for the patient to become discouraged if therapy does not quickly improve the level of continence. Patient teaching is important and should be provided verbally and in writing (Chart 45-9). The patient should be taught to develop and use a log or diary to record timing of pelvic floor muscle exercises, frequency of voiding, any changes in bladder function, and any episodes of incontinence (Miller, 2009).

If pharmacologic treatment is used, its purpose is explained to the patient and family. It is important to tell patients with mixed incontinence that anticholinergic and antispasmodic agents can help decrease urinary urgency and frequency and urge incontinence but do not decrease the urinary incontinence related to stress incontinence. If surgical correction is undertaken, the procedure and its desired outcomes are described to the patient and family. Follow-up

contact with the patient enables the nurse to answer the patient's questions and to provide reinforcement and encouragement.

Urinary Retention

Urinary retention is the inability to empty the bladder completely during attempts to void. Chronic urine retention often leads to **overflow incontinence** (from the pressure of the retained urine in the bladder). **Residual urine** is urine that remains in the bladder after voiding. In a healthy adult younger than 60 years of age, complete bladder emptying should occur with each voiding. In adults older than 60 years of age, 50 to 100 mL of residual urine may remain after each voiding because of the decreased contractility of the detrusor muscle.

Urinary retention can occur postoperatively in any patient, particularly if the surgery affected the perineal or anal regions and resulted in reflex spasm of the sphincters. General anesthesia reduces bladder muscle innervation and suppresses the urge to void, impeding bladder emptying.

Pathophysiology

Urinary retention may result from diabetes, prostatic enlargement, urethral pathology (infection, tumor, calculus), trauma (pelvic injuries), pregnancy, or neurologic disorders such as stroke, spinal cord injury, multiple sclerosis, or Parkinson's disease. Some medications cause urinary retention, either by inhibiting bladder contractility or by increasing bladder outlet resistance (Karch, 2008).

Assessment and Diagnostic Findings

The assessment of a patient for urinary retention is multifaceted because the signs and symptoms are challenging to detect. The following questions serve as a guide in assessment:

- What was the time of the last voiding, and how much urine was voided?
- Is the patient voiding small amounts of urine frequently?
- Is the patient dribbling urine?
- Does the patient complain of pain or discomfort in the lower abdomen? (Discomfort may be relatively mild if the bladder distends slowly.)
- Is the pelvic area rounded and swollen (could indicate urine retention and a distended bladder)?

CHART
45-9

PATIENT EDUCATION

Strategies for Promoting Urinary Continence

- Increase your awareness of the amount and timing of all fluid intake.
- Avoid taking diuretics after 4 PM.
- Avoid bladder irritants, such as caffeine, alcohol, and aspartame (NutraSweet).
- Take steps to avoid constipation: Drink adequate fluids, eat a well-balanced diet high in fiber, exercise regularly, and take stool softeners if recommended.
- Void regularly, five to eight times a day (about every 2 to 3 hours):

First thing in the morning
Before each meal
Before retiring to bed
Once during the night if necessary

- Perform all pelvic floor muscle exercises as prescribed, every day.
- Stop smoking (smokers usually cough frequently, which increases incontinence).

- Does percussion of the suprapubic region elicit dullness (possibly indicating urine retention and a distended bladder)?
- Are other indicators of urinary retention present, such as restlessness and agitation?
- Does a postvoid bladder ultrasound test reveal residual urine?

The patient may verbalize an awareness of bladder fullness and a sensation of incomplete bladder emptying. Signs and symptoms of UTI (hematuria, urgency, frequency, and nocturia) may be present. A series of urodynamic studies, described in Chapter 43, may be performed to identify the type of bladder dysfunction and to aid in determining appropriate treatment. A voiding diary can be used to provide a written record of the amount of urine voided and the frequency of voiding. Postvoid residual urine may be assessed either using straight catheterization or an ultrasound bladder scanner and is considered diagnostic of urinary retention if there is more than 100 mL of residual urine.

Complications

Urine retention can lead to chronic infections that if unresolved predispose the patient to renal calculi (urolithiasis or nephrolithiasis), pyelonephritis, sepsis, or hydronephrosis. In addition, urine leakage can lead to perineal skin breakdown, especially if regular hygiene measures are neglected.

Nursing Management

Strategies are instituted to prevent overdistention of the bladder and to treat infection or correct obstruction. However, many complications can be prevented with careful assessment and appropriate nursing interventions. The nurse explains to the patient why normal voiding is not occurring and monitors urine output closely. The nurse also provides reassurance about the temporary nature of retention and successful management strategies.

Promoting Urinary Elimination

Nursing measures to encourage normal voiding patterns include providing privacy, ensuring an environment and body position conducive to voiding, and assisting the patient with the use of the bathroom or bedside commode, rather than a bedpan, to provide a more natural setting for voiding. If his condition allows, the male patient may stand beside the bed to use the urinal; most men find this position more comfortable and natural.

Additional measures include applying warmth to relax the sphincters (ie, sitz baths, warm compresses to the perineum, showers), giving the patient hot tea, and offering encouragement and reassurance. Simple trigger techniques, such as turning on the water faucet while the patient is trying to void, may also be used. Other examples of trigger techniques are stroking the abdomen or inner thighs, tapping above the pubic area, and dipping the patient's hands in warm water. After surgery or childbirth, prescribed analgesic agents should be administered because pain in the perineal area can make voiding difficult. A combination of techniques may be necessary to initiate voiding.

When the patient cannot void, catheterization is used to prevent overdistention of the bladder (see later discussion of neurogenic bladder and catheterization). In the case of

prostatic obstruction, attempts at catheterization (by the urologist) may not be successful, requiring insertion of a **suprapubic catheter** (catheter inserted through a small abdominal incision into the bladder). After urinary drainage is restored, bladder retraining is initiated for the patient who cannot void spontaneously.

Promoting Home and Community-Based Care

In addition to the strategies listed for promoting urinary continence found in Chart 45-9, modifications to the home environment can provide simple and effective ways to assist in treating urinary incontinence and retention. For example, the patient may need to remove obstacles, such as throw rugs or other objects, to provide easy, safe access to the bathroom. Other modifications that the nurse may recommend include installing support bars in the bathroom; placing a bedside commode, bedpan, or urinal within easy reach; leaving lights on in the bedroom and bathroom; and wearing clothing that is easy to remove quickly.

Neurogenic Bladder

Neurogenic bladder is a dysfunction that results from a lesion of the nervous system and leads to urinary incontinence. It may be caused by spinal cord injury, spinal tumor, herniated vertebral disk, multiple sclerosis, congenital disorders (spina bifida or myelomeningocele), infection, or complications of diabetes mellitus (see Chapters 41, 63, and 64).

Pathophysiology

The two types of neurogenic bladder are spastic (or reflex) bladder and flaccid bladder. Spastic bladder is the more common type and is caused by any spinal cord lesion above the voiding reflex arc (upper motor neuron lesion). The result is a loss of conscious sensation and cerebral motor control. A spastic bladder empties on reflex, with minimal or no controlling influence to regulate its activity.

Flaccid bladder is caused by a lower motor neuron lesion, commonly resulting from trauma. This form of neurogenic bladder is also increasingly being recognized in patients with diabetes mellitus. The bladder continues to fill and becomes greatly distended, and overflow incontinence occurs. The bladder muscle does not contract forcefully at any time. Because sensory loss may accompany a flaccid bladder, the patient feels no discomfort.

Assessment and Diagnostic Findings

Evaluation for neurogenic bladder involves measurement of fluid intake, urine output, and residual urine volume; urinalysis; and assessment of sensory awareness of bladder fullness and degree of motor control. Comprehensive urodynamic studies are also performed.

Complications

The most common complication of neurogenic bladder is infection resulting from urinary stasis and catheterization. Long-term complications include urolithiasis (stones in the urinary tract), vesicoureteral reflux, and hydronephrosis, all of which can lead to destruction of the kidney.

Medical Management

The problems resulting from neurogenic bladder disorders vary considerably from patient to patient and are a major challenge to the health care team. Several long-term objectives appropriate for all types of neurogenic bladders include preventing overdistention of the bladder, emptying the bladder regularly and completely, maintaining urine sterility with no stone formation, and maintaining adequate bladder capacity with no reflux.

Specific interventions include continuous, intermittent, or self-catheterization (discussed later in this chapter); use of an external condom-type catheter; a diet low in calcium (to prevent calculi); and encouragement of mobility and ambulation. A liberal fluid intake is encouraged to reduce the urinary bacterial count, reduce stasis, decrease the concentration of calcium in the urine, and minimize the precipitation of urinary crystals and subsequent stone formation.

A bladder retraining program may be effective in treating a spastic bladder or urine retention. Use of a timed, or habit, voiding schedule may be established. To further enhance emptying of a flaccid bladder, the patient may be taught to “double void.” After each voiding, the patient is instructed to remain on the toilet, relax for 1 to 2 minutes, and then attempt to void again in an effort to further empty the bladder.

Pharmacologic Therapy

Parasympathomimetic medications, such as bethanechol (Urecholine), may help to increase the contraction of the detrusor muscle.

Surgical Management

In some cases, surgery may be carried out to correct bladder neck contractures or vesicoureteral reflux or to perform some type of urinary diversion procedure.

Catheterization

In patients with a urologic disorder or with marginal kidney function, care must be taken to ensure that urinary drainage is adequate and that kidney function is preserved. When urine cannot be eliminated naturally and must be drained artificially, catheters may be inserted directly into the bladder, the ureter, or the renal pelvis (Senese, Hendricks, Morrison, et al., 2006). Catheters vary in size, shape, length, material, and configuration. The type of catheter used depends on its purpose.

Catheterization is performed to achieve the following:

- Relieve urinary tract obstruction
- Assist with postoperative drainage in urologic and other surgeries
- Provide a means to monitor accurate urine output in critically ill patients
- Promote urinary drainage in patients with neurogenic bladder dysfunction or urine retention
- Prevent urinary leakage in patients with stage III to IV pressure ulcers (see Chapter 11)

A patient should be catheterized only if necessary, because catheterization commonly leads to UTI. Catheters

impede most of the natural defenses of the lower urinary tract by obstructing the periurethral ducts, irritating the bladder mucosa, and providing an artificial route for organisms to enter the bladder. Organisms may be introduced from the urethra into the bladder during catheterization, or they may migrate along the epithelial surface of the urethra or external surface of the catheter. In addition, urinary catheters have been associated with other complications, such as bladder spasms, urethral strictures, and pressure necrosis.

Indwelling Catheters

When an indwelling catheter cannot be avoided, a closed drainage system is essential. This drainage system is designed to prevent any disconnections, thereby reducing the risk of contamination. Triple-lumen catheters are commonly used after transurethral prostate surgery (see Chapter 49). This system has a triple-lumen indwelling urethral catheter attached to a closed sterile drainage system. With the triple-lumen catheter, urinary drainage occurs through one channel. The retention balloon of the catheter is inflated with water or air through the second channel, and the bladder is continuously irrigated with sterile irrigating solution through the third channel.

The spout (or drainage port) of any urinary drainage bag can become contaminated when opened to drain the bag. Bacteria enter the urinary drainage bag, multiply rapidly, and then migrate to the drainage tubing, catheter, and bladder. By keeping the drainage bag lower than the patient's bladder and not allowing urine to flow back into the bladder, this risk is reduced.

Suprapubic Catheters

Suprapubic catheterization allows bladder drainage by inserting a catheter or tube into the bladder through a suprapubic (above the pubis) incision or puncture (Fig. 45-3). The catheter or suprapubic drainage tube is then threaded into the bladder and secured with sutures or tape, and the area around the catheter is covered with a sterile dressing. The catheter is connected to a sterile closed drainage system, and the tubing is secured to prevent tension on the catheter. This may be a temporary measure to divert the flow of urine from the urethra when the urethral route is impassable (because of injuries, strictures, prostatic obstruction), after gynecologic or other abdominal surgery when bladder dysfunction is likely to occur, and occasionally after pelvic fractures.

Suprapubic bladder drainage may be maintained continuously for several weeks. When the patient's ability to void is to be tested, the catheter is clamped for 4 hours, during which time the patient attempts to void. After the patient voids, the catheter is unclamped, and the residual urine is measured. If the amount of residual urine is less than 100 mL on two separate occasions (morning and evening), the catheter is usually removed. However, if the patient complains of pain or discomfort, the suprapubic catheter is usually left in place until the patient can void successfully.

Suprapubic drainage offers certain advantages. Patients can usually void sooner after surgery than those with urethral catheters, and they may be more comfortable. The catheter allows greater mobility, permits measurement of

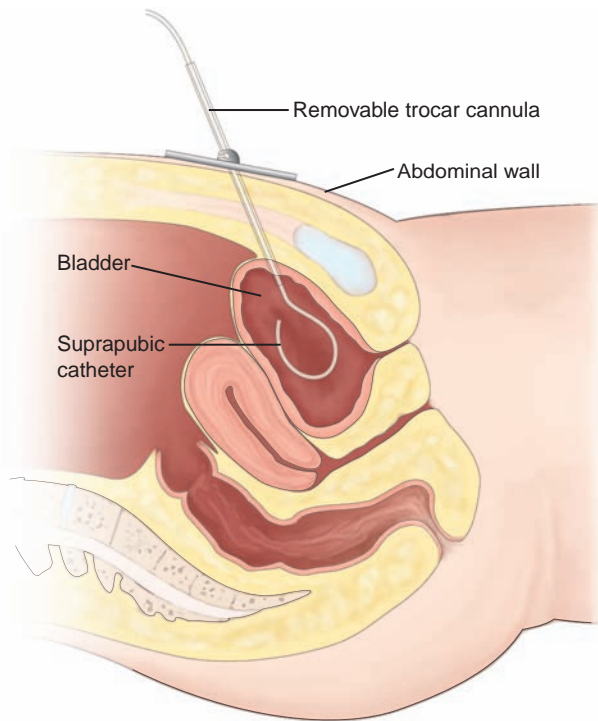

Figure 45-3 Suprapubic bladder drainage. A trocar cannula is used to puncture the abdominal and bladder walls. The catheter is threaded through the trocar cannula, which is then removed, leaving the catheter in place. The catheter is secured by tape or sutures to prevent unintentional removal.

residual urine without urethral instrumentation, and presents less risk of bladder infection. The suprapubic catheter is removed when it is no longer required, and a sterile dressing is placed over the site.

The patient requires liberal amounts of fluid to prevent encrustation around the catheter. Other potential problems include the formation of bladder stones, acute and chronic infections, and problems collecting urine. A wound care specialist/enterostomal therapist, also referred to as a wound-ostomy-contenance nurse (WOCN), may be consulted to assist the patient and family in selecting the most suitable urine collection system and to teach them about its use and care.

Nursing Management

Assessing the Patient and the System

For patients with indwelling catheters, the nurse assesses the drainage system to ensure that it provides adequate urinary drainage. The color, odor, and volume of urine are also monitored. An accurate record of fluid intake and urine output provides essential information about the adequacy of renal function and urinary drainage.

Patients at high risk for UTI from catheterization need to be identified and monitored carefully. These include women; older adults; and patients who are debilitated, malnourished, chronically ill, immunosuppressed, or have diabetes. They are observed for signs and symptoms of UTI: cloudy malodorous urine, hematuria, fever, chills, anorexia, and malaise. Any drainage and excoriation in the area

Physiology Pathophysiology

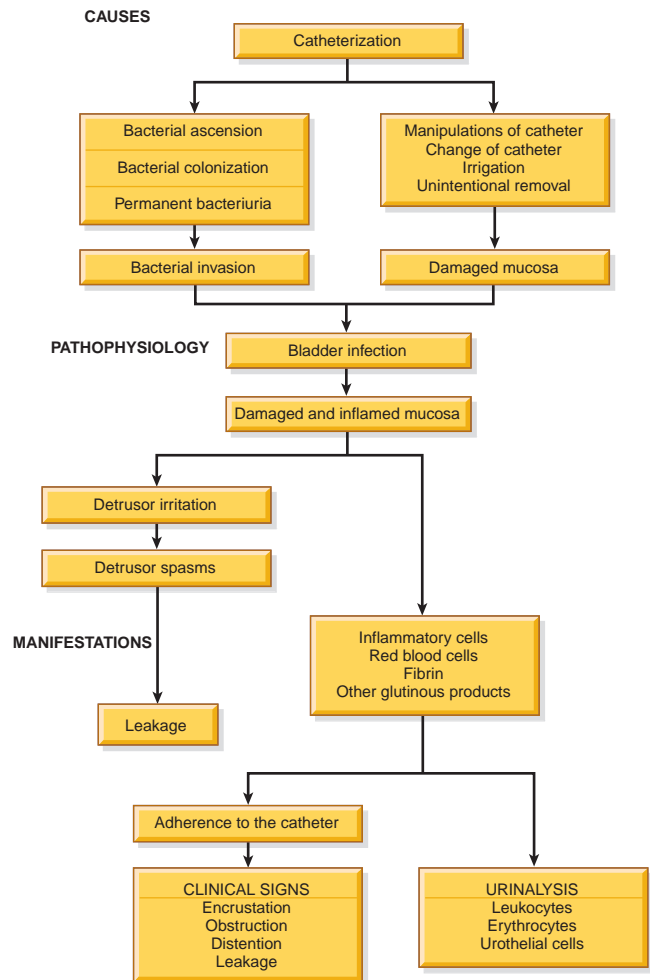

Figure 45-4 Pathophysiology and manifestations of bladder infection with long-term catheterization in elderly patients.

around the urethral orifice is noted. Urine cultures provide the most accurate means of assessing a patient for infection.

Gerontologic Considerations

The elderly patient with an indwelling catheter may not exhibit the typical signs and symptoms of infection. Therefore, any subtle change in physical condition or mental status must be considered a possible indication of infection and promptly investigated because sepsis may occur before the infection is diagnosed. Figure 45-4 summarizes the sequence of events leading to infection and leakage of urine that often follow long-term use of an indwelling catheter in an elderly patient.

Preventing Infection

Certain principles of care are essential to prevent infection in patients with a closed urinary drainage system (Chart 45-10). The catheter is a foreign body in the urethra and produces a reaction in the urethral mucosa with some urethral discharge.

Chart 45-10 • Preventing Infection in the Patient With an Indwelling Urinary Catheter

- Use scrupulous aseptic technique during insertion of the catheter. Use a preassembled, sterile, closed urinary drainage system.
- To prevent contamination of the closed system, *never* disconnect the tubing. The drainage bag must *never* touch the floor. The bag and collecting tubing are changed if contamination occurs, if urine flow becomes obstructed, or if tubing junctions start to leak at the connections.
- If the collection bag *must* be raised above the level of the patient's bladder, clamp the drainage tube. This prevents backflow of contaminated urine into the patient's bladder from the bag.
- Ensure a free flow of urine to prevent infection. Improper drainage occurs when the tubing is kinked or twisted, allowing pools of urine to collect in the tubing loops.
- To reduce the risk of bacterial proliferation, empty the collection bag at least every 8 hours through the drainage spout—more frequently if there is a large volume of urine.
- Avoid contamination of the drainage spout. A receptacle in which to empty the bag is provided for each patient.
- Never irrigate the catheter routinely. If the patient is prone to obstruction from clots or large amounts of sediment, use a three-way system with continuous irrigation.
- Never disconnect the tubing to obtain urine samples, to irrigate the catheter, or to ambulate or transport the patient.
- Never leave the catheter in place longer than is necessary.
- Avoid routine catheter changes. The catheter is changed only to correct problems such as leakage, blockage, or encrustations.
- Avoid unnecessary handling or manipulation of the catheter by the patient or staff.
- Carry out hand hygiene before and after handling the catheter, tubing, or drainage bag.
- Wash the perineal area with soap and water at least twice a day; avoid a to-and-fro motion of the catheter. Dry the area well, but avoid applying powder because it may irritate the perineum.
- Monitor the patient's voiding when the catheter is removed. The patient must void within 8 hours; if unable to void, the patient may require catheterization with a straight catheter.
- Obtain a urine specimen for culture at the first sign of infection.

Vigorous cleansing of the meatus while the catheter is in place is discouraged because the cleansing action can move the catheter back and forth, increasing the risk of infection. To remove obvious encrustations from the external catheter surface, the area is washed gently with soap during the daily bath. The catheter is anchored as securely as possible to prevent it from moving in the urethra. Encrustations arising from urinary salts may serve as a nucleus for stone formation; however, using silicone catheters results in significantly less crust formation.

A liberal fluid intake, within the limits of the patient's cardiac and renal reserve, and an increased urine output must be ensured to flush the catheter and to dilute urinary substances that might form encrustations (Senese, et al., 2006).

Urine cultures are obtained as prescribed or indicated when monitoring the patient for infection; many catheters have an aspiration (puncture) port from which a specimen can be obtained.

Bacteriuria is considered inevitable in patients with indwelling catheters; therefore, controversy remains about the usefulness of taking cultures and treating asymptomatic bacteriuria, because overtreatment may lead to resistant strains of bacteria. Continual observation for fever, chills, and other signs and symptoms of systemic infection is necessary. Infections are treated aggressively.

Minimizing Trauma

Trauma to the urethra can be minimized by:

- Using an appropriate-sized catheter
- Lubricating the catheter adequately with a water-soluble lubricant during insertion
- Inserting the catheter far enough into the bladder to prevent trauma to the urethral tissues when the retention balloon of the catheter is inflated

Manipulation of the catheter is the most common cause of trauma to the bladder mucosa in the catheterized

patient. Infection can occur when urine invades the damaged mucosa.

The catheter is secured properly to prevent it from moving, causing traction on the urethra, or being unintentionally removed, and care is taken to ensure that the catheter position permits leg movement. In male patients, the drainage tube (not the catheter) is taped laterally to the thigh to prevent pressure on the urethra at the penoscrotal junction, which can eventually lead to formation of an urethrocutaneous fistula. In female patients, the drainage tubing attached to the catheter is taped to the thigh to prevent tension and traction on the bladder.

Special care should be taken to ensure that any patient who is confused does not remove the catheter with the retention balloon still inflated, because this could cause bleeding and considerable injury to the urethra.

Retraining the Bladder

When an indwelling urinary catheter is in place, the detrusor muscle does not actively contract the bladder wall to stimulate emptying because urine is continuously draining from the bladder. As a result, the detrusor may not immediately respond to bladder filling when the catheter is removed, resulting in either urine retention or urinary incontinence. This condition, known as postcatheterization detrusor instability, can be managed with bladder retraining (Chart 45-11).

Immediately after the indwelling catheter is removed, the patient is placed on a timed voiding schedule, usually every 2 to 3 hours. At the given time interval, the patient is instructed to void. The bladder is then scanned using a portable ultrasonic bladder scanner, and if the bladder has not emptied completely, straight catheterization may be performed (Altschuler & Diaz, 2006). After a few days, as the nerve endings in the bladder wall become resensitized to the bladder filling and emptying, bladder function usually

Chart 45-11 • Bladder Retraining After Indwelling Catheterization

- Instruct the patient to drink a measured amount of fluid from 8 AM to 10 PM to avoid bladder overdilatation. Offer no fluids (except sips) after 10 PM.
- At specific times, ask the patient to void by applying pressure over the bladder, tapping the abdomen, or running water to trigger the bladder.
- Immediately after the voiding attempt, catheterize the patient to determine the amount of residual urine.
- Measure the volumes of urine voided and obtained by catheterization.
- Palpate the bladder at repeated intervals to assess for distention.
- Instruct the patient who has no voiding sensation to be alert for any signs that indicate a full bladder, such as perspiration, cold hands or feet, or feelings of anxiety.
- Lengthen the intervals between catheterizations as the volume of residual urine decreases. Catheterization is usually discontinued when the volume of residual urine is less than 100 mL.

returns to normal. If the person has had an indwelling catheter in place for an extended period, bladder retraining will take longer; in some cases, function may never return to normal and long-term intermittent catheterization may become necessary.

Assisting With Intermittent Self-Catheterization

Intermittent self-catheterization provides periodic drainage of urine from the bladder. By promoting drainage and eliminating excessive residual urine, intermittent catheterization protects the kidneys, reduces the incidence of UTIs, and improves continence. It is the treatment of choice in some patients with spinal cord injury and other neurologic disorders, such as multiple sclerosis, when the ability to empty the bladder is impaired. Self-catheterization promotes independence, results in few complications, and enhances self-esteem and quality of life.

When teaching the patient how to perform self-catheterization, the nurse must use aseptic technique to minimize the risk of cross-contamination. However, the patient may use a “clean” (nonsterile) technique at home, where the risk of cross-contamination is reduced. Either antibacterial liquid soap or povidone-iodine (Betadine) solution is recommended for cleaning urinary catheters at home. The catheter is thoroughly rinsed with tap water after soaking in the cleaning solution. It must dry before reuse. It should be kept in its own container, such as a plastic food-storage bag.

In teaching the patient, the nurse emphasizes the importance of frequent catheterization and emptying the bladder at the prescribed time. The average daytime clean intermittent catheterization schedule is every 4 to 6 hours and just before bedtime. If the patient is awakened at night with an urge to void, catheterization may be performed after an attempt is made to void normally.

The female patient assumes a Fowler’s position and uses a mirror to help locate the urinary meatus. She lubricates the catheter and inserts it 7.5 cm (3 inches) into the ure-

thra, in a downward and backward direction. The male patient assumes a Fowler’s or sitting position, lubricates the catheter, and retracts the foreskin of the penis with one hand while grasping the penis and holding it at a right angle to the body. (This maneuver straightens the urethra and makes it easier to insert the catheter.) He inserts the catheter 15 to 25 cm (6 to 10 inches) until urine begins to flow. After removal, the catheter is cleaned, rinsed, dried, and placed in a plastic bag or case. Patients who follow an intermittent catheterization routine should consult a primary health care provider at regular intervals to assess urinary function and to detect complications. If the patient cannot perform intermittent self-catheterization, a family member or caregiver may be taught to carry out the procedure at regular intervals during the day.

An alternative to self-catheterization is creation of the Mitrofanoff umbilical appendicovesicostomy, which provides easy access to the bladder, but requires an extensive surgical procedure. In this procedure, the bladder neck is closed and the appendix is used to create access to the bladder from the skin surface through a submucosal tunnel created with the appendix. One end of the appendix is brought to the skin surface and used as a stoma and the other end is tunneled into the bladder. The appendix serves as an artificial urinary sphincter when an alternative is necessary to empty the bladder. A surgically prepared continent urine reservoir with a sphincter mechanism is required in cases of bladder cancer and severe **interstitial cystitis** (inflammation of the bladder wall). Various types of urologic stomas may be used when a radical **cystectomy** (surgical removal of the bladder) is necessary.

UROLITHIASIS AND NEPHROLITHIASIS

Urolithiasis and nephrolithiasis refer to stones (calculi) in the urinary tract and kidney, respectively. Urinary stones account for more than 320,000 hospital admissions each year. The occurrence of urinary stones occurs predominantly in the third to fifth decades of life and affects men more than women. About half of patients with a single renal stone have another episode within 5 years (Colella, Kochis, Galli, et al., 2005).

Pathophysiology

Stones are formed in the urinary tract when urinary concentrations of substances such as calcium oxalate, calcium phosphate, and uric acid increase. Referred to as supersaturation, this is dependent on the amount of the substance, ionic strength, and pH of the urine. Stones may be found anywhere from the kidney to the bladder and may vary in size from minute granular deposits, called sand or gravel, to bladder stones as large as an orange. The different sites of calculi formation in the urinary tract are shown in Figure 45-5.

Stone formation is not clearly understood, and there are a number of theories about their causes. One theory is that there is a deficiency of substances that normally prevent crystallization in the urine, such as citrate, magnesium, nephrocalcin, and uropontin (Porth & Matfin, 2009). Another theory relates to fluid volume status of the patient

Figure 45-5 Examples of potential sites of calculi formation (urolithiasis) in the urinary tract.

(stones tend to occur more often in dehydrated patients). Certain factors favor the formation of stones, including infection, urinary stasis, and periods of immobility, all of which slow renal drainage and alter calcium metabolism. In addition, increased calcium concentrations in the blood and urine promote precipitation of calcium and formation of stones (about 75% of all renal stones are calcium based). Causes of hypercalcemia (high serum calcium) and hypercalciuria (high urine calcium) may include the following:

- Hyperparathyroidism
- Renal tubular acidosis
- Cancers
- Granulomatous diseases (eg, sarcoidosis, tuberculosis), which may cause increased vitamin D production by the granulomatous tissue
- Excessive intake of vitamin D
- Excessive intake of milk and alkali
- Myeloproliferative diseases (leukemia, polycythemia vera, multiple myeloma), which produce an unusual proliferation of blood cells from the bone marrow

For patients with stones containing uric acid, struvite, or cystine, a thorough physical examination and metabolic workup are indicated because of associated disturbances contributing to the stone formation. Uric acid stones (5% to 10% of all stones) may be seen in patients with gout or myeloproliferative disorders. Struvite stones account for 15% of urinary calculi and form in persistently alkaline, ammonia-rich urine caused by the presence of urease-splitting bacteria such as *Proteus*, *Pseudomonas*, *Klebsiella*, *Staphylococcus*, or *Mycoplasma* species. Predisposing factors for struvite stones include neurogenic bladder, foreign bodies, and recurrent UTIs. Cystine stones (1% to 2% of all stones) occur exclusively in patients with a rare inherited defect in renal absorption of cystine (an amino acid) (Porth & Matfin, 2009).

Several conditions as well as certain metabolic risk factors predispose patients to stone formation. These include

anatomic derangements such as polycystic kidney disease, horseshoe kidneys, chronic strictures, and medullary sponge disease. Urinary stone formation can occur in patients with inflammatory bowel disease and in those with an ileostomy or bowel resection because these patients absorb more oxalate. Medications known to cause stones in some patients include antacids, acetazolamide (Diamox), vitamin D, laxatives, and high doses of aspirin (Karch, 2008). However, in many patients, no cause may be found.

Clinical Manifestations

Signs and symptoms of stones in the urinary system depend on the presence of obstruction, infection, and edema. When stones block the flow of urine, obstruction develops, producing an increase in hydrostatic pressure and distending the renal pelvis and proximal ureter. Infection (pyelonephritis and UTI with chills, fever, and frequency) can be a contributing factor with struvite stones (Porth & Matfin, 2009). Some stones cause few, if any, symptoms while slowly destroying the functional units (nephrons) of the kidney; others cause excruciating pain and discomfort.

Stones in the renal pelvis may be associated with an intense, deep ache in the costovertebral region. Hematuria is often present; pyuria may also be noted. Pain originating in the renal area radiates anteriorly and downward toward the bladder in the female and toward the testis in the male. If the pain suddenly becomes acute, with tenderness over the costovertebral area, and nausea and vomiting appear, the patient is having an episode of renal colic. Diarrhea and abdominal discomfort may occur. These GI symptoms are due to renointestinal reflexes and the anatomic proximity of the kidneys to the stomach, pancreas, and large intestine.

Stones lodged in the ureter (ureteral obstruction) cause acute, excruciating, colicky, wavelike pain, radiating down the thigh and to the genitalia. Often, the patient has a desire to void, but little urine is passed, and it usually contains blood because of the abrasive action of the stone. This group of symptoms is called ureteral colic. Colic is mediated by prostaglandin E, a substance that increases ureteral contractility and renal blood flow and that leads to increased intraureteral pressure and pain. In general, the patient spontaneously passes stones 0.5 to 1 cm in diameter. Stones larger than 1 cm in diameter usually must be removed or fragmented (broken up by lithotripsy) so that they can be removed or passed spontaneously.

Stones lodged in the bladder usually produce symptoms of irritation and may be associated with UTI and hematuria. If the stone obstructs the bladder neck, urinary retention occurs. If infection is associated with a stone, the condition is far more serious, with urosepsis threatening the patient's life.

Assessment and Diagnostic Findings

The diagnosis is confirmed by x-rays of the kidneys, ureters, and bladder (KUB) or by ultrasonography, IV urography, or retrograde pyelography. Blood chemistries and a 24-hour urine test for measurement of calcium, uric acid, creatinine, sodium, pH, and total volume are part of the diagnostic workup. Dietary and medication histories and family history of renal stones are obtained to identify factors predisposing the patient to the formation of stones.

When stones are recovered (stones may be freely passed by the patient or removed through special procedures), chemical analysis is carried out to determine their composition. Stone analysis can provide a clear indication of the underlying disorder. For example, calcium oxalate or calcium phosphate stones usually indicate disorders of oxalate or calcium metabolism, whereas urate stones suggest a disturbance in uric acid metabolism (Porth & Matfin, 2009).

Medical Management

The goals of management are to eradicate the stone, determine the stone type, prevent nephron destruction, control infection, and relieve any obstruction that may be present. The immediate objective of treatment of renal or ureteral colic is to relieve the pain until its cause can be eliminated. Opioid analgesic agents are administered to prevent shock and syncope that may result from the excruciating pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in treating renal stone pain because they provide specific pain relief. They also inhibit the synthesis of prostaglandin E, reducing swelling and facilitating passage of the stone. Generally once the stone has passed, the pain is relieved. Hot baths or moist heat to the flank areas may also be helpful. Unless the patient is vomiting or has heart failure or any other condition requiring fluid restriction, fluids are encouraged. This increases the hydrostatic pressure behind the stone, assisting it in its downward passage. A high, around-the-clock fluid intake reduces the concentration of urinary crystalloids, dilutes the urine, and ensures a high urine output.

Nutritional Therapy

Nutritional therapy plays an important role in preventing renal stones (Dudek, 2006) (Chart 45-12). Fluid intake is the mainstay of most medical therapy for renal stones.

CHART
45-12

PATIENT EDUCATION Preventing Kidney Stones

- Avoid protein intake; usually protein is restricted to 60 g/day to decrease urinary excretion of calcium and uric acid.
- A sodium intake of 3 to 4 g/day is recommended. Table salt and high-sodium foods should be reduced, because sodium competes with calcium for reabsorption in the kidneys.
- Low-calcium diets are not generally recommended, except for true absorptive hypercalciuria. Evidence shows that limiting calcium, especially in women, can lead to osteoporosis and does not prevent renal stones.
- Avoid intake of oxalate-containing foods (eg, spinach, strawberries, rhubarb, tea, peanuts, wheat bran).
- During the day, drink fluids (ideally water) every 1 to 2 hours.
- Drink two glasses of water at bedtime and an additional glass at each nighttime awakening to prevent urine from becoming too concentrated during the night.
- Avoid activities leading to sudden increases in environmental temperatures that may cause excessive sweating and dehydration.
- Contact your primary health care provider at the first sign of a urinary tract infection.

Unless fluids are contraindicated, patients with renal stones should drink eight to ten 8-ounce glasses of water daily or have IV fluids prescribed to keep the urine dilute. A urine output exceeding 2 L/day is advisable.

Calcium Stones

Historically, patients with calcium-based renal stones were advised to restrict calcium in their diet. However, recent evidence has questioned the advisability of this practice, except for patients with type II absorptive hypercalciuria (half of all patients with calcium stones), in whom stones are clearly the result of excess dietary calcium. Liberal fluid intake is encouraged along with dietary restriction of protein and sodium; however, dietary changes cannot be recommended with confidence because of insufficient evidence. It was once thought that a high-protein diet was associated with increased urinary excretion of calcium and uric acid, thereby causing a supersaturation of these substances in the urine. Similarly, a high sodium intake was thought to increase the amount of calcium in the urine. These beliefs have not been supported by research (Flagg, 2007). Medications such as ammonium chloride may be used, and if increased parathormone production (resulting in increased serum calcium levels in blood and urine) is a factor in the formation of stones, therapy with thiazide diuretics may be beneficial in reducing the calcium loss in the urine and lowering the elevated parathormone levels (Porth & Matfin, 2009).

Uric Acid Stones

For uric acid stones, the patient is placed on a low-purine diet to reduce the excretion of uric acid in the urine. Foods high in purine (shellfish, anchovies, asparagus, mushrooms, and organ meats) are avoided, and other proteins may be limited. Allopurinol (Zyloprim) may be prescribed to reduce serum uric acid levels and urinary uric acid excretion.

Cystine Stones

A low-protein diet is prescribed, the urine is alkalinized, and fluid intake is increased.

Oxalate Stones

A dilute urine is maintained and the intake of oxalate is limited. Many foods contain oxalate; however, only certain foods increase the urinary excretion of oxalate. These include spinach, strawberries, rhubarb, chocolate, tea, peanuts, and wheat bran.

Interventional Procedures

If the stone does not pass spontaneously or if complications occur, common interventions include endoscopic or other procedures. For example, ureteroscopy, extracorporeal shock wave lithotripsy (ESWL), or endourologic (percutaneous) stone removal may be necessary.

Ureteroscopy (Fig. 45-6A) involves first visualizing the stone and then destroying it. Access to the stone is accomplished by inserting a ureteroscope into the ureter and then inserting a laser, electrohydraulic lithotripter, or ultrasound device through the ureteroscope to fragment and remove the stones. A stent may be inserted and left in place for 48 hours or more after the procedure to keep the ureter

Figure 45-6 Methods of treating renal stones. **A**, During a cystoscopy, which is used for removing small stones located in the ureter close to the bladder, a ureteroscope is inserted into the ureter to visualize the stone. The stone is then fragmented or captured and removed. **B**, Extracorporeal shock water lithotripsy (ESWL) is used for most symptomatic, nonpassable upper urinary stones. Electromagnetically generated shock waves are focused over the area of the renal stone. The high-energy dry shock waves pass through the skin and fragment the stone. **C**, Percutaneous nephrolithotomy is used to treat larger stones. A percutaneous tract is formed and a nephroscope is inserted through it. Then the stone is extracted or pulverized.

patient. Hospital stays are generally brief, and some patients can be treated as outpatients.

ESWL is a noninvasive procedure used to break up stones in the calyx of the kidney (Fig. 45-6B). After the stones are fragmented to the size of grains of sand, the remnants of the stones are spontaneously voided. In ESWL, a high-energy amplitude of pressure, or shock wave, is generated by the abrupt release of energy and transmitted through water and soft tissues. When the shock wave encounters a substance of different intensity (a renal stone), a compression wave causes the surface of the stone to fragment. Repeated shock waves focused on the stone eventually reduce it to many small pieces that are excreted in the urine.

Discomfort from the multiple shocks may occur, although the shock waves usually do not cause damage to other tissue. The patient is observed for obstruction and infection resulting from blockage of the urinary tract by stone fragments. All urine is strained after the procedure; voided gravel or sand is sent to the laboratory for chemical analysis. Several treatments may be necessary to ensure disintegration of stones. Although lithotripsy is a costly treatment, its cost is offset by a decrease in the length of hospital stay and avoidance of a surgical procedure.

Endourologic methods of stone removal (Fig. 45-6C) may be used to extract renal calculi that cannot be removed by other procedures. A percutaneous nephrostomy or a percutaneous nephrolithotomy (which are similar procedures) may be performed. A nephroscope is introduced through a percutaneous route into the renal parenchyma. Depending on its size, the stone may be extracted with forceps or by a stone retrieval basket. If the stone is too large to initially be removed, an ultrasound probe inserted through a nephrostomy tube is used to pulverize the stone. Small stone fragments and stone dust are then removed.

Electrohydraulic lithotripsy is a similar method in which an electrical discharge is used to create a hydraulic shock wave to break up the stone. A probe is passed through the cystoscope, and the tip of the lithotripter is placed near the stone. The strength of the discharge and pulse frequency can be varied. This procedure is performed under topical anesthesia. After the stone is extracted, the percutaneous nephrostomy tube is left in place for a time to ensure that the ureter is not obstructed by edema or blood clots. The most common complications are hemorrhage, infection, and urinary extravasation. After the tube is removed, the nephrostomy tract usually closes spontaneously.

Chemolysis, stone dissolution using infusions of chemical solutions (eg, alkylating agents, acidifying agents) for the purpose of dissolving the stone, is an alternative treatment sometimes used in patients who are at risk for complications with other types of therapy, who refuse to undergo other methods, or who have stones (struvite) that dissolve easily. A percutaneous nephrostomy is performed, and the warm chemical solution is allowed to flow continuously onto the stone. The solution exits the renal collecting system by means of the ureter or the nephrostomy tube. The pressure inside the renal pelvis is monitored during the procedure.

Several of these treatment modalities may be used in combination to ensure removal of the stones.

Surgical Management

Surgical removal was the major mode of therapy before the advent of lithotripsy. However, today, surgery is performed in only 1% to 2% of patients. Surgical intervention is indicated if the stone does not respond to other forms of treatment. It may also be performed to correct anatomic abnormalities within the kidney to improve urinary drainage. If the stone is in the kidney, the surgery performed may be a nephrolithotomy (incision into the kidney with removal of the stone) or a nephrectomy, if the kidney is nonfunctional secondary to infection or hydronephrosis. Stones in the kidney pelvis are removed by a pyelolithotomy, those in the ureter by ureterolithotomy, and those in the bladder by cystotomy. If the stone is in the bladder, an instrument may be inserted through the urethra into the bladder, and the stone crushed. Such a procedure is called a cystolitholapaxy. Nursing management following kidney surgery is discussed in Chapter 44.

NURSING PROCESS

THE PATIENT WITH KIDNEY STONES

Assessment

The patient with suspected renal stones is assessed for pain and discomfort as well as associated symptoms, such as nausea, vomiting, diarrhea, and abdominal distention.

The severity and location of pain are determined, along with any radiation of the pain. Nursing assessment also includes observing for signs and symptoms of UTI (chills, fever, frequency, and hesitancy) and obstruction (frequent urination of small amounts, oliguria, or anuria). The urine is inspected for blood and is strained for stones or gravel.

The history focuses on factors that predispose the patient to urinary tract stones or that may have precipitated the current episode of renal or ureteral colic. The patient's knowledge about renal stones and measures to prevent their occurrence or recurrence is also assessed.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the nursing diagnoses in the patient with renal stones may include the following:

- Acute pain related to inflammation, obstruction, and abrasion of the urinary tract
- Deficient knowledge regarding prevention of recurrence of renal stones

Collaborative Problems/Potential Complications

Based on assessment data, potential complications that may develop include the following:

- Infection and urosepsis (from UTI and pyelonephritis)
- Obstruction of the urinary tract by a stone or edema with subsequent acute renal failure

Planning and Goals

The major goals for the patient may include relief of pain and discomfort, prevention of recurrence of renal stones, and absence of complications.

Nursing Interventions

Relieving Pain

Severe acute pain is often the presenting symptom of a patient with renal and urinary calculi and requires immediate attention. Opioid analgesic agents (IV or intramuscular) may be prescribed and administered to provide rapid relief along with an IV NSAID. The patient is encouraged and assisted to assume a position of comfort. If activity brings pain relief, the patient is assisted to ambulate. The pain level is monitored closely, and an increase in severity is reported promptly to the physician so that relief can be provided and additional treatment initiated.

Monitoring and Managing Potential Complications

Increased fluid intake is encouraged to prevent dehydration and increase hydrostatic pressure within the urinary tract to promote passage of the stone. If the patient cannot take adequate fluids orally, IV fluids are prescribed. The total urine output and patterns of voiding are monitored. Ambulation is encouraged as a means of moving the stone through the urinary tract.

All urine is strained through gauze because uric acid stones may crumble. Any blood clots passed in the urine should be crushed and the sides of the urinal and bedpan inspected for clinging stones. Because renal stones increase the risk of infection, sepsis, and obstruction of the urinary tract, the patient is instructed to report decreased urine volume, bloody or cloudy urine, fever, and pain.

Patients with calculi require frequent nursing observation to detect the spontaneous passage of a stone. The patient is instructed to immediately report any sudden increases in pain intensity because of the possibility of a stone fragment obstructing a ureter. Vital signs, including temperature, are monitored closely to detect early signs of infection. UTIs may be associated with renal stones due to an obstruction from the stone or from the stone itself. All infections should be treated with the appropriate antibiotic agent before efforts are made to dissolve the stone.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Because the risk of recurring renal stones is high, the nurse provides education about the causes of kidney stones and recommendations to prevent their recurrence (see Chart 45-12). The patient is encouraged to follow a regimen to avoid further stone formation, including maintaining a high fluid intake because stones form more readily in concentrated urine. A patient who has shown a tendency to form stones should drink enough fluid to excrete greater than 2000 mL (preferably 3000 to 4000 mL) of urine every 24 hours.

Urine cultures may be performed every 1 to 2 months the first year and periodically thereafter. Recurrent UTI is treated vigorously. Because prolonged immobilization slows renal drainage and alters calcium metabolism, increased mobility is encouraged whenever possible. In addition, excessive ingestion of vitamins (especially vitamin D) and minerals is discouraged.

If lithotripsy, percutaneous stone removal, ureteroscopy, or other surgical procedures for stone removal have been performed, the nurse instructs the patient about the signs and symptoms of complications that need to be reported to the physician. The importance of follow-up to assess kidney

function and to ensure the eradication or removal of all kidney stones is emphasized to the patient and family.

If ESWL has been performed, the nurse must provide instructions for home care and necessary follow-up. The patient is encouraged to increase fluid intake to assist in the passage of stone fragments, which may occur for 6 weeks to several months after the procedure. The patient and family are instructed about signs and symptoms of complications. It is also important to inform the patient to expect hematuria (it is anticipated in all patients), but it should disappear within 4 to 5 days. If the patient has a stent in the ureter, hematuria may be expected until the stent is removed. The patient is instructed to check his or her temperature daily and notify the physician if the temperature is greater than 38°C (about 101°F) or the pain is unrelieved by the prescribed medication. The patient is also informed that a bruise may be observed on the treated side of the back.

CONTINUING CARE. Close monitoring of the patient in follow-up care ensures that treatment has been effective and that no complications have developed. The nurse has the opportunity to assess the patient's understanding of ESWL and possible complications. Additionally, the nurse has the opportunity to assess the patient's understanding of factors that increase the risk of recurrence of renal calculi and strategies to reduce those risks.

It is necessary to assess the patient's ability to monitor urinary pH and interpret the results during follow-up visits. Because of the high risk of recurrence, the patient with renal stones needs to understand the signs and symptoms of stone formation, obstruction, and infection and the importance of reporting these signs promptly. If medications are prescribed for the prevention of stone formation, the nurse explains their actions, importance, and side effects to the patient.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Reports relief of pain
2. States increased knowledge of health-seeking behaviors to prevent recurrence
 - a. Consumes increased fluid intake (at least eight 8-ounce glasses of fluid per day)
 - b. Participates in appropriate activity
 - c. Consumes diet prescribed to reduce dietary factors predisposing to stone formation
 - d. Recognizes symptoms (fever, chills, flank pain, hematuria) to be reported to health care provider
 - e. Monitors urinary pH as directed
 - f. Takes prescribed medication as directed to reduce stone formation
3. Experiences no complications
 - a. Reports no signs or symptoms of infection or urosepsis
 - b. Voids 200 to 400 mL per voiding of clear urine without evidence of bleeding
 - c. Experiences absence of urgency, frequency, and hesitancy
 - d. Maintains normal body temperature

GENITOURINARY TRAUMA

Various types of injuries of the flank, back, or upper abdomen may result in trauma to the ureters, bladder, or urethra. Approximately 10% of all injuries seen in the emergency department involve the genitourinary system (Tanagho & McAninch, 2007). (Renal trauma is discussed in Chapter 44.)

Specific Injuries

Ureteral Trauma

Penetrating trauma and unintentional injury during surgery are the major causes of trauma to the ureters. Gunshot wounds account for 95% of ureteral injuries, which may range from contusions to complete transection. Unintentional injury to the ureter may occur during gynecologic or urologic surgery. There are no specific signs or symptoms of ureteral injury; many traumatic injuries are discovered during exploratory surgery. If the ureteral trauma is not detected and urine leakage continues, fistulas can develop.

IV urography detects 90% of ureteral injuries and can be performed on the operating table in patients undergoing emergency surgery. Surgical repair with placement of stents (to divert urine away from an anastomosis) is usually necessary.

Bladder Trauma

Injury to the bladder may occur with pelvic fractures and multiple trauma or from a blow to the lower abdomen when the bladder is full. Blunt trauma may result in contusion evident as an ecchymosis—a large bruise resulting from escape of blood into the tissues and involving a segment of the bladder wall—or in rupture of the bladder extraperitoneally, intraperitoneally, or both. Complications from these injuries include hemorrhage, shock, sepsis, and extravasation of blood into the tissues, which must be treated promptly.

Urethral Trauma

Urethral injuries usually occur with blunt trauma to the lower abdomen or pelvic region. Many patients also have associated pelvic fractures. The classic triad of symptoms comprises blood at the urinary meatus, inability to void, and a distended bladder.

Medical Management

The goals of management in patients with genitourinary trauma are to control hemorrhage, pain, and infection and to maintain urinary drainage. Genitourinary trauma is frequently associated with renal trauma (see Chapter 44). Hematocrit and hemoglobin levels are monitored closely; decreasing values can indicate hemorrhage within the genitourinary system. The patient is also monitored for oliguria, signs of hemorrhagic shock, and signs and symptoms of acute peritonitis.

Surgical Management

In urethral trauma, unstable patients who need monitoring of urine output may need a suprapubic catheter inserted. The patient is catheterized after urethrography has been performed to minimize the risk of urethral disruption and

extensive, long-term complications, such as stricture, incontinence, and impotence. Surgical repair may be performed immediately or at a later time. Delayed surgical repair tends to be the favored procedure because it is associated with fewer long-term complications, such as impotence, strictures, and incontinence. After surgery, an indwelling urinary catheter may remain in place for up to 1 month.

Nursing Management

The patient with genitourinary trauma should be assessed frequently during the first few days after injury to detect flank and abdominal pain, muscle spasm, and swelling over the flank.

During this time, patients can be instructed about care of the incision and the importance of an adequate fluid intake. In addition, instructions about changes that should be reported to the physician, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function, are provided. The patient with a ruptured bladder may have gross bleeding for several days after repair. Guidelines for increasing activity gradually, lifting, and driving are also provided in accordance with the physician's prescription.

Follow-up nursing care includes monitoring the blood pressure to detect hypertension and advising the patient to restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding.

URINARY TRACT CANCERS

In 2009, the American Cancer Society (ACS) estimated that there were more than 131,000 new cases in the urinary system. Urinary tract cancers include those of the urinary bladder; kidney and renal pelvis; ureters; and other urinary structures, such as the prostate. (Renal cancer is discussed in Chapter 44, and prostate cancer is discussed in Chapter 49.) Malignant tumors include transitional cell carcinomas (90%), squamous cell carcinomas (5% to 8%), adenocarcinomas (1% to 2%), sarcomas (less than 1%), and other types of cancers.

Cancer of the Bladder

Cancer of the urinary bladder is more common in people older than 55 years of age. It affects more men than women (4:1) and is more common in Caucasians than in African Americans. Bladder cancer is the fourth leading cause of cancer in American men, accounting for more than 14,000 deaths in the United States annually, and has a high incidence worldwide (ACS, 2009).

Bladder cancer, combined with prostatic cancer, is the most common urologic malignancy, accounting for 90% of all tumors seen. Cancers arising from the prostate, colon, and rectum in males and from the lower gynecologic tract in females may metastasize to the bladder.

Tobacco use continues to be a leading risk factor for all urinary tract cancers. People who smoke develop bladder cancer twice as often as those who do not smoke (Chart 45-13) (ACS, 2009).

CHART
45-13

Risk Factors for Bladder Cancer

- Cigarette smoking: risk proportional to pack-years of smoking
- Exposure to environmental carcinogens: dyes, rubber, leather, ink, or paint
- Recurrent or chronic bacterial infection of the urinary tract
- Bladder stones
- High urinary pH
- High cholesterol intake
- Pelvic radiation therapy
- Cancers arising from the prostate, colon, and rectum in males

Clinical Manifestations

Bladder tumors usually arise at the base of the bladder and involve the ureteral orifices and bladder neck. Visible, painless hematuria is the most common symptom of bladder cancer. Infection of the urinary tract is a common complication, producing frequency and urgency. However, any alteration in voiding or change in the urine may indicate cancer of the bladder. Pelvic or back pain may occur with metastasis.

Assessment and Diagnostic Findings

The diagnostic evaluation includes cystoscopy (the mainstay of diagnosis), excretory urography, CT, ultrasonography, and bimanual examination with the patient anesthetized. Biopsies of the tumor and adjacent mucosa are the definitive diagnostic procedures. Transitional cell carcinomas and carcinomas in situ shed recognizable cancer cells. Cytologic examination of fresh urine and saline bladder washings provide information about the prognosis and staging, especially for patients at high risk for recurrence of primary bladder tumors.

Although the mainstay diagnostic tools such as cytology and CT have a high detection rate, they are costly. Newer diagnostic tools such as bladder tumor antigens, nuclear matrix proteins, adhesion molecules, cytoskeletal proteins, and growth factors are being studied to support the early detection and diagnosis of bladder cancer (ACS, 2009).

Medical Management

Treatment of bladder cancer depends on the grade of the tumor (the degree of cellular differentiation), the stage of tumor growth (the degree of local invasion and the presence or absence of metastasis), and the multicentricity (having many centers) of the tumor. The patient's age and physical, mental, and emotional status are considered when determining treatment modalities.

Surgical Management

Transurethral resection or fulguration (cauterization) may be performed for simple papillomas (benign epithelial tumors). These procedures, described in more detail in Chapter 49, eradicate the tumors through surgical incision or electrical current with the use of instruments inserted through the urethra. After this bladder-sparing surgery, intravesical adminis-

tration of bacille Calmette-Guérin (BCG) is the treatment of choice. BCG is an attenuated live strain of *Mycobacterium bovis*, the causative agent in tuberculosis. The exact action of BCG is unknown, but it is thought to produce a local inflammatory as well as a systemic immunologic response (Sharma, Old & Allison, 2007).

Management of superficial bladder cancers presents a challenge because there are usually widespread abnormalities in the bladder mucosa. The entire lining of the urinary tract, or urothelium, is at risk because carcinomatous changes can occur in the mucosa of the bladder, renal pelvis, ureter, and urethra. About 25% to 40% of superficial tumors recur after transurethral resection or fulguration. Patients with benign papillomas should undergo cytology and cystoscopy periodically for the rest of their lives because aggressive malignancies may develop from these tumors.

A simple cystectomy or a radical cystectomy is performed for invasive or multifocal bladder cancer. Radical cystectomy in men involves removal of the bladder, prostate, and seminal vesicles and immediate adjacent perivesical tissues. In women, radical cystectomy involves removal of the bladder, lower ureter, uterus, fallopian tubes, ovaries, anterior vagina, and urethra. It may include removal of pelvic lymph nodes. Removal of the bladder requires a urinary diversion procedure, which is described later in this chapter.

Although radical cystectomy remains the standard of care for invasive bladder cancer in the United States, researchers are exploring trimodality therapy—transurethral resection of the bladder tumor, radiation, and chemotherapy—in an effort to spare patients the need for cystectomy. This approach to transitional cell bladder cancer mandates lifelong surveillance with periodic cystoscopy. Although most patients respond completely and their bladders remain free from invasive relapse, one fourth develop a relapse of noninvasive disease. This may be managed with transurethral resection of the bladder tumor and intravesical therapies but carries an additional risk that a late cystectomy may be required.

Pharmacologic Therapy

Chemotherapy with a combination of methotrexate (Rheumatrex), 5-fluorouracil (5-FU), vinblastine (Velban), doxorubicin (Adriamycin), and cisplatin (Platinol) has been effective in producing partial remission of transitional cell carcinoma of the bladder in some patients. IV chemotherapy may be accompanied by radiation therapy. Topical chemotherapy (intravesical chemotherapy or instillation of antineoplastic agents into the bladder, resulting in contact of the agent with the bladder wall) is considered when there is a high risk of recurrence, when cancer in situ is present, or when tumor resection has been incomplete. Topical chemotherapy delivers a high concentration of medication (thiotepa [Thioplex], doxorubicin, mitomycin [Mutamycin], and BCG [TheraCys]) to the tumor to promote tumor destruction. Bladder cancer may also be treated by direct infusion of the cytotoxic agent through the bladder's arterial blood supply to achieve a higher concentration of the chemotherapeutic agent with fewer systemic toxic effects.

BCG is now considered the most effective intravesical agent for recurrent bladder cancer, especially superficial transitional cell carcinoma, because it is an immunotherapeutic

agent that enhances the body's immune response to cancer. BCG has a 43% advantage in preventing tumor recurrence, a significantly better rate than the 16% to 21% advantage of intravesical chemotherapy. In addition, BCG is particularly effective in the treatment of carcinoma in situ, eradicating it in more than 80% of cases. In contrast to intravesical chemotherapy, BCG has also been shown to decrease the risk of tumor progression (Sharma, et al., 2007).

The optimal course of BCG appears to be a 6-week course of weekly instillations, followed by a 3-week course at 3 months for tumors that do not respond. In high-risk cancers, maintenance BCG administered in a 3-week course at 6, 12, 18, and 24 months may limit recurrence and prevent progression (Sharma, et al., 2007). However, the adverse effects associated with this prolonged therapy may limit its widespread applicability.

The patient is allowed to eat and drink before the instillation procedure. Once the bladder is full, the patient must retain the intravesical solution for 2 hours before voiding. At the end of the procedure, the patient is encouraged to void and to drink liberal amounts of fluid to flush the medication from the bladder.

Radiation Therapy

Radiation of the tumor may be performed preoperatively to reduce microextension of the neoplasm and viability of tumor cells, thus reducing the chances that the cancer may recur in the immediate area or spread through the circulatory or lymphatic systems. Radiation therapy is also used in combination with surgery or to control the disease in patients with inoperable tumors.

For more advanced bladder cancer or for patients with intractable hematuria (especially after radiation therapy), a large, water-filled balloon placed in the bladder produces tumor necrosis by reducing the blood supply of the bladder wall (hydrostatic therapy). The instillation of formalin, phenol, or silver nitrate relieves hematuria and strangury (slow and painful discharge of urine) in some patients.

Investigational Therapy

The use of photodynamic techniques in treating superficial bladder cancer is under investigation. This procedure involves systemic injection of a photosensitizing material (hematoporphyrin), which the cancer cell picks up. A laser-generated light then changes the hematoporphyrin in the cancer cell into a toxic agent. This process has received renewed interest with regulatory approval of several photosensitizing medications and light applicators as potential palliative and curative treatments (Huang, 2005).

URINARY DIVERSIONS

Urinary diversion procedures are performed to divert urine from the bladder to a new exit site, usually through a surgically created opening (stoma) in the skin. These procedures are primarily performed when a bladder tumor necessitates cystectomy. Urinary diversion has also been used in managing pelvic malignancy, birth defects, strictures, trauma to the ureters and urethra, neurogenic bladder, chronic infection causing severe ureteral and renal damage, and

intractable interstitial cystitis. It may also be used as a last resort in managing incontinence.

Controversy exists about the best method of establishing permanent diversion of the urinary tract. New techniques are frequently introduced in an effort to improve patient outcomes and quality of life. The age of the patient, condition of the bladder, body build, degree of obesity, degree of ureteral dilation, status of renal function, and the patient's learning ability and willingness to participate in postoperative care are all taken into consideration when determining the appropriate surgical procedure.

The extent to which the patient accepts urinary diversion depends to a large degree on the location or position of the stoma, whether the drainage device (pouch or bag) establishes a watertight seal to the skin, and the patient's ability to manage the pouch and drainage apparatus.

There are two types of urinary diversion. In a cutaneous urinary diversion, urine drains through an opening created in the abdominal wall and skin (Fig. 45-7). In a **continent urinary diversion**, a portion of the intestine is used to create a new reservoir for urine (Fig. 45-8).

Cutaneous Urinary Diversions

ILEAL CONDUIT

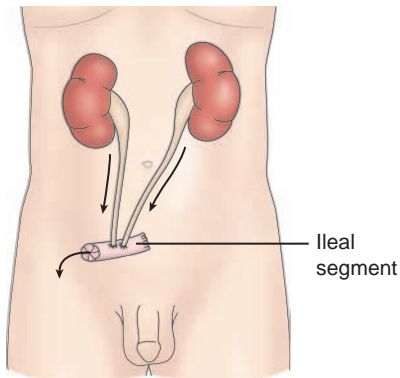

The **ileal conduit** (ileal loop) is the oldest and most common of the urinary diversion procedures in use because of the low number of complications and surgeons' familiarity with the procedure. In an ileal conduit, the urine is diverted by implanting the ureter into a 12-cm loop of ileum that is led out through the abdominal wall. This loop of ileum is a simple conduit (passageway) for urine from the ureters to the surface. A loop of the sigmoid colon may also be used. An ileostomy bag is used to collect the urine. The resected (cut) ends of the remaining intestine are anastomosed (connected) to provide an intact bowel (Diepenbrock, 2007).

Stents, usually made of thin, pliable tubing, are placed in the ureters to prevent occlusion secondary to postsurgical edema. The bilateral ureteral stents allow urine to drain from the kidney to the stoma and provide a method for accurate measurement of urine output. They may be left in place 10 to 21 days postoperatively. Jackson-Pratt tubes or other types of drains are inserted to prevent the accumulation of fluid in the space created by removal of the bladder.

After surgery, a skin barrier and a transparent, disposable urinary drainage bag are applied around the conduit and connected to drainage. A custom-cut appliance is used until the edema subsides and the stoma shrinks to normal size. The clear bag allows the stoma to be inspected and the patency of the stent and the urine output to be monitored. The ileal bag drains urine (not feces) continuously. The appliance (bag) usually remains in place as long as it is watertight; it is changed when necessary to prevent leakage of urine.

Complications

Complications that may follow placement of an ileal conduit include wound infection or wound dehiscence, urinary leakage, ureteral obstruction, hyperchloremic acidosis, small bowel obstruction, ileus, and gangrene of the stoma. Delayed

A Conventional ileal conduit.

The surgeon transplants the ureters to an isolated section of the terminal ileum (ileal conduit), bringing one end to the abdominal wall. The ureter may also be transplanted into the transverse sigmoid colon (colon conduit) or proximal jejunum (jejunal conduit).

B Cutaneous ureterostomy.

The surgeon brings the detached ureter through the abdominal wall and attaches it to an opening in the skin.

C Vesicostomy.

The surgeon sutures the bladder to the abdominal wall and creates an opening (stoma) through the abdominal and bladder walls for urinary drainage.

D Nephrostomy.

The surgeon inserts a catheter into the renal pelvis via an incision in the flank or by percutaneous catheter placement into the kidney.

Figure 45-7 Types of cutaneous diversions include (A) the conventional ileal conduit, (B) cutaneous ureterostomy, (C) vesicostomy, and (D) nephrostomy.

complications include ureteral obstruction, contraction or narrowing of the stoma (stenosis), renal deterioration due to chronic reflux, pyelonephritis, and renal calculi.

Nursing Management

In the immediate postoperative period, urine volumes are monitored hourly. Throughout the patient's hospitalization, the nurse monitors closely for complications, reports signs and symptoms of them promptly, and intervenes quickly to prevent their progression.

A urine output below 30 mL/h may indicate dehydration or an obstruction in the ileal conduit, with possible backflow or leakage from the ureteroileal anastomosis. After the physician's order is obtained, a catheter may be inserted through the urinary conduit to monitor the patient for possible stasis or residual urine from a constricted stoma. Urine may drain through the bilateral ureteral stents as well as around the stents. If the ureteral stents are not draining, the nurse may be instructed to carefully irrigate with 5 to 10 mL

sterile normal saline solution, being careful not to exert tension that could dislodge the stent. Hematuria may be noted in the first 48 hours after surgery but usually resolves spontaneously.

Providing Stoma and Skin Care

Because the patient requires specialized care, a consultation is initiated with a WOCN. The stoma is inspected frequently for color and viability. A healthy stoma is pink or red. A change from this normal color to purple, brown, or black suggests that the vascular supply may be compromised. If cyanosis and a compromised blood supply persist, surgical intervention may be necessary. The stoma is not sensitive to touch, but the skin around the stoma becomes sensitive if urine or the appliance irritates it. The skin is inspected for (1) signs of irritation and bleeding of the stoma mucosa, (2) encrustation and skin irritation around the stoma (from alkaline urine coming in contact with exposed skin), and (3) wound infections.

A Indiana pouch. The surgeon introduces the ureters into a segment of ileum and cecum. Urine is drained periodically by inserting a catheter into the stoma.

B Continent ileal urinary diversions (Kock pouch). The surgeon transplants the ureters to an isolated segment of small bowel, ascending colon, or ileocolonic segment and develops an effective continence mechanism or valve. Urine is drained by inserting a catheter into the stoma.

C In male patients, the Kock pouch can be modified by attaching one end of the pouch to the urethra, allowing more normal voiding. The female urethra is too short for this modification.

D Ureterosigmoidostomy. The surgeon introduces the ureters into the sigmoid colon, thereby allowing urine to flow through the colon and out of the rectum.

Figure 45-8 Types of continent urinary diversions include (A) the Indiana pouch; (B, C) the Kock pouch, also called a continent ileal diversion; and (D) ureterosigmoidostomy.

Testing Urine and Caring for the Ostomy

Moisture in bed linens or clothing or the odor of urine around the patient should alert the nurse to the possibility of leakage from the appliance, potential infection, or a problem in hygienic management. Because severe alkaline encrustation can accumulate rapidly around the stoma, the urine pH is kept below 6.5 by administration of ascorbic acid by mouth. Urine pH is determined by testing the urine draining from the stoma, not from the collecting appliance. A properly fitted appliance is essential to prevent exposure of the skin around the stoma to urine. If the urine is foul-smelling, the stoma is catheterized, if prescribed, to obtain a urine specimen for culture and sensitivity testing.

Encouraging Fluids and Relieving Anxiety

Because mucous membrane is used in forming the conduit, the patient may excrete a large amount of mucus mixed with urine. This causes anxiety in many patients. To help relieve this anxiety, the nurse reassures the patient that this

is a normal occurrence after an ileal conduit procedure. The nurse encourages adequate fluid intake to flush the ileal conduit and decrease the accumulation of mucus.

Selecting the Ostomy Appliance

Various urine collection appliances are available, and the nurse is instrumental (often with consultation with a WOCN) in selecting an appropriate one. The urinary appliance may consist of one or two pieces and may be disposable (usually used once and discarded) or reusable. The choice of appliance is determined by the location of the stoma and by the patient’s normal activity, manual dexterity, visual function, body build, economic resources, and preference.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Patient education begins in the hospital but continues into the home setting because patients are usually discharged

within days of surgery. The nurse teaches the patient how to assess and manage the urinary diversion as well as how to deal with body image changes. A WOCN is invaluable in consulting with the nurse on various aspects of care and patient education.

Changing the Appliance. The patient and family are taught to apply and change the appliance so that they are comfortable carrying out the procedure and can do so proficiently. Ideally, the appliance system is changed before the system leaks and at a time that is convenient for the patient. Many patients find that early morning is most convenient because the urine output is reduced. A variety of appliances are available; an average collecting appliance lasts 3 to 7 days before leakage occurs.

Regardless of the type of appliance used, a skin barrier is essential to protect the skin from irritation and excoriation. To maintain skin integrity, a skin barrier or leaking pouch is never patched with tape to prevent accumulation of urine under the skin barrier or faceplate. The patient is instructed to avoid moisturizing soaps when cleaning the area because they interfere with the adhesion of the pouch. Because the degree to which the stoma protrudes is not the same in all patients, there are various accessories and custom-made appliances to solve individual problems. Patient guidelines for applying reusable and disposable systems are presented in Chart 45-14.

Controlling Odor. The patient is instructed to avoid foods that give the urine a strong odor (eg, asparagus, cheese, eggs). Today, most appliances contain odor barriers, but a few drops of liquid deodorizer or diluted white vinegar may be introduced through the drain spout into the bottom of

the pouch with a syringe or eyedropper to reduce odors. Ascorbic acid by mouth helps acidify the urine and suppress urine odor. Patients should be cautioned not to put aspirin tablets in the pouch to control odor because they may ulcerate the stoma. Also, the patient is reminded that odor will develop if the pouch is worn longer than recommended and not cared for properly.

Managing the Ostomy Appliance. The patient is instructed to empty the pouch by means of a drain valve when it is one-third full because the weight of more urine will cause the pouch to separate from the skin. Some patients prefer wearing a leg bag attached with an adapter to the drainage apparatus. To promote uninterrupted sleep, a collecting bottle and tubing (one unit) are snapped onto an adapter that connects to the ileal appliance. A small amount of urine is left in the bag when the adapter is attached to prevent the bag from collapsing against itself. The tubing may be threaded down the pajama or pants leg to prevent kinking. The collecting bottle and tubing are rinsed daily with cool water and once a week with a 3:1 solution of water and white vinegar.

Cleaning and Deodorizing the Appliance. Usually, the reusable appliance is rinsed in warm water and soaked in a 3:1 solution of water and white vinegar or a commercial deodorizing solution for 30 minutes. It is rinsed with tepid water and air-dried away from direct sunlight. (Hot water and exposure to direct sunlight dry the pouch and increase the incidence of cracking.) After drying, the appliance may be powdered with cornstarch and stored. Two appliances are necessary—one to be worn while the other is air-drying.

CHART
45-14

PATIENT EDUCATION

Using Urinary Diversion Collection Appliances

Applying a Reusable Pouch System

1. Gather all necessary supplies.
2. Prepare new appliance according to the manufacturer's directions.
 - Apply double-faced adhesive disk that has been properly sized to fit the reusable pouch face-plate. Remove paper backing and set pouch aside, or apply thin layer of contact cement to one side of the reusable pouch faceplate. Set pouch aside.
3. Remove soiled pouch gently. Lay aside to clean later.
4. Clean peristomal skin (skin around stoma) with small amount of soap and water. Rinse thoroughly and dry. If a film of soap remains on the skin and the site does not dry, the appliance will not adhere adequately.
5. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine and keep the skin dry throughout the appliance change.
6. Inspect peristomal skin for irritation.
7. A skin protector wipe or barrier ring may be applied before centering the faceplate opening directly over the stoma.
8. Position appliance over stoma and press gently into place.
9. If desired, use a pouch cover or apply cornstarch under the pouch to prevent perspiration and skin irritation.
10. Clean soiled pouch and prepare for reuse.

Applying a Disposable Pouch System

1. Gather all necessary supplies.
2. Measure stoma and prepare an opening in the skin barrier about an $\frac{1}{8}$ -inch larger than the stoma and the same shape as the stoma.
3. Remove paper backing from skin barrier and set aside.
4. Gently remove old appliance and set aside.
5. Clean peristomal skin with warm water and dry thoroughly.
6. Inspect peristomal skin (skin around stoma) for irritation.
7. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine and keep the skin dry during the appliance change.
8. Center opening of skin barrier over stoma and apply with firm, gentle pressure to attain a water-tight seal.
9. If using a two-piece system, snap pouch onto the flanged wafer that adheres to skin.
10. Close drainage tap or spout at bottom of pouch.
11. A pouch cover can be used or cornstarch applied under pouch to prevent perspiration and skin irritation.
12. Apply hypoallergenic tape around the skin barrier in a picture-frame manner.
13. Dispose of soiled appliance.

Continuing Care

Follow-up care is essential to determine how the patient has adapted to the altered body image changes and lifestyle changes. Referral for home care is indicated to determine how well the patient and family are coping with the changes necessitated by altered urinary drainage. The home care nurse assesses the patient's physical status and emotional response to urinary diversion. Additionally, the nurse assesses the ability of the patient and family to manage the urinary diversion and appliance, reinforces previous teaching, and provides additional information (eg, community resources, sources of ostomy supplies, insurance coverage for supplies).

As the postoperative edema subsides, the home care nurse assists in determining the appropriate changes needed in the ostomy appliance. The size of the stoma is measured every 3 to 6 weeks for the first few months postoperatively. The correct appliance size is determined by measuring the widest part of the stoma with a ruler. The permanent appliance should be no more than 1.6 mm (1/8 inch) larger than the diameter of the stoma and the same shape as the stoma to prevent contact of the skin with drainage.

The nurse teaches the patient and family about resources (see the list of resources at end of this chapter). Local chapters of the ACS can provide medical equipment and supplies and other resources for the patient who has undergone ostomy surgery for cancer.

The home care nurse assesses the patient for potential long-term complications such as ureteral obstruction, stenosis, hernias, or deterioration of renal function. The nurse also reinforces previous teaching about these complications.

CUTANEOUS URETEROSTOMY

A cutaneous ureterostomy (see Fig. 45-7), in which the ureters are directed through the abdominal wall and attached to an opening in the skin, is used for selected patients with ureteral obstruction (ie, advanced pelvic cancer) because it requires less extensive surgery than other urinary diversion procedures. It is also an appropriate procedure for patients who have had previous abdominal irradiation.

A urinary appliance is fitted immediately after surgery. The management of the patient with a cutaneous ureterostomy is similar to the care of the patient with an ileal conduit, although the stomas are usually flush with the skin or retracted.

Continent Urinary Diversions

CONTINENT ILEAL URINARY RESERVOIR (INDIANA POUCH)

The most common continent urinary diversion is the Indiana pouch, created for the patient whose bladder is removed or no longer functions. The Indiana pouch uses a segment of the ileum and cecum to form the reservoir for urine (see Fig. 45-8A). The ureters are tunneled through the muscular bands of the intestinal pouch and anastomosed. The reser-

voir is made continent by narrowing the efferent portion of the ileum and sewing the terminal ileum to the subcutaneous tissue, forming a continent stoma flush with the skin. The pouch is sewn to the anterior abdominal wall around a cecostomy tube. Urine collects in the pouch until a catheter is inserted and the urine is drained (Diepenbrock, 2007).

The pouch must be drained at regular intervals by a catheter to prevent absorption of metabolic waste products from the urine, reflux of urine to the ureters, and UTI. Postoperative nursing care of the patient with a continent ileal urinary pouch is similar to nursing care of the patient with an ileal conduit. However, these patients usually have additional drainage tubes (cecostomy catheter from the pouch, stoma catheter exiting from the stoma, ureteral stents, and Penrose drain, as well as a urethral catheter). All drainage tubes must be carefully monitored for patency and amount and type of drainage. In the immediate postoperative period, the cecostomy tube is irrigated two or three times daily to remove mucus and prevent blockage.

Other variations of continent urinary reservoirs include the **Kock pouch** (U-shaped pouch constructed of ileum, with a nipplelike one-way valve; see Fig. 45-8B, C) and the **Charleston pouch** (uses the ileum and ascending colon as the pouch, with the appendix and colon junction serving as the one-way valve mechanism). With both of these methods, the pouch must be drained at regular intervals by a catheter.

URETEROSIGMOIDOSTOMY

Ureterosigmoidostomy, another form of continent urinary diversion, is an implantation of the ureters into the sigmoid colon (see Fig. 45-8D). It is usually performed in patients who have had extensive pelvic irradiation, previous small bowel resection, or coexisting small bowel disease.

After surgery, voiding occurs from the rectum (for life), and an adjustment in lifestyle will be necessary because of urinary frequency. Drainage has a consistency equivalent to watery diarrhea, and the patient has some degree of nocturia. Patients usually need to plan activities around the frequent need to urinate, which in turn may affect the patient's social life. However, patients have the advantage of urinary control without having to wear an external appliance.

Nursing Management

In addition to the usual preoperative regimen, the patient may be placed on a liquid diet for several days preoperatively to reduce residue in the colon. Antibiotic agents (neomycin, kanamycin) are administered to disinfect the bowel. Ureterosigmoidostomy requires a competent anal sphincter, adequate renal function, and active renal peristalsis. The degree of anal sphincter control may be determined by assessing the patient's ability to retain enemas.

The postoperative regimen initially includes placing a catheter in the rectum to drain the urine and prevent reflux of urine into the ureters and kidneys. The tube is taped to the buttocks, and special skin care is given around the anus to prevent excoriation. Irrigations of the rectal tube may be prescribed, but force is never used because of the danger of introducing bacteria into the newly implanted ureters.

Monitoring Fluid and Electrolytes

In ureterosigmoidostomy, larger areas of the bowel mucosa are exposed to urine and electrolyte reabsorption. As a result, electrolyte imbalance and acidosis may occur. Potassium and magnesium in the urine may cause diarrhea. Fluid and electrolyte balance is maintained in the immediate postoperative period by closely monitoring the serum electrolyte levels and administering appropriate IV fluids. Acidosis may be prevented by placing the patient on a low-chloride diet supplemented with sodium potassium citrate.

The patient should be instructed never to wait longer than 2 to 3 hours before emptying urine from the intestine. This keeps rectal pressure low and minimizes the absorption of urinary constituents from the colon. It is essential to teach the patient about the symptoms of UTI: fever, flank pain, urgency, and frequency.

Retraining the Anal Sphincter

After the rectal catheter is removed, the patient learns to control the anal sphincter through special sphincter exercises. At first, urination is frequent. With reassurance and encouragement and the passage of time, the patient gains greater control and learns to differentiate between the need to void and the need to defecate.

Promoting Dietary Measures

Specific dietary instructions include avoidance of gas-forming foods (flatus can cause stress incontinence and offensive odors). Other ways to avoid gas are to avoid chewing gum, smoking, and any other activity that involves swallowing air. Salt intake may be restricted to prevent hyperchloremic acidosis. Potassium intake is increased through foods and medication because potassium may be lost in acidosis.

Monitoring and Managing Potential Complications

Pyelonephritis (upper UTI) due to reflux of bacteria from the colon is fairly common. Long-term antibiotic therapy may be prescribed to prevent infection. A late complication is adenocarcinoma of the sigmoid colon, possibly from cellular changes due to exposure of the colonic mucosa to urine. Urinary carcinogens promote late malignant transformation of the colon after a ureterosigmoidostomy, warranting lifelong medical follow-up.

Other Urinary Diversion Procedures

Variations in urinary diversion surgical procedures are devised frequently in an effort to identify and perfect procedures that will improve patient outcomes and reduce the incidence of postoperative problems. These include cecal, patched cecal, and Mainz reservoirs. These techniques involve isolating a part of the large intestine to form a reservoir for urine and creating an abdominal stoma. Another surgical procedure, the Caley procedure, uses a portion of the ileum as a bladder substitute. In this procedure, the isolated ileum serves as the reservoir for urine; it is anastomosed directly to the portion of the remaining urethra after cystectomy. This procedure permits emptying of the bladder through the urethra. However, the Caley procedure ap-

plies only to men because the entire urethra is removed when a cystectomy is performed in women.

NURSING PROCESS

THE PATIENT UNDERGOING URINARY DIVERSION SURGERY

Preoperative Assessment

The following are key preoperative nursing assessment concerns:

- Cardiopulmonary function assessments are performed because patients undergoing cystectomy are often older people who may be at greater risk for cardiac and respiratory complications.
- A nutritional status assessment is important because of possible poor nutritional intake related to underlying health problems.
- Learning needs are assessed in consultation with a WOCN to evaluate the patient's and the family's understanding of the procedure as well as the changes in physical structure and function that result from the surgery. The patient's self-concept and self-esteem are assessed, in addition to methods for coping with stress and loss. The patient's mental status, manual dexterity and coordination, and preferred method of learning are noted because they affect postoperative self-care.

Preoperative Nursing Diagnoses

Based on the assessment data, the preoperative nursing diagnoses for the patient undergoing urinary diversion surgery may include the following:

- Anxiety related to anticipated losses associated with the surgical procedure
- Imbalanced nutrition, less than body requirements related to inadequate nutritional intake
- Deficient knowledge about the surgical procedure and postoperative care

Preoperative Planning and Goals

The major goals for the patient may include relief of anxiety, improved preoperative nutritional status, and increased knowledge about the surgical procedure, expected outcomes, and postoperative care.

Preoperative Nursing Interventions

Relieving Anxiety

The threat of cancer and removal of the bladder create anxiety related to changes in body image. Patients may face problems adapting to an external appliance, a stoma, a surgical incision, and altered toileting habits. Men must also adapt to sexual impotency; a penile implant is considered if the patient is a candidate for the procedure. Women also have anxiety related to altered appearance, body image, and self-esteem. A supportive approach, both physical and psychosocial, is needed and includes assessing the patient's self-concept and manner of coping with stress and loss; helping the patient to identify ways to maintain his or her lifestyle and independence with as few changes as possible; and

encouraging the patient to express fears and anxieties about the ramifications of the upcoming surgery. A visitor from the Ostomy Visitation Program of the ACS can provide emotional support and make adaptation easier both before and after surgery.

Ensuring Adequate Nutrition

In addition to cleansing the bowel to minimize fecal stasis, decompress the bowel, and minimize postoperative ileus, a low-residue diet is prescribed. In addition, antibiotic medications are administered to reduce pathogenic flora in the bowel and to reduce the risk of infection. Because the patient undergoing a urinary diversion procedure for cancer may be severely malnourished due to the tumor, radiation enteritis, and anorexia, enteral or parenteral nutrition may be prescribed to promote healing. Adequate preoperative hydration is imperative to ensure urine flow during surgery and to prevent hypovolemia during the prolonged surgical procedure.

Explaining Surgery and Its Effects

Participation of a WOCN is invaluable for informed preoperative teaching and postoperative care planning. Explanations of the surgical procedure, the appearance of the stoma, the rationale for preoperative bowel preparation, the reasons for wearing a collection device, and the anticipated effects of the surgery on sexual functioning are part of patient teaching. The placement of the stoma site is planned preoperatively with the patient standing, sitting, and lying down to locate the stoma away from bony prominences, skin creases, and folds. The stoma should also be placed away from old scars, the umbilicus, and the belt line.

For ease of self-care, the patient must be able to see and reach the site comfortably. The site is marked with indelible ink so that it can be located easily during surgery. The patient is assessed for allergies or sensitivity to tape or adhesives. Patch testing of certain appliances may be necessary before the ostomy equipment is selected. This is particularly important if the patient is or may be allergic to latex (see Chapter 18).

Preoperative Evaluation

To measure the effectiveness of care, the nurse evaluates the patient's preoperative anxiety level and nutritional status as well as preexisting knowledge and expectations of surgery.

Expected Patient Outcomes

Expected patient outcomes may include:

1. Exhibits reduced anxiety about surgery and expected losses
 - a. Verbalizes fears with health care team and family
 - b. Expresses positive attitude about outcome of surgery
2. Exhibits adequate nutritional status
 - a. Maintains adequate intake before surgery
 - b. Maintains body weight
 - c. States rationale for enteral or parenteral nutrition if needed
 - d. Exhibits normal skin turgor, moist mucous membranes, adequate urine output, and absence of excessive thirst

3. Demonstrates knowledge about the surgical procedure and postoperative course
 - a. Identifies limitations expected after surgery
 - b. Discusses expected immediate postoperative environment (tubes, equipment, nursing surveillance)
 - c. Practices deep-breathing, coughing, and foot exercises

Postoperative Assessment

The role of the nurse in the immediate postoperative period is to prevent complications and to assess the patient carefully for any signs and symptoms of complications. The catheters and any drainage devices are monitored closely. Urine volume, patency of the drainage system, and color of the drainage are assessed. A sudden decrease in urine volume or increase in drainage is reported promptly to the physician because these may indicate obstruction of the urinary tract, inadequate blood volume, or bleeding. In addition, the patient's need for pain control is assessed regularly as with all postoperative patients.

Postoperative Diagnosis

Nursing Diagnoses

Based on the assessment data, the major postoperative nursing diagnoses for the patient following urinary diversion surgery may include the following:

- Risk for impaired skin integrity related to problems in managing the urine collection appliance
- Acute pain related to surgical incision
- Disturbed body image related to urinary diversion
- Potential for sexual dysfunction related to structural and physiologic alterations
- Deficient knowledge about management of urinary function

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Peritonitis due to disruption of anastomosis
- Stoma ischemia and necrosis due to compromised blood supply to stoma
- Stoma retraction and separation of mucocutaneous border due to tension or trauma

Postoperative Planning and Goals

The major goals for the patient may include maintaining skin integrity, relieving pain, increasing self-esteem, developing appropriate coping mechanisms to accept and deal with altered urinary function and sexuality, increasing knowledge about management of urinary function, and preventing potential complications.

Postoperative Nursing Interventions

Postoperative management focuses on monitoring urinary function, preventing postoperative complications (infection and sepsis, respiratory complications, fluid and electrolyte imbalances, fistula formation, and urine leakage), and promoting patient comfort. Catheters or drainage systems are monitored, and urine output is monitored carefully. A nasogastric tube is inserted during surgery to decompress the GI tract and to relieve pressure on the

intestinal anastomosis. It is usually kept in place for several days after surgery. As soon as bowel function resumes, as indicated by bowel sounds, the passage of flatus, and a soft abdomen, oral fluids are permitted. Until that time, IV fluids and electrolytes are administered. The patient is assisted to ambulate as soon as possible to prevent complications of immobility.

Maintaining Skin Integrity

Strategies to promote skin integrity begin with reducing and controlling those factors that increase the patient's risk of poor nutrition and poor healing. As indicated previously, meticulous skin care and management of the drainage system are provided by the nurse until the patient can manage them and is comfortable doing so. Care is taken to keep the drainage system intact to protect the skin from exposure to drainage. Supplies must be readily available to manage the drainage in the immediate postoperative period. Consistency in implementing the skin care program throughout the postoperative period results in maintenance of skin integrity and patient comfort. Additionally, maintenance of skin integrity around the stoma enables the patient and family to adjust more easily to the alterations in urinary function and helps them learn skin care techniques.

Relieving Pain

Analgesic medications are administered liberally postoperatively to relieve pain and promote comfort, thereby allowing the patient to turn, cough, and perform deep-breathing exercises. Patient-controlled analgesia and regular administration of analgesic agents around the clock are two options that may be used to ensure adequate pain relief. A pain intensity scale is used to evaluate the adequacy of the medication and the approach to pain management.

Improving Body Image

The patient's ability to cope with the changes associated with the surgery depends to some degree on his or her body image and self-esteem before the surgery and the support and reaction of others. Allowing the patient to express concerns and anxious feelings can help, especially in adjusting to the changes in toileting habits. The nurse can also help improve the patient's self-concept by teaching the skills needed to be independent in managing the urinary drainage devices. Education about ostomy care is conducted in a private setting to encourage the patient to ask questions without fear of embarrassment. Explaining why the nurse must wear gloves when performing ostomy care can prevent the patient from misinterpreting the use of gloves as a sign of aversion to the stoma.

Exploring Sexuality Issues

Patients who experience altered sexual function as a result of the surgical procedure may mourn this loss. Encouraging the patient and partner to share their feelings about this loss with each other and acknowledging the importance of sexual function and expression may encourage the patient and partner to seek sexual counseling and to explore alternative ways of expressing sexuality. A visit from another "ostomate" who is functioning fully in society and family life may also assist the patient and family in recognizing that full recovery is possible.

Monitoring and Managing Potential Complications

Complications are not unusual because of the complexity of the surgery, the underlying reason (cancer, trauma) for the urinary diversion procedure, and the patient's frequently less-than-optimal nutritional status. Complications may include respiratory disorders (eg, atelectasis, pneumonia), fluid and electrolyte imbalances, breakdown of any anastomosis, sepsis, fistula formation, fecal or urine leakage, and skin irritation. If these occur, the patient will remain hospitalized for an extended length of time and will probably require parenteral nutrition, GI decompression by means of nasogastric suction, and further surgery. The goals of management are to establish drainage, provide adequate nutrition for healing to occur, and prevent sepsis.

PERITONITIS. Peritonitis can occur postoperatively if urine leaks at the anastomosis. Signs and symptoms include abdominal pain and distention, muscle rigidity with guarding, nausea and vomiting, paralytic ileus (absence of bowel sounds), fever, and leukocytosis.

Urine output must be monitored closely, because a sudden decrease in output with a corresponding increase in drainage from the incision or drains may indicate urine leakage. In addition, the urine drainage device is observed for leakage. The pouch is changed if a leak is observed. Small leaks in the anastomosis may seal themselves, but surgery may be needed for larger leaks.

Vital signs (blood pressure, pulse and respiratory rates, temperature) are monitored. Changes in vital signs, as well as increasing pain, nausea and vomiting, and abdominal distention, are reported to the physician and may indicate peritonitis.

STOMA ISCHEMIA AND NECROSIS. The stoma is monitored because ischemia and necrosis of the stoma can result from tension on the mesentery blood vessels, twisting of the bowel segment (conduit) during surgery, or arterial insufficiency. The new stoma must be inspected at least every 4 hours to assess the adequacy of its blood supply. The stoma should be red or pink. If the blood supply to the stoma is compromised, the color changes to purple, brown, or black. These changes are reported immediately to the physician. The physician or WOCN may insert a small, lubricated tube into the stoma and shine a flashlight into the lumen of the tube to assess for superficial ischemia or necrosis. A necrotic stoma requires surgical intervention. If the ischemia is superficial, the dusky stoma is observed and may slough its outer layer in several days.

STOMA RETRACTION AND SEPARATION. Stoma retraction and separation of the mucocutaneous border can occur as a result of trauma or tension on the internal bowel segment used for creation of the stoma. In addition, mucocutaneous separation can occur if the stoma does not heal as a result of accumulation of urine on the stoma and mucocutaneous border. Using a collection drainage pouch with an antireflux valve is helpful because the valve prevents urine from pooling on the stoma and mucocutaneous border. Meticulous skin care to keep the area around the stoma clean and dry promotes healing. If a separation of the mucocutaneous border occurs, surgery is not usually needed. The separated area is protected by applying karaya powder, stoma adhesive paste,

and a properly fitted skin barrier and pouch. By protecting the separation, healing is promoted. If the stoma retracts into the peritoneum, surgical intervention is mandatory.

If surgery is needed to manage these complications, the nurse provides explanations to the patient and family. The need for additional surgery is usually perceived as a setback by the patient and family. Emotional support of the patient and family is provided along with physical preparation of the patient for surgery.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. A major postoperative objective is to assist the patient to achieve the highest level of independence and self-care possible. The nurse and WOCN work closely with the patient and family to instruct and assist them in all phases of managing the ostomy. Adequate supplies and complete instruction are necessary to enable the patient and a family member to develop competence and confidence in their skills. Written and verbal instructions are provided, and the patient is encouraged to contact the nurse or physician with follow-up questions. Follow-up telephone calls from the nurse to the patient and family after discharge may provide added support and provide another opportunity to answer their questions. Follow-up visits and reinforcement of correct skin care and appliance management techniques also promote skin integrity. Specific techniques for managing the appliance are described in Chart 45-14.

The patient is encouraged to participate in decisions regarding the type of collecting appliance and the time of day to change the appliance. The patient is assisted and encouraged to look at and touch the stoma early to overcome any fears. The patient and family need to know the characteristics of a normal stoma:

- Pink and moist, like the inside of the mouth
- Insensitive to pain because it has no nerve endings
- Vascular, which means it may bleed when cleaned

Additionally, if a segment of the GI tract was used to create the urinary diversion, mucus may be visible in the urine. By learning what is normal, the patient and family become familiar with what signs and symptoms they should report to the physician or nurse and what problems they can handle themselves.

Information provided to the patient and the extent of involvement in self-care are determined by the patient's physical recovery and ability to accept and acquire the knowledge and skill needed for independence. Verbal and written instructions are provided, and the patient is given the opportunity to practice and demonstrate the knowledge and skills needed to manage urinary drainage.

CONTINUING CARE. Follow-up care is essential to determine how the patient has adapted to the body image changes and lifestyle adjustments. Visits from a home care nurse are important to assess the patient's adaptation to the home setting and management of the ostomy. Teaching and reinforcement may assist the patient and family to cope with altered urinary function. It is also necessary to assess for long-term complications that may occur, such as pouch leakage or rupture, stone formation, stenosis of the stoma, deterioration in renal function, or incontinence.

Long-term monitoring for anemia is performed to identify vitamin B deficiency, which may occur when a significant

portion of the terminal ileum is removed. This may take several years to develop and can be treated with vitamin B injections. The patient and family are informed about the United Ostomy Association and any local ostomy support groups to provide ongoing support, assistance, and education.

Postoperative Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Maintains skin integrity
 - a. Maintains intact skin and demonstrates skill in managing drainage system and appliance
 - b. States actions to take if skin excoriation occurs
2. Reports relief of pain
3. Exhibits improved body image as evidenced by the following:
 - a. Voices acceptance of urinary diversion, stoma, and appliance
 - b. Demonstrates increasingly independent self-care, including hygiene and grooming
 - c. States acceptance of support and assistance from family members, health care providers, and other ostomates
4. Copes with sexuality issues
 - a. Verbalizes concern about possible alterations in sexuality and sexual function
 - b. Reports discussion of sexual concerns with partner and appropriate counselor
5. Demonstrates knowledge needed for self-care
 - a. Performs self-care and proficient management of urinary diversion and appliance
 - b. Asks questions relevant to self-management and prevention of complications
 - c. Identifies signs and symptoms needing care from physician, nurse, or other health care providers
6. Absence of complications as evidenced by the following:
 - a. Reports absence of pain or tenderness in abdomen
 - b. Has temperature within normal range
 - c. Reports no urine leakage from incision or drains
 - d. Has urine output within desired volume limits
 - e. Maintains stoma that is red or pink, moist, and appropriate in size without edema
 - f. Has intact and healed border of the stoma

CRITICAL THINKING EXERCISES

EBP 1 As the head nurse in a long-term care facility, you are approached by the daughter of one of the residents. She requests that her mother, who can ambulate with assistance, have an indwelling urinary catheter inserted "for convenience sake." What is the evidence base that determines your response? Identify the criteria used to evaluate the strength of the evidence.

EBP 2 As one of the nurses in a busy urology practice, you often care for elderly women with incontinence. Describe the major types of incontinence and compare

and contrast them. What are the evidence-based management techniques used in treating the different types of incontinence?

3 A 35-year-old man is admitted to a medical-surgical nursing unit with a suspected renal stone. Describe the pathophysiology of renal stone formation. What diagnostic tests should be performed to confirm the diagnosis? What is the most common priority nursing diagnosis in the patient admitted with a renal stone? What history and physical findings are common in the patient who is trying to pass the stone? If the patient does not pass the stone or develops complications, what are the interventional procedures available for stone removal?

4 You are caring for a 78-year-old patient after the creation of an ileal conduit. What is the best description of the ileal conduit? Describe the complications that may follow the placement of an ileal conduit. What assessments do you commonly perform in the immediate post-operative period? What is the role of a WOCN in the care of this patient?

Reproductive Function

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With a Difficult Health Care Choice Involving Losses

Mrs. Cole is a 49-year-old woman who has been undergoing cancer staging after positive breast biopsy results. The surgeon has informed her that she has stage IIB infiltrating ductal carcinoma. The surgeon has discussed with her two different surgical approaches—breast conserving or modified radical mastectomy (MRM). If she chooses MRM, Mrs. Cole must decide whether she will undergo breast reconstruction or use a breast prosthesis. The nurse notes that Mrs. Cole is trembling and near tears. Mrs.

Cole tells the nurse that she is uncertain about how her husband will respond if she chooses MRM. She is also concerned that she will not feel feminine after MRM but states she is very frightened about anything less since a friend died of metastatic breast cancer.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
DECISIONAL CONFLICT —Uncertainty about course of action to be taken when choice among competing actions involves risk, loss, or challenge to personal life values	ACTIVE LISTENING —Attending closely to and attaching significance to a patient’s verbal and nonverbal messages	DECISION MAKING —Ability to make judgments and choose between two or more alternatives
ANTICIPATORY GRIEVING —Intellectual and emotional responses and behaviors by which individuals, families, and communities work through the process of modifying self-concept based on the perception of potential loss	DECISION-MAKING SUPPORT —Providing information and support for a patient who is making a decision regarding health care	GRIEF RESOLUTION —Adjustment to actual or impending loss
	ANTICIPATORY GUIDANCE —Preparation of a patient for an anticipated developmental and/or situational crisis GRIEF WORK FACILITATION —Assistance with the resolution of a significant loss EMOTIONAL SUPPORT —Provision of reassurance, acceptance and encouragement during times of stress	PSYCHOSOCIAL ADJUSTMENT: LIFE CHANGE —Adaptive psychosocial response of an individual to a significant life change

Assessment and Management of Female Physiologic Processes

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe female reproductive function.
- 2 Describe approaches to effective sexual assessment.
- 3 Describe indicators of domestic violence and abuse of women and methods of identifying and treating women who are survivors of abuse.
- 4 Identify the diagnostic examinations and tests used to determine alteration in female reproductive function and describe the nurse's role before, during, and after these examinations and procedures.
- 5 Identify types of menstrual disorders and related nursing implications.
- 6 Describe nursing care for patients with premenstrual syndrome.
- 7 Develop a teaching plan for women who are approaching or have completed menopause.
- 8 Describe methods of contraception and implications for health care and education.
- 9 Describe the nursing management of the patient having an abortion.
- 10 Describe the causes and management of infertility.
- 11 Use the nursing process to plan for the care of the patient with an ectopic pregnancy.
- 12 Discuss the healthy older woman and health teaching related to aging.

GLOSSARY

adnexa: the fallopian tubes and ovaries
amenorrhea: absence of menstrual flow
androgens: hormones produced by the ovaries and adrenals that affect many aspects of female health, including follicle development, libido, oiliness of hair and skin, and hair growth
cervix: bottom (inferior) part of the uterus that is located in the vagina
chandelier sign: pain on gentle movement of the cervix; associated with pelvic infection
corpus luteum: site of a follicle that changes after ovulation to produce progesterone
cystocele: weakness of the anterior vaginal wall that allows the bladder to protrude into the vagina

GLOSSARY (Continued)

dysmenorrhea: painful menstruation
dyspareunia: difficult or painful sexual intercourse
endometrial ablation: procedure performed through a hysteroscope in which the lining of the uterus is burned away or ablated to treat abnormal uterine bleeding
endometriosis: condition in which endometrial tissue implants in other areas of the pelvis; may produce dysmenorrhea or infertility
endometrium: lining of the uterus
estrogen: hormone that develops and maintains the female reproductive system
follicle-stimulating hormone (FSH): hormone released by the pituitary gland to stimulate estrogen production and ovulation
fornix: upper part of the vagina
fundus: body of the uterus
graafian follicle: cystic structure that develops on the ovary as ovulation begins
hymen: tissue that covers the vaginal opening partially or completely before vaginal penetration
hysteroscopy: a procedure performed using a long telescope-like instrument inserted through the cervix to diagnose uterine problems
introitus: perineal opening to the vagina
luteal phase: stage in the menstrual cycle in which the endometrium becomes thicker and more vascular
luteinizing hormone (LH): hormone released by the pituitary gland that stimulates progesterone production
menarche: beginning of menstrual function
menopause: permanent cessation of menstruation resulting from the loss of ovarian follicular activity
menstruation: sloughing and discharge of the lining of the uterus if conception does not take place
ovaries: almond-shaped reproductive organs that produce eggs at ovulation and play a major role in hormone production
ovulation: discharge of a mature ovum from the ovary
perimenopause: the period immediately prior to menopause and the first year after menopause
polyp (cervical or endometrial): growth of tissue on the cervix or endometrial lining; usually benign
progesterone: hormone produced by the corpus luteum
proliferative phase: stage in the menstrual cycle before ovulation when the endometrium proliferates
rectocele: weakness of the posterior vaginal wall that allows the rectal cavity to protrude into the submucosa of the vagina
secretory phase: stage of the menstrual cycle in which the endometrium becomes thickened, more vascular, and edematous
uterine prolapse: relaxation of pelvic tone that allows the cervix and uterus to descend into the lower vagina

Women are becoming more knowledgeable about their health. Nurses who work with them need to understand normal female anatomy and physiology and the physical, developmental, psychological, and sociocultural influences on women's health, health practices, and use of health care resources. Health assessment, maintenance, and promotion across the lifespan must consider women's growth and development, sexuality, contraception, preconception care, conception, prenatal care, effects of pregnancy on health, perimenopause, menopause, and aging. It is also necessary to consider how medications and diseases affect women. In addition, women's sexuality is complex and often affected by many factors, and related issues need careful evaluation and treatment. Because women use the health care system more often than men and make up the majority of health care workers, addressing women's health needs and concerns improves quality and access for women and their families.

ROLE OF NURSES IN WOMEN'S HEALTH

As their presence in the labor market continues to increase, women face challenges in their roles, lifestyles, and family patterns. Furthermore, they encounter environmental hazards and stress, prompting greater attention on health and health-promoting practices. As a result, many women are taking a greater interest in and responsibility for their own health and health care, although not all women have the time, finances, or other resources to do so.

In recent years, many women have delayed pregnancy and childbearing until well after they have established careers, in part because of the wide variety of contraceptive methods that are available. Advances in the treatment of infertility have enabled many women previously unable to have children to become pregnant and have allowed couples well into their 40s to have children. Women who have many roles and multiple responsibilities (eg, workers, wives, mothers, parental caretakers) often "multitask"; they have little time for themselves and often put the needs of others before their own health needs. Nurses must be sensitive to these needs and knowledgeable about preventive health care for women. Nurses are in an ideal position to encourage women to determine their own health goals and behaviors, teach about health promotion and illness prevention, offer intervention strategies, and provide support, counseling, and ongoing monitoring. Areas of special interest in health promotion include the following:

- Normal physical changes and optimal personal hygiene
- Strategies for detecting and preventing disease, especially sexually transmitted diseases (STDs), also referred to as sexually transmitted infections (STIs), including human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS)
- Issues related to sexuality and sexual function, such as contraception; preconception, prenatal, and postnatal care; sexual satisfaction; and menopause

- Diet, exercise, and health-promoting practices that maintain and enhance health, including having a normal weight for height
- Appropriate stress management to reduce the detrimental effects of stress on health and well-being
- Treatment for substance abuse and smoking

Nurses need to model a healthy lifestyle for their patients. It is important that nurses promote positive practices and behaviors related to the reproductive and sexual health of all patients. Necessary strategies include the following:

- Recommending regular examinations to promote health, detect health problems at an early stage, assess problems related to gynecologic and reproductive function, and discuss questions or concerns related to sexual function and sexuality
- Providing an open, nonjudgmental environment (crucial in providing nursing and health care, especially when patients are discussing personal issues). Nurses must convey understanding and sensitivity and be alert to cues about unspoken patient concerns.
- Recognizing signs and symptoms of abuse and screening all patients in a private and safe environment
- Recognizing cultural differences and beliefs and respecting sexual orientation

ASSESSMENT OF THE FEMALE REPRODUCTIVE SYSTEM

Anatomic and Physiologic Overview

Anatomy of the Female Reproductive System

The female reproductive system consists of external and internal pelvic structures. Other anatomic structures that affect the female reproductive system include the hypothalamus and pituitary gland of the endocrine system.

External Genitalia

The external genitalia (the vulva) include two thick folds of tissue called the labia majora and two smaller lips of delicate tissue called the labia minora, which lie within the labia majora. The upper portions of the labia minora unite, forming a partial covering for the clitoris, a highly sensitive organ composed of erectile tissue. Between the labia minora, below and posterior to the clitoris, is the urinary meatus, the external opening of the female urethra, which is about 3 cm (less than 1.5 in) long. Below this orifice is a larger opening, the vaginal orifice or **introitus** (Fig. 46-1). On each side of the vaginal orifice is a vestibular (Bartholin's) gland, a bean-sized structure that empties its mucous secretion through a small duct. The opening of the duct lies within the labia minora, external to the hymen. The area between the vagina and rectum is called the perineum.

Figure 46-1 External female genitalia.

Internal Reproductive Structures

The internal structures consist of the vagina, uterus, ovaries, and fallopian or uterine tubes (Fig. 46-2).

Vagina

The vagina, a canal lined with mucous membrane, is 7.5 to 10 cm (3 to 4 in) long and extends upward and backward from the vulva to the cervix. Anterior to it are the bladder and the urethra, and posterior to it lies the rectum. The anterior and posterior walls of the vagina normally touch each other. The upper part of the vagina, the **fo**rnix, surrounds the **ce**rvix (the inferior part of the uterus).

Uterus

The uterus, a pear-shaped, muscular organ, is about 7.5 cm (3 in) long and 5 cm (2 in) wide at its upper part. Its walls are about 1.25 cm (0.5 in) thick. The size of the uterus varies, depending on parity (number of viable births) and uterine abnormalities (eg, fibroids, which are a type of tumor that may distort the uterus). A nulliparous woman

Figure 46-2 Internal female reproductive structures.

(one who has not completed a pregnancy to the stage of fetal viability) usually has a smaller uterus than a multiparous woman (one who has completed two or more pregnancies to the stage of fetal viability). The uterus lies posterior to the bladder and is held in position by several ligaments. The round ligaments extend anteriorly and laterally to the internal inguinal ring and down the inguinal canal, where they blend with the tissues of the labia majora. The broad ligaments are folds of peritoneum extending from the lateral pelvic walls and enveloping the fallopian tubes. The uterosacral ligaments extend posteriorly to the sacrum. The uterus has two parts: the cervix, which projects into the vagina, and a larger upper part, the **fundus** or body, which is covered posteriorly and partly anteriorly by peritoneum. The triangular inner portion of the fundus narrows to a small canal in the cervix that has constrictions at each end, referred to as the external os and internal os. The upper lateral parts of the uterus are called the cornua. From here, the oviducts or fallopian (or uterine) tubes extend outward, and their lumina are internally continuous with the uterine cavity (Porth & Matfin, 2009).

Ovaries

The **ovaries** lie behind the broad ligaments and behind and below the fallopian tubes. They are oval bodies about 3 cm (1.2 in) long. At birth, they contain thousands of tiny egg cells, or ova. The ovaries and the fallopian tubes together are referred to as the **adnexa**.

Function of the Female Reproductive System

Ovulation

At puberty (usually between 12 and 14 years of age, but earlier for some; 10 or 11 years of age is not uncommon), the ova begin to mature and menstrual cycles begin. In the follicular phase, an ovum enlarges as a type of cyst called a **graafian follicle** until it reaches the surface of the ovary, where transport occurs. The ovum (or oocyte) is discharged into the peritoneal cavity. This periodic discharge of matured ovum is referred to as **ovulation**. The ovum usually finds its way into the fallopian tube, where it is carried to the uterus. If it is penetrated by a spermatozoon, the male reproductive cell, a union occurs and conception takes place. After the discharge of the ovum, the cells of the graafian follicle undergo a rapid change. Gradually, they become yellow (**corpus luteum**) and produce **progesterone**, a hormone that prepares the uterus for receiving the fertilized ovum. Ovulation usually occurs 2 weeks prior to the next menstrual period.

Menstrual Cycle

The menstrual cycle is a complex process involving the reproductive and endocrine systems. The ovaries produce steroid hormones, predominantly estrogens and progesterone. Several different **estrogens** are produced by the ovarian follicle, which consists of the developing ovum and its surrounding cells. The most potent of the ovarian

estrogens is estradiol. Estrogens are responsible for developing and maintaining the female reproductive organs and the secondary sex characteristics associated with the adult female. Estrogens play an important role in breast development and in monthly cyclic changes in the uterus (Porth & Matfin, 2009).

Progesterone is also important in regulating the changes that occur in the uterus during the menstrual cycle. It is secreted by the corpus luteum, which is the ovarian follicle after the ovum has been released. Progesterone is the most important hormone for conditioning the **endometrium** (the mucous membrane lining the uterus) in preparation for implantation of a fertilized ovum. If pregnancy occurs, the progesterone secretion becomes largely a function of the placenta and is essential for maintaining a normal pregnancy. In addition, progesterone, working with estrogen, prepares the breast for producing and secreting milk. **Androgens** are also produced by the ovaries and adrenal glands, but only in small amounts. These hormones are involved in the early development of the follicle and also affect the female libido (Porth & Matfin, 2009).

Two gonadotropic hormones are released by the pituitary gland: **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**. FSH is primarily responsible for stimulating the ovaries to secrete estrogen. LH is primarily responsible for stimulating progesterone production. Feedback mechanisms, in part, regulate FSH and LH secretion. For example, elevated estrogen levels in the blood inhibit FSH secretion but promote LH secretion, whereas elevated progesterone levels inhibit LH secretion. In addition, gonadotropin-releasing hormone (GnRH) from the hypothalamus affects the rate of FSH and LH release.

The secretion of ovarian hormones follows a cyclic pattern that results in changes in the uterine endometrium and in **menstruation** (Fig. 46-3, Table 46-1). This cycle is typically 28 days in length, but there are many normal variations (from 21 to 42 days). In the **proliferative phase** at the beginning of the cycle (just after menstruation), FSH output increases, stimulating estrogen secretion. This causes the endometrium to thicken and become more vascular. In the **secretory phase** near the middle portion of the cycle (day 14 in a 28-day cycle), LH output increases, stimulating ovulation. Under the combined stimulus of estrogen and progesterone, the endometrium reaches the peak of its thickening and vascularization. In the **luteal phase**, which begins after ovulation, progesterone is secreted by the corpus luteum.

If the ovum is fertilized, estrogen and progesterone levels remain high, and the complex hormonal changes of pregnancy follow. If the ovum has not been fertilized, FSH and LH output diminishes, estrogen and progesterone secretion falls, the ovum disintegrates, and the endometrium, which has become thick and congested, becomes hemorrhagic. The product, menstrual flow, consisting of old blood, mucus, and endometrial tissue, is discharged through the cervix and into the vagina. After the menstrual flow stops, the cycle begins again; the endometrium proliferates and thickens from estrogenic

Figure 46-3 One menstrual cycle and the corresponding changes in the endometrium.

stimulation, and ovulation recurs (Porth & Matfin, 2009).

Menopausal Period

The menopausal period marks the end of a woman's reproductive capacity. It usually occurs between 45 and 52 years of age but may occur as early as 42 or as late as 55; the median age is 51 years. Perimenopause precedes this and can begin as early as 35 years of age. Physical, emotional, and menstrual changes may occur, and this transition offers another opportunity for health promotion and disease prevention teaching and counseling. **Menopause** is not a pathologic phenomenon but a normal part of aging and maturation. Menstruation ceases, and because the ovaries are no longer active, the

Ovary	Degenerating corpus luteum; beginning follicular development				Growth and maturation of follicle				Ovulation				Active corpus luteum				Degenerating corpus luteum													
Estrogen Production	Low				Increasing				High				Declining, then a secondary rise				Decreasing													
Progesterone Production	None				Low				Low				Increasing				Decreasing													
FSH Production	Increasing				High, then declining				Low				Low				Increasing													
LH Production	Low				Low, then increasing				High				High				Decreasing													
Endometrium	Degeneration and shedding of superficial layer. Coiled arteries dilate, then constrict again.				Reorganization and proliferation of superficial layer				Continued growth				Active secretion and glandular dilation; highly vascular; edematous				Vasoconstriction of coiled arteries; beginning degeneration													

reproductive organs become smaller. No more ova mature; therefore, no ovarian hormones are produced. (An earlier menopause may occur if the ovaries are surgically removed or are destroyed by radiation or chemotherapy or because of an unknown etiology.) Multifaceted changes also occur throughout the woman's body. These changes are neuroendocrinologic, biochemical, and metabolic and are related to normal maturation or aging (Table 46-2).

Assessment

A nurse who is obtaining information from a patient for the health history and performing physical assessment is in an ideal position to discuss the woman's general health issues, health promotion, and health-related concerns. Relevant

topics include fitness, nutrition, cardiovascular risks, health screening, sexuality, menopause, abuse, health risk behaviors, emotional well-being, and immunizations. Recommendations for health screening are summarized in Chart 46-1.

Health History

In addition to the general health history, the nurse asks about past illnesses and experiences specific to a woman's health. Data should be collected about the following:

- Menstrual history (including **menarche**, length of cycles, duration and amount of flow, presence of cramps or pain, bleeding between periods or after intercourse, bleeding after menopause)
- Pregnancies (number of pregnancies, outcomes of pregnancies)

Table 46-2 AGE-RELATED CHANGES IN THE FEMALE REPRODUCTIVE SYSTEM

	Physiologic Changes	Signs and Symptoms
Cessation of ovarian function and decreased estrogen production	Decreased ovulation	Decreased/loss of ability to conceive; increased infertility
	Onset of menopause	Irregular menses with eventual cessation of menses
	Vasomotor instability and hormonal fluctuations	Hot flashes or flushing; night sweats, sleep disturbances; mood swings; fatigue
	Decreased bone formation	Bone loss and increased risk for osteoporosis and osteoporotic fractures; loss of height
	Decreased vaginal lubrication	Dyspareunia, resulting in lack of interest in sex
	Thinning of urinary and genital tracts	Increased risk for urinary tract infection
Relaxation of pelvic musculature	Increased pH of vagina	Increased incidence of inflammation (atrophic vaginitis) with discharge, itching, and vulvar burning
	Thinning of pubic hair and shrinking of labia	
	Prolapse of uterus, cystocele, rectocele	Dyspareunia, incontinence, feelings of perineal pressure

*Each individual's risks (family history, personal history) influence the need for specific assessments and their frequency.

- Exposure to medications (diethylstilbestrol [DES], immunosuppressive agents, others)
- Pain with menses (**dysmenorrhea**), pain with intercourse (**dyspareunia**), pelvic pain
- Symptoms of vaginitis (ie, odor or itching)
- Problems with urinary function, including frequency, urgency, and incontinence
- Bowel problems
- Sexual history
- STDs and methods of treatment
- Current or previous sexual abuse or physical abuse
- Past surgery or other procedures on reproductive tract structures (including female genital mutilation or female circumcision)
- Chronic illness or disability that may affect health status, reproductive health, need for health screening, or access to health care
- Presence of or family history of a genetic disorder. Chart 46-2 presents information about genetic reproductive disorders.

In collecting data related to reproductive health, the nurse can teach the patient about normal physiologic processes, such as menstruation and menopause, and assess possible abnormalities. Many problems experienced by young or middle-age women can be corrected easily. However, if they are not treated, they may result in anxiety and health problems. Issues related to sexuality and sexual function are typically more often brought to the attention of the gynecologic or women's health care provider than other health care providers; however, nurses caring for all women should consider these issues part of routine health assessment.

Sexual History

A sexual assessment includes both subjective and objective data. Health and sexual histories, physical examination findings, and laboratory results are all part of the database. The purpose of a sexual history is to obtain information that provides a picture of a woman's sexuality and sexual practices and to promote sexual health. The sexual history may enable a patient to discuss sexual matters openly and

CHART
46-2GENETICS IN NURSING PRACTICE
Reproductive Disorders

Various reproductive disorders are influenced by genetic factors. Some examples are:

- Hereditary breast or ovarian cancer syndromes
- Hereditary nonpolyposis colon cancer syndrome (risk for uterine cancer)
- Müllerian aplasia
- 21-Hydroxylase deficiency (female masculinization)
- Turner syndrome (45,XO)
- Klinefelter syndrome (47,XXY)

Nursing Assessments**Family History Assessment**

- Assess family history for other family members with similar reproductive problems/abnormalities.
- Inquire about ethnic background (eg, Ashkenazi Jewish populations and hereditary breast/ovarian cancer mutations).
- Inquire about relatives with other cancers, including early-onset ovarian, uterine, renal, prostate cancers.

Patient Assessment

- In females with delayed puberty or primary amenorrhea, assess for clinical features of Turner syndrome (short stature, webbing of the neck, widely spaced nipples).
- In males with delayed puberty or infertility, assess for clinical features of Klinefelter syndrome (tall stature, gynecomastia, learning disabilities).
- Assess for other congenital anomalies in females with Müllerian defect, including renal and vertebral anomalies.

Management Issues Specific to Genetics

- Inquire whether genetics testing (DNA chromosomal, metabolic) has been carried out on affected family member(s).
- If indicated, refer for further genetics counseling and evaluation so that family members can discuss inheritance,

risk to other family members, availability of genetics testing, and gene-based interventions.

- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed gene-related reproductive disorders.
- Participate in management and coordination of care of patients with genetic conditions, individuals predisposed to develop or pass on a genetic condition.

to discuss sexual concerns with an informed health professional. This information can be obtained after the gynecologic–obstetric or genitourinary history is completed. By incorporating the sexual history into the general health history, the nurse can move from areas of lesser sensitivity to areas of greater sensitivity after establishing initial rapport.

Taking the sexual history becomes a dynamic process reflecting an exchange of information between the patient and the nurse and provides the opportunity to clarify myths and explore areas of concern that the patient may not have felt comfortable discussing in the past. In obtaining a sexual history, the nurse must not assume the patient's sexual preference until clarified. When asking about sexual health, the nurse also cannot assume that the patient is married or unmarried. Asking a patient to label herself as single, married, widowed, or divorced may be considered by some women as inappropriate. Asking about a partner or about current meaningful relationships may be a less offensive way to initiate a sexual history.

The PLISSIT (permission, limited information, specific suggestions, intensive therapy) model of sexual assess-

ment and intervention may be used to provide a framework for nursing interventions (Annon, 1976). The assessment begins by introducing the topic and asking the woman for permission to discuss issues related to sexuality with her.

The nurse can begin by explaining the purpose of obtaining a sexual history (eg, "I ask all my patients about their sexual health. May I ask you some questions about this?"). History taking continues by inquiring about present sexual activity and sexual orientation (eg, "Are you currently having sex? With a man, a woman, or both?"). Inquiries about possible sexual dysfunction may include, "Are you having any problems related to your current sexual activity?" Such problems may be related to medication, life changes, disability, or the onset of physical or emotional illness. A patient can be asked about her thoughts on what is causing the current problem.

Information about sexual function can be introduced during the health history. As the discussion progresses, the nurse may offer specific suggestions for interventions. A professional who specializes in sex therapy may provide more intensive therapy if necessary. By initiating an

assessment about sexual concerns, the nurse communicates to the patient that issues about changes or problems in sexual functioning are valid health issues, which provides a safe environment for discussing these sensitive topics. Young women may be apprehensive about having irregular periods, may be concerned about STDs, or may need contraception. They may want information about using tampons, emergency contraception, or issues related to pregnancy. Perimenopausal women may have concerns about irregular menses. Menopausal women may be concerned about vaginal dryness and discomfort with intercourse. Women of any age may have concerns about relationships, sexual satisfaction, orgasm, or masturbation.

Risk of STDs can be assessed by asking about the number of sexual partners in the past year or in the patient's lifetime. An open-ended question related to the patient's need for further information should be included (eg, "Do you have any questions or concerns about your sexual health?"). Women can be advised that intercourse should never be painful; pain should be investigated by a care provider. They should also be encouraged to talk openly about their sexual feelings with their partner; in an intimate relationship, feelings are facts (Sarrel, 2005).

Female Genital Mutilation or Cutting

Female genital mutilation (FGM), or cutting, refers to the partial or total removal of the external female genitalia or other injury to female organs. Over 140 million girls and women have been subjected to this practice. Some cultures accept FGM as a rite of passage to womanhood and believe that this practice promotes hygiene, protects virginity and family honor, prevents promiscuity, improves female attractiveness and male sexual pleasure, and enhances fertility. FGM is considered an acceptable practice in many cultures, mostly in Africa and the Middle East. However, FGM is illegal in the United States and many organizations (eg, World Health Organization, Amnesty International) consider it a health and human rights issue and are working to end it. An increasing number of women entering the United States health care system underwent FGM before coming to the United States (Turner, 2007), and others have undergone FGM since their arrival in this country. Some of these women think that the practice is acceptable and do not consider themselves mutilated, whereas others believe it to be harmful and feel that they have been traumatized.

FGM is usually performed when a girl is between 4 and 10 years of age, but it may be performed on a newborn, adolescent, at the time of marriage, or during the first pregnancy. Short-term complications of FGM include hemorrhage, cellulitis, lacerations, urinary dysfunction, and infection. Long-term complications include urinary dysfunction, chronic vaginitis and pelvic infections, inability to undergo pelvic examination, painful intercourse, impaired sexual response, anemia, increased risk of HIV infection due to tearing of scar tissue, and psychological and psychosexual sequelae. Because FGM can affect sexual function, menstrual hygiene, and bladder function, the possibility of FGM must be considered in the sexual history, particularly in women from cultures and countries where the practice is common.

Nurses who care for patients who have undergone FGM need to be sensitive, empathetic, knowledgeable, culturally competent, and nonjudgmental (Turner, 2007). Respect for others' health beliefs, practices, and behaviors, and recognition of the complexity of issues involved is crucial. The nurse should use the woman's terminology. "Cutting" is a more acceptable term than mutilation. Speculums are not used in some developing countries; the function of this instrument should be explained and an appropriate-sized speculum used to examine women who have experienced FGM.

Domestic Violence

Domestic violence is a broad term that includes child abuse, elder abuse, and abuse of women and men. Abuse can be emotional, physical, sexual, or economic. Abuse involves fear of one partner by another and control by threats, intimidation, and physical abuse. Abuse is related to the need to maintain control of a partner and is rooted in sex role inequality.

More than 6 million women experience domestic violence each year, and battered women are encountered daily in nursing practice. Battering involves repeated physical or sexual assault in a context of coercive control and, more broadly, emotional degradation, threats, and intimidation. Violence is rarely a one-time occurrence in a relationship; it usually continues and escalates in severity. This is an important point to emphasize when a woman states that her partner has hurt her but has promised to change. Batterers can change their behavior but not without extensive counseling and motivation. If a woman states that she is being hurt, sensitive care is required (Chart 46-3).

By knowing about this major public health problem, being alert to abuse-related problems, and learning how to elicit information from women about abuse in their lives, nurses can offer intervention for a problem that might otherwise go undetected and can save lives by making women safer through education and support. Asking each woman about violence in her life in a safe environment (ie, a private room with the door closed) is part of a comprehensive assessment and universal screening. Asking about abuse directly is effective in identifying the presence of abuse and should be included in the health history of all women (Chart 46-4). The third and fourth questions of the screening questionnaire are specifically directed at abuse in women with disabilities.

No specific signs or symptoms are diagnostic of battering; however, nurses may see an injury that does not fit the account of how it happened (eg, a bruise on the side of the upper arm after "I walked into a door"). Manifestations of abuse may involve suicide attempts, drug and alcohol abuse, frequent emergency department visits, vague pelvic pain, somatic complaints, and depression. However, there may be no obvious signs or symptoms. Women in abusive situations often report that they do not feel well, possibly because of the stress of fear and anticipation of impending abuse.

The assessment for abuse by health professionals has lagged behind community awareness and response (Alpert, 2007). In addition to asking about domestic abuse, nurses need to provide resources and referral, as well as to follow written protocols of their institution or agency to ensure

Chart 46-3 • Managing Reported Domestic Abuse

1. Reassure the woman that she is not alone. *Rationale: Women often believe that they are alone in experiencing abuse at the hands of their partners.*
2. Express your belief that no one should be hurt, that abuse is the fault of the batterer and is against the law. *Rationale: Doing so lets the woman know that no one deserves to be abused and that she has not caused the abuse.*
3. Assure the woman that her information is confidential, although it does become part of her medical record. *If children are suspected of being abused or are being abused, the law requires that this be reported to the authorities.* Some states require reporting of spousal or partner abuse. Domestic violence agencies and medical and nursing groups disagree with this policy and are trying to have it changed. Serious opposition is based on the fact that reporting does not and cannot currently guarantee a woman's safety and may place her in more danger. It may also interfere with a patient's willingness to discuss her personal life and concerns with care providers. This places a serious barrier in the way of comprehensive nursing care. If nurses are in doubt about laws on reporting abuse, they need to check with their local or state domestic violence agency. *Rationale: Women are often afraid that their information will be reported to the police or protective services and their children may be taken away.*
4. Document the woman's statement of abuse and take photographs of any visible injuries if written formal consent has been obtained. (Emergency departments usually have a camera available if one is not on the nursing unit.) *Rationale: Doing so provides documentation of injuries that may be needed for later legal or criminal proceedings.*
5. Provide teaching. *Rationale: The following options may be life-saving for the woman and her children:*
 - Inform the woman that shelters are available to ensure safety for her and her children. (Lengths of stay in shelters vary by state but are often up to 2 months. Staff often assist with housing, jobs, and the emotional distress that accompanies the break-up of the family.) Provide list of shelters.
 - Inform the woman that violence gets worse, not better.
 - If the woman chooses to go to a shelter, let her make the call.
 - If the woman chooses to return to the abuser, remain nonjudgmental and provide information that will make her safer than she was before disclosing her situation.
 - Make sure that the woman has a 24-hour hotline telephone number that provides information and support (Spanish translation and a device for the deaf are also available), police number, and 911.
 - Assist her to set up a safety plan in case she decides to return home. (A safety plan is an organized plan for departure with packed bags and important papers hidden in a safe spot.)

comprehensive care (Furniss, McCaffrey, Parnell, et al., 2007).

Incest and Childhood Sexual Abuse

More than one in five women has experienced incest or childhood sexual abuse, and nurses frequently encounter women who have been sexually traumatized. It has been reported that female survivors of sexual abuse have more health problems and undergo more surgery than women

who were not victims of abuse. Victims of childhood sexual abuse are reported to experience more chronic depression, posttraumatic stress disorder, morbid obesity, marital instability, gastrointestinal problems, and headaches, as well as use health care services more frequently than people who were not victims. In women, chronic pelvic pain is often associated with physical violence, emotional neglect, and sexual abuse in childhood (McFarlane, Malecha, Watson, et al., 2005). Women who have experienced rape or sexual abuse may be very anxious about pelvic examinations, labor, pelvic or breast irradiation, or any treatment or examination that involves hands-on treatment or requires removal of clothing. Nurses should be prepared to offer support and referral to psychologists, community resources, and self-help groups.

Rape and Sexual Assault

Sexual assault occurs about every 2 minutes in the United States (U.S. Department of Justice, 2007). Men, women, and children may be victims. Many rapes occur on dates. Sexual assault nurse examiners, emergency department staff, and gynecologists perform the painstaking collection of forensic evidence that is needed for criminal prosecution. Oral, anal, and genital tissue is examined for evidence of trauma, semen, or infection. Saliva, hair, and fingernail evidence is also collected. Cultures are obtained for STDs, and prophylactic antibiotics are prescribed. The postexposure prophylaxis recommended by the Centers for Disease Control and Prevention (CDC) consists of ceftriaxone (Rocephin), metronidazole (Flagyl), and azithromycin (Zithromax) (CDC, 2006, 2007). The first injection of hepatitis B

Screening for Abuse

Abuse Assessment Screen-Disability (AAS-D)

- Within the last year, have you been hit, slapped, kicked, pushed, shoved, or otherwise physically hurt by someone?
- Within the last year, has anyone forced you to have sexual activities?
- Within the last year, has anyone prevented you from using a wheelchair, cane, respiratory, or other assistive devices?
- Within the last year, has anyone you depend on refused to help you with an important personal need, such as taking your medicine, getting to the bathroom, getting out of bed, bathing, getting dressed, or getting food or drink?

Center for Research on Women with Disabilities. Abuse Assessment Screen-Disability. www.bcm.edu/crowd/?PMID=1325m

vaccine may also be given if the patient is not already immune, with subsequent doses given at 1 to 2 months and 4 to 6 months (CDC, 2006). HIV testing is offered and is repeated in 3 to 6 months. HIV prophylaxis is not universally recommended but is considered when mucosal exposure to contamination has occurred. Prophylaxis against chlamydia and gonorrhea is provided. Emergency contraception is explained and provided if requested and appropriate. Emotional counseling is provided, and follow-up treatment visits are arranged. Rape trauma syndrome is the emotional reaction to a sexual assault and may consist of shock, sleep disturbances, nightmares, flashbacks, anxiety, anger, mood swings, and depression. It is important and helpful for survivors to discuss the experience and to obtain professional counseling.

Screening for abuse, rape, and violence should be part of routine assessment because women often do not report or seek treatment for assault. Often, the assailant is a partner, husband, or date. Nurses may encounter women with infections or pregnancies related to sexual assault who require support, understanding, and comprehensive care.

Health Issues in Women With Disabilities

Approximately 20% of women have disabilities and encounter physical, architectural, and attitudinal barriers that may limit their full participation in society. Women with disabilities may experience stereotyping and increased risk of abuse. They have reported that others, including health care providers, often equate them with their disability. Studies have shown that women with disabilities receive less primary health care and preventive health screening than

other women, often because of access problems and health care providers who focus on the causes of disability rather than on health issues that are of concern to all women (Smeltzer, 2006, 2007). To address these issues, the health history must include questions about barriers to health care encountered by women with disabilities and the effect of their disability on their health status and health care. Other issues to be addressed are identified in Chart 46-5. If a patient has hearing loss, vision loss, or another disability that affects communication, it may be necessary to obtain the assistance of an interpreter or to establish another method of communication. Nurses assessing women with disabilities may require additional time and the assistance of others to be certain that accurate information is obtained in a sensitive and unhurried manner (Smeltzer, 2007; Smeltzer & Sharts-Hopko, 2005). Women with disabilities may have had previous negative experiences with health care providers (Smeltzer, Sharts-Hopko, Ott, et al., 2007), and it is important that nurses provide them with knowledgeable and sensitive care. See Chapter 10 for further discussion of health care of patients with disabilities.

Gerontologic Considerations

Care of older women with gynecologic concerns requires knowledge and understanding. Many older women are functioning at various levels across the health spectrum; some function at a high level in their jobs or families, whereas others may be very ill. Nurses need to be prepared to care for older women who may be bright, energetic, and ambitious or who are coping with multiple family crises,

CHART
46-5

Assessing a Woman With a Disability

Health History

Address questions directly to the woman herself rather than to people accompanying her. Ask about:

- Self-care limitations resulting from her disability (ability to feed and dress self, use of assistive devices, transportation requirements, other assistance needed)
- Sensory limitations (lack of sensation, low vision, deaf or hard of hearing)
- Accessibility issues (ability to get to health care provider, transfer to examination table, accessibility of office/clinic of health care provider, previous experiences with health care providers, health screening practices; her understanding of physical examination)
- Cognitive or developmental changes that affect understanding
- Limitations secondary to disability that affect general health issues and reproductive health and health care
- Sexual function and concerns (those of all women and those that may be affected by the presence of a disabling condition)
- Menstrual history and menstrual hygiene practices
- Physical, sexual, or psychological abuse (including abuse by care providers; abuse by neglect, withholding or withdrawing assistive devices or personal or health care)

- Presence of secondary disabilities (ie, those resulting from the patient's primary disability: pressure ulcers, spasticity, osteoporosis, etc.)
- Health concerns related to aging with a disability

Physical Assessment

Provide instructions directly to the woman herself rather than to people accompanying her; provide written or audiotaped instructions.

Ask the woman what assistance she needs for the physical examination and provide assistance if needed:

- Undressing and dressing
- Providing a urine specimen
- Standing on scale to be weighed (provide alternative means of obtaining weight if she is unable to stand on scale)
- Moving on and off the examination table
- Assuming, changing, and maintaining positions

Consider the fatigue experienced by the woman during a lengthy examination and allow rest.

Provide assistive devices and other aids/methods needed to allow adequate communication with the patient (interpreters, signers, large-print written materials).

Complete examination that would be indicated for any other woman; having a disability is *never* justification for omitting parts of the physical examination, including the pelvic examination.

including their own health issues as well as for those who are experiencing a life-altering or life-threatening health problem. Older women are at risk for several conditions, including diabetes, dyslipidemia, hypertension, and thyroid disease, all of which have symptoms that may be dismissed as typical aging. Nurses can help prevent morbidity and mortality from these conditions by encouraging women to obtain regular health screenings (Thakur & Supiano, 2007). In addition, knowledge related to heart disease prevention, pharmacology, diet, signs of dementia or cognitive decline, fall prevention, osteoporosis prevention, gynecologic and breast cancers, and sexuality are important for providing high-level nursing care. Health disparities, cultural competency, and end-of-life issues also need to be considered.

Physical Assessment

Periodic examinations and routine cancer screening are important for all women. Annual breast and pelvic examinations are important for all women 18 years of age or older and for those who are sexually active, regardless of age. Patients deserve understanding and support because of the emotional and physical considerations associated with gynecologic examinations. Women may be embarrassed by the usual questions asked by a gynecologist or women's health care provider. Because gynecologic conditions are of a personal and private nature to most women, such information is shared only with those directly involved in patient care (as is true with all patient information).

Throughout the examination, the nurse explains the procedures to be performed. This not only encourages the woman to relax but also provides an opportunity for her to ask questions and minimizes the negative feelings that many women associate with gynecologic examinations.

The first pelvic examination is often anxiety producing; the nurse can alleviate many of these feelings with explanations and teaching (Chart 46-6). It may be helpful to emphasize that a pelvic examination should not usually be un-

comfortable. Before the examination begins, the patient is asked to empty her bladder and to provide a urine specimen if urine tests are part of the total assessment. Voiding ensures patient comfort and eases the examination because a full bladder can make palpation of pelvic organs uncomfortable for the patient and difficult for the examiner.

Positioning

Although several positions may be used for the pelvic examination, the supine lithotomy position is used most commonly, although the upright lithotomy position (in which the woman assumes a semisitting posture) may also be used. This position offers several advantages:

- It is more comfortable for some women.
- It allows better eye contact between patient and examiner.
- It may provide an easier means for the examiner to carry out the bimanual examination.
- It enables the woman to use a mirror to see her anatomy (if she chooses) to visualize any conditions that require treatment or to learn about using certain types of contraceptive methods.

In the supine lithotomy position, the patient lies on the table with her feet on foot rests or stirrups. She is encouraged to relax so that her buttocks are positioned at the edge of the examination table, and she is asked to relax and spread her thighs as widely apart as possible. If the patient is unable to lie safely on the examination table or unable to maintain the supine lithotomy position because of acute illness or disability, the Sims' position (or alternate positions) may be used. In Sims' position, the patient lies on her left side with her right leg bent at a 90-degree angle. The right labia may be retracted to gain adequate access to the vagina. The presence of a disability does not justify skipping any parts of the physical assessment, including the pelvic examination.

The following equipment is obtained and readily available: a good light source; a vaginal speculum; clean examination gloves; lubricant, spatula, cytobrush, glass slides, fixative solution or spray; and diagnostic testing supplies for screening for occult rectal blood if the woman is older than 40 years of age. Latex-free gloves should be available if the patient or clinician is allergic to latex. This allergy is becoming more prevalent in nurses and other health care providers and patients and is potentially life-threatening. Patients should be questioned about previous reactions to latex. (See Chapter 18 for a latex screening form and Chapter 53 for more information on latex allergy.)

Inspection

After the patient is prepared, the examiner inspects the labia majora and minora, noting the epidermal tissue of the labia majora; the skin fades to the pink mucous membrane of the vaginal introitus. Lesions of any type (eg, venereal warts, pigmented lesions [melanoma]) are evaluated. In the nulliparous woman, the labia minora come together at the opening of the vagina. In a woman who has delivered children vaginally, the labia minora may gape and vaginal tissue may protrude.

Trauma to the anterior vaginal wall during childbirth may have resulted in incompetency of the musculature, and

CHART
46-6

PATIENT EDUCATION The Pelvic Examination

A pelvic examination includes assessment of the appearance of the vulva, vagina, and cervix and the size and shape of the uterus and ovaries to ensure reproductive health and absence of illness. The following should make the examination proceed more smoothly:

- You may have a feeling of fullness or pressure during the examination, but you should not feel pain. It is important to relax, because if you are very tense, you may feel discomfort.
- It is normal to feel uncomfortable and apprehensive.
- A narrow, warmed speculum will be inserted to visualize the cervix.
- A Papanicolaou (Pap) smear will be obtained and should not be uncomfortable.
- You may watch the examination with a mirror if you choose.
- The examination usually takes no longer than 5 minutes.
- Draping will be used to minimize exposure and reduce embarrassment.

a bulge caused by the bladder protruding into the submucosa of the anterior vaginal wall (**cystocele**) may be seen. Childbirth trauma may also have affected the posterior vaginal wall, producing a bulge caused by rectal cavity protrusion (**rectocele**). The cervix may descend under pressure through the vaginal canal and be seen at the introitus (**uterine prolapse**). See Chapter 47 for a discussion of these structural changes. To identify such protrusions, the examiner asks the patient to “bear down.”

The introitus should be free of superficial mucosal lesions. The labia minora may be separated by the fingers of the gloved hand and the lower part of the vagina palpated. In women who have not had vaginal intercourse, a **hymen** of variable thickness may be felt circumferentially within the vaginal opening. The hymenal ring usually permits the insertion of one finger. Rarely, the hymen totally occludes the vaginal entrance (imperforate hymen).

In women who have had intercourse, a rim of scar tissue representing the remnants of the hymenal ring may be palpated circumferentially around the vagina near its opening. The greater vestibular glands (Bartholin’s glands) lie between the labia minora and the remnants of the hymenal ring. An abscess of the Bartholin’s gland can cause discomfort and requires incision and drainage.

Speculum Examination

The bivalved speculum, either metal or plastic, is available in many sizes. Metal specula are soaked, scrubbed, and sterilized between patients. Some clinicians and some patients prefer plastic specula, which permit one-time use. The speculum can be warmed with a heating pad or warm water to make insertion more comfortable for the patient. The speculum is not usually lubricated because commercial lubricants may interfere with cervical cytology (Papanicolaou [Pap] smear) findings.

The speculum is gently inserted into the posterior portion of the introitus and slowly advanced to the top of the vagina; this should not be painful or uncomfortable for the woman. The speculum is then slowly opened and the set-screw of the thumb rest is tightened to hold the speculum open (Fig. 46-4).

Inspecting the Cervix

The cervix is inspected. In nulliparous women, the cervix usually is 2 to 3 cm wide and smooth. In women who have borne children, the cervix may have a laceration, usually transverse, giving the cervical os a “fishmouth” appearance. Epithelium from the endocervical canal may have grown onto the surface of the cervix, appearing as beefy-red surface

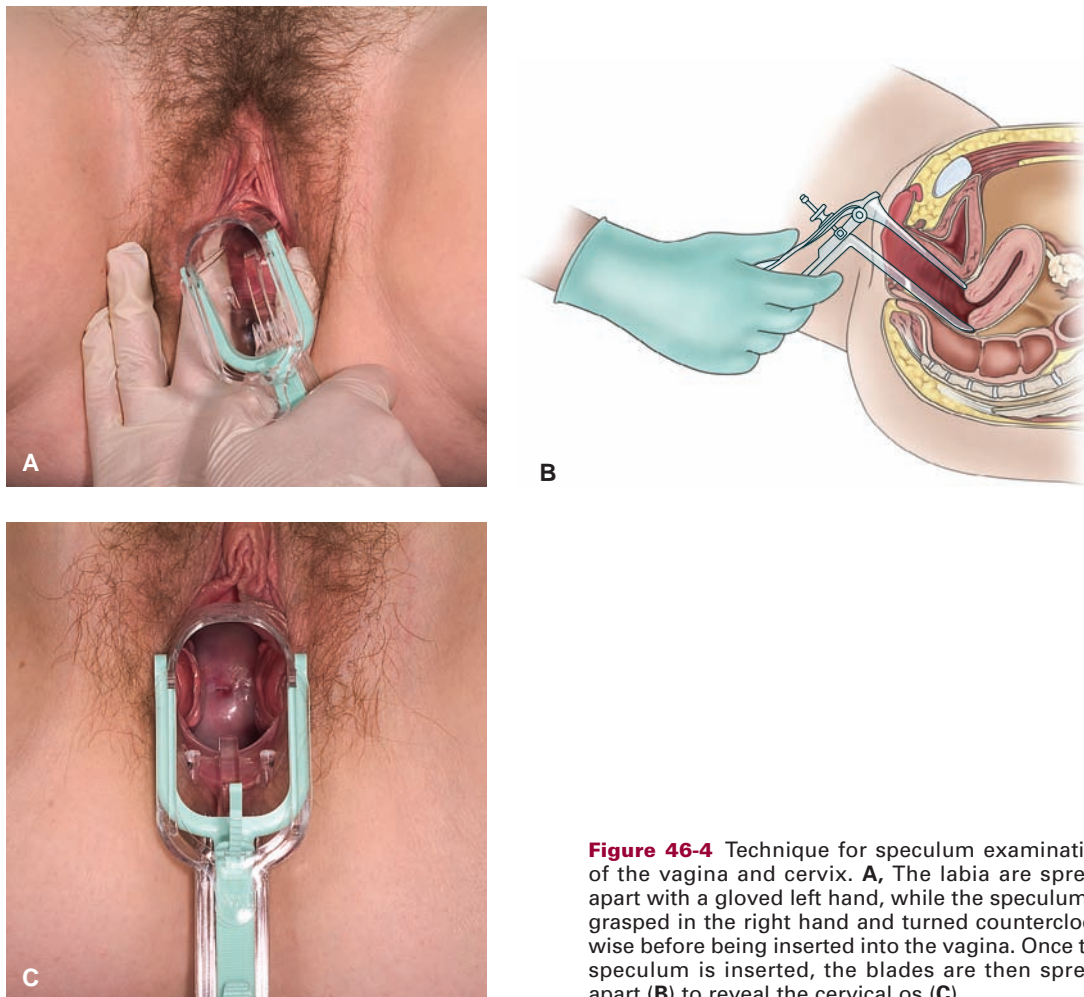

Figure 46-4 Technique for speculum examination of the vagina and cervix. **A**, The labia are spread apart with a gloved left hand, while the speculum is grasped in the right hand and turned counterclockwise before being inserted into the vagina. Once the speculum is inserted, the blades are then spread apart (**B**) to reveal the cervical os (**C**).

epithelium circumferentially around the os. Occasionally, the cervix of a woman whose mother took DES during pregnancy has a hooded appearance (a peaked aspect superiorly or a ridge of tissue surrounding it); this is evaluated by colposcopy when identified.

Malignant changes may not be obviously differentiated from the rest of the cervical mucosa. Small, benign cysts may appear on the cervical surface. These are usually bluish or white and are called nabothian cysts. A **polyp** of endocervical mucosa may protrude through the os and usually is dark red. Polyps can cause irregular bleeding; they are rarely malignant and usually are removed easily in an office or clinic setting. A carcinoma may appear as a cauliflower-like growth that bleeds easily when touched. Bluish coloration of the cervix is a sign of early pregnancy (Chadwick's sign).

Obtaining Pap Smears and Other Samples

A Pap smear is obtained by rotating a small spatula at the os, followed by a cervical brush rotated in the os. The material obtained is spread on a glass slide and sprayed/fixed immediately, or inserted into liquid (thin "prep"). A small broomlike device can also be used to obtain specimens for the Pap smear.

A specimen of any purulent material appearing at the cervical os is obtained for culture. A sterile applicator is used to obtain the specimen, which is immediately placed in an appropriate medium for transfer to a laboratory. In a patient who has a high risk of infection, routine cultures for gonococcal and chlamydial organisms are recommended because of the high incidence of both diseases and the complications of pelvic infection, fallopian tube damage, and subsequent infertility.

Vaginal discharge, which may be normal or may result from vaginitis, may be present. Table 46-3 summarizes the characteristics of vaginal discharge found in different conditions.

Inspecting the Vagina

The vagina is inspected as the examiner withdraws the speculum. It is smooth in young girls and thickens after puberty, with many rugae (folds) and redundancy in the epithelium. In menopausal women, the vagina thins and has fewer rugae because of decreased estrogen.

Bimanual Palpation

To complete the pelvic examination, the examiner performs a bimanual examination, usually from a standing position. The fingers are advanced vertically along the vaginal canal, and the vaginal wall is palpated. Any firm part of the vaginal wall may represent old scar tissue from childbirth trauma but may also require further evaluation.

Cervical Palpation

The cervix is palpated and assessed for its consistency, mobility, size, and position. The normal cervix is uniformly firm but not hard. Softening of the cervix is a finding in early pregnancy. Hardness and immobility of the cervix may reflect invasion by a neoplasm. Pain on gentle movement of the cervix is called a positive **chandelier sign** or positive cervical motion tenderness (recorded as +CMT) and usually indicates a pelvic infection.

Uterine Palpation

To palpate the uterus, the examiner places the opposite hand on the abdominal wall halfway between the umbilicus and the pubis and presses firmly toward the vagina. Movement of the abdominal wall causes the body of the uterus to descend, and the organ becomes freely movable between the hand used to examine the abdomen and the fingers of the hand used to examine the pelvis. Uterine size, mobility, and contour can be estimated through palpation. Fixation of the uterus in the pelvis may be a sign of **endometriosis** or malignancy.

The body of the uterus is normally twice the diameter and twice the length of the cervix, curving anteriorly toward the abdominal wall. Some women have a retroverted or retroflexed uterus, which tips posteriorly toward the sacrum, whereas others have a uterus that is neither anterior nor posterior and is described as midline.

Adnexal Palpation

Next, the right and left adnexal areas are palpated to evaluate the fallopian tubes and ovaries. The fingers of the hand examining the pelvis are moved first to one side, then to the other, while the hand palpating the abdominal area is moved correspondingly to either side of the abdomen and downward. The adnexa (ovaries and fallopian tubes) are trapped between the two hands and palpated for an obvious mass, tenderness, and mobility. Commonly, the ovaries are slightly tender, and the patient is informed that slight discomfort on palpation is normal.

Vaginal and Rectal Palpation

Bimanual palpation of the vagina and cul-de-sac is accomplished by placing the index finger in the vagina and the middle finger in the rectum. To prevent cross-contamination between the vaginal and rectal orifices, the examiner puts on new gloves. A gentle movement of these fingers toward each other compresses the posterior vaginal wall and the anterior rectal wall and assists the examiner in identifying the integrity of these structures. During this procedure, the patient may sense an urge to defecate. The nurse assures the

Table 46-3 CHARACTERISTICS OF VAGINAL DISCHARGE

Cause of Discharge	Symptoms	Odor	Consistency/Color
Physiologic	None	None	Mucus/white
<i>Candida</i> species infection	Itching, irritation	Yeast odor or none	Thin to thick, curdlike/white
Bacterial vaginosis	Odor	Fishy, often noticed after intercourse	Thin/grayish or yellow
<i>Trichomonas</i> species infection	Irritation, odor	Malodorous	Copious, often frothy/yellow-green
Atrophic	Vulvar or vaginal dryness	Occasional mild malodor	Usually scant and mucoid/may be blood-tinged

patient that this is unlikely to occur. Ongoing explanations are provided to reassure and educate the patient about the procedure.

Gerontologic Considerations

Yearly examinations are important; they identify problems of the reproductive tract in aging women early. Some older women do not have regular gynecologic examinations. For example, a woman who delivered her children at home may never have had a pelvic examination. Some women regard it as an embarrassing and unpleasant procedure. Nurses play an important role; they can encourage all women to have an annual gynecologic examination. Nurses can make the examination a time for education and reassurance rather than a time of embarrassment.

Perineal pruritus is abnormal in elderly women and should be evaluated because it may indicate a disease process (diabetes or malignancy). Vulvar dystrophy, a thickened or whitish discoloration of tissue, may be visible, and biopsy is needed to rule out abnormal cells. Topical cortisone and hormone creams may be prescribed for symptomatic relief.

With relaxing pelvic musculature, uterine prolapse and relaxation of the vaginal walls can occur. Appropriate evaluation and surgical repair can provide relief if the patient is a candidate for surgery. After surgery, the patient should know that tissue repair and healing may require more time with aging. Pessaries (latex devices that provide support) are often used if surgery is contraindicated or before surgery to see if surgery can be avoided. They are fitted by a health care provider and may reduce discomfort and pressure. Use of a pessary requires the patient to have routine gynecologic examinations to monitor for irritation or infection. The patient must be assessed for allergy prior to insertion of a latex pessary (see Chapter 47 for details about pessaries).

Diagnostic Evaluation

Cytologic Test for Cancer (Pap Smear)

The Pap smear is used to detect cervical cancer. Cervical secretions are gently removed from the cervical os and may be transferred to a glass slide and fixed immediately by spraying with a fixative or immersed in solution (Fig. 46-5). If the Pap smear reveals atypical cells, the liquid method allows for human papillomavirus (HPV) testing (see Chapter 47 for further discussion of HPV, a commonly transmitted STD that can cause venereal warts or cervical cancer). HPV DNA testing is helpful in that it can detect high-risk types that may require careful monitoring. HPV infection is often temporary, especially in healthy young women.

The proper technique for obtaining a cervical specimen for cytologic study is described in Chart 46-7. A Pap smear should be performed when a patient is not menstruating, because blood usually interferes with interpretation. To avoid washing away cellular material, the patient should be instructed not to douche before having a Pap smear taken.

Terminology used to describe findings includes the following categories:

- Normal
- Atypical squamous cells of undetermined significance (ASCUS), either HPV + or –
- Low-grade squamous intraepithelial lesion (LSIL), which is equivalent to cervical intraepithelial neoplasia (CIN; grade 1) and to mild changes related to exposure to HPV
- High-grade squamous intraepithelial lesion (HGSIL), which equates to moderate and severe dysplasia, carcinoma in situ (CIS), as well as CIN grade 2 and CIN grade 3

The terms in the last category are precursors to invasive carcinoma of the cervix that indicate the need for evaluation and treatment.

Figure 46-5 Method of using an Ayre spatula to obtain cervical secretions for cytology. **A**, Speculum in place and the Ayre spatula in position at the cervical os. **B**, The tip of the spatula is placed in the cervical os and the spatula rotated 360 degrees, firmly but non-traumatically. **C**, Instead of the cells being smeared on a slide, the sampling device is rinsed or twirled in the small vial containing the transport medium and sent to the laboratory.

 CHART
46-7

Guidelines for Obtaining an Optimal Pap Smear

Equipment Needed

- Speculum
- Gloves
- Slide, spatula, and cytobrush or thin prep kit

Implementation

Nursing Action

1. Do not obtain a Pap smear if the woman is menstruating or has other frank bleeding (exception: high suspicion of neoplasia).
2. If performing more than one test (eg, Pap and GC), obtain the Pap smear first.
3. Label the frosted end of the slide with the patient's name in pencil or label Thin-prep Pap bottle.
4. Put on gloves before gently inserting the unlubricated speculum. (Speculum may be moistened with warm water.)
5. Place the longer end of the Ayre spatula in the cervical canal and rotate it in a full circle to obtain a sample from the exocervix. Spread the material obtained onto the Pap smear slide.
6. Insert a cytobrush 2 cm into the cervical canal and rotate 180 degrees. Roll the brush onto the Pap smear slide. (With Thin-prep Pap smears, the brushings are not spread onto a slide. The spatula and brush are placed in a bottle of fixative and swirled.)
7. In women who have had a hysterectomy for a gynecological cancer, use a cotton applicator moistened with saline solution to obtain a sampling of cells from the vaginal cuff or posterior vagina. Women who have had a hysterectomy for benign conditions do not require frequent Pap smears.
8. Immediately spray the slide or, if a Thin-prep, swirl the brush and spatula in the solution.

Rationale

1. Blood obscures a proper reading of cells.
2. By performing the Pap smear first, the chance of a bloody smear is avoided.
3. Ink may rub off or blur. Labeling with a pencil prevents improper identification.
4. Gloves provide protection and warm water prevents discomfort. Lubricants may obscure cells on Pap smear.
5. This technique obtains a sampling of the exocervix and squamocolumnar junction.
6. This technique obtains a sampling of the endocervical cells and may sample cells from the squamocolumnar junction if it is high in the canal.
7. Saline solution prevents drying, which makes interpretation difficult for the cytologist and prevents absorption of cells into the cotton, increasing the yield on the slide.
8. Exposure to light or air causes distortion of cells.

The patient may incorrectly assume that an abnormal Pap smear signifies cancer. If the Pap smear (liquid immersion method) shows atypical cells and no high-risk HPV types, the next Pap smear is performed in 1 year. If a specific infection is causing inflammation, it is treated appropriately, and the Pap smear is repeated. If the repeat Pap smear reveals atypical squamous cells with high-risk HPV types, colposcopy may be indicated. Pap smears that indicate LSIL should be repeated in 4 to 6 months and colposcopy performed if the LSIL has not resolved. Patients with Pap smears that indicate HGSIL and CIS require prompt colposcopy.

If the Pap smear results are abnormal, prompt notification, evaluation, and treatment are crucial. Notification of patients is often the responsibility of nurses in a women's health care practice or clinic. Pap smear follow-up is essential because it can prevent cervical cancer. Some women do not adhere to recommendations—particularly women who are young, who are of low socioeconomic status, who have difficulty coping with the diagnosis, or who have no social support. Fear, lack of understanding, and child care responsibilities have all been identified by women as reasons for poor follow-up. Women with a history of abuse, obese women, and women who have had a negative gynecologic

experience may also find returning for follow-up difficult. Interventions are tailored to meet the needs of the particular patient. Intensive telephone counseling, tracking systems, brochures, videos, and financial incentives have all been used to encourage follow-up. The nurse provides clear explanations and emotional support along with a carefully designed setting-specific follow-up protocol designed to meet the needs of the patient.

The Committee on Adolescent Health Care of the American College of Obstetricians and Gynecologists (ACOG, 2006b) issued a set of guidelines for the evaluation and management of abnormal cervical cytology and histology in adolescent females. The committee stressed the need for a complete and accurate sexual history in making decisions about initiation of cervical cytology screening in adolescents.

Colposcopy and Cervical Biopsy

If a Pap smear result requires evaluation, a colposcopy is performed. The colposcope is a portable microscope (magnification from 10X to 25X) that allows the examiner to visualize the cervix and obtain a sample of abnormal tissue for analysis. Nurse practitioners and gynecologists require special training in this diagnostic technique.

After inserting a speculum and visualizing the cervix and vaginal walls, the examiner applies acetic acid to the cervix. Subsequent abnormal findings that indicate the need for biopsy include leukoplakia (white plaque visible before applying acetic acid), acetowhite tissue (white epithelium after applying acetic acid), punctation (dilated capillaries occurring in a dotted or stippled pattern), mosaicism (a tilelike pattern), and atypical vascular patterns. If biopsy specimens show premalignant cells or CIN, the patient usually requires cryotherapy, laser therapy, or a cone biopsy (excision of an inverted tissue cone from the cervix).

Cryotherapy and Laser Therapy

Cryotherapy (freezing cervical tissue with nitrous oxide) and laser treatment are used in the outpatient setting. Cryotherapy may result in cramping and occasional feelings of faintness (vasovagal response). A watery discharge is normal for a few weeks after the procedure as the cervix heals.

Cone Biopsy and Loop Electrosurgical Excision Procedure

If endocervical curettage findings indicate abnormal changes or if the lesion extends into the canal, the patient may undergo a cone biopsy. This can be performed surgically or with a procedure called loop electrosurgical excision procedure (LEEP), which uses a laser beam.

Usually performed in the outpatient setting, LEEP is associated with a high success rate in removal of abnormal cervical tissue. The gynecologist excises a small amount of cervical tissue, and the pathologist examines the borders of the specimen to determine if disease is present. A patient who has received anesthesia for a surgical cone biopsy is advised to rest for 24 hours after the procedure and to leave any vaginal packing in place until it is removed (usually the next day). The patient is instructed to report any excessive bleeding.

The nurse or physician provides guidelines regarding postoperative sexual activity, bathing, and other activities. Because open tissue may be potentially exposed to HIV and other pathogens, the patient is cautioned to avoid intercourse until healing is complete and verified at follow-up. LEEP has a low incidence of complications, but there is a slight increase in the risk of later cervical stenosis or premature deliveries.

Endometrial (Aspiration) Biopsy

Endometrial biopsy, a method of obtaining endometrial tissue, is performed as an outpatient procedure. This procedure is usually indicated in cases of midlife irregular bleeding, postmenopausal bleeding, and irregular bleeding while taking hormone therapy or tamoxifen. A tissue sample obtained through biopsy permits diagnosis of cellular changes in the endometrium.

Women who undergo endometrial biopsy may experience slight discomfort. The examiner may apply a tenaculum (a clamplike instrument that stabilizes the uterus) after the pelvic examination and then inserts a thin, hollow, flexible suction tube (Pipelle or sampler) through the cervix into the uterus.

Findings on aspiration may include normal endometrial tissue, hyperplasia, or endometrial cancer. Simple hyperplasia is an overgrowth of the uterine lining and is usually

treated with progesterone. Complex hyperplasia, which refers to overgrowth of cells with abnormal features, is a risk factor for uterine cancer and is treated with progesterone and careful follow-up. Women who are overweight, who are older than 45 years of age, who have a history of nulliparity and infertility, or who have a family history of colon cancer seem to be at higher risk for hyperplasia. Endometrial cancer is discussed in Chapter 47.

Dilation and Curettage

Dilation and curettage (D & C) may be diagnostic (identifies the cause of irregular bleeding) or therapeutic (often temporarily stops irregular bleeding). The cervical canal is widened with a dilator, and the uterine endometrium is scraped with a curette. The purpose of the procedure is to secure endometrial or endocervical tissue for cytologic examination, to control abnormal uterine bleeding, and as a therapeutic measure for incomplete abortion.

Because D & C is usually carried out under anesthesia and requires surgical asepsis, it is usually performed in the operating room. However, it may take place in the outpatient setting with the patient receiving a local anesthetic supplemented with diazepam (Valium) or midazolam (Versed).

The nurse explains the procedure, preparation, and expectations regarding postoperative discomfort and bleeding. The patient is instructed to void before the procedure. The patient is placed in the lithotomy position, the cervix is dilated with a dilating instrument, and endometrial scrapings are obtained by a curette. A perineal pad is placed over the perineum after the procedure, and excessive bleeding is reported. No restrictions are placed on dietary intake. If pelvic discomfort or low back pain occurs, mild analgesics usually provide relief. The physician indicates when sexual intercourse may be safely resumed. To reduce the risk of infection and bleeding, most physicians advise no vaginal penetration or use of tampons for 2 weeks.

Endoscopic Examinations

Laparoscopy (Pelvic Peritoneoscopy)

A laparoscopy involves inserting a laparoscope (a tube about 10 mm wide and similar to a small periscope) into the peritoneal cavity through a 2-cm (0.75-in) incision below the umbilicus to allow visualization of the pelvic structures (Fig. 46-6). Laparoscopy may be used for diagnostic purposes (eg, in cases of pelvic pain when no cause can be found) or treatment. Laparoscopy facilitates many surgical procedures, such as tubal ligation, ovarian biopsy, myomectomy, hysterectomy, and lysis of adhesions (scar tissue that can cause pelvic discomfort). A surgical instrument (intrauterine sound or cannula) may be positioned inside the uterus to permit manipulation or movement during laparoscopy, affording better visualization. The pelvic organs can be visualized after the injection of carbon dioxide intraperitoneally into the cavity. Called insufflation, this technique separates the intestines from the pelvic organs. If a patient is undergoing sterilization, the fallopian or uterine tubes may be electrocoagulated, sutured, or ligated and a segment removed for histologic verification (clips are an alternative device for occluding the tubes).

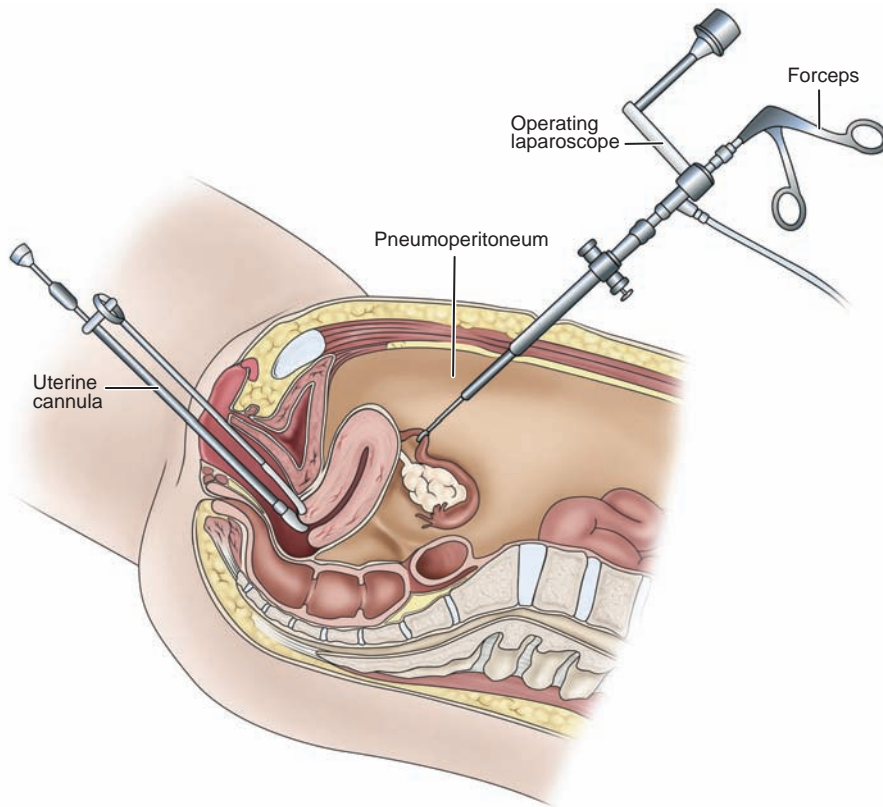

Figure 46-6 Laparoscopy. The laparoscope (*right*) is inserted through a small incision in the abdomen. A forceps is inserted through the scope to grasp the fallopian tube. To improve the view, a uterine cannula (*left*) is inserted into the vagina to push the uterus upward. Insufflation of gas creates an air pocket (pneumoperitoneum), and the pelvis is elevated (note the angle), which forces the intestines higher in the abdomen.

After the laparoscopy is completed, the laparoscope is withdrawn, carbon dioxide is allowed to escape through the outer cannula, the small skin incision is closed with sutures or a clip, and the incision is covered with an adhesive bandage. The patient is carefully monitored for several hours to detect any untoward signs indicating bleeding (most commonly from vascular injury to the hypogastric vessels), bowel or bladder injury, or burns from the coagulator. These complications are rare, making laparoscopy a cost-effective and safe short-stay procedure. The patient may experience abdominal or shoulder pain related to the use of carbon dioxide gas.

Hysteroscopy

Hysteroscopy (transcervical intrauterine endoscopy) allows direct visualization of all parts of the uterine cavity by means of a lighted optical instrument. The procedure is best performed about 5 days after menstruation ceases, in the estrogenic phase of the menstrual cycle. The vagina and vulva are cleansed, and a paracervical anesthetic block is performed or lidocaine spray is used. The instrument used for the procedure, a hysteroscope, is passed into the cervical canal and advanced 1 or 2 cm under direct vision. Uterine-distending fluid (normal saline solution or 5% dextrose in water) is infused through the instrument to dilate the uterine cavity and enhance visibility. Hysteroscopy, which has few complications, is useful for evaluating endometrial pathology.

Hysteroscopy may be indicated as an adjunct to a D & C and laparoscopy in cases of infertility, unexplained bleeding, retained intrauterine device (IUD), and recurrent early pregnancy loss. Treatment for some conditions (eg, fibroid

tumors) can be accomplished during this procedure, and sterilization may also be performed. Hysteroscopy is contraindicated in patients with cervical or endometrial carcinoma or acute pelvic inflammation.

Endometrial ablation (destruction of the uterine lining) is performed with a hysteroscope and resector (cutting loop), roller ball (a barrel-shaped electrode), or laser beam in cases of severe bleeding not responsive to other therapies. Performed in an outpatient setting under general, regional, or local anesthesia, this rapid procedure is an alternative to hysterectomy for some patients. Following uterine distension with fluid infusion, the lining of the uterus is destroyed. Hemorrhage, perforation, and burns can occur.

Other Diagnostic Procedures

Many diagnostic procedures are helpful in evaluating pelvic conditions. These may include x-rays, barium enemas, gastrointestinal x-ray series, intravenous urography, and cystography studies. In addition, because the uterus, ovaries, and fallopian tubes are near the structures of the urinary tract, urologic diagnostic studies, such as x-ray study of the kidney, ureters, and bladder (KUB) and pyelography are used, as are angiography and radioisotope scanning, if needed. Other diagnostic procedures include hysterosalpingography and computed tomography (CT) scanning.

Hysterosalpingography or Uterotubography

Hysterosalpingography (HSG) is an x-ray study of the uterus and the fallopian tubes after injection of a contrast

agent. The diagnostic procedure is performed to evaluate infertility or tubal patency and to detect any abnormal condition in the uterine cavity. Sometimes the procedure is therapeutic because the flowing contrast agent flushes debris or loosens adhesions.

Prior to hysterosalpingography, laxatives and an enema may be administered to evacuate the intestinal tract so that gas shadows do not distort the x-ray findings. A mild sedative or an analgesic agent, such as ibuprofen (Advil, Motrin) may be prescribed. The patient is placed in the lithotomy position and the cervix is exposed with a bivalved speculum. A cannula is inserted into the cervix and the contrast agent is injected into the uterine cavity and the fallopian tubes. X-rays are taken to show the path and the distribution of the contrast agent.

Some patients experience nausea, vomiting, cramps, and faintness. After the test, the patient is advised to wear a perineal pad for several hours, because the radiopaque contrast agent may stain clothing.

Computed Tomography

CT has several advantages over ultrasonography (described below), even though it involves radiation exposure and is more costly. It is more effective than ultrasonography for obese patients or for patients with a distended bowel. CT can also demonstrate a tumor and any extension into the retroperitoneal lymph nodes and skeletal tissue, although it has limited value in diagnosing other gynecologic abnormalities.

Ultrasonography

Ultrasonography (or ultrasound) is a useful adjunct to the physical examination, particularly in obstetric patients or in patients with abnormal pelvic examination findings. It is a simple procedure based on sound wave transmission that uses pulsed ultrasonic waves at frequencies exceeding 20,000 Hz (formerly cycles per second) by way of a transducer placed in contact with the abdomen (abdominal scan) or a vaginal probe (vaginal ultrasound). Mechanical energy is converted into electrical impulses, which in turn are amplified and recorded on an oscilloscope screen while a photograph or video recording of the patterns is taken. The entire procedure takes usually less than 10 minutes and involves no ionizing radiation and no discomfort other than a full bladder, which is necessary for good visualization during an abdominal scan. (A vaginal ultrasound or sonogram does not require a full bladder; however, the vaginal probe can cause mild discomfort in some women.) Saline may be instilled into the uterus (saline infusion sonogram) to help delineate endometrial polyps or fibroids.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) produces patterns that are finer and more definitive than other imaging procedures, and it does not expose patients to radiation. However, MRI is more costly.

NURSING ALERT

All metal devices, including medication skin patches with foil backing, must be removed before MRI is performed to avoid burns.

MANAGEMENT OF FEMALE PHYSIOLOGIC PROCESSES

Many health concerns of women are related to normal changes or abnormalities of the menstrual cycle and may result from women's lack of understanding of the menstrual cycle, developmental changes, and factors that may affect the pattern of the menstrual cycle. Educating women about the menstrual cycle and changes over time is an important aspect of the nurse's role in providing quality care to women. Teaching should begin early, so that menstruation and the lifelong changes in the menstrual cycle can be anticipated and accepted as a normal part of life.

Menstruation

Menstruation, a cyclic vaginal flow of tissue that lines the uterus, occurs about every 28 days during the reproductive years, although normal cycles can vary from 21 to 42 days. The flow usually lasts 4 to 5 days, during which time 50 to 60 mL (4 to 12 tsp) of blood are lost.

A perineal pad or tampon is generally used to absorb menstrual discharge. Tampons are used extensively. There is no significant evidence of untoward effects from their use, provided that there is no difficulty in inserting them. However, tampons should not be used for more than 4 to 6 hours, and superabsorbent tampons should not be used because of their association with toxic shock syndrome. If a tampon is difficult to remove or shreds when removed, less absorbent tampons should be used. If the string breaks or retracts, the woman should squat in a comfortable position, insert one finger into the vagina, try to locate the tampon, and remove it. If she feels uncomfortable attempting this maneuver or cannot remove the tampon, she should consult a gynecologic health care provider promptly.

Psychosocial Considerations

Girls who are approaching menarche (the onset of menstruation) should be instructed about the normal process of the menstrual cycle before it occurs. Psychologically, it is much healthier and appropriate to refer to this event as a "period" rather than as "being sick." With adequate nutrition, rest, and exercise, most women feel little discomfort, although some report breast tenderness and a feeling of fullness 1 or 2 days before menstruation begins. Others report fatigue and some discomfort in the lower back, legs, and pelvis on the first day and temperament or mood changes. Slight deviations from a usual pattern of daily living are considered normal, but excessive deviation may require evaluation. Regular exercise and a healthy diet have been found to decrease discomfort for some women. Heating pads or nonsteroidal anti-inflammatory drugs (NSAIDs) may be very effective for cramps. For women with excessive cramping or dysmenorrhea, referral to a women's health care provider is appropriate; following evaluation, practitioners may prescribe oral contraceptives.

Cultural Considerations

Culture refers to knowledge, beliefs, customs, and values acquired as members of a racial, ethnic, religious, or social group. The United States is becoming more culturally

diverse. Various aspects of culture affect many health care encounters, and these encounters can be positive if nurses understand the various cultures of their patients.

Cultural views and beliefs about menstruation differ. Some women believe that it is detrimental to change a pad or tampon too frequently; they think that allowing the discharge to accumulate increases the flow, which is considered desirable. Some women believe they are vulnerable to illness during menstruation. Others believe it is harmful to swim, shower, have their hair permed, have their teeth filled, or eat certain foods during menstruation. They may also avoid using contraception during menstruation.

In such situations, nurses are in a position to provide women with facts in an accepting and culturally sensitive manner. The objective is to be mindful of these unexpressed, deep-rooted beliefs and to provide the facts with care. Aspects of gynecologic problems cannot always be expressed easily. The nurse needs to convey confidence and openness and to offer facts to facilitate communication. Suggestions to improve care include overcoming language barriers, providing appropriate materials in the patient's language, asking about traditional beliefs and dietary practices, and asking about fears regarding care. Patience, sensitivity, and a desire to learn about other cultures and groups will enhance the nursing care of all women (Chart 46-8).

Perimenopause

Perimenopause is the period extending from the first signs of menopause—usually hot flashes, vaginal dryness, or irregular menses—to beyond the complete cessation of menses. It has also been defined as the period around menopause, lasting to 1 year after the last menstrual period. Women often have varied beliefs about aging, and these must be considered when caring for or educating perimenopausal patients.

Nursing Management

Perimenopausal women often benefit from information about the subtle physiologic changes they are experiencing.

Perimenopause has been described as an opportune time for teaching women about health promotion and disease prevention strategies. When discussing health-related concerns with midlife women, nurses should consider the following issues:

- Sexuality, fertility, contraception, and STDs
- Unintended pregnancy (if contraception is not used correctly and consistently)
- Oral contraceptive use. Oral contraceptives provide perimenopausal women with protection against uterine cancer, ovarian cancer, anemia, pregnancy, and fibrocystic breast changes as well as relief from perimenopausal symptoms. This option should be discussed with perimenopausal women. (Women who smoke and are 35 years of age or older should not take oral contraceptives because of an increased risk of cardiovascular disease.) Contraception is discussed in detail later in this chapter.
- Breast health. About 16% of cases of breast cancer occur in perimenopausal women, so breast self-examination, routine physical examinations, and mammograms are essential.

Women in their 40s are often less concerned with menopause and more interested in their health, well-being, and appearance. They view taking care of themselves as one way to look and feel younger (Beyene, Gilliss & Lee, 2007).

Menopause

Menopause is the permanent physiologic cessation of menses associated with declining ovarian function; during this time, reproductive function diminishes and ends. Postmenopause is the period beginning from about 1 year after menses cease. Menopause may be associated with some atrophy of breast tissue and genital organs, loss in bone density, and vascular changes.

Menopause starts gradually and is usually signaled by changes in menstruation. The monthly flow may increase or

Chart 46-8 • Health Care for Women Who Are Lesbians

Lesbians can generally be defined as women who have sex with or primary emotional partnerships with women, but there is no universally accepted definition; variability exists in relationships and sexual preferences. Lesbians are found in every ethnic group and socioeconomic class. They can be single, celibate, divorced, and are seen in all age groups, including teens and seniors. Most experts believe that sexual orientation is not a conscious choice.

Lesbians have often encountered insensitivity in health care encounters. When they are asked if they are sexually active and respond affirmatively, contraception is immediately urged as health care providers may assume incorrectly that they practice heterosexual intercourse. Similar to many other marginalized groups of women, they often feel invisible and underuse health care. Whether heterosexual or homosexual, nurses need to consider lesbianism within the continuum of human sexual behavior and need to use gender-neutral questions and terms that are nonjudgmental

and accepting. Lesbian teens are at risk for suicide and STDs. Many lesbians do participate in heterosexual activity and often consider themselves at low risk for STDs. Because HPV, herpes infections, and other organisms implicated in STDs are transmitted by secretions and contact, they may need information on STDs and contraception. If sex toys are used and not cleaned, pelvic infections can occur.

Lesbians have lower health screening rates than other women. They are at high risk for cancer, heart disease, depression, and alcohol abuse. They may have a higher body mass index, may bear fewer or no children, and often have fewer health preventive screenings than heterosexual women. These factors may increase the risk of colon, endometrial, ovarian, and breast cancer, as well as cardiovascular disease and diabetes. Adolescent lesbians are at risk for smoking and suicide/depression. Nurses need to understand the unique needs of this population and provide appropriate and sensitive care (Roberts, 2006).

decrease, become irregular, and finally cease. Often, the interval between periods is longer; a lapse of several months between periods is not uncommon. Changes signaling menopause begin to occur as early as the late 30s, when ovulation occurs less frequently, estrogen levels fluctuate, and FSH levels increase in an attempt to stimulate estrogen production.

Clinical Manifestations

Because of these hormonal changes, some women notice irregular menses, breast tenderness, and mood changes long before menopause occurs. The hot or warm flashes and night sweats reported by some women are thought to be caused by hormonal changes and denote vasomotor instability. They may vary in intensity from a barely perceptible warm feeling to a sensation of extreme warmth accompanied by profuse sweating, causing discomfort, sleep disturbances, and subsequent fatigue. Other physical changes may include increased bone loss (discussed later in this chapter).

The entire genitourinary system is affected by the reduced estrogen level. Changes in the vulvovaginal area may include a gradual thinning of pubic hair and a gradual shrinkage of the labia. Vaginal secretions decrease, and women may report dyspareunia (discomfort during intercourse). The vaginal pH increases during menopause, predisposing women to bacterial infections

and atrophic vaginitis. Discharge, itching, and vulvar burning may result.

Some women report fatigue, forgetfulness, weight gain, irritability, trouble sleeping, feeling “blue,” and feelings of panic. Menopausal complaints need to be evaluated carefully because they may indicate other disorders. Most women have few problems and are relieved to be free from menstrual periods.

Psychological Considerations

Women’s reactions and feelings related to loss of reproductive capacity may vary. Some women may experience role confusion, whereas others experience a sense of sexual and personal freedom. Women may be relieved that the child-bearing phase of their lives is over. Each woman’s personal views about menopause and circumstances affect her response and must be considered on an individual basis. Nurses need to be sensitive to all possibilities and take their cues from the patient. Chart 46-9 describes how women with disabilities may view menopause.

Medical Management

Women approaching menopause often have many concerns about their health. Some have concerns based on a family history of heart disease, osteoporosis, or cancer. Each woman needs to be as knowledgeable as possible about her health options and should be encouraged to discuss her

46-9

NURSING RESEARCH PROFILE

Perceptions of Women With Disabilities About Menopause

Harrison, T. & Becker, H. (2007). A qualitative study of menopause among women with disabilities. *Advances in Nursing Science*, 30(2), 123–138.

Purpose

Because of preexisting impairments and treatments associated with disabling conditions, women with disabilities may experience menopause in ways that differ from women without disabilities. Little information about menopause in women with disabilities or their experiences related to menopause is available. The purpose of this study was to examine the perceptions of women with mobility impairments about menopause—how they understand and react to menopause.

Design

A total of 19 women between 42 and 64 years of age were included in this qualitative, decisional support menopause intervention study. The women were interviewed by telephone using a semistructured questionnaire that addressed their experience with menopause, the effect of menopause on their daily lives, their responses to menopause, their prior knowledge about menopause, and their sources of information about menopause. Interviews were audiotaped and then transcribed verbatim. Data were analyzed using qualitative methods to identify and categorize both themes and patterns of the women’s experiences.

Results

The women reported concerns about medical issues related to menopause. They viewed menopause as having possible

negative effects on their health and well-being because of disorders (eg, osteoporosis) that occur in women with mobility limitations well before the onset of menopause. In most cases, they indicated a desire to make decisions about medical management of menopause and its symptoms.

Nevertheless, they considered menopause to be a minor issue compared to the other physical issues they face related to their disability. They indicated that information was their best defense; in addition, they found that knowledge of their own body could be helpful. They reported that they try to avoid health care providers.

Nursing Implications

The concerns related to menopause expressed by women with disabilities should be further explored by nurses. Because women desire a major role in medical decision making related to menopause, they need to be provided with accurate, up-to-date information about results of studies related to all methods of symptom management. Furthermore, the women’s view that they know their own bodies better than anyone else needs to be recognized and taken into consideration when providing care. Lastly, some women with disabilities reported that avoidance of health care providers might be beneficial. This suggests that nurses should take every opportunity to discuss health-related issues and concerns of women with disabilities.

concerns with her primary health care provider so that she can make an informed decision about managing menopausal symptoms and maintaining her health.

Hormone Therapy

Until recently, hormone therapy (HT) was prescribed to prevent hot flashes, reduce the risk of osteoporotic fractures, and decrease the risk of cardiovascular disease. Contrary to long-held beliefs, HT or menopausal hormonal therapy (North American Menopause Society, 2007) (previously referred to as hormone replacement therapy [HRT]) has been found to increase some health disorders and to be less effective in preventing others than previously believed. Although HT decreases hot flashes and reduces the risk of osteoporotic fractures as well as colorectal cancer, studies have shown that it increases the risk of breast cancer, heart attack, stroke, and blood clots (Heiss, Wallace, Anderson, et al., 2008; Writing Group for Women's Health Initiative Investigators, 2002). Thus, the benefits of HT are inadequate given the increased risk of these other disorders. Because of these findings, many women have discontinued HT or are reluctant to begin HT. Although some women have elected to use HT in low doses on the advice of their health care providers, the effect of these low doses has not been studied. The current recommendation for treatment of hot flashes with HT is to use the lowest dose possible for the shortest time possible.

Nurses need to be knowledgeable about HT-related issues to be able to respond to women's questions about HT use.

Methods of Administration

Both estrogen and progestin are prescribed for women who have not had a hysterectomy; progestin prevents proliferation of the uterine lining and hyperplasia. Women who no longer have a uterus because of hysterectomy can take estrogen without progestin (ie, unopposed estrogen) because there is no longer a risk of estrogen-induced hyperplasia of the uterine lining. Although there is a slight increase of risk of stroke in women taking estrogen alone following hysterectomy, the risk of breast cancer is unchanged (Heiss, et al., 2008).

Some women take both estrogen and progestin daily; others take estrogen for 25 consecutive days each month, with progestin taken in cycles (eg, 10 to 14 days of the month). Women who take HT for 25 days often experience bleeding after completing the progestin. Other women take estrogen and progestin every day and usually experience no bleeding. They occasionally have irregular spotting, which should be evaluated by their health care provider. Progestin administration may be oral, transdermal, vaginal, or intrauterine.

Estrogen patches, which are replaced once or twice weekly, are another option but require a progestin along with them if the woman still has a uterus. Another type of patch provides estrogen and progestin treatment. Skin should be dry at the area of application, and cleansing the site with alcohol may improve adhesiveness. Vaginal treatment with an estrogen cream, suppository, or an estradiol ring (Estring) may be used for vaginal dryness or atrophic vaginitis. The estradiol ring is a small, flexible vaginal ring

that slowly releases estrogen in small doses over 3 months. Vaginal estrogen preparations may improve vulvovaginal sensation; however, women who use them should be monitored for endometrial hyperplasia (Speroff & Fritz, 2005).

Risks and Benefits

HT is contraindicated in women with a history of breast cancer, vascular thrombosis, impaired liver function, uterine cancer, and undiagnosed abnormal vaginal bleeding. Because the risk of thromboembolic phenomena is increased with HT, women who elect to take it should be taught the signs and symptoms of deep vein thrombosis and pulmonary embolism and instructed to report these signs and symptoms immediately. Women who take HT should be assessed for leg redness, tenderness, chest pain, and shortness of breath. Furthermore, they need to be informed about the importance of regular follow-up care, including a yearly physical examination and mammogram. An endometrial biopsy is indicated for any irregular bleeding. Because the risk of complications increases the longer HT is used, HT should be used for the shortest time possible (American Heart Association, 2007). Estrogen alone or in combination with a progestin does not reduce risk of dementia or cognitive impairment.

Alternative Therapy for Hot Flashes

Because women often seek information about alternatives to HT use, nurses must be knowledgeable about other approaches women can use to promote their health in the perimenopausal and postmenopausal period. Problematic hot flashes have been treated with venlafaxine (Effexor), paroxetine (Paxil), gabapentin (Neurontin), and clonidine (Catapres). Similarly, vitamin B₆ and vitamin E may be effective. Some women have expressed interest in other alternative treatments (eg, natural estrogens and progestins, black cohosh, ginseng, dong quai, soy products, and several other herbal preparations); however, few data exist about their safety or effectiveness. Therefore, assessment of menopausal women should address their use of complementary and alternative therapies and supplements. The North American Menopause Society provides additional suggestions. Glucose levels also affect hot flashes; thus, nurses can encourage patients to maintain stable glucose levels (Dormire & Becker, 2007).

Maintaining Bone Health

Acceleration of bone loss resulting in osteoporosis and microarchitectural deterioration of bone tissue occurs at menopause and leads to increased bone fragility and risk of fracture. Other factors that increase a woman's risk of osteoporosis include a thin body frame, race (Caucasian or Asian), family history of osteoporosis, nulliparity, early menopause, moderate to heavy alcohol ingestion, smoking, caffeine use, sedentary lifestyle, and a diet low in calcium. About 80% of people with osteoporosis are women, and about half of these women will experience a fracture related to osteoporosis during her lifetime (National Osteoporosis Foundation, 2008). Thus, women are advised to remain active and to begin or continue a regular exercise program of weight-bearing activity, such as walking, which helps maintain bone mass; to take a calcium supplement; to decrease

or stop smoking; and to discuss with their health care provider the use of pharmacologic agents to reduce bone loss if indicated. Osteoporosis and its treatment are described in detail in Chapter 68.

Maintaining Cardiovascular Health

The American Heart Association (2007) recommends a variety of strategies to lower the risk of heart disease in women. These include lifestyle changes and behavioral strategies. Diet, exercise, stress reduction, and a healthy lifestyle all contribute to older women's cardiac health and are an essential part of health promotion. Regular physical exercise increases the heart rate and high-density lipoprotein levels. Weight-bearing exercise (eg, walking, jogging) at least four times a week is recommended. Pharmacologic therapy (eg, aspirin, beta-blockers, "statins," angiotensin-converting enzyme inhibitors) may be indicated in women who have cardiovascular disease or are at high risk for it. Prevention and treatment of cardiovascular disease are discussed in detail in Chapter 26.

Behavioral Strategies

As previously stated, regular physical exercise is beneficial. It may also reduce stress, enhance well-being, and improve self-image. In addition, weight-bearing exercise may prevent loss of muscle tissue and bone tissue.

Women are also encouraged to participate in other health-promoting activities. These include regular health screening recommended for women at the time of menopause: gynecologic examinations, mammograms, colonoscopy, fecal occult blood testing, and bone mineral density testing if at risk for osteoporosis.

Nutritional Therapy

Women are encouraged to decrease their fat and caloric intake and increase their intake of whole grains, fiber, fruit, and vegetables. Women of all ages tend to ingest less than the recommended amount of calcium; therefore, they should be encouraged to increase their intake of foods high in calcium (eg, nonfat yogurt, green leafy vegetables, seafood, and calcium-fortified foods). Calcium and vitamin D supplementation may be helpful in reducing bone loss and preventing the morbidity associated with osteoporotic fractures (National Osteoporosis Foundation, 2008).

Nursing Management

Nurses can encourage women to view menopause as a natural change resulting in freedom from symptoms related to menses. No relationship exists between menopause and mental health problems; however, social circumstances (eg, adolescent children, ill partners, and dependent or ill parents) that may coincide with menopause can be stressful.

Measures should be taken to promote general health. The nurse explains to the patient that cessation of menses is a normal occurrence that is rarely accompanied by nervous symptoms or illness. The current expected lifespan after menopause for the average woman is 30 to 35 years, which may encompass as many years as the childbearing phase of her life. Normal sexual urges continue, and women retain their usual response to sex long after menopause. Many

women enjoy better health after menopause than before, especially those who have experienced dysmenorrhea. The individual woman's evaluation of herself and her worth, now and in the future, is likely to affect her emotional reaction to menopause. Patient teaching and counseling regarding healthy lifestyles, health promotion, and health screening are of paramount importance (Chart 46-10).

Menstrual Disorders

Menstrual disorders may include premenstrual syndrome (PMS); dysmenorrhea; amenorrhea; and excessive bleeding, irregular bleeding, or bleeding between cycles or unrelated to cycles. These disorders need to be discussed with a health care provider and managed individually. Menstrual-related disorders have been reported in as many as 19% of women who report feeling more anxious, sad, nervous, restless, hopeless, and worthless than those without complaints. Affected women are more likely to smoke cigarettes, drink alcohol to excess, and be overweight (Strine, Chapman & Ahluwalia, 2005). Dysmenorrhea may result from endometriosis or anatomic abnormalities or it can be a normal variation. Amenorrhea may be related to pregnancy, thyroid disorders, anatomic abnormalities, and eating disorders. Excessive bleeding may be caused by fibroids, clotting disorders, thyroid disorders, and miscarriage. Irregular bleeding may be secondary to hormonal changes in adolescence or perimenopause or may result from pregnancy, threatened abortion, or a variety of other factors.

PREMENSTRUAL SYNDROME

Premenstrual symptoms are common in ovulating women and can influence quality of life. Symptoms occur in the luteal phase and disappear with the onset of menses. PMS is a combination of bothersome symptoms, and premenstrual dysphoric disorder is a severe type of premenstrual disorder that significantly impairs normal activity (Chart 46-11). The cause of these conditions is unknown; they are diagnosed if symptoms occur during the 5 days prior to the onset of menses, disappear within 4 days of the onset of menses, and occur through several cycles. PMS tends to become less symptomatic with menopause.

Clinical Manifestations

Major symptoms of PMS include physical symptoms such as headache, fatigue, low back pain, painful breasts, and a feeling of abdominal fullness. Behavioral and emotional symptoms may include general irritability, mood swings, fear of losing control, binge eating, and crying spells. Symptoms vary widely from one woman to another and from one cycle to the next in the same woman. Great variability is found in the degree of symptoms. Many women are affected to some degree, but some are severely affected.

A generally stressful life and problematic relationships may be related to the intensity of physical symptoms. Some women report moderate to severe life disruption secondary to PMS that negatively affects their interpersonal relationships. PMS may also be a factor in reduced productivity, work-related injuries, and absenteeism.

CHART
46-10

HOME CARE CHECKLIST

The Woman Approaching Menopause

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe menopause as a normal period in a woman's life.	✓	✓
• State that fatigue and stress may worsen hot flashes.	✓	✓
• State that a nutritious diet and weight control will enhance physical and emotional well-being.	✓	✓
• State the importance of exercising for at least 30 minutes three or four times a week to maintain good health.	✓	✓
• Describe involvement in outside activities as beneficial in reducing anxiety and tension.	✓	✓
• Identify the following as changes that often occur in midlife: departure of children, aging, dependence of parents, possible loss of loved ones.	✓	✓
• Describe this phase of life as having the potential for intellectual growth, personal accomplishment, and initiation of new activities.	✓	✓
• State the following points about sexual activity: Frequent sexual activity helps to maintain the elasticity of the vagina. Contraception is advised until 1 year passes without menses. Safer sex is important at any age. Sexual functioning may be enhanced at midlife.	✓ ✓ ✓ ✓	
• Identify the importance of an annual physical examination to screen for problems and to promote general health.	✓	
• Identify strategies and methods to prevent or manage the following problems: Itching or burning of vulvar areas: see primary health care provider to rule out dermatologic abnormalities and, if appropriate, to obtain a prescription for a lubricating or hormonal cream. Dyspareunia (painful intercourse) due to vaginal dryness; use a water-soluble lubricant, such as K-Y Jelly, Astro-Glide, Replens, hormone cream, or contraceptive foam. Decreased perineal muscle tone and bladder control: practice Kegel exercises daily (contract the perineal muscles as though stopping urination; hold for 5–10 seconds and release; repeat frequently during the day). Dry skin: use mild emollient skin cream and lotions to prevent dry skin. Weight control: join a weight-reduction support group such as Weight Watchers or a similar group if appropriate, or consult a registered dietitian for guidance about the tendency to gain weight, particularly around the hips, thighs, and abdomen. Osteoporosis: observe recommended calcium and vitamin D intake, including calcium supplements, if indicated, to slow the process of osteoporosis; avoid smoking, alcohol, and excessive caffeine, all of which increase bone loss. Perform weight-bearing exercises. Undergo bone density testing when appropriate. Risk for urinary tract infection (UTI): drink 6 to 8 glasses of water daily and take vitamin C (500 mg) as a possible way to reduce the incidence of UTI related to atrophic changes of the urethra. Vaginal bleeding: report any bleeding after 1 year of no menses to a primary health care provider <i>immediately, no matter how minimal</i> .	✓ ✓ ✓ ✓ ✓ ✓ ✓ ✓ ✓ ✓	

Medical Management

Because there is no single treatment or known cure for PMS, women should chart their symptoms so they can anticipate and therefore cope with them. Regular exercise may be helpful. Although women have been advised to avoid caffeine, high-fat foods, and refined sugars, little research demonstrates the efficacy of dietary changes. Alternative therapies that have been used include vitamins B and E, magnesium, and oil of evening primrose cap-

sules. No studies have evaluated the effectiveness of these therapies.

Pharmacologic remedies include selective serotonin reuptake inhibitors (eg, fluoxetine [Prozac, Sarafem]), GnRH agonists, prostaglandin inhibitors (eg, ibuprofen and naproxen [Anaprox, Aleve]), diuretics, antianxiety agents, and calcium supplements. Oral contraceptives containing drospirenone (a synthetic progestin) and extended regimens also may be effective (Coffee, Kuehl, Willis, et al., 2006; Lopez, Kaptein & Helmerhorst, 2008).

Chart 46-11 • Causes, Manifestations, and Treatment of Premenstrual Syndrome**Cause**

- Unknown; may be related to hormonal changes combined with other factors (diet, stress, and lack of exercise)
- Many women have some symptoms related to menses, but PMS affects 2% to 5% of women and is a complex of symptoms that result in dysfunction.

Physical Symptoms

- Fluid retention (eg, bloating, breast tenderness)
- Headache

Affective Symptoms

- Depression
- Anger
- Irritability
- Anxiety
- Confusion

- Withdrawal
- Symptoms begin in the 5 days preceding menses and relief occurs within 4 days of onset of menses. Dysfunction usually occurs in relationships, parenting, work, or school.

Treatment

- Use of social support and family resources
- Nutritious diet consisting of whole grains, fruits, and vegetables; increased water intake may help
- Serotonin reuptake inhibitors
- Alprazolam (Xanax) has been effective but risk of physical and psychological dependence is high.
- Spironolactone, a diuretic, may be effective in treating fluid retention.
- Initiation/maintenance of exercise program
- Stress reduction techniques

Nursing Management

The nurse obtains a health history, noting the time when symptoms began and their nature and intensity. The nurse then determines whether symptoms occur before or shortly after the menstrual flow begins. In addition, the nurse can show the patient how to record the timing and intensity of symptoms. A nutritional history is also elicited to determine if the diet is high in salt, caffeine, or alcohol or low in essential nutrients.

The patient's goals may include reduction of anxiety, mood swings, crying, binge eating, fear of losing control, improved coping with day-to-day stressors, improved relationships with family and coworkers, and increased knowledge about PMS. Positive coping measures are promoted. This may involve encouraging the woman's partner to offer support and assistance with child care. The patient can try to plan her working time to accommodate the days she is less productive because of PMS. The nurse encourages the patient to use exercise, meditation, imagery, and creative activities to reduce stress. The nurse also encourages the patient to take medications as prescribed and provides instructions about the desired effects of the medications. Enrolling in a PMS group may help the patient learn to recognize and cope with this condition.

If the patient has severe symptoms of PMS or premenstrual dysphoric disorder, the nurse assesses her for suicidal, uncontrollable, and violent behavior. An immediate psychiatric evaluation is necessary for women with any suggestions of suicidal tendencies. In rare cases, uncontrollable behavior may lead to violence toward family members. If abuse of children or other members of a patient's family is suspected, it is important to implement and follow reporting protocols. Referral for immediate psychiatric or psychological care and counseling is required.

DYSMENORRHEA

Primary dysmenorrhea is painful menstruation, with no identifiable pelvic pathology. It occurs at the time of menarche or shortly thereafter. It is characterized by crampy pain

that begins before or shortly after the onset of menstrual flow and continues for 48 to 72 hours. Pelvic examination findings are normal. Dysmenorrhea is thought to result from excessive production of prostaglandins, which causes painful contraction of the uterus and arteriolar vasospasm. Psychological factors, such as anxiety and tension, may also contribute to dysmenorrhea. As women become older, dysmenorrhea often decreases and frequently completely resolves after childbirth.

In secondary dysmenorrhea, pelvic pathology such as endometriosis, tumor, or pelvic inflammatory disease (PID) contributes to symptoms. Patients frequently have pain that occurs several days before menses, with ovulation, and occasionally with intercourse.

Assessment and Diagnostic Findings

A pelvic examination is performed to rule out possible disorders, such as endometriosis, PID, adenomyosis, and uterine fibroids. A laparoscopy may be required to identify organic causes.

Management

In primary dysmenorrhea, the reason for the discomfort is explained, and the patient is assured that menstruation is a normal function of the reproductive system. If the patient is young and accompanied by her mother, the mother may also need reassurance. Many young women expect to have painful periods if their mothers did. The discomfort of cramps can be treated once anxiety and concern about its cause are dispelled by adequate explanation. Symptoms usually subside with appropriate medication. Aspirin, a mild prostaglandin inhibitor, may be taken at recommended doses every 4 hours. Other useful prostaglandin antagonists include NSAIDs such as ibuprofen, naproxen, and mefenamic acid (Ponstel). If one medication does not provide relief, another may be recommended. Usually these medications are well tolerated, but some women experience gastrointestinal side effects. Contraindications include allergy, peptic ulcer history, sensitivity to aspirinlike medications, asthma, and pregnancy. Low-dose oral contraceptives

provide relief in more than 90% of patients and may be prescribed for women with dysmenorrhea who are sexually active but do not desire pregnancy.

Continuous low-level local heat may also be effective in relieving primary dysmenorrhea. Heat therapy and medication have been found to work well in combination. The patient is encouraged to continue her usual activities and to increase physical exercise if possible because this relieves discomfort for some women. Taking analgesic agents before cramps start, in anticipation of discomfort, is advised.

Management of secondary dysmenorrhea is directed at diagnosis and treatment of the underlying cause (eg, endometriosis or PID).

AMENORRHEA

Amenorrhea (absence of menstrual flow) is a symptom of a variety of disorders and dysfunctions. Primary amenorrhea (delayed menarche) refers to the situation in which young women older than 16 years of age have not begun to menstruate but otherwise show evidence of sexual maturation, or in which young women have not begun to menstruate and have not begun to show development of secondary sex characteristics by 14 years of age. Amenorrhea may be of considerable concern but often occurs as a result of minor variations in body build, heredity, environment, and physical, mental, and emotional development.

The nurse encourages the patient to express her concerns and anxiety about this problem because the patient may feel that she is different from her peers. A complete physical examination, careful health history, and simple laboratory tests help rule out possible causes, such as metabolic or endocrine disorders and systemic diseases. Treatment is directed toward correcting any abnormalities.

Secondary amenorrhea (an absence of menses for three cycles or 6 months after a normal menarche) may be caused by pregnancy, emotional upset, eating disorder, or excessive exercise. In adolescents, secondary amenorrhea can be caused by minor emotional upset related to being away from home, attending college, tension due to schoolwork, or interpersonal problems. However, the second most common cause is pregnancy, so a pregnancy test is almost always indicated.

Secondary nutritional disturbances may also be factors. Obesity can result in anovulation and subsequent amenorrhea. Eating disorders, such as anorexia and bulimia, often result in lack of menses because the decrease in body fat and caloric intake affects hormonal function. Intense exercise can induce menstrual disturbances. Competitive female athletes often experience amenorrhea. If they do, they may be placed on HT to prevent bone loss related to low estrogen levels. On occasion, a pituitary or thyroid dysfunction may cause amenorrhea. These dysfunctions can be treated successfully by treatment of the underlying endocrine disorder. Infrequent periods (oligomenorrhea) may be related to thyroid disorders, polycystic ovarian syndrome, or premature ovarian failure. Women who are HIV positive are apt to miss menstrual periods and need to be evaluated for pregnancy, thyroid disorders, hyperprolactinemia, and menopause (if appropriate) (Cejtin, Kalinowski, Bacchetti, et al., 2006).

ABNORMAL UTERINE BLEEDING

Dysfunctional uterine bleeding is abnormal bleeding that has no known organic cause. The bleeding is defined as irregular, painless bleeding of endometrial origin that may be excessive, prolonged, or without pattern. Dysfunctional uterine bleeding can occur at any age but is most common at opposite ends of the reproductive lifespan. It is usually secondary to anovulation (lack of ovulation) and is common in adolescents and women approaching menopause.

Adolescents account for many cases of abnormal uterine bleeding; they often do not ovulate regularly as the pituitary–ovarian axis matures. Perimenopausal women also experience this condition because of irregular ovulation secondary to decreasing ovarian hormone production. Other causes may include fibroids, obesity, and hypothalamic dysfunction.

Abnormal or unusual vaginal bleeding that is atypical in time or amount must be evaluated because it could possibly be a manifestation of a major disorder. A physical examination is performed, and the patient is evaluated for conditions such as pregnancy, neoplasm, infection, anatomic abnormalities, endocrine disorders, trauma, blood dyscrasias, platelet dysfunction, and hypothalamic disorders.

Menorrhagia

Menorrhagia is prolonged or excessive bleeding at the time of the regular menstrual flow. In young women the cause is usually related to endocrine disturbance, whereas in later life it usually results from inflammatory disturbances, tumors of the uterus, or hormonal imbalance.

Women with menorrhagia are urged to see a primary health care provider and to describe the amount of bleeding by pad count and saturation (ie, absorbency of perineal pad or tampon and number saturated hourly). Persistent heavy bleeding can result in anemia. It can also be a sign of a bleeding disorder or a result of anticoagulant therapy. Hysterectomy can be challenging in these women; endometrial ablation has been found to be less risky (El-Nashar, Hopkins, Feitoza, et al., 2007).

Metrorrhagia

Metrorrhagia (vaginal bleeding between regular menstrual periods) is probably the most significant form of menstrual dysfunction because it may signal cancer, benign tumors of the uterus, or other gynecologic problems. This condition warrants prompt evaluation and treatment. Although bleeding between menstrual periods by women taking oral contraceptives is usually not serious, irregular bleeding by women taking HT should be evaluated.

Menometrorrhagia is heavy vaginal bleeding between and during periods. It, too, requires evaluation.

Postmenopausal Bleeding

Bleeding 1 year after menses cease at menopause must be investigated, and a malignant condition must be considered until proven otherwise. A vaginal ultrasound can be used to measure the thickness of the endometrial lining. The uterine lining in postmenopausal women should be thin because of low estrogen levels. A lining thicker than 5 mm usually warrants evaluation by endometrial biopsy or a D & C.

Dyspareunia

Dyspareunia (difficult or painful intercourse) can be superficial, deep, primary, or secondary and may occur at the beginning of, during, or after intercourse. Dyspareunia may be related to many factors, including injury during childbirth; lack of vaginal lubrication; a history of incest, sexual abuse, or assault; endometriosis; pelvic infection; vaginal atrophy with menopause; gastrointestinal disorders; fibroids; urinary tract infection; STDs; or vulvodynia (vulvar pain that affects women of all ages without any discernible physical cause). Depending on the cause of dyspareunia, counseling, extra lubrication, or antidepressants may be prescribed. Women's health issues related to sexuality may be affected by many factors. Thus, these issues need to be taken seriously, carefully assessed, and treated.

Contraception

Each year, more than half of the pregnancies in the United States are unintended; this is the highest rate among industrialized nations. Although unintended pregnancies occur in women of all ages, incomes, and racial and ethnic groups, the highest rates occur among adolescents and perimenopausal women. Adolescents are more likely to experience pregnancy complications and are more prone to have low-birthweight babies. In addition, adolescent mothers are less likely to obtain a high school diploma and are more likely subsequently to live in poverty. One of two unplanned pregnancies end in abortion (Paru, Boatwright, Tozer, et al., 2006).

Women may fail to use effective methods of contraception consistently or at all. Of the women who undergo abortions, many were not using contraception when they became pregnant, and others have never used any method of contraception. Decreasing unwanted pregnancies may reduce the number of abortions, abused children, stressed families, and infant mortality and morbidity.

Nurses can assist with information and support. Women can be asked directly when they plan to have their next pregnancy and about their need for contraception. Many women who are sexually active or who are considering becoming sexually active can benefit from learning about contraception. Nurses who are involved in helping patients make contraceptive choices need to listen, take time to answer questions, and teach and assist patients in choosing the method they prefer. It is important for women to receive unbiased and nonjudgmental information, understand the benefits and risks of each method, learn about alternatives and how to use them, and receive positive reinforcement and acceptance of their choice. Some women have received misinformation (ie, contraception causes cancer or weight gain). Adolescents who worry that they may be unable to become pregnant may not be willing to use contraception. Factors related to this fear include a history of an STD, an older partner, a partner who desires a pregnancy, and the adolescent's desire for pregnancy (White, Rosengard, Weitzen, et al., 2006).

ABSTINENCE

Abstinence, or celibacy, is the only completely effective means of preventing pregnancy. Abstinence may not be a

desired or available option for many women because of cultural expectations and their own and their partner's values and sexual needs.

STERILIZATION

After abstinence, sterilization by bilateral tubal occlusion or vasectomy is the most effective means of contraception. Both procedures must be considered permanent because neither is easily reversible. Women and men who choose these methods should be certain that they no longer wish to have children, no matter how the circumstances in their life may change. Often, decisions made hastily may be regretted later. Some gynecologists suggest a waiting period to ensure that patients are certain about a potentially irreversible decision.

Tubal Ligation

Sterilization by tubal ligation is one of the most common surgical procedures performed on women. Tubal ligation is usually performed as a same-day surgical procedure and is carried out by laparoscopy or hysteroscopy, with the patient receiving a general or local anesthetic. After the laparoscope is inserted, the fallopian tubes are visualized and may be coagulated, sutured (Pomeroy procedure), or ligated with silicone bands or a spring clip, thereby disrupting their patency. The use of spring clips is associated with the highest rate of pregnancy following sterilization. In another procedure, transcervical tubal occlusion procedure, a 0.6-inch metal coil or spring is inserted into the fallopian tubes through the cervix, thus avoiding the need for laparoscopy or a surgical incision. This method, referred to as the Essure procedure, is performed via hysteroscopy and obstructs the tubes by inducing scar tissue. Women who have had this procedure should abstain from unprotected intercourse for 3 months to avoid pregnancy until the scar tissue develops and the effectiveness of the procedure is verified by HSG.

Despite a very high rate of effectiveness, all women who have undergone tubal ligation but miss a period should be tested for pregnancy because ectopic and intrauterine pregnancies, although rare, may occur. Ovulation and menstruation are not affected by sterilization, although some women report heavier menstrual bleeding and more cramping after tubal ligation.

Before undergoing tubal ligation, the patient should be informed that an IUD, if present, will be removed. If the patient is taking oral contraceptives, she usually continues them up to the time of the procedure. If a laparoscopic procedure is performed, the patient may experience postoperative abdominal or shoulder discomfort for a few days, related to the carbon dioxide gas and the manipulation of organs. The patient is instructed to report heavy bleeding, fever, or pain that persists or increases. She should avoid intercourse, strenuous exercise, and lifting for 2 weeks. Risks associated with tubal ligation are minimal and are more often related to anesthesia than to the surgery itself. Risk is increased in women with diabetes, previous abdominal or pelvic surgery, or obesity.

Vasectomy

Vasectomy (male sterilization) and hysteroscopic/laparoscopic tubal ligation are compared in Table 46-4. See Chapter 49 for a discussion of vasectomy.

Table 46-4 COMPARISON OF STERILIZATION METHODS

Sterilization Method	Advantages	Disadvantages
Vasectomy	<ul style="list-style-type: none"> • Highly effective • Relieves female of contraceptive burden • Inexpensive in long run • Permanent • Highly acceptable procedure to most patients • Very safe • Quickly performed 	<ul style="list-style-type: none"> • Expensive in short term • Serious long-term effects suggested (although currently unproved) • Permanent (although reversal is possible, it is expensive and requires highly technical and major surgery, and results cannot be guaranteed) • Regret in 5%–10% of patients • No protection against STDs, including HIV • Not effective until sperm remaining in reproductive system are ejaculated
Hysteroscopic and laparoscopic tubal sterilization	<ul style="list-style-type: none"> • Low incidence of complications • Short recovery • Leaves small or no scar • Quickly performed 	<ul style="list-style-type: none"> • Permanent • Reversal difficult and expensive • Sterilization procedures technically difficult • Requires surgeon, operating room (aseptic conditions), trained assistants, medications, surgical equipment (Essure [insertion of coil or spring in fallopian tubes] requires hysteroscopy rather than surgery) • Expensive at the time performed • If failure, high probability of ectopic pregnancy • No protection against STDs, including HIV

HORMONAL CONTRACEPTION

Oral contraceptives block ovarian stimulation by preventing the release of FSH from the anterior pituitary gland. In the absence of FSH, a follicle does not ripen, and ovulation does not occur. Progestins (synthetic forms of progesterone) suppress the LH surge, prevent ovulation, and also render the cervical mucus impenetrable to sperm. Hormonal contraceptive agents may be oral, transdermal, vaginal, or injectable. Combined oral contraceptives that contain both estrogens and progestins are currently used by many women to prevent pregnancy.

Benefits and Risks

Benefits of combined hormonal contraceptive use include a reduction in the incidence of benign breast disease; improvement in acne; and reduced risk of uterine and ovarian cancers, anemia, and pelvic infection. In general, prolonged hormonal contraceptive use has resulted in no definite long-term undesirable effects, although there is an increased risk of gallbladder problems (eg, cholestasis). Resumption of normal menses is delayed 2 to 3 months or longer in about 20% of hormonal contraceptive users. Risks include venous thromboembolism, although its incidence has decreased because the estrogen concentrations used today are less than that used in early preparations. Venous thromboembolism is less than half as likely with hormonal contraceptives than with pregnancy. Fetal anomalies do not appear to be an issue, and normal reproductive tract function and fertility resume after hormonal contraceptive use is discontinued. However, most health care providers recommend that women who wish to become pregnant use a barrier contraceptive method for 1 to 2 months after stopping hormonal contraceptives before attempting to become pregnant to permit a normal period for accurate dating of the pregnancy.

A few patients experience adverse reactions when using hormonal contraceptives. These include nausea, depression, headache, leg cramps, and breast soreness. Usually, these symptoms subside after 3 or 4 months. Because such symptoms are sometimes related to sodium and water retention caused by estrogen, a smaller dose of the hormone or a different hormonal combination may alleviate the problem. Many patients experience spotting in the first month of use of hormonal contraceptive or if they use it irregularly, so they need to be reassured and advised to use it as prescribed. Chart 46-12 compares different oral contraceptive regimens, and Chart 46-13 describes the benefits and risks of oral contraceptive use.

Contraindications

Absolute contraindications to hormonal contraceptives include current or past thromboembolic disorder, cerebrovascular disease, or artery disease; migraine headaches with visual auras; known or suspected breast cancer; known or suspected current or past estrogen-dependent neoplasia; pregnancy; current or past benign or malignant liver tumors; liver dysfunction; clotting disorders; congenital hyperlipidemia; and abnormal vaginal bleeding (ACOG, 2006c).

Relative contraindications include hypertension, bile-induced jaundice, acute phase of mononucleosis, and sickle cell disease. Controlled hypertension in otherwise healthy young nonsmokers is generally not a contraindication to use of combination agents but does require a low dose and careful blood pressure monitoring. Women older than 35 years of age who smoke are at risk for cardiac problems and should not use hormonal contraceptives. Occasionally, neuro-ocular complications arise, but a cause-and-effect relationship has not been established. If visual disturbances occur, hormonal contraceptives should be discontinued.

CHART
46-12

PHARMACOLOGY

Comparison of Hormonal Contraceptive Regimens

There are two kinds of hormonal contraceptives: combined (consisting of an estrogen and a progestin) and progestin only.

Combined Preparations (pills, transdermal patches, vaginal rings)

- Monophasic preparations supply the same dose of estrogen and progestin for 21 days.
- Biphasic preparations and triphasic pills vary the amount of hormonal components during the cycle.
- Usually leads to a lighter-than-normal menstrual flow, which results from withdrawal.

Progestin-Only “Mini” Preparations

- Preparations provide less protection against conception than combined preparations.
- About 40% of women taking progestin-only preparations have ovulatory cycles.
- Progestin-only preparations are useful for women who have had estrogen-related side effects (eg, headaches, hypertension, leg pain, chloasma or skin discoloration, weight gain, or nausea) on combination pills.
- Progestin-only preparations are useful for lactating women who need a hormonal contraceptive method.
- Depo-Provera, a progestin-only injection, lasts for 3 months.
- Implanon, a subdermal implant lasts for 3 years.

Chart 46-14 summarizes patient education guidelines that are important for women using combination hormonal contraceptives.

Coexisting medical disorders may make contraception a complex issue. These disorders include chronic hypertension, lipid disorders, diabetes, migraines, fibroids, obesity, lupus, depression, seizures, and HIV infection or AIDS. Contraception needs to be addressed individually in women with these conditions, and clinicians may prescribe injectable hormonal contraceptives (eg, Depo-Provera) or IUDs (ACOG, 2006c).

Methods of Hormonal Contraception

Various hormonal methods of birth control are approved by the U.S. Food and Drug Administration (FDA). Combination methods include the combination of oral contraceptive pills, vaginal ring (NuvaRing), and transdermal patch (Ortho Evra). Progestin-only methods include the progestin-only pills or minipills, progestin-only emergency contraception (Plan B), once-every-3-month injection (Depo-Provera), levonorgestrel-releasing intrauterine system (Mirena), and single-rod subdermal implant (Implanon).

 **NURSING ALERT**

Patients need to be aware that hormonal contraceptives protect them from pregnancy but not from STDs or HIV infection. In addition, sex with multiple partners or sex without a condom may also result in chlamydial and other infections, including HIV infection.

Oral Contraceptives

Many women currently use oral contraceptive preparations of synthetic estrogens and progestins. A variety of formulations are available. Extended regimens of oral hormonal contraceptive agents are an option for women who have heavy or uncomfortable menstrual bleeding or who wish to have fewer periods. With the use of these regimens, women may have an increased occurrence of breakthrough bleeding; the blood may be dark brown rather than red. It may be more difficult to tell if a pregnancy occurs with this method, although pregnancy is unlikely if pills are taken as prescribed. Studies are ongoing to assess the risks of exposure to increased estrogen resulting from this method.

CHART
46-13

PHARMACOLOGY

Benefits and Risks of Combination Hormonal Contraceptives**Benefits**

- Decreased cramps and bleeding
- Regular bleeding cycle
- Decreased incidence of anemia
- Decrease in acne with some formulations
- Protection from uterine and ovarian cancer
- Decreased incidence of ectopic pregnancy
- Protection from benign breast disease
- Decreased incidence of pelvic infection

Risks

- Rare in healthy women
- Bothersome side effects (eg, breakthrough bleeding, breast tenderness)
- Nausea, weight gain, mood changes
- Small increased risk of developing blood clots, stroke, or heart attack, related more to smoking than to oral contraceptive use alone
- Possible increased incidence of benign liver tumors and gallbladder disorders
- No protection from STDs/STIs (possible increased risk with unsafe sex)

CHART
46-14

PATIENT EDUCATION

Using Combination Contraceptives

- Use condoms to protect against sexually transmitted diseases.
- Take pill at exactly the same time every day *or* put the patch on once a week or remove the vaginal ring after 3 weeks.
- Stop smoking or cut down on smoking.
- Report the following symptoms immediately:
 - A —abdominal pains
 - C —chest pains
 - H —headaches
 - E —eye problems (blurred vision or spots)
 - S —severe leg pains

Transdermal Contraceptives

Ortho Evra is a thin, beige, matchbook-size skin patch that releases an estrogen and a progestin continuously. It is changed every week for 3 weeks, and no patch is used during the fourth week, resulting in withdrawal bleeding. The effectiveness of Ortho Evra is comparable to that of oral contraceptives. Its risks are similar to those of oral contraceptives and include an increased risk of blood clots. The patch may be applied to the torso, chest, arms, or thighs; it should not be applied to the breasts. The patch is convenient and more easily remembered than a daily pill but is not as effective for women who weigh more than 198 lb (90 kg). In addition, it may also irritate skin conditions (eg, psoriasis) in some women and results in higher blood estrogen levels than oral contraceptives.

Vaginal Contraceptives

NuvaRing (etonogestrel/ethinyl estradiol vaginal ring) is a combination hormonal contraceptive that releases estrogen and progestin. It is inserted in the vagina for 3 weeks and then removed, resulting in withdrawal bleeding. It is as effective as oral contraceptives and results in lower hormone blood levels than oral contraceptives. NuvaRing is flexible, does not require sizing or fitting, and is effective when placed anywhere in the vagina. Patients are occasionally reluctant to consider vaginal methods of contraception unless discussed openly and as a convenient alternative to other routes of administration. Some women are uncomfortable with this method and may fear that the ring may migrate or be uncomfortable or be noticed by a partner. The nurse can be helpful in dispelling misconceptions. The patient can be informed that while some women notice a slight increase in vaginal discharge, this effective method of contraception has been found to increase the vaginal health-promoting lactobacillus (ACOG, 2006d; Roumen, 2008). NuvaRing is usually more expensive than oral contraceptives.

Injectable Contraceptives

An intramuscular injection of Depo-Provera (a long-acting progestin) every 3 months inhibits ovulation and provides a reliable, private, and convenient contraceptive method. A subcutaneous formulation is also available. It can be used by lactating women and those with hypertension, liver disease, migraine headaches, heart disease, and hemoglobinopathies.

With continued use, women must be prepared for irregular bleeding episodes and spotting decrease, or amenorrhea.

Advantages of Depo-Provera include reduction of menorrhagia, dysmenorrhea, and anemia due to heavy menstrual bleeding. It may reduce the risk of pelvic infection, has been associated with improvement in hematologic status in women with sickle cell disease, and does not interfere with the efficacy of antiseizure agents. It decreases the risk of endometrial cancer, PID, endometriosis, and uterine fibroids.

Possible side effects of Depo-Provera include irregular menstrual bleeding, bloating, headaches, hair loss, decreased sex drive, bone loss, and weight loss or weight gain. The contraceptive does not protect against STDs. Fertility may be delayed when women discontinue this method; therefore, other methods of contraception may be more appropriate for the woman who wishes to conceive within a year of discontinuing contraception. While Depo-Provera is used, bone density is decreased, and this may be a risk factor for future osteoporosis. Severe allergic response is rare but possible following injection (Haider & Darney, 2007).

Depo-Provera is contraindicated in women who are pregnant and those who have abnormal vaginal bleeding of unknown cause, breast or pelvic cancer, or sensitivity to synthetic progestin. The long-term effects on infants of nursing mothers who use Depo-Provera are unknown but are thought to be negligible.

Implants

Implanon is a single-rod subdermal implant that is usually placed inside the upper arm via a small incision. It is effective for 3 years. Implanon may cause irregular bleeding but may improve dysmenorrhea, and it does not affect bone density. This contraceptive can be used by lactating women.

INTRAUTERINE DEVICE

An IUD is a small plastic device, usually T-shaped, that is inserted into the uterine cavity to prevent pregnancy. A string attached to the IUD is visible and palpable at the cervical os. An IUD prevents conception by causing a local inflammatory reaction that is toxic to spermatozoa and blastocysts, thus preventing fertilization. The IUD does not work by causing abortion.

Advantages include effectiveness over a long period of time, few if any systemic effects, and reduction of patient error. This reversible method of birth control is as effective as sterilization and more effective than barrier methods.

Disadvantages include possible excessive bleeding, cramps, and backaches; a slight risk of tubal pregnancy; slight risk of pelvic infection on insertion; displacement of the device; and, rarely, perforation of the cervix and uterus. If a pregnancy occurs with an IUD in place, the device is removed immediately to avoid infection. Spontaneous abortion (miscarriage) may occur on removal. An IUD is not usually used in women who have not had children because a small nulliparous uterus may not tolerate it. Women with multiple partners, women with heavy or crampy periods, or those with a history of ectopic pregnancy or pelvic infection should be encouraged to use other methods of contraception.

Some clinicians test for chlamydia and gonorrhea prior to insertion to prevent PID.

The ParaGard T 380A, an IUD that has been available for 15 years, is effective for at least 10 years. It prevents fertilization by impairing sperm function as copper has an antispermatic effect. The Levonorgestrel Intrauterine System (LNG-IUS; Mirena), another IUD, releases levonorgestrel, a synthetic progestin used in oral contraceptives, and is effective for at least 5 years. It works by impairing sperm function, thickening cervical mucus, and suppressing the endometrium. It has also been used therapeutically to reduce heavy bleeding; it may prevent the need for hysterectomy in some women with heavy vaginal bleeding. LNG-IUS is also helpful in women with menorrhagia, dysmenorrhea, endometriosis, and fibroids (ACOG, 2006d).

MECHANICAL BARRIERS

Diaphragm

The diaphragm is an effective contraceptive device that consists of a round, flexible spring (50 to 90 mm wide) covered with a domelike latex rubber cup. A spermicidal (contraceptive) jelly or cream is used to coat the concave side of the diaphragm before it is inserted deep into the vagina, covering the cervix completely. The spermicide inhibits spermatozoa from entering the cervical canal. The diaphragm is not felt by the user or her partner when properly fitted and inserted. Because women vary in size, the diaphragm must be sized and fitted by an experienced clinician. The woman is instructed in using and caring for the device. A return demonstration ensures that the woman can insert the diaphragm correctly and that it covers the cervix.

Each time the woman uses the diaphragm, she should examine it carefully. By holding it up to a bright light, she should ensure that it has no pinpoint holes, cracks, or tears. She then applies spermicidal jelly or cream and inserts the diaphragm. The diaphragm should remain in place at least 6 hours after coitus (no more than 12 hours). Additional spermicide is necessary if more than 6 hours have passed before intercourse occurs and before each act of repeated intercourse. On removal, the diaphragm should be cleansed thoroughly with mild soap and water, rinsed, and dried before being stored in its original container.

Disadvantages include allergic reactions in those who are sensitive to latex and an increased incidence of urinary tract infections. Toxic shock syndrome has been reported in some diaphragm users but is rare.

NURSING ALERT

The nurse must assess the woman for possible latex allergy because use of latex barrier methods (eg, diaphragm, cervical cap, male condoms) may cause severe allergic reactions, including anaphylaxis, in patients with latex allergy.

Cervical Cap

The cervical cap is much smaller (22 to 35 mm) than the diaphragm and covers only the cervix. If a woman can feel her cervix, she can usually learn to use a cervical cap. The

chief advantage is that the cap may be left in place for 2 days after coitus. Although convenient to use, the cervical cap may cause cervical irritation; therefore, before fitting a cap, most clinicians obtain a Pap smear and repeat the smear after 3 months. The cap is used with a spermicide and does not require additional spermicide for repeated intercourse.

Contraceptive Sponge

The sponge, another barrier method of contraception, is made of soft, disposable polyurethane foam that is moistened with water and inserted into the vagina before intercourse. It contains and releases a spermicide (eg, nonoxynol-9) that is continuously released into the vagina in small amounts through a 24-hour wear time. The sponge is left in place in the vagina for at least 6 hours after intercourse and can be kept in place for up to 24 additional hours without the need to replace it with repeated acts of intercourse during that period of time. The sponge is sold over the counter and does not require a prescription or special fitting by a health care provider. The sponge should not be used by women with allergy to polyurethane. It should not be used during menstruation. Women who have a history of toxic shock syndrome should not use the contraceptive sponge.

Female Condom

The female condom was developed to give control of barrier protection to women—to provide them with protection from STDs and HIV as well as pregnancy. The female condom (Reality) consists of a cylinder of polyurethane enclosed at one end by a closed ring that covers the cervix and at the other end by an open ring that covers the perineum (Fig. 46-7). (New, improved models are currently pending approval by the FDA.) Advantages include some degree of protection from STDs (HPV, herpes simplex virus, and HIV). Disadvantages include the inability to use the female condom with some positions (ie, standing). Women have found that it can be noisy and slippery.

Spermicides

Spermicides are made from nonoxynol-9 or octoxynol and are available over the counter as foams, gels, films, and suppositories and also on condoms. Spermicides do not protect women from HIV or other STDs (Alan Guttmacher Institute, 2008). In fact, nonoxynol-9 has been found to be associated with minute tears in vaginal tissue with frequent use (eg, daily), possibly increasing the possibility of contracting HIV from an infected partner.

Male Condom

The male condom is an impermeable, snug-fitting cover applied to the erect penis before it enters the vaginal canal. The tip of the condom is pinched while being applied to leave space for ejaculate. If no space is left, ejaculation may cause a tear or hole in the condom and reduce its effectiveness. The penis, with the condom held in place, is removed from the vagina while still erect to prevent the ejaculate from leaking. Condoms are now available in large and small sizes.

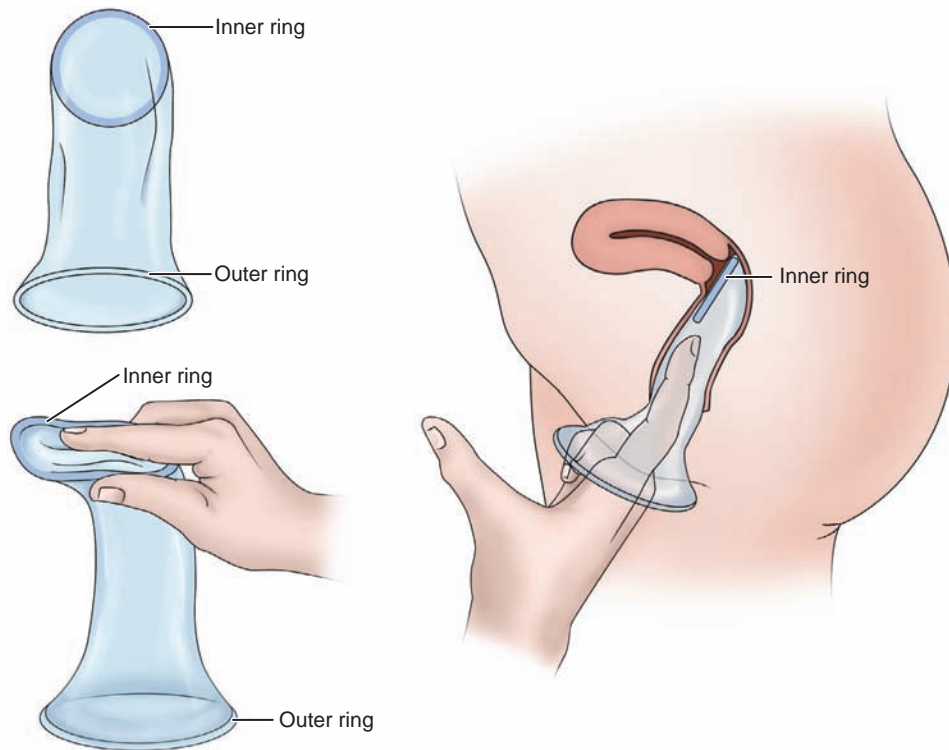

Figure 46-7 Female condom. To insert the female condom, hold the inner ring between the thumb and middle finger. Put the index finger on the pouch between the thumb and other fingers and squeeze the ring. Slide the condom into the vagina as far as it will go. The inner ring keeps the condom in place.

The latex condom also creates a barrier against transmission of STDs (gonorrhea, chlamydial infection, and HIV) by body fluids and may reduce the risk of herpes virus transmission. However, natural condoms (those made from animal tissue) do not protect against HIV infection. Nurses need to reassure women that they have a right to insist that their male partners use condoms and a right to refuse sex without condoms, although women in abusive relationships may increase their risk of abuse by doing so. Some women carry condoms with them to be certain that one is available. Nurses should be familiar and comfortable with instructions about using condoms because many women need to know about this way of protecting themselves from HIV and other STDs. Condoms do not provide complete protection from STDs because HPV may be transmitted by skin-to-skin contact. Other STDs may be transmitted if any abraded skin is exposed to body fluids. This information should be included in patient teaching.

The nurse needs to consider the possibility of latex allergy. Swelling and itching can also occur. Possible warning signs of latex allergy include oral itching after blowing up a balloon or eating kiwis, bananas, pineapples, passion fruit, avocados, or chestnuts. Because many contraceptives are made of latex, patients who experience burning or itching while using latex contraceptives are instructed to see their primary health care provider. Alternatives to latex condoms may include the female condom (Reality) and the male condom (Avanti), made of polyurethane.

COITUS INTERRUPTUS OR WITHDRAWAL

Coitus interruptus (removing the penis from the vagina before ejaculation) requires careful control by the male partner. Although it is a frequently used method of preventing

pregnancy and better than no method, it is considered an unreliable method of contraception.

RHYTHM AND NATURAL METHODS

Natural family planning is any method of conception regulation that is based on awareness of signs and symptoms of fertility during a menstrual cycle. The advantages of natural contraceptive methods include: (1) they are not hazardous to health, (2) they are inexpensive, and (3) they are approved by some religions that do not approve of other methods of contraception. The disadvantage is that they require discipline by the couple, who must monitor the menstrual cycle and abstain from sex during the fertile phase.

Current methods include the calendar method, the basal body temperature method, the ovulation method, and the symptothermal method. The calendar and basal body temperature methods are older than the ovulation method and the symptothermal method. Combinations of these methods are often used (Fehring, Schneider, Raviele, et al., 2007). The fertile phase (in which sexual abstinence is required) is estimated to occur about 14 days before menstruation, although it may occur between the 10th and 17th days. Spermatozoa can fertilize an ovum up to 72 hours after intercourse, and the ovum can be fertilized for 24 hours after leaving the ovary. The pregnancy rate with the rhythm (ie, calendar) method is about 40% yearly.

Women who carefully determine their “safe period,” based on a precise recording of menstrual dates for at least 1 year, and who follow a carefully worked-out formula may achieve very effective protection. A long abstinence period during each cycle is required. These prerequisites require more time and control than many couples have. Changes in

cervical mucus and basal body temperature due to hormonal changes related to ovulation form the scientific basis for the symptothermal method of ovulatory timing. Courses in natural family planning are offered at many Catholic hospitals and some family planning clinics.

Ovulation detection methods (eg, Clearblue Easy Fertility Monitor) are available in most pharmacies. The presence of the enzyme guaiacol peroxidase in cervical mucus signals ovulation 6 days beforehand and also affects mucosal viscosity. Over-the-counter test kits are easy to use and reliable but can be expensive. Ovulation prediction kits are more effective for planning conception than for avoiding it. But if they are used in combination with cervical mucus changes and the calendar method, they may be effective; further research is needed (Fehring, et al., 2007).

Douching is not a contraceptive method and may enhance rather than decrease the chances of conception.

EMERGENCY CONTRACEPTION

The need for emergency contraception may arise after an episode of unprotected sexual intercourse. Therefore, nurses need to be aware of emergency contraception as an option for women and the indications for its use. It is clearly not suitable for long-term avoidance of pregnancy because it is not as effective as oral contraceptives or other reliable methods used regularly. However, it is valuable following intercourse when a pregnancy is not intended and in emergency situations such as rape, a defective or torn condom or diaphragm, or other situations that may result in unwanted conception. Women need to be made aware of emergency contraception and how to obtain it.

Methods of Emergency Contraception

Hormonal Methods

A properly timed, adequate dose of estrogen and a progestin or progestin-only medication after intercourse without effective contraception, or when a method has failed, can prevent pregnancy by inhibiting or delaying ovulation. This method does not interrupt an established pregnancy and does not cause an abortion.

Generally, emergency contraception is currently available only with prescription and is not available over the counter. Emergency contraceptives may be dispensed by pharmacists without a prescription in some states. The sooner emergency contraception is taken, the more effective it is. It is considered safe and effective by the FDA and can be prescribed or purchased as Plan B (progestin only) packages of emergency contraception with patient literature. It can also be prescribed as a specific number of contraceptive pills, depending on the medication and dose used.

This method must be used not more than 5 days following intercourse. Nausea, a common side effect, can be minimized by taking the medication with meals and with an antiemetic agent. Other side effects, such as breast soreness and irregular bleeding, may occur but are transient. Patients who use this method should be advised of the potential failure rate and also counseled about other contraceptive methods. There are no known contraindications to the use of this method, except an established pregnancy (Allen & Goldberg, 2007).

The nurse reviews with the patient instructions for emergency contraception based on the medication regimen prescribed. If the woman is breastfeeding, a progestin-only formulation is prescribed. To avoid exposing infants to synthetic hormones through breast milk, the patient can manually express milk and bottle feed for 24 hours after treatment. The patient should be informed that her next menstrual period may begin a few days earlier or a few days later than expected. She is instructed to return for a pregnancy test if she has not had a menstrual period in 3 weeks and should be offered another visit to provide a regular method of contraception if she does not have one currently.

Postcoital Intrauterine Device Insertion

Postcoital IUD insertion, another form of emergency contraception, involves insertion of a copper-bearing IUD within 5 days of coitus in women who want this method of contraception; however, it may be inappropriate for some women or if contraindications exist. The mechanism of action is unknown, but it is thought that the IUD interferes with fertilization (Allen & Goldberg, 2007). The patient may experience discomfort on insertion and may have heavier menstrual periods and increased cramping. Contraindications include a confirmed or suspected pregnancy or any contraindication to regular copper IUD use. The patient must be informed that there is a risk that insertion of an IUD may disrupt a pregnancy that is already present.

Nursing Management

Patients who use emergency contraception may be anxious, embarrassed, and lacking information about birth control. The nurse must be supportive and nonjudgmental and provide facts and appropriate patient teaching. If the patient repeatedly uses this method of birth control, she should be informed that the failure rate with this method is higher than with a regularly used method. A toll-free telephone information service (1-888-NOT-2-LATE) operates 24 hours a day in English and Spanish and provides information and referrals to health care providers. Nurses can educate and inform women about emergency contraception options to reduce unwanted pregnancies and abortions. See the list of resources at the end of this chapter for more information.

Abortion

Interruption of pregnancy or expulsion of the product of conception before the fetus is viable is called abortion. The fetus is generally considered to be viable any time after the 5th to 6th month of gestation.

SPONTANEOUS ABORTION

It is estimated that 1 of every 5 to 10 conceptions ends in spontaneous abortion. Most of these occur because an abnormality in the fetus makes survival impossible. Other causes may include systemic diseases, hormonal imbalance, or anatomic abnormalities. If a pregnant woman experiences bleeding and cramping, a threatened abortion is diagnosed because an actual abortion is usually imminent.

Spontaneous abortion occurs most commonly in the 2nd or 3rd month of gestation.

There are various types of spontaneous abortion, depending on the nature of the process (threatened, inevitable, incomplete, or complete). In a threatened abortion, the cervix does not dilate. With bed rest and conservative treatment, the abortion may be prevented. If not, an abortion is imminent. If only some of the tissue is passed, the abortion is referred to as incomplete. An emptying or evacuation procedure (D & C, or dilation and evacuation [D & E]) or administration of oral misoprostol (Cytotec) is usually required to remove the remaining tissue. If the fetus and all related tissue are spontaneously evacuated, the abortion is termed complete, and no further treatment is required.

Habitual Abortion

Habitual or recurrent abortion is defined as successive, repeated, spontaneous abortions of unknown cause. As many as 60% of abortions may result from chromosomal anomalies. After two consecutive abortions, the patient is referred for genetic counseling and testing and other possible causes are explored.

If bleeding occurs in a pregnant woman with a past history of habitual abortion, conservative measures, such as bed rest and administration of progesterone to support the endometrium, are attempted to save the pregnancy. Supportive counseling is crucial in this stressful condition. Bed rest, sexual abstinence, a light diet, and no straining on defecation may be recommended in an effort to prevent spontaneous abortion. If infection is suspected, antibiotics may be prescribed.

In the condition known as incompetent or dysfunctional cervix, the cervix dilates painlessly in the second trimester of pregnancy, often resulting in a spontaneous abortion. In such cases, a surgical procedure called cervical cerclage may be used to prevent the cervix from dilating prematurely, although its effectiveness is unclear. It involves placing a purse-string suture around the cervix at the level of the internal os. Bed rest is usually advised to keep the weight of the uterus off the cervix. About 2 to 3 weeks before term or at the onset of labor, the suture is cut. Delivery is usually by cesarean section.

Medical Management

After a spontaneous abortion, all tissue passed vaginally is saved for examination if possible. The patient and all personnel who care for her are alerted to save any discharged material. In the rare case of heavy bleeding, the patient may require blood component transfusions and fluid replacement. An estimate of the bleeding volume can be determined by recording the number of perineal pads and the degree of saturation over 24 hours. When an incomplete abortion occurs, oxytocin may be prescribed to cause uterine contractions before D & E or uterine suctioning.

Nursing Management

Because patients experience loss and anxiety, emotional support and understanding are important aspects of nursing care. Women may be grieving or relieved, depending on their feelings about the pregnancy. Providing opportunities for the patient to talk and express her emotions is helpful

and also provides clues for the nurse in planning more specific care.

ELECTIVE ABORTION

A voluntary induced termination of pregnancy is called an elective abortion and is usually performed by skilled health care providers. In 1973, the U.S. Supreme Court in *Roe v. Wade* ruled that decisions about abortion reside with a woman and her physician in the first trimester. During the second trimester, the state may regulate practice in the interest of a woman's health, and during the final weeks of pregnancy may choose to protect the life of the fetus, except when necessary to preserve the life or health of the woman.

The U.S. rate of abortion is among the highest in the industrialized Western world. These numbers indicate the need for effective contraceptive education, information about emergency contraception, and counseling.

Medical Management

Before the abortion procedure is performed (Chart 46-15), a nurse or counselor trained in pregnancy counseling should talk with the patient and explore her fears, feelings, and options. The nurse then identifies the patient's choice (ie, continuing pregnancy and parenthood; continuing pregnancy followed by adoption; or terminating pregnancy by abortion). If abortion is chosen, the patient has a pelvic examination to determine uterine size. A pelvic ultrasound may also be performed. Laboratory studies before an abortion must include a pregnancy test to confirm the pregnancy, hematocrit to rule out anemia, and Rh determination. Patients with anemia may need an iron supplement, and patients who are Rh-negative may require RhoGAM to prevent isoimmunization. Before the procedure, all patients should be screened for STDs to prevent introducing pathogens upward through the cervix during the procedure.

NURSING ALERT

Women who have resorted to unskilled attempts to end a pregnancy are often critically ill because of infection, hemorrhage, or uterine rupture. If a woman has undergone such efforts to end a pregnancy, prompt medical attention, broad-spectrum antibiotics, and replacement of fluids and blood components may be required before careful attempts are made to evacuate the uterus.

Surgical terminations include D & C or vacuum aspiration of uterine contents. Medications can also be used. Mifepristone (RU-486, Mifeprex) is used only in early pregnancy (up to 49 days from the last menstrual period). It works by blocking progesterone. Cramping and bleeding similar to a heavy menstrual period occur. After counseling and consent and often a sonogram to confirm the pregnancy, mifepristone is administered. This is followed by a dose of misoprostol orally or vaginally. If the pregnancy persists, a suction aspiration is performed. Contraindications include ectopic pregnancy, adrenal failure, allergy to the medications, bleeding disorder, irritable bowel syndrome, or uncontrolled seizure disorders. Several deaths from sepsis have occurred following medical abortion; researchers and the FDA

Chart 46-15 • Types of Elective Abortions**Vacuum Aspiration**

- The cervix is dilated manually with instrumentation or by laminaria (small suppositories made of seaweed that swells as it absorbs water).
 - A uterine aspirator is introduced.
 - Suction is applied, and tissue is removed from the uterus.
- This is the most common type of termination procedure and is used early in pregnancy, up to 14 weeks. Laminaria may be used to soften and dilate the cervix prior to the procedure.

Dilation and Evacuation

Cervical dilation with laminaria followed by vacuum aspiration

Labor Induction

These procedures account for less than 1% of all terminations and generally take place in an inpatient setting.

1. Installation of saline or urea results in uterine contractions.
 - Although rare, serious complications can occur, including cardiovascular collapse, cerebral edema, pulmonary edema, renal failure, and disseminated intravascular coagulopathy (DIC).
2. Prostaglandins
 - Prostaglandins are introduced into the amniotic fluid or by vaginal suppository or intramuscular injection in later pregnancy.
 - Strong uterine contractions begin within 4 hours and usually result in abortion.
 - Gastrointestinal side effects (eg, nausea, vomiting, diarrhea, and abdominal cramping) and fever can occur.
3. Intravenous oxytocin

Used for later abortions for genetic indications. Requires patient to go through labor.

Medical Abortion**Mifepristone**

- Mifepristone (formerly known as RU-486) is a progesterone antagonist that prevents implantation of the ovum.
- Administered orally within 10 days of an expected menstrual period, mifepristone produces a medical abortion in most patients.
- Combined with a prostaglandin suppository, mifepristone causes abortion in up to 95% of patients.
- Prolonged bleeding may occur. Other side effects may include abdominal pain, nausea, vomiting, and diarrhea. This method may not be used in women with adrenal failure, porphyria, or a history of allergy to mifepristone or other prostaglandins. It is less effective when used in pregnancies more than 49 days from the beginning of the last menstrual period.

Methotrexate

- Methotrexate has also been used to terminate pregnancy because it is a teratogen that is lethal to the fetus. It has been found to have minimal risk and few side effects in the woman. Its low cost may provide an alternative for some women.

Misoprostol

- Misoprostol is a synthetic prostaglandin analog that produces cervical effacement and uterine contractions.
- Inserted vaginally, misoprostol is effective in terminating a pregnancy in about 75% of cases.
- When combined with methotrexate or mifepristone, misoprostol's effectiveness rate is high.

are closely monitoring the morbidity and mortality associated with medical abortion. Currently, there is no evidence that a previous medical or surgical abortion increases the risk of adverse future pregnancy outcomes (Virk, Zhang & Olsen, 2007).

Nursing Management

Patient teaching is an important aspect of care for women who elect to terminate a pregnancy. A patient undergoing elective abortion is informed about what the procedure entails and the expected course after the procedure. The patient is scheduled for a follow-up appointment 2 weeks after the procedure and is instructed about signs and symptoms (ie, fever, heavy bleeding, or pain) that should be reported.

Available contraceptive methods are reviewed with the patient at this time. Effectiveness depends on the method used and the extent to which the woman and her partner follow the instructions for use. A woman who has used any method of birth control should be assessed for her understanding of the method and its potential side effects as well as her satisfaction with the method. If the woman has not been using contraception, the nurse explains all methods and their benefits and risks and helps the patient make a contraceptive choice for use after abortion. Related teaching issues, such as the need to use barrier contraceptive de-

vices (ie, condoms) for protection against transmission of STDs and HIV infection and the availability of emergency contraception, are becoming increasingly important.

Psychological support is another important aspect of nursing care. The nurse needs to be aware that women terminate pregnancies for many reasons. Some women terminate pregnancies because of severe genetic defects. Women who have been raped or impregnated in incestuous relationships or by an abusive partner may elect to terminate their pregnancies. The care of a woman undergoing termination of pregnancy is stressful, and assistance needs to be provided in a safe and nonjudgmental way. Nurses have the right to refuse to participate in a procedure that is against their religious beliefs but are professionally obligated not to impose their beliefs or judgments on their patients.

Infertility

Infertility is defined as a couple's inability to achieve pregnancy after 1 year of unprotected intercourse. Primary infertility refers to a couple who has never had a child. Secondary infertility means that at least one conception has occurred, but currently the couple cannot achieve a pregnancy. In the United States, infertility affects 6 million couples. It is often

a complex physical problem, and its causes are usually related to azoospermia, anovulation, or tubal obstruction.

Pathophysiology

Ovarian and Ovulation Factors

Diagnostic studies performed to determine if ovulation is regular and whether the progesterone level and an ovulation index. The ovulation index involves a urine-stick test to determine whether the surge in LH that precedes follicular rupture has occurred. Ovulatory dysfunction is complex, but many women with ovulation disorders have polycystic ovary syndrome, described in Chapter 47, and may be treated with clomiphene (Clomid) to induce ovulation or insulin sensitizing agents. Once insulin levels are normalized, ovulation often occurs. Some women have high prolactin levels, which inhibit ovulation, and they are treated with dopaminergic drugs after a pituitary adenoma is ruled out by MRI. If a woman has premature ovarian failure, oocyte donation may be considered.

Tubal and Uterine Factors

HSG is used to rule out uterine or tubal abnormalities. A contrast agent injected into the uterus through the cervix produces an outline of the shape of the uterine cavity and the patency of the tubes. This process sometimes removes mucus or tissue that is lodged in the tubes. Laparoscopy permits direct visualization of the tubes and other pelvic structures and can assist in identifying conditions that may interfere with fertility (eg, endometriosis).

Fibroids, polyps, and congenital malformations are possible causative factors affecting the uterus. Their presence may be determined by pelvic examination, hysteroscopy, saline

sonogram (a variation of a sonogram), and HSG. Endometriosis, even if mild, is associated with reduced fertility.

Male Factors

An analysis of semen provides information about the number of sperm (density), percentage of moving forms, quality of forward movement (forward progression), and morphology (shape and form). From 2 to 6 mL of watery alkaline semen is normal. A normal count has 60 to 100 million sperm/mL. However, the incidence of impregnation is lessened only when the count decreases to less than 20 million sperm/mL.

Men may also be affected by varicoceles, varicose veins around the testicle, which decrease semen quality by increasing testicular temperature. Retrograde ejaculation or ejaculation into the bladder is assessed by urinalysis after ejaculation. Blood tests for male partners may include measuring testosterone; FSH and LH (both of which are involved in maintaining testicular function); and prolactin levels.

Medical Management

The treatment of infertility is complex and often requires advanced technology. The specific type of treatment depends on the cause of the problem, if it can be identified. Many infertile couples have normal test results for ovulation, sperm production, and fallopian tube patency.

Pharmacologic Therapy

Pharmacologically induced ovulation is undertaken when women do not ovulate on their own or ovulate irregularly. Women older than 37 years are less likely to be fertile. These couples are often treated with clomiphene to stimulate ovulation. Gonadotropin treatment may also be used if conception does not occur. Various other medications are used, depending on the primary cause of infertility (Chart 46-16).

CHART
46-16

PHARMACOLOGY

Medications That Induce Ovulation

- Clomiphene citrate (Clomid, Serophene) is an estrogen antagonist that increases gonadotropin release, resulting in follicular rupture or ovulation. Clomiphene is used when the hypothalamus is not stimulating the pituitary gland to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This medication stimulates follicles in the ovary. It is usually taken for 5 days beginning on the 5th day of the menstrual cycle. Ovulation should occur 4 to 8 days after the last dose. Patients receive instructions about timing intercourse to facilitate fertilization.
- Menotropins (Repronex, Pergonal), a combination of FSH and LH, may be used to stimulate the ovaries to produce eggs. These agents are used for women with deficiencies in FSH and LH. When followed by administration of human chorionic gonadotropin, menotropins stimulates the ovaries, so monitoring by ultrasound and hormone levels is essential because overstimulation may occur.
- Follitropin-alpha (Gonal-F), follitropin-beta (Follistim), and urofollitropin (Bravelle) may be used to treat ovulation disorders or to stimulate a follicle and egg production for intrauterine insemination or in vitro fertilization or other assisted reproductive technologies.
- Gonadotropin-releasing hormone agonists (leuprolide [Lupron, Synarel]) suppress FSH, prevent premature egg release, and shrink fibroids.
- Bromocriptine (Parlodel) may be used in treatment of infertility due to elevated prolactin levels.
- Progesterone (Prometrium Crinone, progesterone in oil) vaginal suppositories help improve the uterine lining after ovulation.
- Urofollitropin (Metrodin, Bravelle), which contains FSH with a small amount of LH, is used in some disorders (eg, polycystic ovarian syndrome) to stimulate follicle growth. Clomiphene is then used to stimulate ovulation.
- Chorionic gonadotropin (Ovidrel, Novarel, Pregnyl), which mimics LH, releases an egg after hyperstimulation and supports the corpus luteum.
- Metformin (Glucophage, Fortamet) may be used in polycystic ovarian syndrome to induce regular ovulation.
- Aspirin and heparin may be used to prevent recurrent pregnancy loss in patients with elevated antiphospholipid antibodies.

Blood tests and ultrasounds are used to monitor ovulation. Multiple pregnancies (ie, twins, triplets or more) may occur with use of these medications. Ovarian hyperstimulation syndrome (OHSS) may also occur. This condition is characterized by enlarged multicystic ovaries and is complicated by a shift of fluid from the intravascular space into the abdominal cavity. The fluid shift can result in ascites, pleural effusion, and edema; hypovolemia may also occur. Risk factors include younger age, history of polycystic ovarian syndrome, high serum estradiol levels, a larger number of follicles, and pregnancy.

Artificial Insemination

Artificial insemination is the deposit of semen into the female genital tract by artificial means. If the sperm cannot penetrate the cervical canal normally, artificial insemination using a partner's or husband's semen or that of a donor may be considered. When the sperm of the woman's partner is defective or absent (azoospermia) or when there is a risk of transmitting a genetic disease, donor sperm may be used. Safeguards are put in place to address legal, ethical, emotional, and religious issues. Written consent is obtained to protect all parties involved, including the woman, the donor, and the resulting child. The donor's semen is frozen, and the donor is evaluated to ensure that he is free of genetic disorders and STDs, including HIV infection.

Certain conditions must be met before semen is transferred to the vagina or uterus. The woman must have no abnormalities of the genital system, the fallopian tubes must be patent, and ova must be available. In the male, sperm need to be normal in shape, amount, motility, and endurance. The time of ovulation should be determined as accurately as possible so that the 2 or 3 days during which fertilization is possible each month can be targeted for treatment.

Ultrasonography and blood studies of varying hormone levels are used to pinpoint the best time for insemination and to monitor for OHSS. Fertilization seldom occurs from a single insemination. Usually, insemination is attempted between days 10 and 17 of the cycle; three different attempts may be made during one cycle. The woman may have received clomiphene or other medications to stimulate ovulation before insemination. The recipient is placed in the lithotomy position on the examination table, a speculum is inserted, and the vagina and cervix are swabbed with a cotton-tipped applicator to remove any excess secretions. The sperm are washed before insertion to remove biochemicals and to select the most active sperm. Semen is drawn into a sterile syringe, and a cannula is attached. The semen is then directed to the external os. In IUI, semen is placed into the uterine cavity.

In Vitro Fertilization

In vitro fertilization (IVF) involves ovarian stimulation, egg retrieval, fertilization, and embryo transfer. This procedure is accomplished by first stimulating the ovary to produce multiple eggs or ova, usually with medications, because success rates are greater with more than one embryo. Many different protocols exist for inducing ovulation with one or more agents. Patients are carefully selected and evaluated, and cycles are carefully monitored using ultrasound and monitoring hormone levels. At the appropriate time, the

ova are recovered by transvaginal ultrasound retrieval. Sperm and eggs are coincubated for up to 36 hours, and the embryos are transferred about 48 hours after retrieval. Implantation should occur in 3 to 5 days.

Gamete intrafallopian transfer (GIFT), a variation of IVF, is the treatment of choice for patients with ovarian failure. GIFT is considered in unexplained infertility and when there is religion-based discomfort with IVF. The most common indications for IVF and GIFT are irreparable tubal damage, endometriosis, unexplained infertility, inadequate sperm, and exposure to DES. Success rates for GIFT vary from 20% to 30%.

Other Assisted Reproductive Technologies

In intracytoplasmic sperm injection (ICSI), an ovum is retrieved as described previously, and a single sperm is injected through the zona pellucida, through the egg membrane, and into the cytoplasm of the oocyte. The fertilized egg is then transferred back to the donor. ICSI is the treatment of choice in severe male factor infertility.

Women who cannot produce their own eggs (ie, premature ovarian failure) have the option of using the eggs of a donor after stimulation of the donor's ovaries. The recipient also receives hormones in preparation for these procedures. Couples may also choose this modality if the female partner has a genetic disorder that may be passed on to children.

Nursing Management

Nursing interventions that are appropriate when working with couples during infertility evaluations include assisting in reducing stress in the relationship, encouraging cooperation, protecting privacy, fostering understanding, and referring the couple to appropriate resources when necessary. Because infertility evaluations and treatments are expensive, time-consuming, invasive, stressful, and not always successful, couples need support in working together to deal with this process.

Resolve, Inc., a nonprofit self-help group that provides information and support for infertile patients, was founded by a nurse who experienced difficulty conceiving. The literature on infertility that is produced by this group is an important resource for patients and professionals. Most areas of the country have local support groups. More information can be obtained by visiting the Resolve Web site or contacting Resolve, Inc.

Smoking is strongly discouraged because it has an adverse effect on the success of assisted reproduction. Diet, exercise, stress reduction techniques, folic acid supplementation, health maintenance, and disease prevention are emphasized in many infertility programs. Couples may also consider adoption, child-free living, and gestational carriers (use of surrogate to carry the fetus for the infertile couple). Nurses can be helpful listeners and information resources in these deliberations.

Preconception/Periconception Health Care

Nurses can be instrumental in encouraging all women of childbearing age, including those with chronic illness or disabilities, to consider issues that may affect health during pregnancy (Smeltzer, 2007; Smeltzer & Wetzel-Effinger,

2009). Women who plan their pregnancies and are healthy and well informed tend to have better outcomes. This is an important issue because half of all pregnancies in the United States are unplanned.

Nurses can make a difference through education and counseling; preconception counseling can decrease the incidence of birth defects. Women who smoke should be encouraged to stop smoking, and it may help to offer smoking cessation classes. Women should take folic acid supplements to prevent neural tube defects. Women with diabetes should have good glycemic control prior to conception. It is necessary to assess rubella immunity and other immunizations as well as a family history of genetic defects; genetic counseling may be appropriate. Women taking teratogenic medications and women concerned about genetic disorders should be encouraged to discuss effective contraception and childbearing plans with their health care provider (see Chart 46-2).

Ectopic Pregnancy

The incidence of ectopic pregnancy and the risk of death due to ectopic pregnancy are decreasing. However, ectopic pregnancy remains the leading cause of pregnancy-related death in the first trimester. Ectopic pregnancy occurs when a fertilized ovum (a blastocyst) becomes implanted on any tissue other than the uterine lining (eg, the fallopian tube, ovary, abdomen, cervix or scar tissue from previous caesarean section). The most common site of ectopic implantation is the fallopian tube (Fig. 46-8).

Possible causes of ectopic pregnancy include salpingitis, peritubal adhesions (after pelvic infection, endometriosis, appendicitis), structural abnormalities of the fallopian tube (rare and usually related to DES exposure), previous ectopic pregnancy, previous tubal surgery, multiple previous induced abortions (particularly if followed by infection), tumors that distort the tube, and IUD and progestin-only contraceptives. PID appears to be the major risk factor. Improved antibiotic therapy for PID usually prevents total tubal closure but may leave a stricture or narrowing, predisposing to ectopic implantation. The odds of recurrent

ectopic pregnancy are three times higher if an infectious pathology caused the first ectopic pregnancy. After a second ectopic pregnancy occurs, assisted reproduction is considered.

Risk factors are important, but all women need to be educated about early treatment and have a high index of suspicion in the case of a period that does not seem normal, the presence of pain, or pain with a suspected pregnancy. Women may have fatal hemorrhage with ruptured ectopic pregnancies if they delay seeking attention or if their health care providers are not alert to the possibility of this diagnosis.

Clinical Manifestations

Signs and symptoms vary depending on whether tubal rupture has occurred. Delay in menstruation from 1 to 2 weeks followed by slight bleeding (spotting) or a report of a slightly abnormal period suggests the possibility of an ectopic pregnancy. Symptoms may begin late, with vague soreness on the affected side (probably due to uterine contractions and distention of the tube), and may proceed to sharp, colicky pain. Most patients experience some pelvic or abdominal pain and some spotting or bleeding. Gastrointestinal symptoms, dizziness, or lightheadedness may occur. Patients may think the abnormal bleeding is a menstrual period, especially if a recent period occurred and was normal.

If implantation occurs in the fallopian tube, the tube becomes more and more distended and can rupture if the ectopic pregnancy remains undetected for 4 to 6 weeks or longer after conception. When the tube ruptures, the ovum is discharged into the abdominal cavity, and the woman experiences agonizing pain, dizziness, faintness, and nausea and vomiting due to the peritoneal reaction to blood escaping from the tube. Air hunger and symptoms of shock may occur, and the signs of hemorrhage—rapid and thready pulse, decreased blood pressure, subnormal temperature, restlessness, pallor, and sweating—are evident. Later, the pain becomes generalized in the abdomen and radiates to the shoulder and neck because of accumulating intraperitoneal blood that irritates the diaphragm.

Assessment and Diagnostic Findings

Ectopic pregnancies must be diagnosed promptly to prevent life-threatening hemorrhage, the major complication of rupture. During vaginal examination, a large mass of clotted blood that has collected in the pelvis behind the uterus or a tender adnexal mass may be palpable, although there are often no abnormal findings. If an ectopic pregnancy is suspected, the patient is evaluated by sonography and human chorionic gonadotropin (hCG) levels. If the ultrasound results are inconclusive, the hCG test is repeated. The levels of hCG (the diagnostic hormone of pregnancy) double in early normal pregnancies every 3 days but are reduced in abnormal or ectopic pregnancies. A less-than-normal increase is cause for suspicion. Serum progesterone levels are also measured. Levels less than 5 ng/mL are considered abnormal; levels greater than 25 ng/mL are associated with a normally developing pregnancy.

Ultrasound, the usual method of diagnosis, can detect a pregnancy between 5 and 6 weeks from the time of the last menstrual period. Detectable fetal heart movement outside

Figure 46-8 Sites of ectopic pregnancy.

the uterus on ultrasound is firm evidence of an ectopic pregnancy. On occasion, an ultrasound study is not definitive and the diagnosis must be made with combined diagnostic aids (beta-hCG and progesterone levels, ultrasound, pelvic examination, and clinical judgment).

Occasionally, the clinical picture makes the diagnosis relatively easy. However, when the clinical signs and symptoms are inconclusive, which is often the case, other procedures may be needed. Laparoscopy can be used because the physician can visually detect an unruptured tubal pregnancy and thereby circumvent the risk of its rupture.

Medical Management

Surgical Management

When surgery is performed early, almost all patients recover rapidly; if tubal rupture occurs, mortality increases. The type of surgery is determined by the size and extent of local tubal damage. Conservative surgery includes “milking” an ectopic pregnancy from the tube. Resection of the involved fallopian tube with end-to-end anastomosis may be effective. Some surgeons attempt to salvage the tube with a salpingotomy, which involves opening and evacuating the tube and controlling bleeding. More extensive surgery includes removing the tube alone (salpingectomy) or with the ovary (salpingo-oophorectomy). Depending on the amount of blood lost, blood component therapy and treatment of hemorrhagic shock may be necessary before and during surgery. Surgery may also be indicated in women unlikely to comply with close monitoring or those who live too far away from a health care facility to obtain the monitoring needed with nonsurgical management.

Methotrexate (Trexall), a chemotherapeutic agent and folic acid antagonist, may be used after surgery to treat any remaining embryonic or early pregnancy tissue, as indicated by a persistent or increasing beta-hCG level. The beta-hCG test is repeated 2 weeks after surgery to ensure that the level is decreasing.

Pharmacologic Therapy

Another option is the use of methotrexate without surgery. Because methotrexate stops the pregnancy from progressing by interfering with DNA synthesis and the multiplication of cells, it interrupts early, small, unruptured ectopic pregnancies. The patient must be hemodynamically stable, have no active renal or hepatic disease, have no evidence of thrombocytopenia or leukopenia, and have a very small, unruptured ectopic pregnancy on ultrasound. Other indications may include no fetal cardiac activity, no active bleeding, and a beta-hCG level of less than 2000 mIU/mL. The medication is administered intramuscularly or orally. Some patients may be treated with intratubal injection of methotrexate. Complete blood count and tests of liver and renal function are conducted to monitor the patient; blood typing is performed in anticipation of the need for transfusions.

Until the pregnancy is resolved, the patient is advised to refrain from alcohol, intercourse, and vitamins containing folic acid, because these may exacerbate the adverse effects of

methotrexate. Abdominal pain may occur within 5 to 10 days and may indicate termination of the pregnancy. This requires careful assessment by the health care provider. Serum levels of beta-hCG are monitored carefully, and these levels should gradually decrease. Ultrasound may also be used for monitoring. Side effects of methotrexate include abdominal cramping, mucositis, and renal and hepatic damage. Allergic reactions have occurred in patients receiving high doses.

NURSING PROCESS

THE PATIENT WITH AN ECTOPIC PREGNANCY

Assessment

The health history includes the menstrual pattern and any (even slight) bleeding since the last menstrual period. The nurse elicits the patient’s description of pain and its location. The nurse asks the patient whether any sharp, colicky pains have occurred. Then the nurse notes whether pain radiates to the shoulder and neck (possibly caused by rupture and pressure on the diaphragm).

In addition, the nurse monitors vital signs, level of consciousness, and the nature and amount of vaginal bleeding. If possible, the nurse assesses how the patient is coping with the abnormal pregnancy and likely loss.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain related to the progression of the tubal pregnancy
- Anticipatory grieving related to the loss of pregnancy and effect on future pregnancies
- Deficient knowledge related to the treatment and effect on future pregnancies

Collaborative Problems/Potential Complications

Based on the assessment data, major complications may include the following:

- Hemorrhage
- Hemorrhagic shock

Planning and Goals

The major goals may include relief of pain; acceptance and resolution of grief and pregnancy loss; increased knowledge about ectopic pregnancy, its treatment, and its outcome; and absence of complications.

Nursing Interventions

Relieving Pain

The abdominal pain associated with ectopic pregnancy may be described as cramping or severe continuous pain. If the patient is to have surgery, preanesthetic medications may provide pain relief. Postoperatively, analgesic agents are administered liberally; this promotes early ambulation and enables the patient to cough and take deep breaths.

Supporting the Grieving Process

Patients' distress levels vary. If the pregnancy was desired, loss may or may not be expressed verbally by the patient and her partner. The impact may not be fully realized until much later. The nurse should be available to listen and provide support. The patient's partner, if appropriate, should participate in this process. Even if the pregnancy was unplanned, a loss has been experienced, and a grief reaction may occur.

Monitoring and Managing Potential Complications

Potential complications of ectopic pregnancy are hemorrhage and shock. Careful assessment is essential to detect the development of these complications. Continuous monitoring of vital signs, level of consciousness, amount of bleeding, and intake and output provides information about the possibility of hemorrhage and the need to prepare for intravenous (IV) therapy. Bed rest is indicated. Hematocrit, hemoglobin, and blood gases are monitored to assess hematologic status and adequacy of tissue perfusion. Significant deviations in these laboratory values are reported immediately, and the patient is prepared for possible surgery. Blood component therapy may be required if blood loss has been rapid and extensive. If hypovolemic shock occurs, the treatment is directed toward reestablishing tissue perfusion and adequate blood volume. See Chapter 15 for a discussion of the IV fluids and medications used in treating shock.

The nurse has an important role in prevention by being alert to patients with abnormal bleeding who may be at risk for an ectopic pregnancy and referring them immediately for care. It is necessary to keep a high index of suspicion in daily practice when a woman of childbearing age, particularly one who is not using an effective method of contraception consistently, reports abdominal discomfort or abnormal bleeding.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. If the patient has experienced life-threatening hemorrhage and shock, these complications are addressed and treated before any in-depth teaching can begin. At this time, the patient's and the nurse's attention is focused on the crisis, not on learning. At a later time, the patient begins to ask questions about what happened and why certain procedures were performed. Procedures are explained in terms that the distressed and apprehensive patient can understand. The patient's partner is included in teaching and explanations when possible. After the patient recovers from postoperative discomfort, it may be more appropriate to address any questions and concerns that she and her partner have, including the effect of this pregnancy or its treatment on future pregnancies. The patient should be advised that ectopic pregnancies may recur. The patient is informed about possible complications and instructed to report early signs and symptoms. It is important to review signs and symptoms with the patient and instruct her to report an abnormal menstrual period promptly.

CONTINUING CARE. Because of the risk of subsequent ectopic pregnancies, the patient is advised to seek preconception counseling before considering future pregnancies and to seek early prenatal care. Follow-up contact allows the

nurse to answer questions and clarify information for the patient and her partner.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Experiences relief of pain
 - a. Reports a decrease in pain and discomfort
 - b. Ambulates as prescribed; performs coughing and deep breathing
2. Begins to accept loss of pregnancy and expresses grief by verbalizing feelings and reactions to loss
3. Verbalizes an understanding of the causes of ectopic pregnancy
4. Experiences no complications
 - a. Exhibits no signs of bleeding, hemorrhage, or shock
 - b. Has decreased amounts of discharge (on perineal pad)
 - c. Has normal skin color and turgor
 - d. Exhibits stable vital signs and adequate urine output
 - e. Levels of beta-hCG return to normal

CRITICAL THINKING EXERCISES

EBP 1 A 50-year-old woman has been experiencing severe hot flashes and resultant insomnia. She is considering beginning hormone therapy (HT) but is concerned about its risks. What information would you give to her? What is the evidence base for that information? What criteria would you use to assess the strength of the evidence? What resources would you recommend to her?

2 A 19-year-old female college student comes to the student health clinic for a gynecologic examination because she anticipates having sex with her new girlfriend. She asks you for advice about avoiding sexually transmitted diseases. What advice would you give her? How would you modify your teaching if she informed you that her new partner has other partners? What other teaching would you provide?

EBP 3 You are working in a women's health practice and are responsible for educating women about menopause and health promotion. Your 48-year-old patient has mild diabetes, and she is obese and has hypertension. She takes oral antidiabetic and antihypertensive medications. She reports that she has a strong family history of heart disease. She is concerned about menopause because her mother and sisters experienced "difficult" menopause. She indicates that she has little time for exercise and eats mostly fast food because of her high-pressure job. What health promotion strategies would you suggest to assist the patient in improving her health status as she approaches menopause? What is the evidence base for those strategies? How would you use that evidence to develop a teaching plan for her?

4 At a health clinic, you meet a 45-year-old woman with postpolio syndrome who uses a battery-powered scooter most of the time because of increasing muscle weakness. She is approaching menopause and is concerned about how her physical limitations secondary to postpolio syndrome might affect her health related to menopause. Describe what health promotion issues would be relevant and the actions, including patient teaching, that are warranted.

chapter 47

Management of Patients With Female Reproductive Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Compare the various types of vaginal infections and the signs, symptoms, and treatments of each.
- 2 Develop a teaching plan for the patient with a vaginal infection.
- 3 Use the nursing process as a framework for care of the patient with a vulvovaginal infection.
- 4 Use the nursing process as a framework for care of the patient with genital herpes.
- 5 Discuss the signs and symptoms, management, and nursing care implications of malignant disorders of the female reproductive tract.
- 6 Use the nursing process as a framework for care of the patient undergoing a hysterectomy.
- 7 Describe indications for a wide excision of the vulva, or vulvectomy, and the preoperative and postoperative nursing interventions.
- 8 Compare nursing interventions indicated for the patient undergoing radiation therapy and chemotherapy for cancer of the female reproductive tract.

GLOSSARY

abscess: a collection of purulent material
acquired immunodeficiency syndrome (AIDS): a disease transmitted by body fluids that results in impaired immune response
Bartholin's cyst: a cyst in a paired vestibular gland in the vulva
brachytherapy: radiation delivered by an internal device placed close to the tumor
candidiasis: infection caused by *Candida* species or yeast; also referred to as monilial vaginitis or yeast infection
colporrhaphy: repair of the vagina
condylomata: warty growths indicative of the human papillomavirus (HPV)
conization: procedure in which a cone-shaped piece of cervical tissue is removed as a result of detection of abnormal cells; also called cone biopsy
cryotherapy: destruction of tissue by freezing (eg, with liquid nitrogen)
cystocele: bulging of the bladder downward into the vagina
douche: rinsing the vaginal canal with fluid
dysplasia: term related to abnormal cell changes found on Pap smear and cervical biopsy reports
endocervicitis: inflammation of the mucosa and the glands of the cervix

GLOSSARY (Continued)

endometriosis: endometrial tissue in abnormal locations; causes pain with menstruation, scarring, and possible infertility
enterocele: is a protrusion of the intestinal wall into the vagina
fibroid tumor: usually benign tumor of the uterus that may cause irregular bleeding; also called myoma or leiomyoma
fistula: abnormal opening between two organs or sites (eg, vesicovaginal, between bladder and vagina; rectovaginal, between rectum and vagina)
hyphae: microscopic findings that indicate monilia
hysterectomy: surgical removal of the uterus
lactobacilli: vaginal bacteria that limit the growth of other bacteria by producing hydrogen peroxide
laparoscope: surgical device inserted through a periumbilical incision to facilitate visualization and surgical procedures
lichen sclerosus: benign disorder of the vulva that usually occurs when estrogen levels are low; characterized by itching
liposomal therapy: chemotherapy delivered in a liposome, a nontoxic drug carrier
loop electrocautery excision procedure (LEEP): procedure in which laser energy is used to remove a portion of cervical tissue after abnormal biopsy findings
mucopurulent cervicitis: inflammation of the cervix with exudate; almost always related to a chlamydial infection
myomectomy: removal of uterine fibroids through an abdominal incision
oophorectomy: surgical removal of an ovary
pelvic exenteration: major surgical procedure in which the pelvic organs are removed
pelvic inflammatory disease (PID): infection of uterus and fallopian tubes, usually from a sexually transmitted disease
perineorrhaphy: surgical repair of perineal lacerations
polycystic ovary syndrome (PCOS): disorder in the hypothalamic-pituitary and ovarian network, resulting in chronic anovulation, androgen excess, and polycystic ovaries
rectocele: bulging of the rectum into the vagina
salpingitis: inflammation of the fallopian tube
salpingo-oophorectomy: removal of the ovary and its fallopian tube (removal of the fallopian tube alone is a salpingectomy)
vaginal vault: term used to describe the vagina following a hysterectomy, which involves removal of the uterus including the cervix
vaginitis: inflammation of the vagina, usually secondary to infection
vestibulitis: inflammation of the vulvar vestibule, or tissue around the opening of the vagina, that often causes pain with intercourse (dyspareunia)
vestibulodynia: most common type of vulvodynia, characterized by sharp pain in response to pressure applied to the vestibular area of the vulva.
vulvar dystrophy: thickening or lesions of the vulva; usually causes itching and may require biopsy to exclude malignancy
vulvectomy: removal of the tissue of the vulva
vulvitis: inflammation of the vulva, usually secondary to infection or irritation
vulvodynia: painful condition that affects the vulva

Disorders of the female reproductive system can be minor or serious but are usually anxiety producing and often distressing. Some disorders are self-limited and cause only minor inconvenience to the woman; others are life-threatening and require immediate attention and long-term therapy. Many disorders are managed by the patient at home, whereas others require hospitalization and surgical intervention. All disorders require that nurses have knowledge, understanding, and skill in patient teaching. Nurses must also be sensitive to the woman's concerns and possible discomfort in discussing and dealing with these disorders.

VULVOVAGINAL INFECTIONS

Vulvovaginal infections are common, and nurses have an important role in providing information that may prevent their occurrence. To help prevent these infections, women need to understand their own anatomy and vulvovaginal health.

The vagina is protected against infection by its normally low pH (3.5 to 4.5), which is maintained in part by the actions of *Lactobacillus acidophilus*, the dominant bacteria in a healthy vaginal ecosystem. These bacteria suppress the growth of anaerobes and produce lactic acid, which maintains normal pH. They also produce hydrogen peroxide, which is toxic to anaerobes. The risk of infection increases if a woman's resistance is reduced by stress or illness, if the pH is altered, or if a pathogen is introduced. Continued research into causes and treatments is needed, along with better ways to encourage growth of **lactobacilli**.

The epithelium of the vagina is highly responsive to estrogen, which induces glycogen formation. The subsequent breakdown of glycogen into lactic acid assists in producing a low vaginal pH. When estrogen decreases during lactation and menopause, glycogen also decreases. With reduced glycogen formation, infections may occur. In addition, as estrogen production ceases during the perimenopausal and postmenopausal periods, the vagina and labia may atrophy (thin), making the vaginal area more susceptible to infection. When patients are treated with antibiotics, the normal vaginal flora are reduced. This results in altered pH and growth of fungal organisms. Other factors that may initiate or predispose to infections include contact with an infected partner and wearing tight, nonabsorbent, and heat-retaining and moisture-retaining clothing (Chart 47-1).

Vaginitis (inflammation of the vagina) is a group of conditions that cause vulvovaginal symptoms such as itching, irritation, burning, and abnormal discharge. Bacterial vaginosis is the most common cause (22% to 50% of symptomatic women), followed by vulvovaginal candidiasis (17% to 39%) and trichomoniasis (4% to 35%) (American College of Obstetricians and Gynecologists [ACOG], 2006a). (Table 47-1). Other types include desquamative vaginitis, atrophic vaginitis, various vulvar dermatologic conditions, and vulvodynia. The normal vaginal discharge, which may occur in slight amounts during ovulation or just before the onset of menstruation, becomes more profuse when vaginitis occurs. Urethritis may accompany vaginitis because of the proximity of the urethra to the vagina. Discharge that occurs with vaginitis may produce itching, odor, redness,

CHART
47-1

Risk Factors for Vulvovaginal Infections

- Premenarche
- Pregnancy
- Perimenopause/Menopause
- Poor personal hygiene
- Tight undergarments
- Synthetic clothing
- Frequent douching
- Allergies
- Use of oral contraceptives
- Use of broad-spectrum antibiotics
- Diabetes mellitus
- Low estrogen levels
- Intercourse with infected partner
- Oral-genital contact (yeast can inhabit the mouth and intestinal tract)
- HIV infection

burning, or edema, which may be aggravated by voiding and defecation. After the causative organism has been identified, appropriate treatment (discussed later) is prescribed. This may include an oral medication or a local medication that is inserted into the vagina using an applicator.

Candidiasis

Vulvovaginal **candidiasis** is a fungal or yeast infection caused by strains of *Candida* (see Table 47-1). *Candida albicans* accounts for most cases, but other strains, such as *Candida glabrata*, may also be implicated. Many women with a healthy vaginal ecosystem harbor *Candida* but are asymptomatic. Certain conditions favor the change from an asymptomatic state to colonization with symptoms. For example, use of antibiotics decreases bacteria, thereby altering the natural protective organisms usually present in the vagina. Although infections can occur at any time, they occur more commonly in pregnancy or with a systemic condition such as diabetes mellitus or human immunodeficiency virus (HIV) infection, or when patients are taking medications such as corticosteroids or oral contraceptives.

Clinical Manifestations

Clinical manifestations include a vaginal discharge that causes pruritus (itching) and subsequent irritation. The discharge may be watery or thick but has a white, cottage cheese-like appearance. Symptoms are usually more severe just before menstruation and may be less responsive to treatment during pregnancy. Diagnosis is made by microscopic identification of spores and **hyphae** on a glass slide prepared from a discharge specimen mixed with potassium hydroxide. With candidiasis, the pH is 4.5 or less.

Medical Management

The goal of management is to eliminate symptoms. Treatments include antifungal agents such as miconazole (Monistat), nystatin (Mycostatin), clotrimazole (Gyne-Lotrimin), and terconazole (Terazol) cream. These agents are inserted into the vagina with an applicator at bedtime. There are

Table 47-1 VAGINAL INFECTIONS AND VAGINITIS

Infection	Cause	Clinical Manifestations	Management Strategies
Candidiasis	<i>Candida albicans</i> , <i>glabrata</i> , or <i>tropicalis</i>	Inflammation of vaginal epithelium, producing itching, reddish irritation White, cheeselike discharge clinging to epithelium	Eradicate the fungus by administering an antifungal agent. Frequently used brand names of vaginal creams and suppositories are Monistat, Femstat, Terazol, and Gyne-Lotrimin. Review other causative factors (eg, antibiotic therapy, nylon underwear, tight clothing, pregnancy, oral contraceptives). Assess for diabetes and HIV infection in patients with recurrent monilia.
<i>Gardnerella</i> -associated bacterial vaginosis	<i>Gardnerella vaginalis</i> and vaginal anaerobes	Usually no edema or erythema of vulva or vagina Gray-white to yellow-white discharge clinging to external vulva and vaginal walls	Administer metronidazole (Flagyl), with instructions about avoiding alcohol while taking this medication. If infection is recurrent may treat partner.
<i>Trichomonas vaginalis</i> vaginitis (STD)	<i>Trichomonas vaginalis</i>	Inflammation of vaginal epithelium, producing burning and itching Frothy yellow-white or yellow-green vaginal discharge	Relieve inflammation, restore acidity, and reestablish normal bacterial flora; provide oral metronidazole for patient and partner.
Bartholinitis (infection of greater vestibular gland)	<i>Escherichia coli</i> <i>Trichomonas vaginalis</i> Staphylococcus Streptococcus Gonococcus	Erythema around vestibular gland Swelling and edema Abscessed vestibular gland	Drain the abscess; provide antibiotic therapy; excise gland of patients with chronic bartholinitis.
Cervicitis: acute and chronic	Chlamydia Gonococcus Streptococcus Many pathogenic bacteria	Profuse purulent discharge Backache Urinary frequency and urgency	Determine the cause: perform cytologic examination of cervical smear and appropriate cultures. Eradicate the gonococcal organism, if present: penicillin (as directed) or spectinomycin or tetracycline, if patient is allergic to penicillin. Tetracycline, doxycycline (Vibramycin) to eradicate chlamydia. Eradicate other causes.
Atrophic vaginitis	Lack of estrogen; glycogen deficiency	Discharge and irritation from alkaline pH of vaginal secretions	Provide topical vaginal estrogen therapy; improve nutrition if necessary; relieve dryness through use of moisturizing medications.

1-night, 3-night, and 7-night treatment courses available. Oral medication (fluconazole [Diflucan]) is also available in a one-pill dose. Relief should be noted within 3 days.

Some vaginal creams are available without a prescription; however, patients are cautioned to use these creams only if they are certain that they have a yeast or monilial infection. Patients often use these remedies for problems other than yeast infections. If a woman is uncertain about the cause of her symptoms or if relief has not been obtained after using these creams, she should be instructed to seek health care promptly. Yeast infections can become recurrent or complicated. Women may have more than four infections in a year and severe symptoms due to preexisting conditions such as diabetes or immunosuppression. Cell-mediated immunity may be a factor. Women with recurrent yeast infections benefit from a comprehensive gynecologic assessment.

Bacterial Vaginosis

Bacterial vaginosis is caused by an overgrowth of anaerobic bacteria and *Gardnerella vaginalis* normally found in the vagina and an absence of lactobacilli (see Table 47-1). Risk

factors include douching after menses, smoking, multiple sex partners, and other sexually transmitted diseases (STDs) (also referred to as sexually transmitted infections [STIs]).

Clinical Manifestations

Bacterial vaginosis can occur throughout the menstrual cycle and does not produce local discomfort or pain. More than half of patients with bacterial vaginosis do not notice any symptoms. Discharge, if noticed, is heavier than normal and gray to yellowish white in color. It is characterized by a fishlike odor that is particularly noticeable after sexual intercourse or during menstruation as a result of an increase in vaginal pH. The pH of the discharge is usually greater than 4.7 because of the amines that result from enzymes from anaerobes. The fishlike odor can be detected readily by adding a drop of potassium hydroxide to a glass slide with a sample of vaginal discharge, which releases amines; this is referred to as a positive “whiff” test. Under the microscope, vaginal cells are coated with bacteria and are described as “clue cells.” Lactobacilli, which serve as a natural host defense, are usually absent. Bacterial vaginosis is not usually considered a serious condition, although it can be associated with premature labor, premature rupture of membranes, endometritis, and recurrent urinary tract infection.

Medical Management

Metronidazole (Flagyl), administered orally twice a day for 1 week, is effective; a vaginal gel is also available. Clindamycin (Cleocin) vaginal cream or ovules (oval suppositories) are also effective. Treatment of patients' partners does not seem to be effective, but use of condoms may be helpful.

Trichomoniasis

Trichomonas vaginalis is a flagellated protozoan that causes a common, usually sexually transmitted vaginitis that is often called "trich"; about 7.4 million cases occur each year (ACOG, 2006a). Trichomoniasis may be transmitted by an asymptomatic carrier who harbors the organism in the urogenital tract (see Table 47-1). It may increase the risk of contracting HIV from an infected partner and may play a role in development of cervical neoplasia, postoperative infections, adverse pregnancy outcomes, pelvic inflammatory disease (PID), and infertility.

Clinical Manifestations

Clinical manifestations include a vaginal discharge that is thin (sometimes frothy), yellow to yellow-green, malodorous, and very irritating. An accompanying vulvitis may result, with vulvovaginal burning and itching. Diagnosis is made most often by microscopic detection of the motile causative organisms or less frequently by culture. Inspection with a speculum often reveals vaginal and cervical erythema (redness) with multiple small petechiae ("strawberry spots"). Testing of a trichomonal discharge demonstrates a pH greater than 4.5.

Medical Management

The most effective treatment for trichomoniasis is metronidazole or tinidazole (Tindamax). Both partners receive a one-time loading dose or a smaller dose three times a day for 1 week. The one-time dose is more convenient; consequently, compliance tends to be greater. The week-long treatment has occasionally been noted to be more effective. Some patients complain of an unpleasant but transient metallic taste when taking metronidazole. Nausea and vomiting, as well as a hot, flushed feeling (disulfiram-like reaction), occur when this medication is taken with an alcoholic beverage. In view of these side effects, patients taking metronidazole are strongly advised to abstain from alcohol.

Metronidazole is not prescribed without examination. It is contraindicated in patients with some blood dyscrasias or central nervous system diseases, in the first trimester of pregnancy, and in women who are breastfeeding. Tinidazole is not considered safe in pregnancy.

Gerontologic Considerations

After menopause, the vaginal mucosa becomes thinner and may atrophy. This condition can be complicated by infection from pyogenic bacteria, resulting in atrophic

vaginitis (see Table 47-1). Leukorrhea (vaginal discharge) may cause itching and burning. Management is similar to that for bacterial vaginosis if bacteria are present. Estrogenic hormones, either taken orally or inserted into the vagina in a cream form, can also be effective in restoring the epithelium.

NURSING PROCESS

The Patient With a Vulvovaginal Infection

Assessment

The woman with vulvovaginal symptoms should be examined as soon as possible after the onset of symptoms. She should be instructed not to **douche** because doing so removes the vaginal discharge needed to make the diagnosis. The area is observed for erythema, edema, excoriation, and discharge. Each of the infection-producing organisms produces its own characteristic discharge and effect (see Table 47-1). The patient is asked to describe any discharge and other symptoms, such as odor, itching, or burning. Dysuria often occurs as a result of local irritation of the urinary meatus. A urinary tract infection may need to be ruled out by obtaining a urine specimen for culture and sensitivity testing.

The patient is asked about the occurrence of factors that may contribute to vulvovaginal infection:

- Physical and chemical factors, such as constant moisture from tight or synthetic clothing, perfumes and powders, soaps, bubble bath, poor hygiene, and use of feminine hygiene products
- Psychogenic factors (eg, stress, fear of STDs, abuse)
- Medical conditions or endocrine factors, such as a predisposition to *Monilia* in a patient who has diabetes
- Use of medications such as antibiotics, which may alter the vaginal flora and allow an overgrowth of monilial organisms
- New sex partner, multiple sex partners, previous vaginal infection

The patient is also asked about factors that could contribute to infection, including hygiene practices (douching), and use or nonuse of condoms and other barrier methods of birth control.

The nurse may prepare a vaginal smear (wet mount) to assist in diagnosing the infection. A common method for preparing the smear is to collect vaginal secretions with an applicator and place the secretions on two separate glass slides. A drop of saline solution is added to one slide and a drop of 10% potassium hydroxide is added to another slide for examination under a microscope. If bacterial vaginosis is present, the slide with normal saline solution added shows epithelial cells dotted with bacteria (clue cells). If *Trichomonas* species is present, small motile cells are seen. In the presence of yeast, the potassium hydroxide slide reveals typical characteristics. Discharge associated with bacterial vaginosis produces a strong odor when mixed with potassium hydroxide. Testing the pH of the discharge with Nitrazine paper assists in proper diagnosis.

Diagnosis

Nursing Diagnoses

Based on the nursing assessment and other data, major nursing diagnoses may include the following:

- Discomfort related to burning, odor, or itching from the infectious process
- Anxiety related to stressful symptoms
- Risk for infection or spread of infection
- Deficient knowledge about proper hygiene and preventive measures

Planning and Goals

Major goals may include relief of discomfort, reduction of anxiety related to symptoms, prevention of reinfection or infection of sexual partner, and acquisition of knowledge about methods for preventing vulvovaginal infections and managing self-care.

Nursing Interventions

Relieving Discomfort

Treatment with the appropriate medication usually relieves discomfort. Sitz baths may be occasionally recommended and may provide temporary relief of symptoms.

Reducing Anxiety

Vulvovaginal infections are upsetting and require treatment. The patient who experiences such an infection may be very anxious about the significance of the symptoms and possible causes. Explaining the cause of symptoms may reduce anxiety related to fear of a more serious illness. Discussing ways to help prevent vulvovaginal infections may help patients adopt specific strategies to decrease infection and the related symptoms.

Preventing Reinfection or Spread of Infection

The patient needs to be informed about the importance of adequate treatment of herself and her partner, if indicated. Other strategies to prevent persistence or spread of infection include abstaining from sexual intercourse when infected, treatment of sexual partners, and minimizing irritation of the affected area. When medications such as antibiotic agents are prescribed for any infection, the nurse instructs the patient about the usual precautions related to using these agents. If vaginal itching occurs several days after use, the patient can be reassured that this is usually not an allergic reaction but may be a yeast or monilial infection resulting from altered vaginal bacteria. Treatment for monilial infection is prescribed.

Another goal of treatment is to reduce tissue irritation caused by scratching or wearing tight clothing. The area needs to be kept clean by daily bathing and adequate hygiene after voiding and defecation. The use of a hairdryer on a cool setting will dry the area and application of topical corticosteroids may decrease irritation.

When teaching the patient about medications such as suppositories and devices such as applicators to dispense cream or ointment, the nurse may demonstrate the procedure by using a plastic model of the pelvis and vagina. The nurse should also stress the importance of hand washing before and after each administration of medication. To prevent the medication from escaping from the vagina, the patient

should recline for 30 minutes after it is inserted, if possible. The patient is informed that seepage of medication may occur, and the use of a perineal pad may be helpful.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Vulvovaginal conditions are treated on an outpatient basis unless a patient has other medical problems. Patient teaching, tact, and reassurance are important aspects of nursing care. Women may express embarrassment, guilt, or anger and may be concerned that the infection could be serious or that it may have been acquired from a sex partner. (In some instances, treatment plans include the partner.)

In addition to reviewing ways of relieving discomfort and preventing reinfection, the nurse assesses each patient's learning needs relative to the immediate problem. The patient needs to know the characteristics of normal as opposed to abnormal discharge. Questions often arise about douching. Normally, douching and use of feminine hygiene sprays are unnecessary because daily baths or showers and proper hygiene after voiding and defecating keep the perineal area clean. Douching tends to eliminate normal flora, reducing the body's ability to ward off infection. In addition, repeated douching may result in vaginal epithelial breakdown and chemical irritation and has been associated with other pelvic disorders. No studies show any benefit from douching (ACOG, 2006a). In the case of recurrent yeast infections, the perineum should be kept as dry as possible. Loose-fitting cotton instead of tight-fitting synthetic, nonabsorbent, heat-retaining underwear is recommended. Use of talcum powder should be discouraged.

Vulvar self-examination is a good health practice for all women. Becoming familiar with one's own anatomy and reporting anything that seems new or different may result in early detection and treatment of any new disorders. Nurses can also play a role in teaching women about the risks of unprotected intercourse, particularly with partners who have had sex with others.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Experiences reduced discomfort
 - a. Cleans the perineum as instructed
 - b. Reports that itching is relieved
 - c. Maintains urine output within normal limits and without dysuria
2. Experiences relief of anxiety
3. Remains free from infection
 - a. Has no signs of inflammation, pruritus, odor, or dysuria
 - b. Notes that vaginal discharge appears normal (thin, clear, not frothy)
4. Participates in self-care
 - a. Takes medication as prescribed
 - b. Wears absorbent underwear
 - c. Avoids unprotected sexual intercourse
 - d. Douches only as prescribed
 - e. Performs vulvar self-examination regularly and reports any new findings to care provider

Human Papillomavirus

Human papillomavirus (HPV) infection is sexually transmitted and is the most common STD in young, sexually active people. An estimated 6.2 million patients acquire these infections every year (Centers for Disease Control and Prevention [CDC], 2006a, 2007). Most infections are self-limiting and without symptoms, and others can cause cervical and anogenital cancers. Infections can be latent (asymptomatic and detected only by DNA hybridization tests for HPV), subclinical (visualized only after application of acetic acid followed by inspection under magnification), or clinical (visible condylomata acuminata).

Pathophysiology

More than 100 types of HPV exist. The most common strains of HPV, 6 and 11, usually cause **condylomata** (warty growths) on the vulva. These are often visible or may be palpable by patients. Condylomata are rarely premalignant but are an outward manifestation of the virus. Strains 6 and 11 are associated with a low risk for cervical cancer. Some HPV strains (16, 18, 31, 33, and 45) may not cause condylomata but do affect the cervix, resulting in abnormal Papanicolaou (Pap) smears. The effects of these strains are usually invisible on examination but may be seen on colposcopy. They may cause cervical changes that may appear as koilocytosis on Pap smear. Seventy percent of all cervical cancers are caused by strains 16 and 18 (Wright, Massad, Dunton, et al., 2007). However, most women with HPV infection do not develop cervical cancer.

The incidence of HPV in young, sexually active women is high. The infection often disappears as the result of an effective immune system response. It is thought that two proteins produced by high-risk types of HPV interfere with tumor suppression by normal cells. Risk factors include being young, being sexually active, having multiple sex partners, and having sex with a partner who has or has had multiple partners.

In 2006, the Advisory Committee on Immunization Practices (ACIP) of the CDC recommended that a newly licensed vaccine (Gardasil) against the four strains of HPV that cause the majority of cases of cervical cancer be routinely administered to girls 11 to 12 years of age—that is, before they become sexually active. Although this vaccine is considered an important medical breakthrough, it does not replace other strategies important in prevention of HPV or the need for cervical cancer screening. It is administered in three intramuscular doses, with the initial dose followed by second dose in 2 months and a third dose 6 months after the first dose. This vaccine, along with regular Pap smears, has the potential to decrease the impact of HPV-related disease (ACOG, 2006b; CDC, 2006a, 2007; Markowitz, Dunne, Saraiya, et al., 2007).

Medical Management

Treatment of external genital warts includes topical application of trichloroacetic acid, podophyllin (Podofin, Podocon), and chemotherapeutic agents, as well as injections of interferon administered by a health care provider.

Topical agents that can be applied by patients to external lesions include podofilox (Condylox) and imiquimod (Aldara). Because the safety of podophyllin, imiquimod, and podofilox during pregnancy has not been determined, these agents should not be used during pregnancy. Electrocautery and laser therapy are alternative therapies that may be indicated for patients with a large number or area of genital warts (CDC, 2007).

Treatment usually eradicates perineal warts or condylomata. However, they may resolve spontaneously without treatment and may also recur even with treatment.

If the treatment includes application of a topical agent by the patient, she needs to be carefully instructed in the use of the agent prescribed and must be able to identify the warts and be able to apply the medication to them. The patient is instructed to anticipate mild pain or local irritation with the use of these agents.

Women with HPV should have annual Pap smears because of the potential of HPV to cause **dysplasia** (changes in cervical cells). Much remains unknown about subclinical and latent HPV disease. Women are often exposed to HPV by partners who are unknowing carriers. Use of condoms can reduce the likelihood of transmission, but transmission can also occur during skin-to-skin contact in areas not covered by condoms.

In many cases, patients are angry about having warts or HPV and do not know who infected them because the incubation period can be long and partners may have no symptoms. Acknowledging the emotional distress that occurs when an STD is diagnosed and providing support and facts are important nursing actions.

Herpesvirus Type 2 Infection (Herpes Genitalis, Herpes Simplex Virus)

Herpes genitalis is a recurrent, life-long viral infection that causes herpetic lesions (blisters) on the external genitalia and occasionally the vagina and cervix. It is an STD but may also be transmitted asexually from wet surfaces or by self-transmission (ie, touching a cold sore and then touching the genital area). The initial infection is usually very painful and lasts about 1 week, but it can also be asymptomatic. Recurrences are less painful and usually produce minor itching and burning. Some patients have few or no recurrences, whereas others have frequent bouts. Recurrences are often associated with stress, sunburn, dental work, or inadequate rest or nutrition—all situations that may tax the immune system.

Since the late 1970s, the incidence of herpes infection has increased fivefold among Caucasian adolescents and young adults. At least 50 million people in the United States have genital herpes infection and most have not been diagnosed (CDC, 2006a). The prevalence of other STDs has decreased slightly, possibly because of increased condom use, but herpes can be transmitted by contact with skin not covered by a condom. Transmission is possible even when a carrier does not have symptoms (subclinical shedding). Lesions increase vulnerability to HIV infection and other STDs. Vaccines for herpes genitalis are in clinical trials.

Pathophysiology

Of the known herpesviruses, six affect humans: (1) herpes simplex type 1 (HSV-1), which usually causes cold sores of the lips; (2) herpes simplex type 2 (HSV-2), or genital herpes; (3) varicella zoster, or shingles; (4) Epstein-Barr virus; (5) cytomegalovirus (CMV); and (6) human B-lymphotrophic virus. HSV-2 appears to be the cause of about 80% of genital and perineal lesions; HSV-1 may cause about 20%.

There is considerable overlap between HSV-1 and HSV-2, which are clinically indistinguishable. Close human contact by the mouth, oropharynx, mucosal surface, vagina, or cervix appears necessary to acquire the infection. Other susceptible sites are skin lacerations and conjunctivae. Usually, the virus is killed at room temperature by drying. When viral replication diminishes, the virus ascends the peripheral sensory nerves and remains inactive in the nerve ganglia. Another outbreak may occur when the host is subjected to stress. In pregnant women with active herpes, infants delivered vaginally may become infected with the virus. There is a risk of fetal morbidity and mortality if this occurs; therefore, a cesarean delivery may be performed if the virus recurs near the time of delivery.

Clinical Manifestations

Itching and pain occur as the infected area becomes red and edematous. Primary infection may begin with macules and papules and progress to vesicles and ulcers. The vesicular state often appears as a blister, which later coalesces, ulcerates, and encrusts. In women, the labia are the usual primary site, although the cervix, vagina, and perianal skin may be affected. In men, the glans penis, foreskin, or penile shaft is typically affected. Influenza-like symptoms may occur 3 or 4 days after the lesions appear. Inguinal lymphadenopathy (enlarged lymph nodes in the groin), minor temperature elevation, malaise, headache, myalgia (aching muscles), and dysuria (pain on urination) are often noted. Pain is evident during the first week and then decreases. The lesions subside in about 1 to 2 weeks unless secondary infection occurs.

Rarely, complications may arise from extragenital spread, such as to the buttocks, upper thighs, or even the eyes as a result of touching lesions and then touching other areas. Patients should be advised to wash their hands after contact with lesions. Other potential problems are aseptic meningitis, neonatal transmission, and severe emotional stress related to the diagnosis.

Medical Management

There is currently no cure for HSV-2 infection, but treatment is aimed at relieving the symptoms. Management goals include preventing the spread of infection, making patients comfortable, decreasing potential health risks, and initiating a counseling and education program. The antiviral agents acyclovir (Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir) can suppress symptoms and shorten the course of the infection. These are effective at reducing the duration of lesions and preventing recurrences. Resistance and long-term side effects do not appear to be major problems. Recurrent episodes are often milder than the initial episode.

NURSING PROCESS

THE PATIENT WITH A GENITAL HERPESVIRUS INFECTION

Assessment

The health history and a physical and pelvic examination are important in establishing the nature of the infectious condition. In addition, patients are assessed for risk of STDs. The perineum is inspected for painful lesions. Inguinal nodes are assessed and are often enlarged and tender during an occurrence of HSV.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain related to the genital lesions
- Risk for infection or spread of infection
- Anxiety related to the diagnosis
- Deficient knowledge about the disease and its management

Planning and Goals

Major goals may include relief of pain and discomfort, control of infection and its spread, relief of anxiety, knowledge of and adherence to the treatment regimen and self-care, and knowledge about implications for the future.

Nursing Interventions

Relieving Pain

The lesions should be kept clean, and proper hygiene practices are advocated. Sitz baths ease discomfort. Clothing should be clean, loose, soft, and absorbent. Aspirin and other analgesics are usually effective in controlling pain. Occlusive ointments and powders are avoided because they prevent the lesions from drying.

If there is considerable pain and malaise, bed rest may be required. The patient is encouraged to increase fluid intake, to be alert for possible bladder distention, and to contact her primary health care provider immediately if she cannot void because of discomfort. Painful voiding may occur if urine comes in contact with the herpes lesions. Discomfort with urination can be reduced by pouring warm water over the vulva during voiding or by sitz baths. When oral acyclovir or other antiviral agents are prescribed, the patient is instructed about when to take the medication and what side effects to note, such as rash and headache. Rest, fluids, and a nutritious diet are recommended to promote recovery.

Preventing Infection and Its Spread

The risk of reinfection and spread of infection to others or to other structures of the body can be reduced by hand washing, use of barrier methods with sexual contact, and adherence to prescribed medication regimens. Avoidance of contact when obvious lesions are present does not eliminate the risk because the virus can be shed in the absence of symptoms, and lesions may not be visible to women.

Relieving Anxiety

Concern about the presence of herpes infection, future occurrences of lesions, and the impact of the infection on future relationships and childbearing may cause considerable patient anxiety. Nurses can be an important support, listening to patients' concerns and providing information and instruction. The patient may be angry with her partner if the partner is the probable source of the infection. The patient may need assistance and support in discussing the infection and its implications with her current sexual partners and in future sexual relationships. The nurse can refer the patient to a support group to assist in coping with the diagnosis (see Resources at the end of the chapter).

Increasing Knowledge About the Disease and Its Treatment

Patient teaching is an essential part of nursing care of the patient with a genital herpes infection. This includes an adequate explanation about the infection and how it is transmitted, management and treatment strategies, strategies to minimize spread of infection, the importance of adherence to the treatment regimen, and self-care strategies. Because of the increased risk of HIV and other STDs in the presence of skin lesions, an important part of patient education in-

volves instructing the patient to protect herself from exposure to HIV and other STDs (Chart 47-2).

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Self-care measures for people with genital herpes appear in Chart 47-2.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Experiences a reduction in pain and discomfort
2. Keeps infection under control
 - a. Demonstrates proper hygiene techniques
 - b. Takes medication as prescribed
 - c. Consumes adequate fluids
 - d. Assesses own current lifestyle (diet, adequate fluid intake, safer sex practices, stress management)
3. Uses strategies to reduce anxiety
 - a. Verbalizes issues and concerns related to genital herpes infection
 - b. Discusses strategies to deal with issues and concerns with current and future sexual partners
 - c. Initiates contact with support group if indicated

CHART
47-2

HOME CARE CHECKLIST

The Patient With Genital Herpes

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State that herpes is transmitted mainly by direct contact.	✓	✓
• State that abstinence from sex is required for a brief period (intercourse is avoided during treatment, but other options such as hand holding and kissing are acceptable).	✓	✓
• State that intercourse during a herpes outbreak not only increases the risk of transmission but also increases the likelihood of contracting HIV and other STDs.	✓	✓
• State that transmission is possible even in the absence of active lesions.	✓	✓
• State that condoms may provide some protection against viral transmission.	✓	✓
• Explain that obstetric care provider should be informed about the history of herpes. In cases of recurrence at time of delivery, cesarean section may be considered.	✓	✓
• Describe appropriate hygiene practices (hand washing, perineal cleanliness, gentle washing of lesions with mild soap and running water and lightly drying lesions) and importance of avoiding occlusive ointments, strong perfumed soaps, or bubble bath.	✓	✓
• State that control of the condition may require changes in sexual behavior and use of medications.	✓	✓
• Describe strategies to avoid self-infection (eg, avoid touching lesions during an outbreak).	✓	✓
• Explain rationale for avoiding self-infection (ie, lesions can become infected from germs on the hand, and the virus from the lesion can be transmitted from the hand to another area of the body or another person).	✓	✓
• Describe health promotion strategies: wear loose, comfortable clothing; eat a balanced diet; get adequate rest and relaxation.	✓	✓
• State rationale for avoiding exposure to the sun as it can cause recurrences (and skin cancer).	✓	✓
• Identify importance of taking medications as prescribed, keeping follow-up appointments with health care provider, and reporting repeated recurrences (may not be as severe as the initial episode).	✓	✓
• Describe possible benefits of joining a group to share solutions and experiences and hear about newer treatments, such as HELP (Herpetics Engaged in Living Productively).	✓	✓

4. Demonstrates knowledge about genital herpes and strategies to control and minimize recurrences
 - a. Identifies methods of transmission of herpes infection and strategies to prevent transmission to others
 - b. Discusses strategies to reduce recurrence of lesions
 - c. Takes medications as prescribed
 - d. Reports no recurrence of lesions

Endocervicitis and Cervicitis

Endocervicitis is an inflammation of the mucosa and the glands of the cervix that may occur when organisms gain access to the cervical glands after intercourse and, less often, after procedures such as abortion, intrauterine manipulation, or vaginal delivery. If untreated, the infection may extend into the uterus, fallopian tubes, and pelvic cavity. Inflammation can irritate the cervical tissue, resulting in spotting or bleeding and **mucopurulent cervicitis**.

Chlamydia and Gonorrhea

Chlamydia and gonorrhea are the most common causes of endocervicitis, although *Mycoplasma* may also be involved. Chlamydia causes about 3 million infections every year in the United States; it is most commonly found in young, sexually active people with more than one partner and is transmitted through sexual intercourse. It can result in serious complications, including pelvic infection, an increased risk for ectopic pregnancy, and infertility. As many as 40% of untreated women develop PID. One in 20 women of reproductive age in the United States is infected (CDC, 2006a). Chlamydial infections of the cervix often produce no symptoms, but cervical discharge, dyspareunia, dysuria, and bleeding may occur. Other complications include conjunctivitis and perihepatitis. If pregnant women are infected, stillbirth, neonatal death, and premature labor may occur. Infants born to infected mothers may experience prematurity, conjunctivitis, and pneumonia.

Chlamydial infection and gonorrhea often coexist. As many as 25% of females who have chlamydial infections also have gonorrhea (CDC, 2006a). The inflamed cervix that results from this infection may leave a woman more vulnerable to HIV transmission from an infected partner. Gonorrhea is also a major cause of PID, tubal infertility, ectopic pregnancy, and chronic pelvic pain. Fifty percent of women with gonorrhea have no symptoms, but without treatment, 40% may develop PID. In males, urethritis and epididymitis may occur. Diagnosis can be confirmed by culture, smear, or other methods, using a swab to obtain a sample of cervical discharge or penile discharge from the patient's partner.

Medical Management

The CDC recommends treating chlamydia with doxycycline (Vibramycin) for 1 week or with a single dose of azithromycin (Zithromax). Because of the high incidence of coinfection with chlamydia and gonorrhea, treatment for

gonorrhea should include treatment for chlamydia as well (CDC, 2006a). Partners must also be treated. Pregnant women are cautioned not to take tetracycline because of potential adverse effects on the fetus. In these cases, erythromycin may be prescribed. Results are usually good if treatment begins early. Possible complications from delayed treatment are tubal disease, ectopic pregnancy, PID, and infertility.

The CDC no longer recommends fluoroquinolones (eg, ciprofloxacin [Cipro], ofloxacin [Floxin], or levofloxacin [Levaquin]) for the treatment of gonorrhea and associated conditions (eg, PID). Instead, the CDC (2007) recommends cephalosporins for the treatment of gonorrhea.

Cultures for chlamydia and other STDs should be obtained from all patients who have been sexually assaulted when they first seek medical attention; patients are treated prophylactically. Cultures should then be repeated in 2 weeks. Annual screening for chlamydia is recommended for all sexually active young women and older women with new sex partners or multiple partners (CDC, 2006a).

Nursing Management

All sexually active women may be at risk for chlamydia, gonorrhea, and other STDs, including HIV. Nurses can assist patients in assessing their own risk. Recognition of risk is a first step before changes in behavior occur. Patients should be discouraged from assuming that a partner is "safe" without open, honest discussion. Nonjudgmental attitudes, educational counseling, and role playing may be helpful.

Because chlamydia, gonorrhea, and other STDs may have a serious effect on future health and fertility and because many of these disorders can be prevented by the use of condoms and spermicides and careful choice of partners, nurses can play a major role in counseling patients about safer sex practices. Exploring options with patients, addressing knowledge deficits, and correcting misinformation may reduce morbidity and mortality.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Nurses can educate women and help them develop communication skills and initiate discussions about sex with their partners. Communicating with partners about sex, risk, postponing intercourse, and using safer sex behaviors, including use of condoms, may be lifesaving. Some young women report having sex but not being comfortable enough to discuss sexual risk issues. Nurses can help women to advocate for their own health by discussing safety with partners prior to sexual activity.

Reinforcing the need for annual screening for chlamydia and other STDs is an important part of patient teaching. Instructions also include the need for the patient to abstain from sexual intercourse until all of her sex partners are treated (CDC, 2006a). The CDC recommends re-screening of all women with chlamydial infections 3 to 4 months after treatment is completed to reduce the risks of infertility.

Pelvic Infection (Pelvic Inflammatory Disease)

Pelvic inflammatory disease (PID) is an inflammatory condition of the pelvic cavity that may begin with cervicitis and may involve the uterus (endometritis), fallopian tubes (**salpingitis**), ovaries (oophoritis), pelvic peritoneum, or pelvic vascular system. Infection, which may be acute, subacute, recurrent, or chronic and localized or widespread, is usually caused by bacteria but may be attributed to a virus, fungus, or parasite. Gonorrheal and chlamydial organisms are the most likely causes. CMV has also been implicated. This condition can result in the fallopian tubes becoming narrowed and scarred, which increases the risk of ectopic pregnancy (fertilized eggs become trapped in the tube), infertility, recurrent pelvic pain, tubo-ovarian **abscess**, and recurrent disease. Rupture of a tubo-ovarian abscess has a 5% to 10% mortality rate and usually necessitates a complete hysterectomy. PID is a common gynecologic cause of hospital admissions in the United States. The true incidence of PID is unknown because some cases are asymptomatic.

Pathophysiology

The exact pathogenesis of PID has not been determined, but it is presumed that organisms usually enter the body through the vagina, pass through the cervical canal, colonize the endocervix, and move upward into the uterus. Under various conditions, the organisms may proceed to one or both fallopian tubes and ovaries and into the pelvis. In bacterial infections that occur after childbirth or abortion, pathogens are disseminated directly through the tissues that support the uterus by way of the lymphatics and blood vessels (Fig. 47-1). In pregnancy, the increased blood supply required by the placenta provides more pathways for infection. These postpartum and postabortion infections tend to be unilateral. Infections can cause perihepatic inflammation when the organism invades the peritoneum.

In gonorrheal infections, the gonococci pass through the cervical canal and into the uterus, where the environment, especially during menstruation, allows them to multiply rapidly and spread to the fallopian tubes and into the pelvis (see Fig. 47-1). The infection is usually bilateral.

In rare instances, organisms (eg, tuberculosis) gain access to the reproductive organs by way of the bloodstream from the lungs (see Fig. 47-1). One of the most common causes of salpingitis (inflammation of the fallopian tube) is chlamydia, possibly accompanied by gonorrhea.

Pelvic infection is most commonly caused by sexual transmission but can also occur with invasive procedures such as endometrial biopsy, surgical abortion, hysteroscopy, or insertion of an intrauterine device. Bacterial vaginosis, a vaginal infection, may predispose women to pelvic infection. Risk factors include early age at first intercourse, multiple sexual partners, frequent intercourse, intercourse without condoms, sex with a partner with an STD, and a history of STDs or previous pelvic infection.

Clinical Manifestations

Symptoms of pelvic infection usually begin with vaginal discharge, dyspareunia, lower abdominal pelvic pain, and tenderness that occurs after menses. Pain may increase with voiding or with defecation. Other symptoms include fever, general malaise, anorexia, nausea, headache, and possibly vomiting. On pelvic examination, intense tenderness may be noted on palpation of the uterus or movement of the cervix (cervical motion tenderness). Symptoms may be acute and severe or low grade and subtle.

Complications

Pelvic or generalized peritonitis, abscesses, strictures, and fallopian tube obstruction may develop. Obstruction may cause an ectopic pregnancy in the future if a fertilized egg cannot pass a tubal stricture, or scar tissue may occlude the tubes, resulting in sterility. Adhesions are common and often result in chronic pelvic pain; they eventually may require removal of the uterus, fallopian tubes, and ovaries. Other complications include bacteremia with septic shock and thrombophlebitis with possible embolization.

Medical Management

Broad-spectrum antibiotic therapy is prescribed, usually a combination of ceftriaxone (Ceftin), azithromycin, or doxycycline. Women with mild infections may be treated as outpatients, but hospitalization may be necessary. Intensive therapy includes bed rest, intravenous (IV) fluids, and IV

Figure 47-1 Pathway by which micro-organisms spread in pelvic infections. **A**, Bacterial infection spreads up the vagina into the uterus and through the lymphatics. **B**, Gonorrhea spreads up the vagina into the uterus and then to the tubes and ovaries. **C**, Bacterial infection can reach the reproductive organs through the bloodstream (hematogenous spread).

antibiotic therapy. If the patient has abdominal distention or ileus, nasogastric intubation and suction are initiated. Careful monitoring of vital signs and symptoms assists in evaluating the status of the infection. Treatment of sexual partners is necessary to prevent reinfection.

Nursing Management

Infection takes a toll, both physically and emotionally. The patient may feel well one day and experience vague symptoms and discomfort the next. She may also suffer from constipation and menstrual difficulties.

A hospitalized patient is maintained on bed rest and is usually placed in the semi-Fowler's position to facilitate dependent drainage. Accurate recording of vital signs and the characteristics and amount of vaginal discharge is necessary as a guide to therapy.

The nurse administers analgesic agents as prescribed for pain relief. Heat applied safely to the abdomen may also provide some pain relief and comfort. In addition, the nurse minimizes the transmission of infection to others by carefully handling perineal pads with gloves, discarding the soiled pad according to hospital guidelines for disposal of biohazardous material, and performing meticulous hand hygiene.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient must be informed of the need for precautions and must be encouraged to take part in procedures to prevent infecting others and protect herself from reinfection. If a partner is not well known or has had other sexual partners recently, use of condoms is essential to prevent infection and sequelae. If reinfection occurs or if the infection spreads, symptoms may include abdominal pain, nausea and vomiting, fever, malaise, malodorous purulent vaginal discharge, and leukocytosis. Patient teaching consists of explaining how pelvic infections occur, how they can be controlled and avoided, and their signs and symptoms. Guidelines and instructions provided to the patient are summarized in Chart 47-3.

All patients who have had PID need to be informed of the signs and symptoms of ectopic pregnancy (pain, abnormal bleeding, delayed menses, faintness, dizziness, and shoulder pain) because they are prone to this complication. (See Chapter 46 for a discussion of ectopic pregnancy.)

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Any discussion of vulvovaginal infections and STDs must include the topic of HIV and **acquired immunodeficiency syndrome (AIDS)**, which is described in Chapter 52. Because HIV infection may be detected through prenatal testing and screening for STDs, nurses and other women's health care clinicians are often the first professionals to provide care for a woman with HIV infection (ACOG, 2007a). Thus, they need to be knowledgeable about this disorder and sensitive to women's issues and concerns.

The incidence of HIV infection and AIDS in women is increasing. If rates of new cases of HIV infection continue to increase, infections in women will outnumber men with HIV (CDC, 2006b). Most women with HIV infection are in the reproductive age group. Heterosexual transmission is the leading cause of new HIV infection in women, surpassing IV/injection drug use as the most common mode of transmission. Younger women are disproportionately at higher risk; 25% to 50% of all women who acquire HIV heterosexually do so in adolescence or in their early 20s. Women are nine times more likely to contract HIV from men than men are from women. The presence of genital ulcers (eg, a herpetic or syphilitic lesion) or a friable cervix increases risk. Intercourse during menses may also increase risk. Syphilis appears to accelerate in HIV-positive patients and proceeds directly from primary to tertiary disease in some patients. Chlamydia is associated with a high risk of HIV (which may be related to inflammatory changes of the cervix, providing

CHART
47-3

HOME CARE CHECKLIST

The Patient With Pelvic Inflammatory Disease

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State that any pelvic pain or abnormal discharge, particularly after sexual exposure, childbirth, or pelvic surgery, should be evaluated as soon as possible.	✓	✓
• State that antibiotics may be prescribed after insertion of intrauterine devices (IUDs).	✓	✓
• Describe proper perineal care procedures (wiping from front to back after defecation or urination).	✓	✓
• State that douching reduces the natural flora that combat infecting organisms and may introduce bacteria upward.	✓	✓
• Identify the importance of consulting a health care provider if unusual vaginal discharge or odor is noted.	✓	✓
• Discuss the importance of following health practices (ie, proper nutrition, exercise, and weight control), and safer sex practices (ie, using condoms, avoiding multiple sexual partners).	✓	✓
• Explain the importance of consistent use of condoms before intercourse or any penile–vaginal contact if there is any chance of transmitting infection.	✓	✓
• State that a gynecologic examination should be performed at least once a year.	✓	✓

entry sites). HIV-positive women have a higher rate of HPV. Infections with HPV and HIV together increase the risk of malignant transformation and cervical cancer. Thus, women with HIV infection should have frequent Pap smears. HIV-positive women also have larger and more painful herpes lesions with more recurrences, probably related to immunosuppression from their disease. Many HIV-infected women have gynecologic disorders, including candidiasis, PID, anogenital warts, and cervical dysplasia (CDC, 2006a).

Women with HIV and women with partners who have HIV must be counseled about safer sex and informed about the dangers of unprotected sex. Inconsistent use of condoms results in a higher seroconversion rate. Because there is a risk of perinatal transmission, decisions to conceive or to use contraception must be based on teaching, accurate information, and care. Pregnant women are advised to have an HIV test. The use of antiretroviral agents by pregnant women significantly decreases perinatal transmission of HIV infection. Therefore, the use of these agents during pregnancy is critical and must also be discussed. For women who choose to avoid conception, use of condoms alone and with oral contraceptives are possible choices.

After informed consent is obtained, women who are at risk for HIV are offered testing by a nurse or counselor. Because patients may be reluctant to discuss risk-taking behavior, routine screening should be offered to all women. Early detection permits early treatment to delay progression of the disease.

Use of antiretroviral therapy has been improving, but barriers to use of health services by disadvantaged women include lack of insurance, current drug use, and difficulty keeping appointments. Depression and abuse are issues that affect women's use of health care services. Prevention of cervical neoplasia and PID need to be part of the teaching for women at risk. The nurse also needs to remember that many women do not see themselves as at risk for acquiring HIV infection. See Chapter 52 for further discussion of HIV infection and AIDS.

STRUCTURAL DISORDERS

Fistulas of the Vagina

A **fistula** is an abnormal, tortuous opening between two internal hollow organs or between an internal hollow organ and the exterior of the body. The name of the fistula indicates the two areas that are connected abnormally: a vesicovaginal fistula is an opening between the bladder and the vagina, and a rectovaginal fistula is an opening between the rectum and the vagina (Fig. 47-2). Fistulas may be congenital in origin. However, in adults, breakdown usually occurs because of tissue damage resulting from injury sustained during surgery, vaginal delivery, irritable bowel disease, radiation therapy, or disease processes such as carcinoma (Rivadeneira, Ruffo, Amrani, et al., 2007).

Clinical Manifestations

Symptoms depend on the specific defect. For example, in a patient with a vesicovaginal fistula, urine escapes continuously into the vagina. With a rectovaginal fistula, there is fecal incontinence, and flatus is discharged through the

Figure 47-2 Common sites for vaginal fistulas: *Vesicovaginal*—bladder and vagina. *Urethrovaginal*—urethra and vagina. *Vaginoperineal*—vagina and perineal area. *Ureterovaginal*—ureter and vagina. *Rectovaginal*—rectum and vagina.

vagina. The combination of fecal discharge with leukorrhea results in malodor that is difficult to control.

Assessment and Diagnostic Findings

A history of the symptoms experienced by the patient is important to identify the structural alterations and to assess the impact of the symptoms on the patient's quality of life. In addition, the use of methylene blue dye helps delineate the course of the fistula. In vesicovaginal fistula, the dye is instilled into the bladder and appears in the vagina. After a negative methylene blue test result, indigo carmine is injected intravenously; the appearance of the dye in the vagina indicates a ureterovaginal fistula. Cystoscopy or IV pyelography may then be used to determine the exact location.

Medical Management

The goal is to eliminate the fistula and to treat infection and excoriation. A fistula may heal without surgical intervention, but surgery is often required. If the primary care provider determines that a fistula will heal without surgical intervention, care is planned to relieve discomfort, prevent infection, and improve the patient's self-concept and self-care abilities. Measures to promote healing include proper nutrition, cleansing douches and enemas, rest, and administration of prescribed intestinal antibiotics. A rectovaginal fistula heals faster when the patient eats a low-residue diet and when the affected tissue drains properly. Warm perineal irrigations promote healing.

Sometimes a fistula does not heal on its own and cannot be surgically repaired. In this situation, care must be planned and implemented on an individual basis. Cleanliness, frequent sitz baths, and deodorizing douches are required, as are perineal pads and protective undergarments. Meticulous skin care is necessary to prevent excoriation. Applying bland creams or lightly dusting with cornstarch may be soothing. In addition, attending to the patient's social and psychological needs is an essential aspect of care.

If the patient is to have a fistula repaired surgically, preoperative treatment of any existing vaginitis is important to ensure success. Usually, the vaginal approach is used to repair vesicovaginal and urethrovaginal fistulas; the abdominal approach is used to repair fistulas that are large or complex. Fistulas that are difficult to repair or that are very large may require surgical repair with a urinary or fecal diversion. Tissue transfer techniques (skin or tissue grafting) may be used (Rivadeneira, et al., 2007).

Because fistulas usually are typically related to obstetric, surgical, or radiation trauma, occurrence in a patient without previous vaginal delivery or a history of surgery must be evaluated carefully. Crohn's disease or lymphogranuloma venereum may be the cause.

Despite the best surgical intervention, fistulas may recur. After surgery, medical follow-up continues for at least 2 years to monitor for a possible recurrence.

Pelvic Organ Prolapse: Cystocele, Rectocele, Enterocele

Age and parity can put strain on the ligaments and structures that make up the female pelvis and pelvic floor. Childbirth can result in tears of the levator sling musculature, resulting in structural weakness. Hormone deficiency also may play a role. Some degree of prolapse (weakening of the vaginal walls allowing the pelvic organs to descend and protrude into the vaginal canal) may be found in many older women. Risk factors include age, parity, and vaginal delivery, and there may also be a familial predisposition (Buschbaum, Duecy, Kerr, et al., 2006).

Cystocele is a downward displacement of the bladder toward the vaginal orifice (Fig. 47-3), resulting from damage to the anterior vaginal support structures. It usually results from injury and strain during childbirth. The condition usually appears some years later when genital atrophy associated with aging occurs, but younger, multiparous, premenopausal women may also be affected.

Rectocele is an upward pouching of the rectum that pushes the posterior wall of the vagina forward. Both rectoceles and perineal lacerations, which occur because of mus-

cle tears below the vagina, may affect the muscles and tissues of the pelvic floor and may occur during childbirth. Sometimes the lacerations may completely sever the fibers of the anal sphincter (complete tear). An **enterocele** is a protrusion of the intestinal wall into the vagina. Prolapse results from a weakening of the support structures of the uterus itself; the cervix drops and may protrude from the vagina. (If complete prolapse occurs, it may also be referred to as procidentia.)

Clinical Manifestations

Because a cystocele causes the anterior vaginal wall to bulge downward, the patient may report a sense of pelvic pressure, fatigue, and urinary problems such as incontinence, frequency, and urgency. Back pain and pelvic pain may occur as well. The symptoms of rectocele resemble those of cystocele, with one exception: instead of urinary symptoms, patients may experience rectal pressure. Constipation, uncontrollable gas, and fecal incontinence may occur in patients with complete tears. Prolapse can result in feelings of pressure and ulcerations and bleeding. Dyspareunia may occur with these disorders.

Medical Management

Kegel exercises, which involve contracting or tightening the vaginal muscles, are prescribed to help strengthen these weakened muscles. The exercises are more effective in the early stages of a cystocele. Kegel exercises are easy to perform and are recommended for all women, including those with strong pelvic floor muscles (Chart 47-4).

A pessary can be used to avoid surgery. This device is inserted into the vagina and positioned to keep an organ, such as the bladder, uterus, or intestine, properly aligned when a cystocele, rectocele, or prolapse has occurred. Pessaries are usually ring shaped or doughnut shaped and are made of various materials, such as rubber or plastic (Fig. 47-4). Rubber pessaries must be avoided in women with latex allergy. The size and type of pessary are selected and fitted by a gynecologic health care provider. The patient should have the pessary removed, examined, and cleaned by her health care provider at prescribed intervals. At these checkups, vaginal walls should be examined for pressure points or

PATIENT EDUCATION

Performing Kegel (Pelvic Muscle) Exercises

Purposes: To strengthen and maintain the tone of the pubococcygeal muscle, which supports the pelvic organs; reduce or prevent stress incontinence and uterine prolapse; enhance sensation during sexual intercourse; and hasten postpartum healing

1. Become aware of pelvic muscle function by “drawing in” the perivaginal muscles and anal sphincter as if to control

urine or defecation, but not contracting the abdominal, buttock, or inner thigh muscles.

2. Sustain contraction of the muscles for up to 10 seconds, followed by at least 10 seconds of relaxation.
3. Perform these exercises 30–80 times a day.

signs of irritation. Normally, the patient experiences no pain, discomfort, or discharge with a pessary, but if chronic irritation occurs, alternative measures may be needed.

A Colpexin sphere is another nonsurgical device used to treat pelvic organ prolapse. This intravaginal device is similar to a pessary, but it supports the pelvic floor muscles and facilitates exercise of these muscles. It is removed daily for cleaning.

Surgical Management

In many cases, surgery helps correct structural abnormalities. The procedure to repair the anterior vaginal wall is called anterior **colporrhaphy**, repair of a rectocele is called a posterior colporrhaphy, and repair of perineal lacerations is called a **perineorrhaphy**. These repairs are frequently performed laparoscopically, resulting in short hospital stays and good outcomes. A **laparoscope** is inserted through a small abdominal incision, the pelvis is visualized, and surgical repairs are performed.

Uterine Prolapse

Usually the uterus and the cervix lie at right angles to the long axis of the vagina with the body of the uterus inclined slightly forward. The uterus is normally freely movable on

examination. Individual variations may result in an anterior, middle, or posterior uterine position. A backward positioning of the uterus, known as retroversion and retroflexion, is not uncommon (Fig. 47-5).

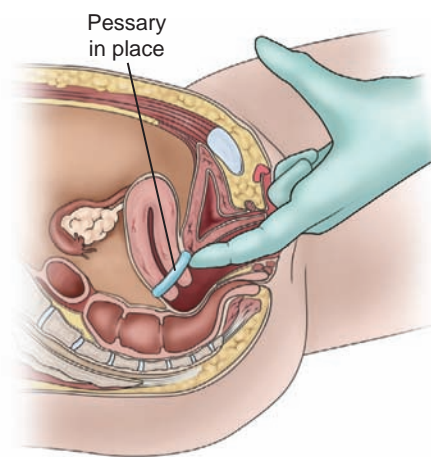

If the structures that support the uterus weaken (typically from childbirth), the uterus may work its way down the vaginal canal (prolapse) and even appear outside the vaginal orifice (procidentia) (Fig. 47-6). As the uterus descends, it may pull the vaginal walls and even the bladder and rectum with it. Symptoms include pressure and urinary problems (incontinence or retention) from displacement of the bladder. The symptoms are aggravated when a woman coughs, lifts a heavy object, or stands for a long time. Normal activities, even walking up stairs, may aggravate the symptoms.

Medical Management

Surgery and pessaries are two options for treatment. With surgery, the uterus is sutured back into place and repaired to strengthen and tighten the muscle bands. In postmenopausal women, the uterus may be removed (**hysterectomy**) or repaired by colpocleisis, or vaginal closure, may be an option for women who do not wish to have sexual intercourse or to bear children and want to avoid hysterectomy (ACOG, 2007b). Pessaries may be the treatment of choice in elderly women or those who are too ill to tolerate surgery.

Nursing Management

Implementing Preventive Measures

Some disorders related to “relaxed” pelvic muscles (cystocele, rectocele, and uterine prolapse) may be prevented.

Figure 47-6 Complete prolapse of the uterus through the introitus.

During pregnancy, early visits to the health care provider permit early detection of problems. During the postpartum period, the woman can be taught to perform Kegel exercises to strengthen the muscles that support the uterus and then to continue them as a preventive action.

Delays in obtaining evaluation and treatment may result in complications such as infection, cervical ulceration, cystitis, and hemorrhoids. The nurse encourages the patient to obtain prompt treatment for these structural disorders.

Implementing Preoperative Nursing Care

Before surgery, the patient needs to know the extent of the proposed surgery, the expectations for the postoperative period, and the effect of surgery on future sexual function. In addition, the patient having a rectocele repair needs to know that before surgery, a laxative and a cleansing enema may be prescribed. She may be asked to administer these at home the day before surgery. A perineal shave may be prescribed as well. The patient is usually placed in a lithotomy position for surgery, with special attention given to moving both legs in and out of the stirrups simultaneously to prevent muscle strain and excess pressure on the legs and thighs. Other preoperative interventions are similar to those described in Chapter 18.

Initiating Postoperative Nursing Care

Immediate postoperative goals include preventing infection and pressure on any existing suture line. This may require

perineal care and may preclude using dressings. The patient is encouraged to void within a few hours after surgery for cystocele and complete tear. If the patient does not void within this period and reports discomfort or pain in the bladder region after 6 hours, she needs to be catheterized. Some physicians prefer to leave an indwelling catheter in place for 2 to 4 days, so some women may return home with a catheter in place. Various other bladder care methods are described in Chapter 45. After each voiding or bowel movement, the perineum is cleansed with warm, sterile saline solution and dried with sterile absorbent material if a perineal incision has been made.

After an external perineal repair, the perineum is kept as clean as possible. Commercially available sprays containing combined antiseptic and anesthetic solutions are soothing and effective, and an ice pack applied locally may relieve discomfort. However, the weight of the ice bag must rest on the bed, not on the patient.

Routine postoperative care is similar to that given after abdominal surgery. The patient is positioned in bed with her head and knees elevated slightly. The patient may go home the day of or the day after surgery; the duration of the hospital stay depends on the surgical approach used.

After surgery for a complete perineal laceration (through the rectal sphincter), special care and attention are required. The bladder is drained through the catheter to prevent strain on the sutures. Throughout recovery, stool-softening agents are administered nightly after the patient begins a soft diet.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Predischarge instructions include information pertaining to the gynecologist's postoperative instructions related to cleanliness, prevention of constipation, recommended exercises, and avoiding lifting heavy objects or standing for prolonged periods. The patient is instructed to report any pelvic pain, unusual discharge, inability to carry out personal hygiene, and vaginal bleeding.

Continuing Care

The patient is advised to continue with perineal exercises, which are recommended to improve muscle strength and tone. She is reminded to return to the gynecologist for a follow-up visit and to consult with the physician about when it is safe to resume sexual intercourse.

BENIGN DISORDERS

Vulvitis and Vulvodynia

Vulvitis, an inflammation of the vulva, may occur with other disorders, such as diabetes, dermatologic problems, or poor hygiene, or it may be secondary to irritation from a vaginal discharge related to a specific vaginitis.

Vulvodynia is a chronic vulvar pain syndrome (ACOG, 2006c). Symptoms may include burning, stinging, irritation, or stabbing pain. The syndrome has been described as primary, with onset at first tampon insertion or sexual

experience, or secondary, beginning months or years after first tampon insertion or sexual experience. It may affect more than 18% of women, usually between 18 and 25 years of age (Bachman, Rosen, Pinn, et al., 2006). Vulvodynia may be classified as organic if it has a known cause (infection, trauma, or irritants) or idiopathic if no cause is known. It can be chronic or unremitting, intermittent or episodic, or may occur only in response to contact. The pathophysiology is unknown. **Vestibulodynia** is the most frequent type of vulvodynia, producing sharp pain on pressure on the vestibule.

Treatment methods for vulvodynia vary. Topical treatments (ie, estrogens, corticosteroids, trichloroacetic acid), surgery, and interferon, as well as biofeedback and dietary changes (Bachman, et al., 2006), have been used. Some cases seem to be similar to peripheral neuralgia and may respond to treatment with tricyclic antidepressants.

Vulvar Cysts

Bartholin's cyst results from the obstruction of a duct in one of the paired vestibular glands located in the posterior third of the vulva, near the vestibule. This cyst is the most common vulvar tumor. A simple cyst may be asymptomatic, but an infected cyst or abscess may cause discomfort. Infection may be due to a gonococcal organism, *Escherichia coli*, or *Staphylococcus aureus* and can cause an abscess with or without involving the inguinal lymph nodes. Skene's duct cysts may result in pressure, dyspareunia, altered urinary stream, and pain, especially if infection is present. Vestibular cysts, located inferior to the hymen, may also occur. Cysts can be treated by resection or with laser, ablation with silver nitrate, and puncture. Asymptomatic cysts do not require treatment. Malignancy can occur, usually in women older than 50 years of age, so drainage and biopsy may be considered.

Medical Management

The usual treatment for a Bartholin's cyst is incision and drainage followed by antibiotic therapy. If a cyst is asymptomatic, treatment is unnecessary. Moist heat or sitz baths may promote drainage and resolution. If surgery is necessary, a Word Bartholin gland catheter is usually used. This catheter, a short latex stem with an inflatable bulb at the distal end, creates a tract that preserves the gland and allows for drainage. A nonopioid analgesic agent may be administered before this outpatient procedure. A local anesthetic agent is injected, and the cyst is incised or lanced and irrigated with normal saline; the catheter is inserted and inflated with 2 to 3 mL of water. The catheter stem is then tucked into the vagina to allow freedom of movement. The catheter is left in place for 4 to 6 weeks until the tract reepithelializes. The patient is informed that discharge should be expected, as the catheter allows drainage of the cyst. She is instructed to contact her primary health care provider if pain occurs because the bulb may be too large for the cavity and fluid may need to be removed. Routine hygiene is encouraged.

Skene's duct cysts can be excised or drained with a Word catheter. Vestibular cysts are excised if symptomatic.

Vulvar Dystrophy

Vulvar dystrophy is a condition found in older women that causes dry, thickened skin on the vulva or slightly raised, whitish papules, fissures, or macules. Symptoms usually consist of varying degrees of itching, but some patients have no symptoms. A few patients with vulvar cancer have associated dystrophy (vulvar cancer is discussed later in this chapter). Biopsy with careful follow-up is the standard intervention. Benign dystrophies include lichen planus, simplex chronicus, **lichen sclerosus**, squamous cell hyperplasia, vulvar **vestibulitis**, and other dermatoses.

Medical Management

Topical corticosteroids (ie, hydrocortisone creams) are the usual treatment. Petrolatum jelly may relieve pruritus. Use is decreased as symptoms resolve. Topical corticosteroids are effective in treating squamous cell hyperplasia. Treatment is often complete in 2 to 3 weeks; this condition is not likely to recur after treatment is completed.

If malignant cells are detected on biopsy, local excision, laser therapy, local chemotherapy, and immunologic treatment are used. Vulvectomy is avoided, if possible, to spare the patient from the stress of disfigurement and possible sexual dysfunction.

Nursing Management

Key nursing responsibilities for patients with vulvar dystrophies focus on teaching. Important topics include hygiene and self-monitoring for signs and symptoms of complications.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Instructions for patients with benign vulvar dystrophies include the importance of maintaining good personal hygiene and keeping the vulva dry. Lanolin or hydrogenated vegetable oil is recommended for relief of dryness. Sitz baths may help but should not be overused because dryness may result or increase. The patient is instructed to notify her primary health care provider about any change or ulceration because biopsy may be necessary to rule out squamous cell carcinoma.

By encouraging all patients to perform genital self-examinations regularly and have any itching, lesions, or unusual symptoms assessed by a health care provider, nurses can help prevent complications and progression of vulvar lesions.

Ovarian Cysts

The ovary is a common site for cysts, which may be simple enlargements of normal ovarian constituents, the graafian follicle, or the corpus luteum, or they may arise from abnormal growth of the ovarian epithelium. The risk of malignancy is much greater in postmenopausal women than in premenopausal patients. Almost all pelvic masses in premenopausal women are benign (ACOG, 2007c).

Ovarian cysts are often detected on routine pelvic examination. Although these cysts are typically benign, they nevertheless should be evaluated to exclude ovarian cancer, particularly in postmenopausal women (ACOG, 2007c).

The patient may or may not report acute or chronic abdominal pain. Symptoms of a ruptured cyst mimic various acute abdominal emergencies, such as appendicitis or ectopic pregnancy. Larger cysts may produce abdominal swelling and exert pressure on adjacent abdominal organs.

Postoperative nursing care after surgery to remove an ovarian cyst is similar to that after abdominal surgery, with one exception. The marked decrease in intra-abdominal pressure resulting from removal of a very large cyst usually leads to considerable abdominal distention. This may be prevented to some extent by applying a snug-fitting abdominal binder.

Some surgeons discuss the option of a hysterectomy when a woman is undergoing bilateral ovary removal because of a suspicious mass; it may increase life expectancy and avoid a later second surgery. Patient preference is a priority in determining its appropriateness.

Polycystic ovary syndrome (PCOS) is another type of cystic disorder that affects the ovaries. This complex endocrine condition involves a disorder in the hypothalamic-pituitary and ovarian network or axis, resulting in chronic anovulation and clinical androgen excess, along with multiple small ovarian cysts called polycystic ovaries. Onset of PCOS may be at menarche or later; it occurs in approximately 5% to 10% of women of childbearing age (Stankiewicz & Norman, 2006). Features include obesity, insulin resistance, impaired glucose tolerance, dyslipidemia, sleep apnea, and infertility. Symptoms are related to androgen excess. Irregular menstrual periods, resulting from lack of regular ovulation, infertility, obesity, and hirsutism, may be a presenting complaint. Cysts form in the ovaries because the hormonal milieu cannot cause ovulation on a regular basis. Women with PCOS may develop insulin resistance and metabolic syndrome, and they may be at higher risk for diabetes and cardiac disorders in later life. Metformin (Glucophage) is also used to decrease the hyperinsulinemia that occurs with PCOS.

Medical Management

The treatment of large ovarian cysts is usually surgical removal. However, oral contraceptives may be used in young, healthy patients to suppress ovarian activity and resolve small cysts that appear to be fluid filled or physiologic.

Oral contraceptives are also usually prescribed to treat PCOS. When pregnancy is desired, medications to stimulate ovulation (clomiphene [Clomid]) are often effective. Lifestyle modification is critical, and weight management is part of the treatment plan.

Benign Tumors of the Uterus: Fibroids (Leiomyomas, Myomas)

Myomatous or **fibroid tumors** of the uterus are estimated to occur in 20% to 40% of women during their reproductive years. It is thought that women are genetically predisposed to develop this condition, which is almost always benign. Fibroids arise from the muscle tissue of the uterus and can be solitary or multiple, in the lining (intracavitary), muscle wall (intramural), and outside surface (serosal) of the uterus. They usually develop slowly in women between 25

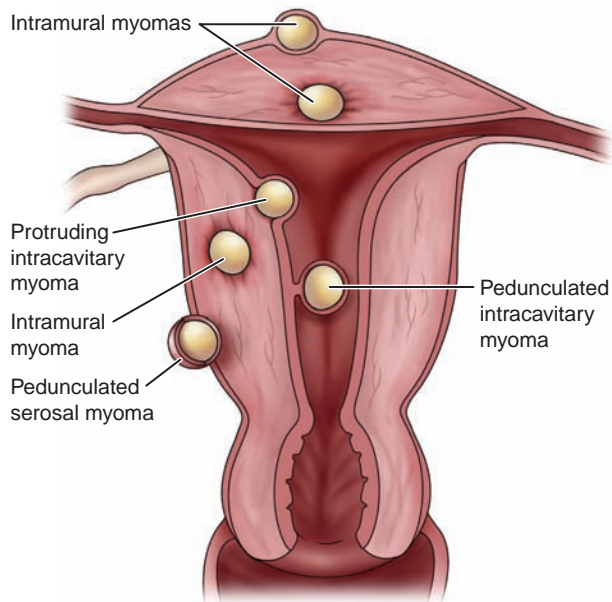

Figure 47-7 Myomas (fibroids). Those that impinge on the uterine cavity are called intracavitary myomas.

and 40 years of age and may become quite large. A growth spurt with enlargement of the fibroid tumor may occur in the decade before menopause, possibly related to anovulatory cycles and high levels of unopposed estrogen. Fibroids are a common reason for hysterectomy because they often result in menorrhagia, which can be difficult to control.

Clinical Manifestations

Fibroids may cause no symptoms, or they may produce abnormal vaginal bleeding. Other symptoms result from pressure on the surrounding organs and include pain, backache, pressure, bloating, constipation, and urinary problems. Menorrhagia (excessive bleeding) and metrorrhagia (irregular bleeding) may occur because fibroids may distort the uterine lining (Fig. 47-7). Fibroids may interfere with fertility.

Medical Management

Treatment of uterine fibroids may include medical or surgical intervention and depends to a large extent on the size, symptoms, and location, as well as the woman's age and her reproductive plans. Fibroids usually shrink and disappear during menopause, when estrogen is no longer produced. Simple observation and follow-up may be all the management that is necessary. The patient with minor symptoms is closely monitored. If she plans to have children, treatment is as conservative as possible. As a rule, large tumors that produce pressure symptoms should be removed (**myomectomy**). A hysterectomy may be performed if symptoms are bothersome and childbearing is completed (see later discussion of nursing care for a patient having a hysterectomy).

Several other alternatives to hysterectomy have been developed for the treatment of excessive bleeding due to fibroids (ACOG, 2007d). These include the following:

- Hysteroscopic resection of myomas: a laser is used through a hysteroscope passed through the cervix; no incision or overnight stay is needed

- Laparoscopic myomectomy: removal of a fibroid through a laparoscope inserted through a small abdominal incision
- Laparoscopic myolysis: a laser or electrical needles are used to cauterize and shrink the fibroid
- Laparoscopic cryomyolysis: electric current is used to coagulate the fibroid
- Uterine artery embolization (UAE): polyvinyl alcohol or gelatin particles are injected into the blood vessels that supply the fibroid via the femoral artery, resulting in infarction and resultant shrinkage. This percutaneous image-guided therapy offers an alternative to hormone therapy or surgery. UAE may result in infrequent but serious complications such as pain, infection, amenorrhea, necrosis, and bleeding. Although rare, deaths and ovarian failure may occur. Women need to weigh the risks and benefits carefully, especially if they have not completed childbearing. This procedure has been found to cause fewer complications than hysterectomy, but women may need further treatment in the future (Dutton, Hirst, McPherson, et al., 2008).
- Magnetic resonance-guided focused ultrasound surgery (MRgFUS): ultrasonic energy is passed through the abdominal wall to target and destroy the fibroid. Although not yet widely used, this noninvasive procedure is approved by the U.S. Food and Drug Administration for premenopausal women with bothersome symptoms due to fibroids and who do not want more children. It is an outpatient treatment (Stewart, Gostout, Rabinovici, et al., 2007).

Medications (eg, leuprolide [Lupron]) or other gonadotropin-releasing hormone (GnRH) analogues, which induce a temporary menopause-like environment, may be prescribed to shrink the fibroids. This treatment consists of monthly injections, which may cause hot flashes and vaginal dryness. Treatment is usually short term (ie, before surgery) to shrink the fibroids, allowing easier surgery, and to alleviate anemia, which may occur as a result of heavy menstrual flow. This treatment is used on a temporary basis because it leads to vasomotor symptoms and loss of bone density.

Antifibrotic agents are under investigation for long-term treatment of fibroids. Mifepristone (RU-486, Mifeprex), a progesterone antagonist, has also been prescribed; it appears to be effective (Fiscella, Eisinger, Meldrum, et al., 2006).

Endometriosis

Endometriosis is a chronic disease that affects between 5% to 15% of women of reproductive age. A benign lesion or lesions with cells similar to those lining the uterus grow aberrantly anywhere in the pelvic cavity outside the uterus. Often, extensive endometriosis causes few symptoms, whereas an isolated lesion may produce severe symptoms. It is a major cause of chronic pelvic pain and infertility.

Endometriosis has been diagnosed more frequently as a result of the increased use of laparoscopy, but diagnosis can often be delayed, and women with this problem often feel as if their complaints are being dismissed. Before

laparoscopy became widely available, major surgery was necessary before a diagnosis could be made. There is a high incidence among patients who bear children late and among those who have fewer children. In countries where tradition favors early marriage and early childbearing, endometriosis is rare. There also appears to be a familial predisposition to endometriosis; it is more common in women whose close female relatives are affected. Other factors that may suggest increased risk include a shorter menstrual cycle (less than every 27 days), flow longer than 7 days, outflow obstruction, and younger age at menarche. Characteristically, endometriosis is found in young, nulliparous women between 25 and 35 years of age and in adolescents, particularly those with dysmenorrhea that does not respond to nonsteroidal anti-inflammatory drugs (NSAIDs) or oral contraceptives.

Pathophysiology

Misplaced endometrial tissue responds to and depends on ovarian hormonal stimulation. During menstruation, this ectopic tissue bleeds, mostly into areas having no outlet, which causes pain and adhesions. The lesions are typically small and puckered, with a blue/brown/gray powder-burn appearance and brown or blue-black appearance, indicating concealed bleeding.

Endometrial tissue contained within an ovarian cyst has no outlet for the bleeding; this formation is referred to as a pseudocyst or chocolate cyst. Adhesions, cysts, and scar tissue may result, causing pain and infertility. Endometriosis may increase the risk of ovarian, renal, thyroid, and breast cancer (Melin, Sparén & Bergqvist, 2008).

Currently the best-accepted theory regarding the origin of endometrial lesions is the transplantation theory, which suggests that a backflow of menses (retrograde menstruation) transports endometrial tissue to ectopic sites through the fallopian tubes. Why some women with retrograde menstruation develop endometriosis and others do not is unknown. Endometrial tissue can also be spread by lymphatic or venous channels.

Clinical Manifestations

Symptoms vary but include dysmenorrhea, dyspareunia, and pelvic discomfort or pain. Dyschezia (pain with bowel movements) and radiation of pain to the back or leg may occur. Depression, loss of work due to pain, and relationship difficulties may result. Infertility may occur because of fibrosis and adhesions or because of a variety of substances (prostaglandins, cytokines, other factors) produced by the implants.

Assessment and Diagnostic Findings

A health history, including an account of the menstrual pattern, is necessary to elicit specific symptoms. On bimanual pelvic examination, fixed tender nodules are sometimes palpated, and uterine mobility may be limited, indicating adhesions. Laparoscopic examination confirms the diagnosis and helps stage the disease. In stage 1, patients have superficial or minimal lesions; stage 2, mild involvement; stage 3, moderate involvement; and stage 4, extensive involvement and dense adhesions, with obliteration of the cul-de-sac.

Medical Management

Treatment depends on the symptoms, the patient's desire for pregnancy, and the extent of the disease. If the woman does not have symptoms, routine examination may be all that is required. Other therapy for varying degrees of symptoms may be NSAIDs, oral contraceptives, GnRH agonists, or surgery. Pregnancy often alleviates symptoms because neither ovulation nor menstruation occurs.

Pharmacologic Therapy

Palliative measures include use of medications, such as analgesic agents and prostaglandin inhibitors, for pain. Hormonal therapy is effective in suppressing endometriosis and relieving dysmenorrhea (menstrual pain). Oral contraceptives are often used. Infrequently, side effects may occur with oral contraceptives, such as fluid retention, weight gain, and nausea. These can usually be managed by changing brands or formulations. Depo-Provera, an injectable contraceptive agent, may also be used.

Several types of hormonal therapy are also available in addition to oral contraceptives. A synthetic androgen, danazol (Danocrine), causes atrophy of the endometrium and subsequent amenorrhea. The medication inhibits the release of gonadotropin with minimal overt sex hormone stimulation. The drawbacks of this medication are that it is expensive and may cause troublesome side effects such as fatigue, depression, weight gain, oily skin, decreased breast size, mild acne, hot flashes, and vaginal atrophy. GnRH agonists decrease estrogen production and cause subsequent amenorrhea. Side effects are related to low estrogen levels (eg, hot flashes and vaginal dryness). Loss of bone density is often offset by concurrent use of estrogen. Leuprolide, an GnRH agonist, is injected monthly to suppress hormones and induce an artificial menopause, thus avoiding menstrual effects and relieving endometriosis. Some clinicians prescribe a combination of therapies. Most women continue treatment despite side effects, and symptoms diminish for 80% to 90% of women with mild to moderate endometriosis. Hormonal medications are not used in patients with a history of abnormal vaginal bleeding or liver, heart, or kidney disease. Bone density is followed carefully because of the risk of bone loss; hormone therapy is usually short term.

Surgical Management

If conservative measures are not helpful, surgery may be necessary to relieve pain and enhance the possibility of pregnancy. Surgery may be combined with use of medical therapy. The procedure selected depends on the patient. Laparoscopy may be used to fulgurate (cut with high-frequency current) endometrial implants and to release adhesions. Laser surgery is another option made possible by laparoscopy. Laser therapy vaporizes or coagulates the endometrial implants, thereby destroying this tissue. Other surgical options include endocoagulation and electrocoagulation, laparotomy, abdominal hysterectomy, **oophorectomy**, bilateral **salpingo-oophorectomy**, and appendectomy. For women older than 35 years of age or those willing to sacrifice reproductive capability, total hysterectomy is an option. Endometriosis recurs in many women.

Nursing Management

The health history and physical examination focus on specific symptoms (eg, pain) and when and how long they have been bothersome, the effect of prescribed medications, and the woman's reproductive plans. This information helps in determining the treatment plan. Explaining the various diagnostic procedures may help to alleviate the patient's anxiety. Patient goals include relief of pain, dysmenorrhea, dyspareunia, and avoidance of infertility.

As the treatment progresses, the woman with endometriosis and her partner may find that pregnancy is not easily possible, and the psychosocial impact of this realization must be recognized and addressed. Alternatives, such as in vitro fertilization or adoption, may be discussed at an appropriate time and referrals offered.

The nurse's role in patient education is to dispel myths and encourage the patient to seek care if dysmenorrhea or dyspareunia occurs. The Endometriosis Association (see Resources at the end of this chapter) is a helpful resource for patients seeking further information and support for this condition, which can cause disabling pain and severe emotional distress.

Chronic Pelvic Pain

Chronic pelvic pain is a common disorder of women that may be related to several of the previously discussed gynecologic disorders. Fifteen percent to 20% of women have chronic pelvic pain—that is, pelvic pain that persists for more than 6 months. It may be cyclic or intermittent and noncyclic. Causes may be reproductive, genitourinary, or gastrointestinal. A history of abuse, PID, endometriosis, interstitial cystitis, musculoskeletal disorders, irritable bowel syndrome, and previous surgery resulting in abdominal adhesions may be associated with chronic pelvic pain. Dysmenorrhea, dyspareunia, and lower abdominal pain may also be associated with sexual and physical abuse (Pikarinen, Saisto, Schei, et al., 2007).

Chronic pelvic pain is often difficult to treat. Treatment depends on physical and diagnostic test results and may include antidepressants, analgesics, oral contraceptives, GnRH agonists, exercise, and surgery.

Adenomyosis

In adenomyosis, the tissue that lines the endometrium invades the uterine wall. The incidence is highest in women 40 to 50 years of age. Symptoms include hypermenorrhea (excessive and prolonged bleeding), acquired dysmenorrhea, polymenorrhea (abnormally frequent bleeding), and premenstrual staining. Physical examination findings on palpation include an enlarged, firm, and tender uterus. Treatment depends on the severity of bleeding and pain. Hysterectomy may offer greater relief than more conservative therapies.

Endometrial Hyperplasia

This condition, a build-up of endometrial tissue, can be a precursor to endometrial cancer and often results from unopposed estrogen from any source. Estrogen therapy alone

without progesterone in a woman with a uterus can cause this condition. Women with anovulatory cycles, PCOS, or obesity may all have high circulating levels of estrogen. Tamoxifen (Nolvadex) may also be a causative factor (ACOG, 2006d). Diagnosis is by biopsy or ultrasound findings of thickness of the endometrium. Hyperplasia with atypia on a pathology or biopsy report indicates risk of progression. Progestin treatment may be effective, but hysterectomy may be advised if pathology from an endometrial biopsy shows atypia. Abnormal bleeding is the most common symptom.

MALIGNANT CONDITIONS

The projected incidence and estimated mortality for female reproductive cancers in the United States are (American Cancer Society [ACS], 2009):

- Cervical cancer: about 11,300 new cases and 4,100 deaths
- Uterine cancer: about 42,100 new cases and 7,800 deaths
- Ovarian cancer: about 21,600 new cases and 14,600 deaths
- Vaginal cancer: about 2,160 new cases and 770 deaths
- Vulvar cancer: about 3,600 new cases and 900 deaths

Cervical cancer is the second most prevalent cancer in women worldwide and the fifth leading cause of cancer deaths. Worldwide, the incidence is declining. Pap smears in developed countries have resulted in increased detection of preinvasive lesions and decreased cancer death rates. Eighty percent of all cases of cervical cancer are found in developing countries, where early detection methods are often not available (U.S. Cancer Statistics Working Group, 2007).

Although death rates from all cancers are decreasing in the United States and other developed countries, cancer in developing countries is increasing. Many of these cases affect women. Although infectious diseases and HIV are often high priorities in these countries, the toll of increasing malignancies needs to be considered.

Although some cancers are difficult to detect or prevent, annual pelvic examination with a Pap smear is a painless and relatively inexpensive method of early detection. Health care providers can encourage women to follow this health practice by providing nonstressful examinations that are educational and supportive and offer women an opportunity to ask questions and clarify misinformation. If more women understood that gynecologic examinations and Pap smears do not have to be uncomfortable or embarrassing, early detection rates would likely improve and lives would be saved.

Many women diagnosed with gynecologic malignancies experience depression and anxiety. The occurrence of physical symptoms may cause psychological distress. Intervention directed toward physical and psychological symptoms requires a multidisciplinary approach.

Nurses should be aware of ongoing clinical trials that are being conducted to identify effective treatments for many conditions. They are often in a position to answer questions about clinical trials and to encourage patients to consider

participation if appropriate. Women's participation in cancer research may occur in part because women are unaware of ongoing relevant research.

Cancer of the Cervix

Carcinoma of the cervix is predominantly squamous cell cancer. Cervical cancer is less common than it once was because of early detection of cell changes by Pap smear. However, it is still the third most common female reproductive cancer and is estimated to affect more than 11,300 women in the United States every year (ACS, 2009). Risk factors are presented in Chart 47-5.

Preventive measures include regular pelvic examinations and Pap tests for all women, especially older women past childbearing age. This decreases the chance of dying from cervical cancer from 1 in 250 to 1 in 2,000. Preventive counseling should encourage delaying first intercourse, avoiding HPV infection, participating in safer sex only, smoking cessation, and receiving HPV immunization (see earlier discussion).

There are several different types of cervical cancer. Most of these cancers are squamous cell carcinomas and the remainder are adenocarcinomas or mixed adenosquamous carcinomas. Adenocarcinomas begin in mucus-producing glands and are often due to HPV infection. Most cervical cancers, if not detected and treated, spread to regional pelvic lymph nodes, and local recurrence is not uncommon.

Clinical Manifestations

Early cervical cancer rarely produces symptoms. If symptoms are present, they may go unnoticed as a thin watery vaginal discharge often noticed after intercourse or douching. When symptoms such as discharge, irregular bleeding,

or pain or bleeding after sexual intercourse occur, the disease may be advanced. Advanced disease should not occur if all women have access to gynecologic care and avail themselves of it. The nurse's role in access to care and its utilization is crucial.

In advanced cervical cancer, the vaginal discharge gradually increases and becomes watery and, finally, dark and foul-smelling from necrosis and infection of the tumor. The bleeding, which occurs at irregular intervals between periods (metrorrhagia) or after menopause, may be slight (just enough to spot the undergarments) and occurs usually after mild trauma or pressure (eg, intercourse, douching, or bearing down during defecation). As the disease continues, the bleeding may persist and increase. Leg pain, dysuria, rectal bleeding, and edema of the extremities signal advanced disease.

As the cancer advances, it may invade the tissues outside the cervix, including the lymph glands anterior to the sacrum. In one third of patients with invasive cervical cancer, the disease involves the fundus. The nerves in this region may be affected, producing excruciating pain in the back and the legs that is relieved only by large doses of opioid analgesics. If the disease progresses, it often produces extreme emaciation and anemia, usually accompanied by fever due to secondary infection and abscesses in the ulcerating mass, and by fistula formation. Because the survival rate for in situ cancer is 100% and the rate for women with more advanced stages of cervical cancer decreases dramatically, early detection is essential.

Assessment and Diagnostic Findings

Diagnosis may be made on the basis of abnormal Pap smear results, followed by biopsy results identifying severe dysplasia (cervical intraepithelial neoplasia type III [CIN III], high-grade squamous intraepithelial lesions [HGSIL; also referred to as HSIL], or carcinoma in situ; see below). HPV infections are usually implicated in these conditions. Carcinoma in situ is technically classified as severe dysplasia and is defined as cancer that has extended through the full thickness of the epithelium of the cervix, but not beyond. This is often referred to as preinvasive cancer.

In its very early stages, invasive cervical cancer is found microscopically by Pap smear. In later stages, pelvic examination may reveal a large, reddish growth or a deep, ulcerating lesion. The patient may report spotting or bloody discharge.

When the patient has been diagnosed with invasive cervical cancer, clinical staging estimates the extent of the disease so that treatment can be planned more specifically and prognosis reasonably predicted. The tumor, nodes, and metastases (TNM) system is the most widely used staging system. The TNM classification is also used in describing cancer stages. In this system, T refers to the extent of the primary tumor, N to lymph node involvement, and M to metastasis, or spread of the disease.

Signs and symptoms are evaluated, and x-rays, laboratory tests, and special examinations, such as punch biopsy and colposcopy, are performed. Depending on the stage of the cancer, other tests and procedures may be performed to determine the extent of disease and appropriate treatment. These tests may include dilation and curettage (D & C),

CHART
47-5

Risk Factors for Cervical Cancer

- Sexual activity:
 - Multiple sex partners
 - Early age (younger than 20) at first coitus (exposes the vulnerable young cervix to potential viruses from a partner)
- Sex with uncircumcised males
- Sexual contact with males whose partners have had cervical cancer
- Early childbearing
- Exposure to human papillomavirus, types 16 and 18
- HIV infection and other causes of immunodeficiency
- Smoking and exposure to secondhand smoke
- Exposure to diethylstilbestrol (DES) in utero
- Family history of cervical cancer
- Low socioeconomic status (may be related to early marriage and early childbearing)
- Nutritional deficiencies (folate, beta-carotene, and vitamin C levels are lower in women with cervical cancer than in women without it)
- Chronic cervical infection
- Overweight status

computed tomography (CT), magnetic resonance imaging (MRI), IV urography, cystography, positron emission tomography, and barium x-ray studies.

Medical Management

Precursor or Preinvasive Lesions

When precursor lesions, such as low-grade squamous intraepithelial lesion (LGSIL; also referred to as LSIL) (CIN I and II or mild to moderate dysplasia), are found by colposcopy and biopsy, careful monitoring by frequent Pap smears or conservative treatment is possible. Conservative treatment may consist of monitoring, **cryotherapy** (freezing with nitrous oxide), or laser therapy. A **loop electrocautery excision procedure (LEEP)** may also be used to remove abnormal cells. In this procedure, a thin wire loop with laser is used to cut away a thin layer of cervical tissue. LEEP is an outpatient procedure usually performed in a gynecologist's office; it takes only a few minutes. Analgesia is given before the procedure, and a local anesthetic agent is injected into the area. This procedure allows the pathologist to examine the removed tissue sample to determine if the borders of the tissue are disease free. Another procedure called a cone biopsy or **conization** (removing a cone-shaped portion of the cervix) is performed when biopsy findings demonstrate CIN III or HGSIL (equivalent to severe dysplasia) and carcinoma in situ.

If preinvasive cervical cancer (carcinoma in situ) occurs when a woman has completed childbearing, a simple hysterectomy (removal of the uterus only) is usually recommended. If a woman has not completed childbearing and invasion is less than 1 mm, conization may be sufficient. Frequent follow-up examinations are necessary to monitor for recurrence.

Patients who have precursor or premalignant lesions need reassurance that they do not have invasive cancer. However, the importance of close follow-up is emphasized because the condition, if untreated for a long time, may progress to cancer. Patients with cervical cancer in situ also need to know that this is usually a slow-growing and nonaggressive type of cancer that is not expected to recur after appropriate treatment.

Invasive Cancer

Treatment of invasive cervical cancer depends on the stage of the lesion, the patient's age and general health, and the judgment and experience of the physician. Surgery and radiation treatment (intracavitary and external) are most often used. Surgical procedures that may be used to treat cervical cancer are summarized in Chart 47-6. When tumor invasion is less than 3 mm, a hysterectomy is often sufficient. Invasion exceeding 3 mm usually requires a radical hysterectomy with pelvic node dissection and aortic node assessment. Stage 1B1 tumors are treated with radical hysterectomy and radiation. Stage 1B2 tumors are treated individually, because no single correct course of treatment has been identified and many variable options may be considered.

A procedure called a radical trachelectomy is an alternative to hysterectomy in women with invasive cervical cancer who are young and want to have children. In this procedure, the cervix is gripped with retractors and pulled

Chart 47-6 • Surgical Procedures for Cervical Cancer

- Total hysterectomy—removal of the uterus, cervix, and ovaries
- Radical hysterectomy—removal of the uterus, ovaries, fallopian tubes, proximal vagina, and bilateral lymph nodes through an abdominal incision (*Note:* “radical” indicates that an extensive area of the paravaginal, paracervical, parametrial, and uterosacral tissues is removed with the uterus.)
- Radical vaginal hysterectomy—vaginal removal of the uterus, ovaries, fallopian tubes, and proximal vagina
- Bilateral pelvic lymphadenectomy—removal of the common iliac, external iliac, hypogastric, and obturator lymphatic vessels and nodes
- Pelvic exenteration—removal of the pelvic organs, including the bladder or rectum and pelvic lymph nodes, and construction of diversional conduit, colostomy, and vagina
- Radical trachelectomy—removal of the cervix and selected nodes to preserve childbearing capacity in a woman of reproductive age with cervical cancer

down into the vagina until it is visible. The affected tissue is excised while the rest of the cervix and uterus remain intact. A drawstring suture is used to close the cervix.

Frequent follow-up after surgery by a gynecologic oncologist is imperative because the risk of recurrence is 35% after treatment for invasive cervical cancer. Recurrence usually occurs within the first 2 years. Recurrences are often in the upper quarter of the vagina, and ureteral obstruction may be a sign. Weight loss, leg edema, and pelvic pain may be signs of lymphatic obstruction and metastasis. Micrometastases have been found in patients with negative lymph nodes.

Radiation, which is often part of treatment to reduce recurrent disease, may be delivered by an external beam or by **brachytherapy** (method by which the radiation source is placed near the tumor) or both. The field to be irradiated and dose of radiation are determined by stage, volume of tumor, and lymph node involvement. Treatment can be administered daily for 4 to 6 weeks followed by one or two treatments of intracavitary radiation. Interstitial therapy may be used when vaginal placement has become impossible because of tumor or stricture.

Platinum-based agents are being used to treat advanced cervical cancer. They are often used in combination with radiation therapy, surgery, or both. Studies are ongoing to find the best approach to treat advanced cervical cancer. Vaginal stenosis is a frequent side effect of radiation. Sexual activity, with lubrication, is preventive, as is use of a vaginal dilator to avoid severe permanent vaginal stenosis.

Some patients with recurrences of cervical cancer are considered for **pelvic exenteration**, in which a large portion of the pelvic contents is removed. This is a complex, extensive surgical procedure that is reserved for women with a high likelihood of cure. Unilateral leg edema, sciatica, and ureteral obstruction indicate likely disease progression. Patients with these symptoms have advanced disease and are not considered candidates for this major surgical procedure.

Surgery is often complex because it is performed close to the bowel, bladder, ureters, and great vessels. Complications can be considerable and include pulmonary emboli, pulmonary edema, myocardial infarction, cerebrovascular accident, hemorrhage, sepsis, small bowel obstruction, fistula formation, obstruction of the ileal conduit, bladder dysfunction, and pyelonephritis, most often in the first 18 months. Vein constriction must be avoided postoperatively. Patients with varicose veins or a history of thromboembolic disease may be treated prophylactically with heparin. Anti-embolism stockings are prescribed to reduce the risk of deep vein thrombosis (DVT). Nursing care of these patients is complex and requires coordination and care by experienced health care professionals. Pelvic exenteration is discussed in further detail later in this chapter.

Cancer of the Uterus (Endometrium)

Although the incidence of cancer of the uterine endometrium (fundus or corpus) has stabilized, the death rate from this cancer has increased, possibly because of increased lifespan and coexisting comorbidities. This cancer is the most frequently occurring gynecological cancer in the United States. After breast, colorectal, and lung cancer, endometrial cancer is the fourth most common cancer in women. More than 42,100 new cases of uterine cancer occur each year, with more than 7,800 deaths (ACS, 2009). Most women are diagnosed between 55 and 64 years of age. Seventy percent of women with endometrial cancer are obese; obesity increases the risk of morbidity and mortality from this disease. This disease occurs twice as often in Caucasian women as in African American women, who have a less favorable prognosis, and research is needed to explain this disparity (Sorosky, 2008). Cumulative exposure to estrogen is considered the major risk factor (Chart 47-7). This exposure occurs with the use of estrogen therapy without the use of progestin, early menarche, late menopause, nulliparity, and anovulation. Other risk factors include obesity, infertility, and diabetes, as well as use of tamoxifen. This medication, taken for treatment or prevention of breast cancer, may cause proliferation of the uterine lining (ACOG, 2006d). Women who take it should be monitored by their oncologists and gynecologic health care providers.

CHART
47-7

Risk Factors for Uterine Cancer

- Age: at least 55 years; median age, 61 years
- Obesity that results in increased estrone levels (related to excess weight) resulting from conversion of androstenedione to estrone in body fat, which exposes the uterus to unopposed estrogen
- Unopposed estrogen therapy (estrogen used without progesterone, which offsets the risk of unopposed estrogen)
- Other: nulliparity, truncal obesity, late menopause (after 52 years of age) and use of tamoxifen

Pathophysiology

Most uterine cancers are endometrioid (ie, originating in the lining of the uterus). There are three types. Type 1, which accounts for the majority of cases, is estrogen related and occurs in younger, obese, and perimenopausal women. It is usually low grade and endometrioid. Type 2, which occurs in about 10% of cases, is high grade and usually serous cell or clear cell. It affects older women and African American women. Type 3, which also occurs in about 10% of cases, is the hereditary and genetic types, some of which are related to Lynch II syndrome. (This syndrome is associated with the occurrence of breast, ovarian, colon, endometrial, and other cancers throughout a family.)

Assessment and Diagnostic Findings

All women should be encouraged to have annual checkups, including a gynecologic examination. Any woman who is experiencing irregular bleeding should be evaluated promptly. If a menopausal woman experiences bleeding, an endometrial aspiration or biopsy is performed to rule out hyperplasia, a possible precursor of endometrial cancer. The procedure is quick and usually painless. Ultrasonography can also be used to measure the thickness of the endometrium. (Postmenopausal women should have a very thin endometrium due to low levels of estrogen; a thicker lining warrants further investigation.) A biopsy or aspiration for tissue pathology is diagnostic.

Medical Management

Treatment of endometrial cancer consists of total or radical hysterectomy (discussed later in this chapter) and bilateral salpingo-oophorectomy and node sampling. It is necessary to monitor cancer antigen 125 (CA-125) levels, because elevated levels are a significant predictor of extrauterine disease or metastasis. Depending on the stage, the therapeutic approach is individualized and is based on stage, type, differentiation, degree of invasion, and node involvement. Adjuvant radiation may be used in a patient who is considered high risk. Vaginal brachytherapy is being studied as adjuvant therapy. Whole pelvis radiotherapy may be used if there is any spread beyond the uterus. Recurrent cancer usually occurs inside the **vaginal vault** or in the upper vagina, and metastasis usually occurs in lymph nodes or the ovary. Recurrent lesions in the vagina are treated with surgery and radiation. Recurrent lesions beyond the vagina are treated with hormonal therapy or chemotherapy. Progestin therapy is used frequently. Patients should be prepared for such side effects as nausea, depression, rash, or mild fluid retention with progestin therapy.

Cancer of the Vulva

Primary cancer of the vulva represents 4% of all gynecologic malignancies and is seen mostly in postmenopausal women, although its incidence in younger women is increasing. The median age for cancer limited to the vulva is 50 years, whereas the median age for invasive vulvar cancer is 70 years. Possible risk factors include smoking, HPV infection, HIV infection, and immunosuppression. Squamous cell carcinoma

accounts for most primary vulvar tumors. Less common are Bartholin's gland cancer, vulvar sarcoma, and malignant melanoma. Little is known about what causes this disease; however, increased risk may be related to chronic vulvar irritation. In younger women, HPV infection may be implicated, especially types 16, 18, and 31. Prevention includes delaying onset of sexual activity to avoid early exposure to HPV and avoidance of smoking. Regular pelvic examinations, Pap smears, and vulvar self-examination are helpful in early detection. Women with persistent irritation or itching should be encouraged to seek evaluation.

Clinical Manifestations

Long-standing pruritus and soreness are the most common symptoms of vulvar cancer. Itching occurs in half of all patients with vulvar malignancy. Bleeding, foul-smelling discharge, and pain may also be present and are usually signs of advanced disease. Cancerous lesions of the vulva are visible and accessible and grow relatively slowly. Early lesions appear as a chronic dermatitis; later, patients may note a lump that continues to grow and becomes a hard, ulcerated, cauliflower-like growth. Biopsy should be performed on any vulvar lesion that persists, ulcerates, or fails to heal quickly with proper therapy. Vulvar malignancies may appear as a lump or mass, redness, or a lesion that fails to heal.

Nurses are in an ideal position to encourage women to perform vulvar self-examinations regularly. Using a mirror, patients can see what constitutes normal female anatomy and learn about changes that should be reported (eg, lesions, ulcers, masses, and persistent itching). Nurses must urge women to seek health care if they notice anything abnormal, because vulvar cancer is one of the most curable of all malignant conditions.

Medical Management

Vulvar intraepithelial lesions are preinvasive and are also called vulvar carcinoma in situ. They may be treated by local excision, laser ablation, application of chemotherapeutic creams, or cryosurgery.

When invasive vulvar carcinoma exists, primary treatment may include wide excision or removal of the vulva (**vulvectomy**). An effort is made to individualize treatment, depending on the extent of the disease. A wide excision is performed only if lymph nodes are normal. More pervasive lesions require vulvectomy with deep pelvic node dissection. Vulvectomy is very effective at prolonging life but is frequently followed by complications (ie, scarring, wound breakdown, leg swelling, vaginal stenosis, or rectocele). To reduce complications, only necessary tissue is removed. External beam radiation may be used, resulting in sunburn-like irritation that usually resolves in 6 to 12 months. Laser therapy and chemotherapy are other possible treatment options.

If a widespread area is involved or the disease is advanced, a radical vulvectomy with bilateral groin dissection may be performed. Antibiotic and heparin prophylaxis may be prescribed preoperatively and continued postoperatively to prevent infection, DVT, and pulmonary emboli. Anti-embolism stockings are applied to reduce the risk of DVT.

Although the role of systemic chemotherapy in the treatment of vulvar cancer remains to be determined,

chemotherapy may be useful when used in combination with radiation therapy for the treatment of advanced disease. The combination of radiation and chemotherapy may reduce the size of the cancer, resulting in less extensive subsequent surgery (ACS, 2009).

Clinical trials to determine the most effective treatment are difficult to conduct because there are few patients with this condition. Morbidity with recurrence of the disease is high, and patterns of recurrence vary. Reconstruction after vulvectomy is performed by plastic surgeons when appropriate and desired.

Nursing Management

Assessment

The health history is a valuable tool for establishing rapport with the patient. The reason the patient is seeking health care is apparent. What the nurse can tactfully elicit is the reason why a delay, if any, occurred, in seeking health care—for example, because of modesty, economics, denial, neglect, or fear (abusive partners sometimes prevent women from seeking health care). Factors involved in any delay in seeking health care and treatment may also affect recovery. The patient's health habits and lifestyle are assessed, and her receptivity to teaching is evaluated. Psychosocial factors are also assessed. Preoperative preparation and psychological support begin at this time.

Preoperative Nursing Interventions

Relieving Anxiety

Prior to surgery, the patient must be allowed time to talk and ask questions. Fear often decreases when a woman who is to undergo wide excision of the vulva or vulvectomy learns that the possibility for subsequent sexual relations is good and that pregnancy is possible after a wide excision. The nurse reinforces the information the physician has given to the patient and addresses the patient's questions and concerns.

Preparing Skin for Surgery

Skin preparation may include cleansing the lower abdomen, inguinal areas, upper thighs, and vulva with a detergent germicide for several days before the surgical procedure. The patient may be instructed to do this at home.

Postoperative Nursing Interventions

Relieving Pain

Because of the wide excision, the patient may experience severe pain and discomfort even with minimal movement. Therefore, analgesic agents are administered preventively (ie, around the clock at designated times) to relieve pain, increase the patient's comfort level, and allow mobility. Patient-controlled analgesia (see Chapter 13) may be used to relieve pain and promote patient comfort. Careful positioning using pillows usually increases comfort, as do soothing back rubs. A low Fowler's position or, occasionally, a pillow placed under the knees reduces pain by relieving tension on the incision; however, efforts must be made to avoid pressure behind the knees, which increases the risk of DVT. Positioning the patient on her side, with pillows between her

legs and against the lumbar region, provides comfort and reduces tension on the surgical wound.

Improving Skin Integrity

A pressure-reducing mattress may be used to prevent pressure ulcers. Moving from one position to another requires time and effort; use of an overhead trapeze bar may help the patient move herself more easily. Ambulation may be attempted on the second day.

The extent of the surgical incision and the type of dressing are considered when choosing strategies to promote skin integrity. Intact skin needs to be protected from drainage and moisture. Dressings are changed as needed to ensure patient comfort, to perform wound care and irrigation (if prescribed), and to permit observation of the surgical site.

The wound is usually cleansed daily with warm, normal saline irrigations or other antiseptic solutions as prescribed, or a transparent dressing may be in place over the wound to minimize exposure to the air and subsequent pain. The appearance of the surgical site and the characteristics of drainage are assessed and documented. After the dressings are removed, a bed cradle may be used to keep the bed linens away from the surgical site. The patient is always protected from exposure when visitors arrive or someone else enters the room.

Supporting Positive Sexuality and Sexual Function

The patient who undergoes vulvar surgery usually experiences concerns about body image, sexual attractiveness, and functioning. Establishing a trusting nurse–patient relationship is important for the patient to feel comfortable expressing her concerns and fears. The patient is encouraged to discuss her concerns with her sexual partner.

Because alterations in sexual sensation and functioning depend on the extent of surgery, the nurse needs to know about any structural and functional changes resulting from the surgery. Referral of the patient and her partner to a sex counselor may help them address these changes and resume satisfying sexual activity.

Monitoring and Managing Potential Complications

Location, extent, and exposure of the surgical site and incision put the patient at risk for contamination of the site and infection and sepsis. The patient is monitored closely for local and systemic signs and symptoms of infection: purulent drainage, redness, increased pain, fever, and increased white blood cell count. The nurse assists in obtaining specimens for culture if infection is suspected and administers antibiotic agents as prescribed. Hand hygiene, always a crucial infection-preventing measure, is of particular importance along with wearing masks whenever there is an extensive area of exposed tissue. Catheters, drains, and dressings are handled carefully with gloves on to avoid cross-contamination. A low-residue diet prevents straining on defecation and wound contamination.

The patient is at risk for DVT because of the positioning required during surgery, postoperative edema, and the usually prolonged immobility needed to promote healing. Anti-embolism stockings are applied, and the patient is encouraged and reminded to perform ankle exercises to minimize venous pooling, which leads to DVT. The patient is en-

couraged and assisted in changing positions by using the overhead trapeze bar. Pressure behind the knees is avoided when positioning the patient because this may increase venous pooling. The patient is assessed for signs and symptoms of DVT (leg pain, redness, warmth, edema) and pulmonary embolism (chest pain, tachycardia, dyspnea). Fluid intake is encouraged to prevent dehydration, which also increases the risk of DVT.

The extent of the surgical incision and possibly wide excision of tissue increase the risk of postoperative bleeding and hemorrhage. Although the pressure dressings that are applied after surgery minimize the risk, the patient must be monitored closely for signs of hemorrhage and resulting hypovolemic shock. These signs may include decreased blood pressure; increased pulse rate; decreased urine output; decreased mental status; and cold, clammy skin.

If hemorrhage and shock occur, interventions include fluid replacement, blood component therapy, and vasopressor medications. Laboratory results (eg, hematocrit and hemoglobin levels) and hemodynamic monitoring are used to assess the patient's response to treatment. Depending on the specific cause of hemorrhage, the patient may be returned to the operating room. See Chapter 15 for a detailed discussion of shock.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Preparing the patient for hospital discharge begins before hospital admission. The patient and family are informed about what to expect during the immediate postoperative and recovery periods. Depending on the changes resulting from the surgery, the patient and her family may need instruction about wound care, urinary catheterization, and possible complications. The patient is encouraged to share her concerns and to assume increasing responsibility for her own care. She is encouraged and assisted in learning to care for the surgical site. A referral for home care is made as indicated.

Continuing Care

Shortened hospital stays may result in the patient's discharge during the early postoperative recovery stage to home or a subacute facility. During this phase, the patient's physical status and psychological responses to the surgery are assessed. In addition, the patient is assessed for complications and healing of the surgical site. During home visits, the nurse assesses the home to determine if modifications are needed to facilitate care. The home visit is used to reinforce previous teaching and to assess the patient's and the family's understanding of and adherence to the prescribed treatment strategies. Follow-up phone calls by the nurse to the patient between home visits are usually reassuring to the patient and family, who may be responsible for performing complex care procedures. Attention to the patient's psychological responses is important because the patient may become discouraged and depressed because of alterations in body image and a slow recovery. Communication between the nurse involved in the patient's immediate postoperative care and the home care nurse is essential to ensure continuity of care.

Cancer of the Vagina

Cancer of the vagina is rare and usually takes years to develop. Primary cancer of the vagina is usually squamous in origin. Malignant melanoma and sarcomas can occur. Risk factors include previous cervical cancer, in utero exposure to diethylstilbestrol (DES), previous vaginal or vulvar cancer, previous radiation therapy, history of HPV, or pessary use. Any patient with previous cervical cancer should be examined regularly for vaginal lesions.

Before 1970, vaginal cancer occurred primarily in postmenopausal women. In the 1970s, it was shown that maternal ingestion of DES, prescribed from 1938 to 1971 to enhance pregnancy outcomes, affected female offspring who were exposed in utero. DES was prescribed under many brand names, and it is unclear how many pregnant women received it. All patients should be asked about DES exposure if they were born or were pregnant between 1938 and 1971. Benign genital tract abnormalities, such as vaginal adenosis (abnormal tissue growth), cervical irregularities (collars, hoods, septae, cockscombs), and uterine abnormalities, have occurred in approximately one third of exposed women. Clear cell carcinoma of the vagina or cervix may also occur as a result of DES exposure; the risk is 0.14 to 1.4 in 1000 women. However, most female offspring of mothers who took DES are now between 40 and 75 years of age, and diagnosis of this condition has been decreasing. Vigilance is still necessary because it is unknown how long women remain at risk (ACS, 2009). Colposcopy is indicated for all women exposed to DES in utero. If colposcopic examination discloses adenosis or a significant cervical or vaginal lesion, follow-up is essential. In addition, health care providers should be aware that men who were exposed to DES in utero may have an increased risk of developing epididymal cysts.

Vaginal pessaries, used to support prolapsed tissues, can be a source of chronic irritation. As such, they have been associated with vaginal cancer, but only when the devices were not cared for properly (ie, the device was not cleaned regularly or the patient did not return to the health care provider regularly for vaginal examinations).

Patients often do not have symptoms but may report slight bleeding after intercourse, spontaneous bleeding, vaginal discharge, pain, and urinary or rectal symptoms (or both). Diagnosis is often by Pap smear of the vagina. Encouraging close follow-up by health care providers is the primary focus of nursing interventions with women who were exposed to DES in utero. Emotional support for mothers who received DES before its risks were discovered and their daughters who were exposed to DES in utero is essential.

Medical Management

Treatment of early lesions may include local excision, topical chemotherapy, or laser. Laser therapy is a common treatment option in early vaginal and vulvar cancer. Surgery for more advanced lesions depends on the size and the stage of the cancer. If radical vaginectomy is required, a vagina can be reconstructed with tissue from the intestine, muscle, or skin grafts. After vaginal reconstructive surgery and radiation, regular intercourse may be helpful in preventing vaginal

stenosis. Water-soluble lubricants are helpful in reducing pain with intercourse (dyspareunia).

Following surgery, radiation therapy may be administered by a variety of methods, including external beam radiation, which is usually an outpatient procedure, or brachytherapy, which is internal radiation therapy. Internal radiation may be given with intracavitary radioactive material contained in a seed, wire, needle, or tube, which is placed into a cavity such as the uterus or vagina. Interstitial radiation is another type of internal radiation treatment in which the radioactive material is placed in or near the cancer but not into a body cavity and is used in cervical and ovarian malignancies. These treatments may be high dose for a short period or low dose, which may take longer. Treatment during hospitalization or during outpatient therapy depends on several factors, including the status of the patient and the mode of delivery.

Cancer of the Fallopian Tubes

Malignancies of the fallopian tube are the least common type of genital cancer. Although this type of cancer can occur at any age, the average age at diagnosis is 55 years. Symptoms include abdominal pain, abnormal bleeding, and vaginal discharge. An enlarged fallopian tube may be found on sonogram if dilated and fluid filled or it may appear or be palpated as a mass. Surgery followed by radiation therapy is the usual treatment.

Cancer of the Ovary

Ovarian cancer is the leading cause of gynecological cancer deaths in the United States (Jemal, Siegel, Ward, et al., 2007). Despite careful physical examination, ovarian tumors are often difficult to detect because they are usually deep in the pelvis. No early screening mechanism exists at present, although tumor markers are being explored. Transvaginal ultrasound and CA-125 antigen testing may be reassuring for women who have a high risk for this condition, and clinical trials are under way to evaluate the effect of these screening modalities on mortality from ovarian cancer. Tumor-associated antigens are helpful in determining follow-up care after diagnosis and treatment but not in early general screening.

Epidemiology

One woman in 70 will develop ovarian cancer in her lifetime. The incidence of this type of cancer increases after 40 years of age and peaks in the early 80s; the median age of affected women is 63 years. The frequency of ovarian cancer is highest in industrialized countries, except for Japan, where it is low. The incidence seems to be remaining constant, and 5-year survival has improved (Bhoola & Hoskins, 2006). Pregnancy and use of oral contraceptives decrease risk. Mutations of *BRCA1* and *BRCA2* increase risk; the lifetime risk for women with these mutations is 28% to 40% (the higher percentage is in Ashkenazi Jews).

A woman with ovarian cancer has a threefold to fourfold increased risk of breast cancer, and a woman with breast

cancer has an increased risk of ovarian cancer. A family history, older age, low parity, and obesity may increase risk of ovarian cancer. However, most women who develop ovarian cancer have no known risk factors, and no definitive causative factors have been determined.

Genetic testing is indicated when three or more cases of closely related family members have premenopausal breast cancer or ovarian cancer. One member with cancer is tested, and if the results are positive, other members without cancer may undergo testing. This testing is available at centers with genetics counselors or nurses with expertise in genetics counseling. Many health care providers advocate pelvic examinations every 6 months for women who have one or two relatives with ovarian cancer. It is recommended that women with a family history of breast or ovarian cancer undergo periodic screening.

Much more needs to be learned about the risks associated with some mutations, the reliability of testing, and the efficacy of follow-up. Confidentiality and insurance risks are ethical issues that need clarification. Because there are no primary methods of preventing breast or ovarian cancer, emotional distress is also an issue. Patients with concerns about their family history should be referred to a cancer genetics center to obtain information and testing, if indicated. Women with inherited types of ovarian cancer tend to be younger when the diagnosis is made than the average age at the time of diagnosis. Prophylactic oophorectomy in women with genetic mutations has been found to be associated with decreased risk of ovarian and other gynecologic cancers as well as breast cancer and is an option for women who have completed childbearing (ACOG, 2008a). Hereditary nonpolyposis colon cancer increases the risk of uterine cancer and slightly increases the risk of ovarian cancer.

Pathophysiology

Types of tumors include germ cell tumors, which arise from the cells that produce eggs; stromal cell tumors, which arise in connective tissue cells that produce hormones; and epithelial tumors, which originate from the outer surface of the ovary. Most ovarian cancers are epithelial in origin. Of the many different cell types in ovarian cancer, epithelial tumors constitute 90%. Germ cell tumors and stromal tumors make up the other 10%.

Primary peritoneal carcinoma is closely related to ovarian cancer. Extraovarian primary peritoneal carcinoma (EOPPC) resembles ovarian cancer histologically and can occur in women with and without ovaries. Symptoms and treatment are similar. Because of the possibility of EOPPC, oophorectomy does not guarantee that the patient will not develop carcinoma following hysterectomy.

Clinical Manifestations

Symptoms of ovarian cancer are nonspecific and may include increased abdominal girth, pelvic pressure, bloating, back pain, constipation, abdominal pain, urinary urgency, indigestion, flatulence, increased waist size, leg pain, and pelvic pain. Symptoms are often vague, so many women tend to ignore them. Ovarian cancer is often silent, but enlargement of the abdomen from an accumulation of fluid is the most common sign. All women with gastrointestinal symptoms and without a known diagnosis must be evaluated

for potential ovarian cancer. Vague, undiagnosed, persistent gastrointestinal symptoms should alert the nurse to the possibility of an early ovarian malignancy. A palpable ovary in a woman who has gone through menopause is investigated immediately because ovaries normally become smaller and less palpable after menopause.

Assessment and Diagnostic Findings

Any enlarged ovary must be investigated. Pelvic examination often does not detect early ovarian cancer, and pelvic imaging techniques are not always definitive. Ovarian tumors are classified as benign if there is no proliferation or invasion, borderline if there is proliferation but no invasion, and malignant if there is invasion. Fifteen percent of all new cases of ovarian tumors are classified as borderline and have low malignancy potential. However, by the time of diagnosis, most ovarian cancers are advanced (Ryerson, Ehemann, Burton, et al., 2007).

Surgical Management

Surgical staging, exploration, and reduction of tumor mass are the basics of treatment. Surgical removal is the treatment of choice; the preoperative workup may include a barium enema or colonoscopy, upper gastrointestinal series, MRI, ultrasound, chest x-rays, and IV urography. CT may be used preoperatively to rule out intra-abdominal metastasis. Staging the tumor by the TNM system is performed to guide treatment (Chart 47-8). Likely treatment involves a total abdominal hysterectomy with removal of the fallopian tubes and ovaries and possibly the omentum (bilateral salpingo-oophorectomy and omentectomy); tumor debulking; para-aortic and pelvic lymph node sampling; diaphragmatic biopsies; random peritoneal biopsies; and cytologic washings. Postoperative management may include taxanes or platinum-based chemotherapy (discussed in next section).

Borderline tumors resemble ovarian cancer but have much more favorable outcomes. Women diagnosed with this type of cancer tend to be younger (early 40s). A conservative surgical approach is now used. The affected ovary is removed, but the uterus and the contralateral ovary may remain in place. Adjuvant therapy may not be warranted.

Chart 47-8 • Stages of Ovarian Cancer

- I** Cancer is contained within the ovary (or ovaries).
- II** Cancer is in one or both ovaries and has involved other organs (ie, uterus, fallopian tubes, bladder, the sigmoid colon, or the rectum) within the pelvis.
- III** Cancer involves one or both ovaries, and one or both of the following are present: (1) cancer has spread beyond the pelvis to the lining of the abdomen; (2) cancer has spread to lymph nodes.
- IV** The most advanced stage of ovarian cancer. Cancer is in one or both ovaries. There is distant metastasis to the liver, lungs, or other organs outside the peritoneal cavity; ovarian cancer cells in the pleural cavity are evidence of stage IV disease.

Pharmacologic Therapy

Chemotherapy is usually administered IV on an outpatient basis using a combination of platinum and taxane agents. Paclitaxel (Taxol) plus carboplatin (Paraplatin) are most often used because of their excellent clinical benefits and manageable toxicity. Leukopenia, neurotoxicity, and fever may occur.

Because paclitaxel often causes leukopenia, patients may need to take granulocyte colony-stimulating factor as well. Paclitaxel is contraindicated in patients with hypersensitivity to medications formulated in polyoxyethylated castor oil and in patients with baseline neutropenia. Because of possible adverse cardiac effects, paclitaxel is not used in patients with cardiac disorders. Hypotension, dyspnea, angioedema, and urticaria indicate severe reactions that usually occur soon after the first and second doses are administered. The nurse must be prepared to assist in treating anaphylaxis. Patients should be prepared for inevitable hair loss.

Carboplatin may be used in the initial treatment and in patients with recurrence. It should be used with caution in patients with renal impairment. Usually, six cycles are given. A positive clinical response is normalization of the tumor marker CA-125, negative CT results, and a normal physical and gynecologic examination.

Liposomal therapy, delivery of chemotherapy in a liposome, allows the highest possible dose of chemotherapy to the tumor target with a reduction in adverse effects. Liposomes are used as drug carriers because they are nontoxic, biodegradable, easily available, and relatively inexpensive. This encapsulated chemotherapy allows increased duration of action and better targeting. The encapsulation of doxorubicin (Doxil) lessens the incidence of nausea, vomiting, and alopecia. Patients must be monitored for bone marrow suppression and gastrointestinal and cardiac effects.

Combination IV and intraperitoneal chemotherapy is an option for some patients. However, this treatment may result in pain; fatigue; and hematologic, gastrointestinal, metabolic, and neurologic toxicities, thus decreasing the quality of life (ACOG, 2008b). Because of these effects, the decision to use intraperitoneal chemotherapy is individualized.

Genetic engineering and identification of cancer genes may make gene therapy a future possibility; gene therapy is under investigation. Emerging proteomic technologies (tissue-based protein analysis) look promising; they may allow earlier diagnosis and treatment decision making. New biomarkers need further validation, but protein signature patterns are now being tested. These technologies may result in individualized treatment strategies for epithelial ovarian cancer.

Recurrence of ovarian cancer is common, and many patients may require treatment with multiple agents. Therefore, ovarian cancer may be considered a chronic disease, with treatment directed toward control of the cancer, maintenance of quality of life, and palliation. Liposomal preparations, intraperitoneal drug administration, anti-cancer vaccines, monoclonal antibodies directed against cancer antigens, gene therapy, and antiangiogenic treatments (to prevent formation of new blood vessels in an effort to halt growth of ovarian cancer) may be used in the treatment of

recurrence. Gemcitabine (Gemzar), topotecan (Hycamtin), paclitaxel, carboplatin, and doxorubicin are all being studied in clinical trials in advanced ovarian cancer (Bhoola & Hoskins, 2006).

Nursing Management

Nursing measures include those related to the patient's treatment plan, which may include surgery, chemotherapy, palliative care, or a combination of these. Emotional support, comfort measures, and information, plus attentiveness and caring, are important components of nursing care for the patient and her family (Bohnenkamp, LeBaron & Yoder, 2007a).

Nursing interventions after pelvic surgery to remove the tumor are similar to those after other abdominal surgeries. If ovarian cancer occurs in a young woman and the tumor is unilateral, it is removed. Childbearing, if desired, is encouraged in the near future. After childbirth, surgical reexploration may be performed, and the remaining ovary may be removed. If both ovaries are involved, bilateral oophorectomy is performed and chemotherapy follows. Chart 47-9 describes symptom clusters in women who are survivors of ovarian cancer.

Patients with advanced ovarian cancer may develop ascites and pleural effusion. Nursing care may include administering IV fluids prescribed to alleviate fluid and electrolyte imbalances, administering parenteral nutrition to provide adequate nutrition, providing postoperative care after intestinal bypass to alleviate any obstruction, controlling pain, and managing drainage tubes. Comfort measures for women with ascites may include providing small frequent meals, decreasing fluid intake, administering diuretic agents, and providing rest. Patients with pleural effusion may experience shortness of breath, hypoxia, pleuritic chest pain, and cough. Thoracentesis is usually performed to relieve these symptoms. The patient with ovarian cancer often has complex needs and benefits from the assistance and support of an oncology nurse specialist (Bohnenkamp, LeBaron & Yoder, 2007b).

Hysterectomy

Hysterectomy is the surgical removal of the uterus to treat cancer, dysfunctional uterine bleeding, endometriosis, non-malignant growths, persistent pain, pelvic relaxation and prolapse, and previous injury to the uterus. In the United States, approximately 5.5 of every 1000 women undergo hysterectomy each year (Wu, Wechter, Geller, et al., 2007). The number is thought to be leveling off because the number of other therapeutic options (ie, laser therapy, endometrial ablation, UAE, and medications to shrink fibroid tumors) has increased.

A total hysterectomy involves removal of the uterus and the cervix. Hysterectomy can be supracervical or subtotal, in which the uterus is removed but the cervix is spared. Radical hysterectomy involves removal of the uterus as well as the surrounding tissue, including the upper third of the vagina and pelvic lymph nodes. The procedure can be performed through the vagina, through an abdominal incision,

CHART
47-9NURSING RESEARCH PROFILE
Quality of Life in Survivors of Ovarian Cancer

Fox, S. W. & Lyon, D. (2007). Symptom clusters and quality of life in survivors of ovarian cancer. *Cancer Nursing*, 30(5), 270–282.

Purpose

The purpose of this study was to identify relationships among depression, fatigue, and pain in survivors of ovarian cancer to determine if a possible cluster of symptoms exists in patients with ovarian cancer. Further, the researchers examined the relationship of a cluster of symptoms to quality of life (QOL) in women with ovarian cancer. Few studies have addressed symptoms in women with ovarian cancer, even though it is the fourth leading cause of cancer-related deaths in the United States.

Design

This correlational study involved secondary data analysis from 76 women with ovarian cancer. The study from which the data were obtained addressed the psychometric properties of a new health-related QOL instrument. The subjects were recruited from an online information and support group. The Short Form-36 Health Status Survey (SF-36) was used to address symptoms of depression, fatigue, and bodily pain. The Fox Simple Quality of Life Scale (FSQOLS) was used to measure QOL. The reliability and validity of both the SF-36 and the FSQOLS have been established. Statistical analysis, including multiple regression, was used to identify possible symptom clusters and the relationship of clusters with QOL.

Findings

Scores of women were compared to those of other groups. The scores on pain and depression of the ovarian cancer survivors were similar to those of a group of similar age of a well population; however, they had significantly greater fatigue than the well population. Depression was significantly correlated with fatigue ($r = .49$), and fatigue was significantly correlated with pain ($r = .35$). Although the sample of 76 women with ovarian cancer had a mean QOL score of 99 (on a scale of 25 to 125, with higher scores representing better QOL), depression ($r = .58$) and fatigue ($r = .51$) were significantly correlated with QOL. There was not a significant correlation of pain with QOL. Together, depression and fatigue explained 41% of the variance in QOL, with the depression accounting for most of the variance in QOL scores.

Nursing Implications

Because fatigue and depression are common in patients with ovarian cancer and significantly affect QOL, nurses need to address these issues in their care of patients who are ovarian cancer survivors. The results of this study may help nurses and other health care providers target the symptoms that have the greatest effect on QOL. Most women in this study were not actively engaged in treatment; thus, other symptom clusters might be more relevant in patients who are in different phases of treatment.

or laparoscopically (in which the uterus is removed in sections through small incisions using a laparoscope). Malignant conditions usually require a total abdominal hysterectomy and bilateral salpingo-oophorectomy (removal of fallopian tubes and ovaries).

A laparoscopically assisted approach can also be used for vaginal hysterectomy, with excellent results and rapid recovery. This procedure is performed as a short-stay procedure or ambulatory surgery in carefully selected patients.

Preoperative Management

Patients are advised to discontinue anticoagulant medications, NSAIDs such as aspirin, and vitamin E prior to surgery to reduce the risk of bleeding. Pregnancy is ruled out on the day of surgery. Prophylactic antibiotics may be administered prior to surgery and discontinued the next day. Prevention of thromboembolic events is critical, and methods may include heparin and use of anti-embolism stockings or an intermittent pneumatic compression device.

Postoperative Management

The principles of general postoperative care for abdominal surgery apply. Major risks are infection and hemorrhage. In addition, because the surgical site is close to the bladder, voiding problems may occur, particularly after a vaginal hysterectomy. Also, edema or nerve trauma may cause temporary loss of bladder tone (bladder atony), and an indwelling catheter may be inserted.

NURSING PROCESS**THE PATIENT UNDERGOING A HYSTERECTOMY****Assessment**

The health history and the physical and pelvic examination are completed, and laboratory tests are performed. Additional assessment data include the patient's psychosocial responses, because the need for a hysterectomy may elicit strong emotional reactions. If the hysterectomy is performed to remove a malignant tumor, anxiety related to fear of cancer and its consequences adds to the stress of the patient and her family. Women who have had a hysterectomy may be at risk for psychological and physical symptoms. Alternatively, women may note improved physical and mental health after hysterectomy as troublesome symptoms may be alleviated.

Diagnosis**Nursing Diagnoses**

Based on all the assessment data, the major nursing diagnoses may include the following:

- Anxiety related to the diagnosis of cancer, fear of pain, possible perception of loss of femininity or child-bearing potential
- Disturbed body image related to altered fertility and fears about sexuality and relationships with partner and family

- Acute pain related to surgery and other adjuvant therapy
- Deficient knowledge of the perioperative aspects of hysterectomy and postoperative self-care

Collaborative Problems/Potential Complications

Based on assessment data, potential complications may include the following:

- Hemorrhage
- DVT
- Bladder dysfunction
- Infection

Planning and Goals

The major goals may include relief of anxiety, acceptance of loss of the uterus, absence of pain or discomfort, increased knowledge of self-care requirements, and absence of complications.

Nursing Interventions

Relieving Anxiety

Anxiety stems from several factors: unfamiliar environment, the effects of surgery on body image and reproductive ability, fear of pain and other discomfort, and, possibly, feelings of embarrassment about exposure of the genital area in the perioperative period. The nurse determines what the experience means to the patient and encourages her to verbalize her concerns. Throughout the preoperative, postoperative, and recovery periods, explanations are given about physical preparations and procedures that are performed.

Patient education addresses the outcomes of surgery, possible feelings of loss, and options for management of symptoms of menopause. Women vary in their preferences; many want a choice of treatment options, a part in decision making, accurate and useful information at the appropriate time, support from their health care providers, and access to professional and lay support systems (Bohnenkamp, et al., 2007a).

Improving Body Image

The patient may have strong emotional reactions to having a hysterectomy and strong personal feelings related to the diagnosis, views of significant others who may be involved (family, partner), religious beliefs, and fears about prognosis. Concerns such as the inability to have children and the effect on femininity may surface, as may questions about the effects of surgery on sexual relationships, function, and satisfaction. The patient needs reassurance that she will still have a vagina and that she can experience sexual intercourse after temporary postoperative abstinence while tissues heal. Information that sexual satisfaction and orgasm arise from clitoral stimulation rather than from the uterus reassures many women. Most women note some change in sexual feelings after hysterectomy, but they vary in intensity. In some cases, the vagina is shortened by surgery, and this may affect sensitivity or comfort.

When hormonal balance is upset, as often occurs with reproductive system disorders, the patient may experience depression and heightened emotional sensitivity to people and situations. The nurse needs to approach and evaluate each patient individually in light of these factors. A nurse who

exhibits interest, concern, and willingness to listen to the patient's fears will help the patient progress through the surgical experience.

Relieving Pain

Postoperative pain and discomfort are common. Therefore, the nurse assesses the intensity of the patient's pain and assists the patient with analgesia as prescribed. Excision of a large tumor could cause edema because of the sudden release of pressure. In the postoperative period, fluids and food may be restricted for 1 or 2 days. If the patient has abdominal distention or flatus, a rectal tube and application of heat to the abdomen may be prescribed. When abdominal auscultation reveals return of bowel sounds and peristalsis, additional fluids and a soft diet are permitted. Early ambulation facilitates the return of normal peristalsis (Bohnenkamp, et al., 2007b).

Monitoring and Managing Potential Complications

HEMORRHAGE. Vaginal bleeding and hemorrhage may occur after hysterectomy. To detect these complications early, the nurse counts the perineal pads used, assesses the extent of saturation with blood, and monitors vital signs. Abdominal dressings are monitored for drainage if an abdominal surgical approach was used. In preparation for hospital discharge, the nurse gives prescribed guidelines for activity restrictions to promote healing and to prevent postoperative bleeding. Because many women may go home the day of surgery or within a day or two, they are instructed to contact the nurse or surgeon if bleeding is excessive.

DEEP VEIN THROMBOSIS. Because of positioning during surgery, postoperative edema, and decreased activity postoperatively, the patient is at risk for DVT and pulmonary embolism (PE). To minimize the risk, anti-embolism stockings are applied. In addition, the patient is encouraged and assisted to change positions frequently, although pressure under the knees is avoided, and to exercise her legs and feet while in bed. The nurse helps the patient ambulate early in the postoperative period. In addition, the nurse assesses for DVT or phlebitis (leg pain, redness, warmth, edema) and PE (chest pain, tachycardia, dyspnea). If the patient is being discharged home soon after surgery, she is instructed to avoid prolonged sitting in a chair with pressure at the knees, sitting with crossed legs, and inactivity. Furthermore, she is instructed to contact her health care provider if symptoms of DVT or PE occur.

BLADDER DYSFUNCTION. Because of possible difficulty in voiding postoperatively, occasionally an indwelling catheter may be inserted before or during surgery and is left in place in the immediate postoperative period. If a catheter is in place, it is usually removed shortly after the patient begins to ambulate. After the catheter is removed, urinary output is monitored; additionally, the abdomen is assessed for distention. If the patient does not void within a prescribed time, measures are initiated to encourage voiding (eg, assisting the patient to the bathroom, pouring warm water over the perineum). If the patient cannot void, catheterization may be necessary. On rare occasions, the patient may be discharged home with the catheter in place and is instructed in its management.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The information provided to the patient is tailored to her needs. She must know what limitations or restrictions, if any, to expect. She is instructed to check the surgical incision daily and to contact her primary health care provider if redness or purulent drainage or discharge occurs. She is informed that her periods are now over but that she may have a slightly bloody discharge for a few days; if bleeding recurs after this time, it should be reported immediately. The patient is instructed about the importance of an adequate oral intake and of maintaining bowel and urinary tract function. The patient is informed that she is likely to recover quickly, but that postoperative fatigue is not unusual.

The patient should resume activities gradually. This does not mean sitting for long periods, because doing so may cause blood to pool in the pelvis, increasing the risk of thromboembolism. The nurse explains that showers are preferable to tub baths to reduce the possibility of infection and to avoid the dangers of injury that may occur when getting in and out of the bathtub. The patient is instructed to avoid straining, lifting, having sexual intercourse, or driving until her surgeon permits these activities (Bohnenkamp, et al., 2007b). Vaginal discharge, foul odor, excessive bleeding, any leg redness or pain, or an elevated temperature should be reported to the primary health care provider promptly. The nurse reinforces information given to patients by their surgeons regarding activities and restrictions.

CONTINUING CARE. Follow-up telephone contact provides the nurse with the opportunity to determine whether the patient is recovering without problems and to answer any questions that may have arisen. The patient is reminded about postoperative follow-up appointments. If the patient's ovaries were removed and she finds vasomotor symptoms troublesome, hormone therapy (HT, previously referred to as hormone replacement therapy [HRT]) may be considered. Providing information about the findings of the Women's Health Initiative (2002) study about the benefits and risks of HT promotes informed decision making about its use. Estrogen alone does not seem to increase the risk of breast cancer and may decrease coronary plaques but may increase the risk of Alzheimer's dementia and thromboses (Heiss, Wallace, Anderson, et al., 2008). The patient is reminded to discuss risks and benefits of HT and alternative therapies with her primary care provider. Decisions about use of HT need to be made individually in consultation with this provider.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Experiences decreased anxiety
2. Has improved body image
 - a. Discusses changes resulting from surgery with her partner
 - b. Verbalizes understanding of her disorder and the treatment plan
 - c. Displays minimal depression or anxiety
3. Experiences minimal pain and discomfort
 - a. Reports relief of abdominal pain and discomfort
 - b. Ambulates without pain
4. Verbalizes knowledge and understanding of self-care
 - a. Practices deep-breathing, turning, and leg exercises as instructed
 - b. Increases activity and ambulation daily
 - c. Reports adequate fluid intake and adequate urinary output
 - d. Identifies reportable symptoms
 - e. Schedules and keeps follow-up appointments
5. Absence of complications
 - a. Has minimal vaginal bleeding and exhibits normal vital signs
 - b. Ambulates early
 - c. Notes no chest or calf pain and no redness, tenderness, or swelling in the extremities
 - d. Reports no urinary problems or abdominal distention

Radiation Therapy

Radiation may be used in the treatment of cervical, uterine, and ovarian cancers either alone or in combination with surgery and chemotherapy. Several approaches are used to deliver radiation to the female reproductive system: external radiation, intraoperative radiation therapy (IORT), and internal (intracavitary) irradiation or brachytherapy. The cervix and uterus can serve as a receptacle for radioactive sources for internal radiation therapy.

Methods of Radiation Therapy

External Radiation Therapy

This method of delivering radiation destroys cancerous cells at the skin surface or deeper in the body. Other methods of delivering radiation therapy are more commonly used to treat cancer of the female reproductive system than this method.

Intraoperative Radiation Therapy

IORT allows radiation to be applied directly to the affected area during surgery. An electron beam is directed at the disease site. This direct-view irradiation may be used when para-aortic nodes are involved or for unresectable (inoperable) or partially resectable neoplasms. Benefits include accurate beam direction (which precisely limits the radiation to the tumor) and the ability during treatment to block sensitive organs from radiation. IORT is usually combined with external beam irradiation preoperatively or postoperatively.

Internal (Intracavitary) Irradiation

After the patient receives an anesthetic agent and an examination, specially prepared applicators are inserted into the endometrial cavity and vagina. These devices are not loaded with radioactive material until the patient returns to her room. X-rays are obtained to verify the precise relationship of the applicator to the normal pelvic anatomy and to the tumor. When this step is completed, the radiation oncologist loads the applicators with predetermined amounts of radioactive material. This procedure, called afterloading,

Figure 47-8 Placement of tandem and ovoids for internal radiation therapy.

allows for precise control of the radiation exposure received by the patient, with minimal exposure of physicians, nurses, and other health care personnel. A patient undergoing internal radiation treatment remains isolated in a private room until the application is completed. Adjacent rooms may need to be evacuated and a lead shield placed at the doorway to the patient's room.

Of the various applicators developed for intracavitary treatment, some are inserted into the endometrial cavity and endocervical canal as multiple small irradiators (eg, Heyman capsules). Others consist of a central tube (a tandem or intrauterine “stem”) placed through the dilated endocervical canal into the uterine cavity, which remains in a fixed relationship with the irradiators placed in the upper vagina on each side of the cervix (vaginal ovoids) (Fig. 47-8).

When the applicator is inserted, an indwelling urinary catheter is also inserted. Vaginal packing is inserted to keep the applicator in place and to keep other organs, such as the bladder and rectum, as far from the radioactive source as possible. The objective of the internal treatment is to maintain the distribution of internal radiation at a fixed dosage throughout the application, which may last 24 to 72 hours, depending on dose calculations made by the radiation physicist.

Automated high-dose rate (HDR) intracavitary brachytherapy systems have been developed that allow outpatient radiation therapy. Treatment time is shorter, thereby decreasing patient discomfort. Staff exposure to radiation is also avoided. Isotopes of radium and cesium are used for intracavitary irradiation.

Nursing Considerations for Radiation Safety

Special precautions for the safety of the patient and the nurse are important considerations when the patient is receiving radiation therapy. The Radiation Safety Department will identify specific safety precautions to those people who will be in contact with the patient, including health care providers and family. Of the many nursing concerns, primary concerns include providing the patient with emotional support and physical comfort. Further details about nursing management are provided in Chapter 16.

CRITICAL THINKING EXERCISES

EBP 1 A 55-year-old patient has been diagnosed with ovarian cancer. She reports that she has a strong family history of cancer; two sisters have breast cancer. Her mother died of cancer when the patient was a child, and she is not certain of the type of cancer. Because of her strong family history, she is concerned about the health status of her twin daughters who are in their early 30s. She has asked you to discuss the risks for cancer with them. Explain what counseling and education you will provide to the patient and her daughters. Identify the evidence base for the counseling and education and the strength of that evidence. How will you approach your counseling and education?

2 A 65-year-old woman with rheumatoid arthritis who has had surgery for breast cancer is scheduled to undergo radical vulvectomy to treat vulvar cancer. She reports that she is very anxious because of her previous surgery. Describe the preoperative teaching for her and the postoperative care that can be anticipated. How will her history of breast cancer and rheumatoid arthritis affect her care? What modifications in care, postoperative teaching, and discharge planning may be necessary because of these health issues? How will your discharge planning be modified if the patient tells you that she provides care at home for her husband who has signs of early Alzheimer's disease?

3 A 38-year-old woman with a diagnosis of fibroids has been admitted to the outpatient surgery center for uterine artery embolization. When you are completing the preoperative admission procedures, she asks you about the effect of the procedure on future sexual relationships and on her ability to become pregnant in the future. What teaching is indicated for this woman based on her concerns and on her risk for future fertility? What nursing care is important to minimize the risk of complications?

EBP 4 A 17-year-old patient is seeking contraception. She explains that she has not had a sexual relationship but wants to be prepared for future sexual relationships. She also asks you for your recommendation about receiving the new HPV vaccine. What recommendations would you give her about contraception and the HPV vaccine? What is the evidence base for your recommendations? How would you approach the topic of safer sex, contraception, and HPV vaccine with her in responding to her request for information?

Assessment and Management of Patients With Breast Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Summarize the guidelines for the early detection of breast cancer.
- 2 Develop a teaching plan for breast self-examination for patients and consumer groups.
- 3 Identify and describe the different types of breast disorders, both benign and malignant.
- 4 Identify the examinations and biopsy procedures used to diagnose breast disorders.
- 5 Describe the different modalities used to treat breast cancer.
- 6 Use the nursing process as a framework for care of the patient undergoing surgery for the treatment of breast cancer.
- 7 Describe the physical, psychosocial, and rehabilitative needs of the patient who has had breast surgery for the treatment of breast cancer.

GLOSSARY

adjuvant chemotherapy: use of anticancer medications in addition to other treatments to delay or prevent a recurrence of the disease

adjuvant hormonal therapy: use of synthetic hormones or other medications given after primary treatment to increase the chances of a cure by stopping or slowing the growth of certain cancers that are affected by hormone stimulation (sometimes called endocrine or antiestrogen therapy)

aromatase inhibitors: medications that block the production of estrogens by the adrenal glands

atypical hyperplasia: abnormal increase in the number of cells in a specific area within the ductal or lobular areas of the breast; this abnormal proliferation increases the risk for cancer

benign proliferative breast disease: various types of atypical, yet noncancerous, breast tissue that increase the risk for breast cancer

brachytherapy: form of partial breast radiation in which a radioactive source is placed within the lumpectomy site

BRCA1 and BRCA2: genes on chromosome 17 that, when damaged or mutated, increase a woman's risk for breast and/or ovarian cancer compared with women without the mutation

breast conservation treatment: surgery to remove a breast tumor and a margin of tissue around the tumor without removing any other part of the breast; may or may not include lymph node removal and radiation therapy

dose-dense chemotherapy: administration of chemotherapeutic agents at standard doses with shorter time intervals between each cycle of treatment

ductal carcinoma in situ (DCIS): cancer cells starting in the ductal system of the breast not penetrating surrounding tissue

GLOSSARY (Continued)

estrogen and progesterone receptor assay: test to determine whether the breast tumor is nourished by hormones; this information helps to determine prognosis and treatment

fibrocystic breast changes: term used to describe certain benign changes in the breast, typically associated with palpable nodularity, lumpiness, swelling, or pain

fine-needle aspiration (FNA): removal of fluid for diagnostic analysis from a cyst or cells from a mass using a needle and syringe

galactography: use of mammography after an injection of radiopaque dye to diagnose problems in the ductal system of the breast

gynecomastia: overdeveloped breast tissue typically seen in adolescent boys

lobular carcinoma in situ (LCIS): atypical change and proliferation of the lobular cells of the breast; previously considered a premalignant condition but now considered a marker of increased risk for invasive breast cancer

lymphedema: chronic swelling of an extremity due to interrupted lymphatic circulation, typically from an axillary lymph node dissection

mammoplasty: surgery to reconstruct or change the size or shape of the breast; can be performed for reduction or augmentation

mastalgia: breast pain, usually related to hormonal fluctuations or irritation of a nerve

mastitis: inflammation or infection of the breast

modified radical mastectomy: removal of the breast tissue, nipple-areola complex, and a portion of the axillary lymph nodes

Paget's disease: form of breast cancer that begins in the ductal system and involves the nipple, areola, and surrounding skin

prophylactic mastectomy: removal of the breast to reduce the risk of breast cancer in women considered to be at high risk

sentinel lymph node: first lymph node(s) in the lymphatic basin that receives drainage from the primary tumor in the breast; identified by a radioisotope and/or blue dye

stereotactic core biopsy: computer-guided method of core needle biopsy that is useful when masses in the breast cannot be felt but can be visualized using mammography

surgical biopsy: Surgical removal of all or a portion of a mass for microscopic examination by a pathologist

tissue expander followed by permanent implant: series of breast-reconstructive surgeries after a mastectomy; involves stretching the skin and muscle before inserting the permanent implant

total mastectomy: removal of the breast tissue and nipple-areola complex

transverse rectus abdominis myocutaneous (TRAM) flap: method of breast reconstruction in which a flap of skin, fat, and muscle from the lower abdomen, with its attached blood supply, is rotated to the mastectomy site

ultrasonography: imaging method using high-frequency sound waves to diagnose whether masses are solid or fluid filled

In many cultures, the breast plays a significant role in a woman's sexuality and self-identity. A breast disorder, whether benign or malignant, can cause great anxiety and fear of potential disfigurement, loss of sexual attractiveness, and even death. Nurses, therefore, must have expertise in the assessment and management of not only the physical symptoms but also the psychosocial symptoms associated with breast disorders.

BREAST ASSESSMENT

Anatomic and Physiologic Overview

Male and female breasts mature comparably until puberty, when in females estrogen and other hormones initiate breast development. This development usually occurs from 10 to 16 years of age, although the range can vary from 9 to 18 years. Stages of breast development are described as Tanner stages 1 through 5.

- Stage 1 describes a prepubertal breast.
- Stage 2 is breast budding, the first sign of puberty in a female.
- Stage 3 involves further enlargement of breast tissue and the areola (a darker tissue ring around the nipple).
- Stage 4 occurs when the nipple and areola form a secondary mound on top of the breast tissue.
- Stage 5 is the continued development of a larger breast with a single contour.

The breasts are located between the second and sixth ribs over the pectoralis muscle from the sternum to the midaxillary line. An area of breast tissue, called the tail of Spence, extends into the axilla. Fascial bands, called Cooper's ligaments, support the breast on the chest wall. The inframammary fold (or crease) is a ridge of fat at the bottom of the breast.

Each breast contains 12 to 20 cone-shaped lobes, which are made up of glandular elements (lobules and ducts) and separated by fat and fibrous tissue that binds the lobes together. Milk is produced in the lobules and then carried

through the ducts to the nipple. Figure 48-1 shows the anatomy of the fully developed breast.

Assessment

Health History

When a patient presents with a breast problem, the nurse conducts a general health assessment, including history of medical disorders and previous surgery; family history of diseases, particularly cancer; gynecologic and obstetric history; present medications (including prescriptions, vitamins, and herbal); past and present use of hormonal contraceptives, hormone therapy (HT) (formerly referred to as hormone replacement therapy [HRT]), or fertility treatments; and social habits (eg, smoking, drinking alcohol). Psychosocial information, such as the patient's marital status, occupation, and availability of resources and support people, is obtained. Any recent x-rays or other diagnostic tests are noted. Focused questions pertaining to the breast disorder are asked concerning the onset of the disorder and the length of time it has been present. In addition, the patient is asked if any masses are palpable and if there is any associated pain, swelling, redness, nipple discharge, or skin changes. Knowledge and comfort in practicing breast self-examination (BSE) should also be ascertained from the patient.

Physical Assessment: Female Breast

A female breast examination can be conducted during any general physical or gynecologic examination or whenever the patient reports an abnormality. The American Cancer Society (ACS) recommends that women at average risk for breast cancer undergo a clinical breast examination at least every 3 years while in their 20s and 30s and then annually thereafter (Smith, Cokkinides & Brawley, 2008). A thorough breast examination, including instruction in BSE, takes at least 10 minutes.

Figure 48-1 A, Anatomy of the breast. B, Areas of breast, including the tail of Spence.

Inspection

Examination begins with inspection. The patient is asked to disrobe to the waist and sit in a comfortable position facing the examiner. The breasts are inspected for size and symmetry. A slight variation in the size of each breast is common and generally normal. The skin is inspected for color, venous pattern, thickening, or edema. Erythema (redness) may indicate benign local inflammation or superficial lymphatic invasion by a neoplasm. A prominent venous pattern can signal increased blood supply required by a tumor. Edema and pitting of the skin may result from a neoplasm blocking lymphatic drainage, giving the skin an orange-peel appearance (*peau d'orange*), a classic sign of advanced breast cancer. Nipple inversion of one or both breasts is not uncommon and is significant only when of recent origin. Ulceration, rashes, or spontaneous nipple discharge requires evaluation. Examples of abnormal breast findings on inspection can be found in Chart 48-1.

To elicit skin dimpling or retraction that may otherwise go undetected, the examiner instructs the patient to raise both arms overhead. This maneuver normally elevates both breasts equally. The patient is then instructed to place her hands on her waist and push in. These movements, which cause contraction of the pectoral muscles, do not normally alter the breast contour or nipple direction. Any dimpling or retraction during these position changes suggests an underlying mass. The clavicular and axillary regions are inspected for swelling, discoloration, lesions, or enlarged lymph nodes.

Palpation

The breasts are palpated with the patient sitting up (upright) and lying down (supine). In the supine position the patient's shoulder is first elevated with a small pillow to help balance the breast on the chest wall. Failure to do this allows the breast tissue to slip laterally, and a breast mass may be missed. The entire surface of the breast and the axillary tail is systematically palpated using the flat part (pads) of the second, third, and fourth fingertips, held together, making dime-size circles. The examiner may choose to proceed in a clockwise direction, following imaginary concentric circles from the outer limits of the breast toward the nipple. Other acceptable methods are to palpate from each number on the face of the clock toward the nipple in a clockwise fashion or along imaginary vertical lines on the breast (Fig. 48-2).

Palpation of the axillary and clavicular areas is easily performed with the patient seated (Fig. 48-3). To examine the axillary lymph nodes, the examiner gently abducts the patient's arm from the thorax. With the left hand, the patient's left forearm is grasped and supported. The right hand is then free to palpate the axillae. Any lymph nodes that may be lying against the thoracic wall are noted. Normally, these lymph nodes are not palpable, but if they are enlarged, their location, size, mobility, and consistency are noted. During palpation, the examiner notes any patient-reported tenderness or masses. If a mass is detected, it is described by its location (eg, left breast, 2 cm from the nipple at 2 o'clock position). Size, shape, consistency, border delineation, and mobility are included in the description.

The breast tissue of the adolescent is usually firm and lobular, whereas that of the postmenopausal woman is more likely to feel thinner and fattier. During pregnancy and lactation, the breasts are firmer and larger with lobules that are more distinct. Hormonal changes cause the areola to darken. Cysts are commonly found in menstruating women and are usually well defined and freely movable. Premenstrually, cysts may be larger and more tender. Malignant tumors, on the other hand, tend to be hard, poorly defined, and nontender. A physician should further evaluate any abnormalities detected during inspection and palpation.

Physical Assessment: Male Breast

Breast cancer can occur in men. Examination of the male breast and axillae should be included in a physical examination. The nipple and areola are inspected for masses and nipple discharge. The same procedure for palpating the female axillae is used when assessing the male axillae.

Gynecomastia is the firm enlargement of glandular tissue beneath and immediately surrounding the areola of the male. This is different from the enlargement of soft, fatty tissue, which is caused by obesity.

Diagnostic Evaluation

Breast Self-Examination

The nurse plays an important role in BSE education, a modality used for the early detection of breast cancer. BSE can be taught in a variety of settings—either on a one-to-one basis or in a group. It can also be initiated by a health care practitioner during a patient's routine physical examination.

Variations in breast tissue occur during the menstrual cycle, pregnancy, and the onset of menopause. Women on HT can also experience fluctuations. Normal changes must be distinguished from those that may signal disease. Most women notice increased tenderness and lumpiness before their menstrual periods; therefore, BSE is best performed after menses (day 5 to day 7, counting the first day of menses as day 1). Also, many women have grainy-textured breast tissue, but these areas are usually less nodular after menses. Younger women may find BSE particularly difficult because of the density of their breast tissue. As women age, their breasts become fattier and may be easier to examine.

It is estimated that only 25% to 30% of women perform BSE proficiently and regularly each month. Some find BSE to be anxiety producing; others find it too difficult to differentiate between normal changes and worrisome findings. Even women who perform BSE and detect a change may delay seeking medical attention because of fear, economic factors, lack of education, and modesty. Despite these factors, many women discover their own breast cancers. For this reason, BSE should be taught and encouraged but not overemphasized. The ACS recommends that women, beginning in their early 20s, be told about the benefits and limitations of BSE. It is then up to the individual woman whether to perform BSE regularly, irregularly, or not at all (Smith, et al., 2008).

Instructions about BSE should also be provided to men if they have a family history of breast cancer, because they may have an increased risk of male breast cancer.

Chart 48-1 • Abnormal Findings During Inspection of the Breasts

Retraction Signs

- Signs include skin dimpling, creasing, or changes in the contour of the breast or nipple
- May be secondary to contraction of fibrotic tissue that can occur with underlying malignancy
- May be secondary to scar tissue formation after breast surgery
- Retraction signs may appear only with position changes

Retraction signs

Retraction with compression

Increased Venous Prominence

- Unilateral localized increase in venous pattern associated with malignant tumors
- Normal with bilateral and symmetrical breast enlargement associated with pregnancy and lactation

Increased venous prominence

Peau d'Orange (Edema)

- Associated with inflammatory breast cancer
- Caused by interference with lymphatic drainage
- Breast skin has orange peel appearance
- Skin pores enlarge
- May be noted on the areola
- Skin becomes thick, hard, and immobile

Peau d'orange

Nipple Inversion

- Considered normal if long-standing
- Associated with fibrosis and malignancy if recent development

Nipple inversion

Acute Mastitis (Inflammation of the Breasts)

- Associated with lactation but may occur at any age
- Nipple cracks or abrasions noted
- Breast skin reddened and warm to touch
- Tenderness
- Systemic signs include fever and increased pulse

Paget's Disease (Malignancy of Mammary Ducts)

- Early signs: erythema of nipple and areola
- Late signs: thickening, scaling, and erosion of the nipple and areola

Paget's disease

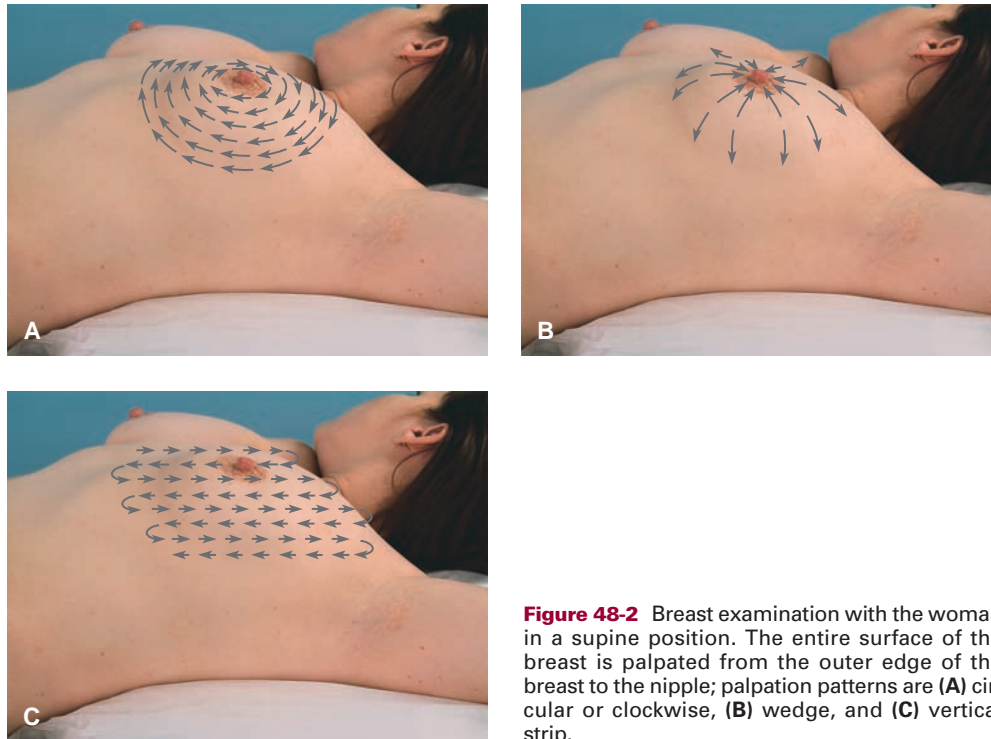

Figure 48-2 Breast examination with the woman in a supine position. The entire surface of the breast is palpated from the outer edge of the breast to the nipple; palpation patterns are (A) circular or clockwise, (B) wedge, and (C) vertical strip.

Patients who elect to perform BSE should receive proper instruction on technique (Chart 48-2). They should be informed that routine BSE will help them become familiar with their “normal abnormalities.” If a change is detected, they should seek medical attention.

Patients should be instructed about optimal timing for BSE (5 to 7 days after menses begin for premenopausal women and once monthly for postmenopausal women). When demonstrating examination techniques, the feel of normal breast tissue should be reviewed and ways to identify breast changes discussed. Patients should then perform a BSE demonstration on themselves or on a breast model. Patients who have had breast cancer surgery should be instructed to examine their breast or chest wall for any new changes or nodules that may indicate a recurrence of the disease.

BSE videos, shower cards, and pamphlets can be obtained from local chapters of the ACS.

Mammography

Mammography is a breast-imaging technique that has been shown to reduce breast cancer mortality rates. It can detect nonpalpable lesions and assist in diagnosing palpable masses. The procedure takes about 15 minutes and can be performed in a hospital radiology department or independent imaging center. Two views are taken of each breast. The breast is mechanically compressed from top to bottom (craniocaudal view) and side to side (mediolateral oblique view) (Fig. 48-4). Women may experience some fleeting discomfort because maximum compression is necessary for proper visualization. The new mammogram is compared with previous mammograms, and any changes may indicate a need for further investigation. Mammography may detect a breast tumor before it is clinically palpable (ie, smaller than 1 cm); however, it has limitations. The false-negative rate ranges between 5% and 10%. Younger women, or those taking HT, may have dense breast tissue, making it more difficult to detect lesions with mammography.

Patients scheduled for a mammogram may voice concern about exposure to radiation. The radiation exposure is equivalent to about 1 hour of exposure to sunlight, so patients would have to have many mammograms in a year to increase their cancer risk. The benefits of this test outweigh the risks. To ensure that a mammogram is reliable, it is important that a woman find a reputable facility. A facility that is certified by the Mammography Quality Standards Act must meet stringent quality standards, be accredited by the U.S. Food and Drug Administration (FDA) and be inspected annually.

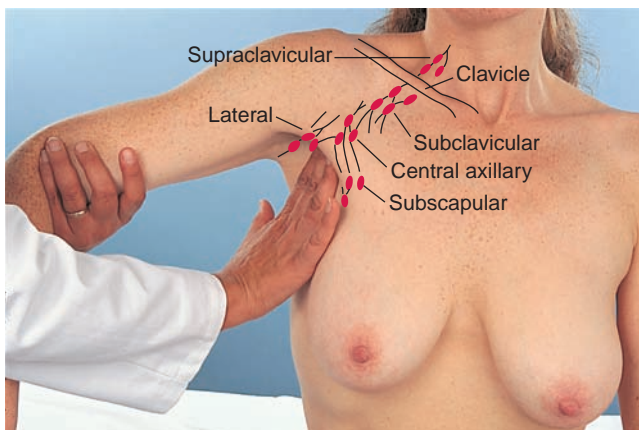

Figure 48-3 Palpating axillary nodes in breast examination.

CHART
48-2

PATIENT EDUCATION

Breast Self-Examination (BSE)

Step 1

1. Stand in front of a mirror.
2. Check both breasts for anything unusual.
3. Look for discharge from the nipple, puckering, dimpling, or scaling of the skin.

The next two steps are done to check for any changes in the contour of your breasts. As you do them, you should be able to feel your muscles tighten.

Step 2

1. Watch closely in the mirror as you clasp your hands behind your head and press your hands forward.
2. Note any change in the contour of your breasts.

Step 4

1. Raise your left arm.
2. Use three or four fingers of your right hand to feel your left breast firmly, carefully, and thoroughly.
3. Beginning at the outer edge, press the flat part of your fingers in small circles, moving the circles slowly around the breast.
4. Gradually work toward the nipple.
5. Be sure to cover the whole breast.
6. Pay special attention to the area between the breast and the underarm, including the underarm itself.
7. Feel for any unusual lumps or masses under the skin.
8. If you have any spontaneous discharge during the month—whether or not it is during your BSE—see your doctor.
9. Repeat the examination on your right breast.

Step 3

1. Next, press your hands firmly on your hips and bow slightly toward the mirror as you pull your shoulders and elbows forward.
 2. Note any change in the contour of your breasts.
- Some women do the next part of the examination in the shower. Your fingers will glide easily over soapy skin, so you can concentrate on feeling for changes inside the breast.

Step 5

1. Step 4 should be repeated lying down.
2. Lie flat on your back with your left arm over your head and a pillow or folded towel under your left shoulder. (This position flattens your breast and makes it easier to check.)
3. Use the same circular motion described above.
4. Repeat on your right breast.

Adapted from U.S. Department of Health and Human Services, Public Health Service, *What you need to know about breast cancer*. Bethesda, MD: National Institutes of Health.

Current mammographic screening guidelines of the ACS recommend a mammogram every year beginning at 40 years of age. There is no upper age limit at which mammography should be discontinued as long as the woman is in good health (Smith, et al., 2008). Women who are at increased risk because of a strong family history should seek

the opinion of a breast specialist regarding the optimal age to begin screening mammography. A general guideline is to begin screening 10 years earlier than the age at which the youngest family member developed breast cancer but not before 25 years of age. In families with a history of breast cancer, a downward shift in age of diagnosis of about

Figure 48-4 The mammography procedure (A) relies on x-ray imaging to produce the mammogram (B), which in this case reveals a breast lump.

10 years is seen (eg, grandmother diagnosed with breast cancer at 48 years of age, mother diagnosed with breast cancer at 38 years of age, then daughter should begin screening at age 28 years of age).

Despite the decreased mortality rates associated with mammographic screening, many women are not undergoing this simple procedure. Only 52.9% of non-Hispanic white women older than 40 years of age reported having mammography within the past year. Recent data also suggest a decline in the use of mammography. The screening rate in 2000 was 70% and decreased to 66% in 2005 (Breen, Cronin, Meissner, et al., 2007). The percentage was even lower for women in racial and ethnic minority groups, particularly in those who immigrated to the United States in the past 10 years. Low rates of screening were also seen in women with less education and no health insurance. The implementation of screening programs such as the National Breast and Cervical Cancer Early Detection Program of the Centers for Disease Control and Prevention (CDC) helps low-income, uninsured, and underserved women gain access not only to mammograms but to clinical breast examinations, Papanicolaou (Pap) tests, diagnostic testing for abnormal screening tests, and surgical consultation (CDC, 2007). The program was established in 1991 and has provided more than 7 million screening examinations and diagnosed more than 30,000 patients with breast cancer. Nurses are in key positions to educate women about the current ACS screening guidelines and the benefits of mammography. They can also help identify and provide information to women who may benefit from such screening programs as the one operated by the CDC.

Newer techniques for breast screening include digital mammography and computer-assisted detection (CAD) programs. Digital mammography records x-ray images on a computer instead of on film, thus allowing radiologists to

adjust the contrast and focus on an image without having to take additional x-rays. Compared with conventional film mammography, digital mammography has been shown to be significantly better at detecting breast cancer in women younger than 50 years of age, women with dense breast tissue, and premenopausal and perimenopausal women. CAD is designed to assist radiologists in the identification of suspicious areas on a mammogram. Trials of CAD programs have generally, but not always, shown improvements in detection rates (Helvie, 2007). The effectiveness of both digital mammography and CAD continues to be evaluated.

Galactography

Galactography is a diagnostic procedure that involves injection of less than 1 mL of radiopaque material through a cannula inserted into a ductal opening on the areola, which is followed by a mammogram. It is performed to evaluate an abnormality within the duct when the patient has bloody nipple discharge on expression, spontaneous nipple discharge, or a solitary dilated duct noted on mammography.

Ultrasonography

Ultrasonography (ultrasound) is used as a diagnostic adjunct to mammography to help distinguish fluid-filled cysts from other lesions. A thin coating of lubricating jelly is spread over the area to be imaged. A transducer is then placed on the breast. The transducer transmits high-frequency sound waves through the skin toward the area of concern. The sound waves that are reflected back form a two-dimensional image, which is then displayed on a computer screen. No radiation is emitted during the procedure.

Ultrasonography has advantages and disadvantages. Although it can diagnose cysts with great accuracy, it cannot definitively rule out malignant lesions. Microcalcifications, which are detectable on mammography, cannot be identified on ultrasonography. Finally, examination techniques and interpretation criteria are not standardized.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the breast is rapidly gaining in popularity. This highly sensitive test has become a useful diagnostic adjunct to mammography. A magnet is linked to a computer that creates detailed images of the breast without exposure to radiation. An intravenous (IV) injection of gadolinium, a contrast dye, is given to improve visibility. The patient lies face down and the breast is placed through a depression in the table. A coil is placed around the breast, and the patient is placed inside the MRI machine. The entire procedure takes about 30 to 40 minutes.

MRI is most useful in patients with proven breast cancer when assessing for multifocal (more than one tumor in the same quadrant of the breast) or multicentric (more than one tumor in different quadrants of the breast) disease, chest wall involvement, tumor recurrence, or response to chemotherapy. The procedure can also identify occult (undetectable) breast cancer and determine the integrity of saline or silicone breast implants. Recent studies have shown that MRI is a highly sensitive screening tool that can be used to identify breast cancer in women at high risk for the disease (Orel, 2008). The ACS now recommends an annual MRI scan in addition to mammography in women at

high risk for breast cancer (ie, those with greater than 20% lifetime risk). Candidates include women who have a *BRCA1* or *BRCA2* mutation, a first-degree relative with either of these mutations, certain rare genetic syndromes, or radiation to the chest between 10 and 30 years of age (Saslow, Boetes, Burke, et al., 2007). MRI should be used in addition to mammography, not instead of it.

Some disadvantages of MRI include high cost, variations in technique and interpretation, and the potential for patient claustrophobia. The procedure cannot always accurately distinguish between malignant and benign breast conditions. MRI is contraindicated in patients with implantable metal devices (eg, aneurysm clips, pacemakers, ports of tissue expanders) because of the metallic force. Foil-backed medication patches (eg, nicotine, nitroglycerine, fentanyl) must be removed prior to MRI to avoid burns to the skin.

Procedures for Tissue Analysis

Percutaneous Biopsy

Percutaneous biopsy is performed on an outpatient basis to sample palpable and nonpalpable lesions. Less invasive than a surgical biopsy, percutaneous biopsy is a needle or core biopsy that obtains tissue by making a small puncture in the skin. Table 48-1 outlines the different types of biopsies that can be performed to obtain a tissue diagnosis.

Fine-Needle Aspiration

Fine-needle aspiration (FNA) is a noninvasive biopsy technique that is generally well tolerated by most women. A local anesthetic may or may not be used. A small gauge needle (25- or 22-gauge) attached to a syringe is inserted into the mass or area of nodularity. Suction is applied to the syringe, and multiple passes are made through the mass. A simple cyst often disappears on aspiration, and the fluid is usually discarded. If no fluid is obtained, any cellular material obtained in the hub of the needle is spread on a glass slide or placed in a preservative and sent to the laboratory for analysis. For nonpalpable masses, the same procedure can be performed by a radiologist using ultrasound guidance (ultrasound-guided FNA).

FNA is less expensive than other diagnostic methods and results are usually available quickly. However, false-negative or false-positive results are possible, and appropriate follow-up depends on the clinical judgment of the treating physician.

Core Needle Biopsy

Core needle biopsy is similar to FNA, except that a larger gauge needle is used (usually 14-gauge). A local anesthetic is applied, and tissue cores are removed via a spring-loaded device. This procedure allows for a more definitive diagnosis than FNA, because actual tissue, not just cells, is removed. It is often performed for relatively large tumors that are close to the skin surface.

Stereotactic Core Biopsy

Stereotactic core biopsy is performed on nonpalpable lesions detected by mammography. The patient lies prone on the stereotactic table. The breast is suspended through an opening in the table and compressed between two x-ray plates. Images are then obtained using digital mammography. The exact coordinates of the lesion to be sampled are located with the aid of a computer. Next, a local anesthetic is injected into the entry site on the breast. A small nick is made in the skin, a core needle is inserted, and samples of the tissue are taken for pathologic examination. Often, several passes are taken to ensure that the lesion is well sampled. Postbiopsy films are then taken to check that sampling has been adequate. A small titanium clip is often placed at the biopsy site so that the site can easily be located if further treatment is indicated.

Stereotactic biopsy is quite accurate and often allows the patient to avoid a surgical biopsy. However, there is a small false-negative rate. Appropriate follow-up depends on the final pathologic diagnosis and the clinical judgment of the treating physician. Use of a titanium clip does not preclude subsequent MRIs.

Ultrasound-Guided Core Biopsy

The principles for ultrasound-guided core biopsy are similar to those of stereotactic core biopsy, but by using ultrasound guidance, computer coordination and mammographic compression are not necessary. Ultrasound-guided core biopsy does not use radiation and is also faster and less expensive than stereotactic core biopsy.

Magnetic Resonance Imaging–Guided Core Biopsy

Recently, the technology has become available to perform core biopsies under MRI guidance. The number of facilities that are equipped to perform this procedure is increasing.

Table 48-1 TYPES OF BREAST BIOPSIES

Procedure	Palpable Mass	Health Professional Who Performs Procedure	Nature of Breast Tissue Removed
Fine-needle aspiration	Yes	Surgeon	Cellular material
Core needle biopsy	Yes	Surgeon	Tissue core
Stereotactic core biopsy	No	Radiologist	Tissue core
Ultrasound-guided core biopsy	No	Radiologist	Tissue core
MRI-guided core biopsy	No	Radiologist	Tissue core
Excisional biopsy	Yes	Surgeon	Entire mass
Incisional biopsy	Yes	Surgeon	Tissue core
Wire needle localization biopsy; may be guided by mammogram, ultrasound, or MRI	No	Radiologist inserts wire, surgeon performs biopsy	Entire mass

Surgical Biopsy

Surgical biopsy is usually performed using local anesthesia and IV sedation. After an incision is made, the lesion is excised and sent to a laboratory for pathologic examination.

Types of Surgical Breast Biopsy

Excisional Biopsy. Excisional biopsy is the standard procedure for complete pathological assessment of a palpable breast mass. The entire mass, plus a margin of surrounding tissue, is removed. This type of biopsy may also be referred to as a lumpectomy. Depending on the clinical situation, a frozen section analysis of the specimen may be performed at the time of the biopsy by the pathologist, who does an immediate reading intraoperatively and provides a provisional diagnosis. This can help confirm a diagnosis in a patient who had no previous tissue analysis performed.

Incisional Biopsy. Incisional biopsy surgically removes a portion of a mass. This is performed to confirm a diagnosis and to conduct special studies (eg, ER/PR, HER-2/neu [also referred to as ERBB2]; see later discussion for explanation of these terms) that will aid in determining treatment, which are discussed later in this chapter. Complete excision of the area may not be possible or immediately beneficial to the patient, depending on the clinical situation. This procedure is often performed on women with locally advanced breast cancer or on women with suspected cancer recurrence, whose treatment may depend on the results of these special studies. However, pathological information may be easily obtained from core needle biopsy, and incisional biopsy is becoming less common.

Wire Needle Localization. Wire needle localization is a technique used to locate nonpalpable masses or suspicious calcium deposits detected on a mammogram, ultrasound, or MRI that require an excisional biopsy. The radiologist inserts a long, thin wire through a needle, which is then inserted into the area of abnormality using x-ray or ultrasound guidance (whichever imaging technique originally identified the abnormality). The wire remains in place after the needle is withdrawn to ensure the precise location. The patient is then taken to the operating room, where the surgeon follows the wire to the tip and excises the area.

Nursing Management

During the preoperative visit, the nurse assesses the patient for any specific educational, physical, or psychosocial needs that she may have. This can be accomplished by reviewing her medical and psychosocial history and encouraging her to verbalize her fears, concerns, and questions. Patients are often worried not only about the procedure but also about the potential implications of the pathology results. Providing a thorough explanation about what to expect in a supportive manner can help alleviate anxiety. Patients often have difficulty absorbing all the information given to them; therefore, written materials should be provided to reinforce teaching.

The nurse instructs the patient to discontinue any agents that can increase the risk of bleeding, including products containing aspirin, nonsteroidal anti-inflammatory drugs

(NSAIDs), vitamin E supplements, herbal substances (such as ginkgo biloba and garlic supplements), and warfarin (Coumadin). The patient may be instructed not to eat or drink for several hours or after midnight the night before the procedure, depending on the type of biopsy planned. Most breast biopsy procedures today are performed with the use of moderate sedation and local anesthesia.

Immediate postoperative assessment includes monitoring the effects of the anesthesia and inspecting the surgical dressing for any signs of bleeding. Once the sedation has worn off, the nurse reviews the care of the biopsy site, pain management, and activity restrictions with the patient. Prior to discharge from the ambulatory surgical center or the office, the patient must be able to tolerate fluids, ambulate, and void. The patient must have somebody to accompany her home. The dressing covering the incision is usually removed after 48 hours, but the Steri-Strips, which are applied directly over the incision, should remain in place for approximately 7 to 10 days. The use of a supportive bra following surgery is encouraged to limit movement of the breast and reduce discomfort. A follow-up telephone call from the nurse 24 to 48 hours after the procedure can provide the patient with the opportunity to ask any questions and can be a source of great comfort and reassurance.

Most women return to their usual activities the day after the procedure but are encouraged to avoid jarring or high-impact activities for 1 week to promote healing of the biopsy site. Discomfort is usually minimal, and most women find acetaminophen (Tylenol) sufficient for pain relief, although a mild opioid may be prescribed if needed.

Follow-up after the biopsy includes a return visit to the surgeon for discussion of the final pathology report and assessment of the healing of the biopsy site. Depending on the results of the biopsy, the nurse's role varies. If the pathology report is benign, the nurse reviews incision care and explains what the patient should expect as the biopsy site heals (ie, changes in sensation may occur weeks or months after the biopsy due to nerve injury within the breast tissue). If a diagnosis of cancer is made, the nurse's role changes dramatically. This is discussed in depth later in this chapter.

CONDITIONS AFFECTING THE NIPPLE

Nipple Discharge

Nipple discharge in a woman who is not lactating may be related to many causes, such as carcinoma, papilloma, pituitary adenoma, cystic breasts, and various medications. Oral contraceptives, pregnancy, HT, chlorpromazine (Thorazine)-type medications, and frequent breast stimulation may be contributing factors. In some athletic women, nipple discharge may occur during running or aerobic exercises. Nipple discharge should be evaluated by a health care provider, but it is not often a cause for alarm. One in three women has clear discharge on expression, which is usually normal. A green discharge could indicate an infection. Any

discharge that is spontaneous, persistent, or unilateral is of more concern. Although bloody discharge can indicate a malignancy, it is often caused by a benign wartlike growth on the lining of the duct called an intraductal papilloma.

Nipple discharge should be evaluated for the presence of occult (hidden) blood by performing a guaiac test. A galactogram can also be performed to detect abnormalities within the duct that may be causing the discharge. If there is a high level of suspicion, a surgical biopsy called a duct excision may be indicated.

Fissure

A fissure is a longitudinal ulcer that may develop in breastfeeding women. If the nipple becomes irritated, a painful, raw area may form and become a site of infection. Daily washing with water, massage with breast milk or lanolin, and exposure to air are helpful. Breastfeeding can be continued with the use of a nipple shield if necessary. If the fissure is severe or extremely painful, the woman is advised to stop breastfeeding. A breast pump can be used until breastfeeding can be resumed. Persistent ulceration requires further diagnosis and therapy. Guidance from a nurse or lactation consultant may be helpful because nipple irritation can result from improper positioning (ie, the infant has not grasped the areola fully) during breastfeeding.

BREAST INFECTIONS

Mastitis

Mastitis, an inflammation or infection of breast tissue, occurs most commonly in breastfeeding women, although it may also occur in nonlactating women. The infection may result from a transfer of micro-organisms to the breast by the patient's hands or from a breastfed infant with an oral, eye, or skin infection. Mastitis may also be caused by blood-borne organisms. As inflammation progresses, the breast texture becomes tough or doughy, and the patient complains of dull to severe pain in the infected region. A nipple that is discharging purulent material, serum, or blood should be investigated.

Treatment consists of antibiotics and local application of cold compresses to relieve discomfort. A broad-spectrum antibiotic agent may be prescribed for 7 to 10 days. The patient should wear a snug bra and perform personal hygiene carefully. Adequate rest and hydration are important aspects of management.

Lactational Abscess

A breast abscess may develop as a consequence of acute mastitis. The area affected becomes tender and red. Purulent matter can usually be aspirated with a needle, but incision and drainage may be required. Specimens of the aspirated material are obtained for culture so that an organism-specific antibiotic can be prescribed.

BENIGN CONDITIONS OF THE BREAST

Breast Pain

Breast pain (**mastalgia**) may be cyclical or noncyclical. Cyclical pain is usually related to hormonal fluctuations and accounts for nearly 75% of all complaints. Noncyclical pain is far less common and does not vary with the menstrual cycle. Women who experience injury or trauma to the breast or those who had a breast biopsy may experience noncyclical pain. Patients should be reassured that breast pain is rarely indicative of cancer. However, if the pain persists after menses begins, the patient should see her primary health care provider.

Nursing Management

The nurse may recommend that the patient wear a supportive bra both day and night for a week, decrease her salt and caffeine intake, and take ibuprofen (Advil) as needed for its anti-inflammatory actions. Vitamin E supplements or oil of evening primrose (an over-the-counter herbal preparation) may also be helpful.

Cysts

Cysts are fluid-filled sacs that develop as breast ducts dilate. Cysts occur most commonly in women 30 to 55 years of age and may be exacerbated during perimenopause. Although their cause is unknown, cysts usually disappear after menopause, suggesting that estrogen is a factor. Cystic areas often fluctuate in size and are usually larger premenstrually. They may be painless or may become very tender premenstrually. Occasionally, a patient may report an intermittent shooting sensation or a dull ache. Various breast masses are compared in Table 48-2. Cysts that are confirmed on an ultrasound and are not bothersome can often be left alone. To confirm a diagnosis or to relieve pain, FNA can be performed. Cysts do not increase the risk of breast cancer.

Fibrocystic breast changes, which is often called fibrocystic breast disease, is a nonspecific term used to describe an array of benign findings. The changes do not necessarily indicate a cystic process.

Fibroadenomas

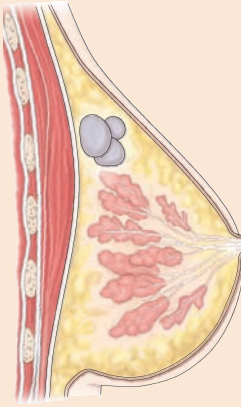

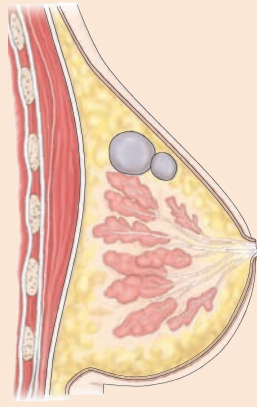

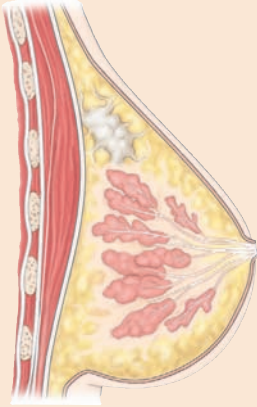

Fibroadenomas are firm, round, movable, benign tumors. They can occur from puberty to menopause with a peak incidence at 30 years of age. These masses are nontender and are sometimes removed for definitive diagnosis.

Benign Proliferative Breast Disease

The two most common diagnoses of **benign proliferative breast disease** found on biopsy are atypical hyperplasia and lobular carcinoma in situ. These diagnoses increase a woman's risk of breast cancer.

Table 48-2 COMPARISON OF VARIOUS BREAST MASSES

The most common breast masses are due to cysts, fibroadenomas, or malignancy. Biopsy is usually needed for confirmation, but the following characteristics are diagnostic clues:

Characteristics	Cysts	Fibroadenomas	Malignancy
			
Age	30–55 years, regress after menopause except with use of estrogen therapy	Puberty to menopause	30–90 years; most common, 40–80 years
Number	Single or multiple	Usually single	Usually single
Shape	Round	Round, disk, or lobular	Irregular or stellate
Consistency	Soft to firm, usually elastic	Usually firm	Firm or hard
Mobility	Mobile	Mobile	May be fixed to skin or underlying tissues
Tenderness	Usually tender	Usually nontender	Usually nontender
Retraction signs	Absent	Absent	May be present

Atypical Hyperplasia

Atypical hyperplasia is an abnormal increase in the ductal (atypical ductal hyperplasia) or lobular (atypical lobular hyperplasia) cells in the breast and is usually found incidentally in mammographic abnormalities. Atypical hyperplasia increases a woman’s risk of breast cancer about four to five times compared with that of the general population (Hanby & Hughes, 2008).

Lobular Carcinoma in Situ

Lobular carcinoma in situ (LCIS) is characterized by a proliferation of cells within the breast lobules. LCIS is usually found incidentally on pathologic diagnosis because it cannot be seen on mammography and does not form a palpable lump. The term LCIS is misleading because it is not a carcinoma. Historically, LCIS was considered a premalignant condition but is now considered a marker for increased risk of invasive carcinoma. A patient with LCIS may later develop an invasive carcinoma in either breast that is either ductal or lobular in origin. LCIS increases a woman’s risk of breast cancer about 8 to 10 times compared with that of the general population (Hanby & Hughes, 2008).

Other Benign Conditions

Cystosarcoma phyllodes is a rare fibroepithelial lesion that tends to grow rapidly. It is rarely malignant and is treated with surgical excision. If it is malignant, mastectomy may follow. Lymph node removal is usually not performed because metastasis is rare.

Fat necrosis is a condition of the breast that is often associated with a history of trauma. Surgical procedures such as a breast biopsy can cause fat necrosis. It may be indistinguishable from carcinoma, and the entire mass is usually excised.

Intraductal papilloma is a wartlike growth that often involves the large milk ducts near the nipple, causing bloody nipple discharge. Surgery usually involves removal of the papilloma and a segment of the duct where the papilloma is found.

Superficial thrombophlebitis of the breast (Mondor disease) is an uncommon condition that is usually associated with pregnancy, trauma, or breast surgery. Pain and redness occur as a result of a superficial thrombophlebitis in the vein that drains the outer part of the breast. The mass is usually linear, tender, and erythematous. Treatment consists of analgesics and heat.

MALIGNANT CONDITIONS OF THE BREAST

Breast cancer is a major health problem in the United States. At present, there is no cure. It is estimated that more than 190,000 women and 1900 men develop the disease and more than 40,000 die of it annually (ACS, 2009). Incidence rates, however, have decreased by 3.5% per year from 2001 to 2004 after increasing since 1980. Between 1990 and 2002, the mortality rate for breast cancer decreased by 2.2%, suggesting that the combination of early detection and improved treatment modalities had an effect on overall survival.

Current statistics indicate that over an entire lifetime (birth to death), a woman's risk of developing breast cancer is one in eight. When broken down by age, the risk by 39 years of age is 1 in 210, and it increases to 1 in 26 by 59 years of age. Approximately 80% of breast cancers are diagnosed in women older than 50 years of age (Jemal, et al., 2008).

Types of Breast Cancer

Ductal Carcinoma in Situ

The increased use of mammography as a screening tool has contributed to the dramatic increase in the diagnosis of **ductal carcinoma in situ (DCIS)**. An estimated 67,000 new cases are diagnosed annually (Jemal, et al., 2008). DCIS is characterized by the proliferation of malignant cells inside the milk ducts without invasion into the surrounding tissue. Therefore, it is a noninvasive form of cancer (also called intraductal carcinoma). DCIS is frequently manifested on a mammogram with the appearance of calcifications, and it is considered breast cancer stage 0.

If DCIS is left untreated, there is an increased likelihood that it will progress to invasive cancer. Deciding on the best surgical treatment option can be very complex. DCIS can be categorized in terms of its aggressiveness depending on a variety of factors, including histological subtype (comedo is more aggressive than noncomedo), size of tumor, and whether it is multicentric (present in different quadrants of the breast). These factors, together with patient preference, are important determinants in making treatment decisions. The most traditional treatment is total or simple mastectomy (removal of the breast only), with a cure rate of 98% to 99% (Boughey, Gonzalez, Bonner, et al., 2007). The trend today is toward less aggressive surgery; **breast conservation treatment** (limited surgery followed by radiation) is being performed with increasing frequency. In rare cases, lumpectomy alone is an option. The National Surgical Adjuvant Breast and Bowel Project B-24 study demonstrated that the addition of tamoxifen (Nolvadex) significantly reduced local recurrence rates after surgery and radiation (Daly, 2006). The medication is usually prescribed for 5 years.

Invasive Cancer

The National Comprehensive Cancer Network (NCCN), a nonprofit group of the world's 21 leading cancer centers, disseminates estimates for various types of cancer.

Infiltrating Ductal Carcinoma

Infiltrating ductal carcinoma, the most common histologic type of breast cancer, accounts for 80% of all cases. The tumors arise from the duct system and invade the surrounding tissues. They often form a solid irregular mass in the breast.

Infiltrating Lobular Carcinoma

Infiltrating lobular carcinoma accounts for 10% to 15% of breast cancers. The tumors arise from the lobular epithelium and typically occur as an area of ill-defined thickening in the breast. They are often multicentric and can be bilateral.

Medullary Carcinoma

Medullary carcinoma accounts for about 5% of breast cancers, and it tends to be diagnosed more often in women younger than 50 years of age. The tumors grow in a capsule inside a duct. They can become large and may be mistaken for a fibroadenoma. The prognosis is often favorable.

Mucinous Carcinoma

Mucinous carcinoma accounts for about 3% of breast cancers and often presents in postmenopausal women 75 years of age and older. A mucin producer, the tumor is also slow growing and thus the prognosis is more favorable than in many other types.

Tubular Ductal Carcinoma

Tubular ductal carcinoma accounts for about 2% of breast cancers. Because axillary metastases are uncommon with this histology, prognosis is usually excellent.

Inflammatory Carcinoma

Inflammatory carcinoma is a rare (1% to 3%) and aggressive type of breast cancer that has unique symptoms. The cancer is characterized by diffuse edema and brawny erythema of the skin, often referred to as *peau d'orange* (resembling an orange peel). This is caused by malignant cells blocking the lymph channels in the skin. An associated mass may or may not be present; if there is a mass, it is often a large area of indiscrete thickening. Inflammatory carcinoma can be confused with an infection because of its presentation. The disease can spread to other parts of the body rapidly. Chemotherapy often plays an initial role in controlling disease progression, but radiation and surgery may also be useful.

Paget's Disease

Paget's disease of the breast accounts for 1% of diagnosed cases of breast cancer. Symptoms typically include a scaly, erythematous, pruritic lesion of the nipple. Paget's disease often represents ductal carcinoma in situ of the nipple but may have an invasive component. If no lump can be felt in the breast tissue and the biopsy shows DCIS without invasion, the prognosis is very favorable.

Risk Factors

There is no single, specific cause of breast cancer. A combination of genetic, hormonal, and possibly environmental factors may increase the risk of its development (Table 48-3). More than 80% of all cases of breast cancer are sporadic, meaning that patients have no known family history of the disease. The remaining cases are either familial (there is a family history of breast cancer but it is not passed on genetically) or genetically acquired. There is no evidence that smoking, silicone breast implants, use of antiperspirants, underwire bras, or abortion (induced or spontaneous) increases the risk of the disease.

As stated previously, breast cancer can be genetically inherited, resulting in significant risk. Approximately 5% to 10% of breast cancer cases develop as a result of genetic mutations. Factors that may indicate a genetic link include multiple first-degree relatives with early-onset breast

Table 48-3 RISK FACTORS FOR BREAST CANCER

Risk Factor	Comments
Female gender	99% of cases occur in women.
Increasing age	Increasing age is associated with an increased risk.
Personal history of breast cancer	Once treated for breast cancer, the risk of developing breast cancer in same or opposite breast is significantly increased.
Family history of breast cancer	Having first-degree relative with breast cancer (mother, sister, daughter) increases the risk twofold; having two first-degree relatives increases the risk fivefold. The risk is higher if the relative was premenopausal at the time of diagnosis. The risk is increased if a father or brother had breast cancer (exact risk is unknown).
Genetic mutation	BRCA1 and BRCA2 mutations account for the majority of inherited cases of breast cancer (see additional information in text).
Hormonal Factors	
• Early menarche	Before 12 years of age
• Late menopause	After 55 years of age
• Nulliparity	No full-term pregnancies
• Late age at first full-term pregnancy	After 30 years of age
• Hormone therapy (formerly referred to as hormone replacement therapy)	Current or recent use of combined postmenopausal hormone therapy (estrogen and progesterone) Long-term use (several years or more)
Exposure to ionizing radiation during adolescence and early adulthood	The risk is highest if breast tissue was exposed while still developing (during adolescence) such as women who received mantle radiation (to the chest area) for treatment of Hodgkin lymphoma in their younger years.
History of benign proliferative breast disease	Having had atypical ductal or lobular hyperplasia or lobular carcinoma in situ increases the risk.
Obesity	Obesity and weight gain during adulthood increases the risk of postmenopausal breast cancer. During menopause, estrogen is primarily produced in fat tissue. More fat tissue can increase estrogen levels, thereby increasing breast cancer risk.
High-fat diet (controversial)	More research is needed.
Alcohol intake (beer, wine, or liquor)	Two to five drinks daily increases the risk about one and a half times.

cancer, breast and ovarian cancer in the same family, male breast cancer, and Ashkenazi Jewish background. **BRCA1** and **BRCA2** are tumor suppressor genes that normally function to identify damaged DNA and thereby restrain abnormal cell growth. Mutations in these genes are responsible for the majority of hereditary breast cancer in the United States. **BRCA1** mutations have been associated with a 65% to 87% estimated lifetime risk, and **BRCA2** mutations have been associated with a 45% to 84% risk. Carriers also have a significantly increased risk for ovarian cancer, approaching 30% (Turnbull & Rahman, 2008). Men with **BRCA** mutations, particularly the **BRCA2** mutation, also have an increased risk of breast cancer. A recent study reported that there is a broad variation in breast cancer risk among carriers of **BRCA1** and **BRCA2** when different variables are considered. A gene carrier was found to be at significantly higher risk if a relative was diagnosed with breast cancer at an early age (Begg, Haile & Borg, 2008).

Protective Factors

Certain factors may be protective in relation to the development of breast cancer. A systematic review of 48 studies showed that physical activity reduced the risk of breast cancer in postmenopausal women by 20% to 80%; the evidence was much weaker for premenopausal women with the disease (Monninkhof, Elias, Vlems, et al., 2007). Studies to determine the most effective exercises and how often to perform them are ongoing.

Breastfeeding is also thought to decrease risk because it prevents the return of menstruation, thereby decreasing exposure to endogenous estrogen. Having completed a full-term pregnancy before 30 years of age is also thought to be protective.

Breast Cancer Prevention Strategies in the High-Risk Patient

Patients often overestimate or underestimate their risk of developing breast cancer. A consultation with a breast specialist is of paramount importance prior to embarking on any of the prevention strategies that follow. Once patients have an accurate assessment of their risk, along with the knowledge of the pros and cons of each prevention strategy, they can make a decision that is most appropriate for their situation.

Long-Term Surveillance

Long-term surveillance is a form of secondary prevention that focuses on early detection of the disease. As recommended by the ACS, women with a 20% or greater lifetime risk benefit from additional screening with MRI (Saslow, et al., 2007). Clinical breast examinations may be performed twice a year starting as early as 25 years of age. Mammograms may also be performed as early as 25 years of age. Data concerning the effectiveness of BSE are limited. In addition to yearly mammography and MRI, other screening tests, including ultrasonography, may be useful.

Chemoprevention

Chemoprevention is a primary prevention modality that aims to prevent the disease. In April 1998, the results of the Breast Cancer Prevention Trial were released to the general public. This national, randomized, double-blind clinical trial evaluated tamoxifen (20 mg daily for 5 years) versus a placebo in more than 13,000 women considered to be at high risk for breast cancer. The women who received

tamoxifen had a 49% reduction in the incidence of breast cancer (Fisher, Constantino, Wickerham, et al., 1998), suggesting that tamoxifen was an effective chemopreventive agent. Subsequently, the FDA approved its use in high-risk women. Nurses can help women who are considering this option by providing them with information about the benefits, risks, and possible side effects of tamoxifen.

Raloxifene (Evista) is a medication that is used for the prevention and treatment of osteoporosis. The results of the Multiple Outcomes of Raloxifene Evaluation trial in postmenopausal women with osteoporosis showed that women who received raloxifene instead of placebo had a 76% reduction in invasive breast cancer (Cummings, Eckert, Krueger, et al., 1999).

A national, randomized clinical trial, the Study of Tamoxifen and Raloxifene (STAR), compared these two agents for the prevention of breast cancer in postmenopausal women (Vogel, Costantino, Wickerham, et al., 2006). Results showed that raloxifene is as effective as tamoxifen in reducing breast cancer risk and has fewer side effects, including fewer uterine cancers, blood clots, and cataracts. In September 2007 the FDA approved the use of raloxifene as a chemopreventive agent in postmenopausal women.

Prophylactic Mastectomy

Prophylactic mastectomy is another primary prevention modality. This procedure can reduce the risk of breast cancer by 90% (Alschuler, Nekhlyudov, Rolnick, et al., 2008) and is sometimes referred to as a “risk-reducing” mastectomy. The procedure consists of a total mastectomy (removal of breast tissue only) and is usually accompanied by immediate breast reconstruction. Possible candidates include women with a strong family history of breast cancer, a diagnosis of LCIS or atypical hyperplasia, a mutation in a BRCA gene, an extreme fear of cancer (“cancer phobia”), or previous cancer in one breast.

A patient who is considering prophylactic mastectomy is often faced with a very controversial and emotional decision. A multidisciplinary approach should be used to help the patient arrive at a decision that is best for her. Consultation with a genetics counselor, plastic surgeon, medical oncologist, and psychiatrist can be invaluable. The patient needs to understand that this surgery is elective and not emergent. The nurse can play a valuable role in providing the patient with information, clarification, and support during the decision-making process.

Clinical Manifestations

Breast cancers can occur anywhere in the breast but are usually found in the upper outer quadrant, where the most breast tissue is located. Generally, the lesions are nontender, fixed rather than mobile, and hard with irregular borders. Complaints of diffuse breast pain and tenderness with menstruation are usually associated with benign breast disease.

With the increased use of mammography, more women are seeking treatment at earlier stages of the disease. These women often have no signs or symptoms other than a mammographic abnormality. Unfortunately, some women with advanced disease seek initial treatment after ignoring symptoms. Advanced signs may include skin dimpling, nipple retraction, or skin ulceration.

Assessment and Diagnostic Findings

Techniques to determine the diagnosis of breast cancer include various types of biopsy, which have been described previously. Tumor staging and analysis of additional prognostic factors are used to determine the prognosis and optimal treatment regimen (see below).

Staging

Staging involves classifying the cancer by the extent of disease. Clinical staging involves the physician’s estimate of the size of the breast tumor and the extent of axillary lymph node involvement. Such staging is determined by physical examination and imaging studies. Pathological staging is done when the pathologist examines the surgically excised breast tissue under the microscope and determines the exact size of the breast tumor and the exact number of lymph nodes involved.

The staging of breast cancer has become complex. Classification of tumors that are stage 0 (DCIS, LCIS, or Paget’s disease of the nipple with no invasion), stage I (tumors that are 2 cm or less with no involvement of axillary lymph nodes), and stage IV (tumors of any size, with distant metastases) is fairly straightforward. However, classification of tumors that are stage II and stage III, which represent a wide spectrum of breast cancers, is more difficult. Factors that play a role in determining stages II and III include the number and characteristics of axillary lymph nodes, the status of other regional lymph nodes such as internal mammary nodes or supraclavicular nodes, and the presence or absence of involvement of the skin or underlying muscle. Based on these factors, stage II and stage III breast cancers are further subdivided into stage IIA, IIB, IIIA, IIIB, and IIIC. For a detailed explanation of the staging system, the reader is referred to the *American Joint Committee on Cancer Staging Manual* (Greene, Page, Fleming, et al., 2002) or to the ACS Web site (see Resources below).

Other diagnostic tests may be performed before or after the surgery to help in the staging of the disease. The extent of testing often depends on the clinical presentation of the disease and may include chest x-rays, computed tomography (CT), MRI, positron emission tomography (PET) scan, bone scans, and blood work (complete blood count, comprehensive metabolic panel, tumor markers [ie, carcinoembryonic antigen, cancer antigen 15-3]).

Prognosis

Several different factors must be taken into consideration when determining the prognosis of a patient with breast cancer. The two most important factors are tumor size and whether the tumor has spread to the lymph nodes under the arm (axilla).

Generally, the smaller the tumor, the better the prognosis. Carcinoma of the breast is not a pathologic entity that develops overnight. It starts with a genetic alteration in a single cell and takes time to divide and double in size. A carcinoma may double in size 30 times to become 1 cm or larger, at which point it becomes clinically apparent. Doubling time varies, but breast tumors are often present for several years before they become palpable. Nurses can reassure patients that once breast cancer is diagnosed, they have a safe period of several weeks to make decisions regarding treatment.

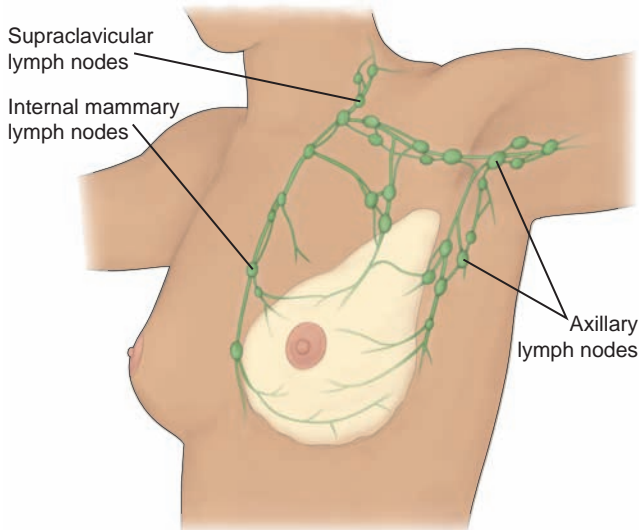

Figure 48-5 Lymphatic drainage of the breast.

Prognosis also depends on the extent of spread of the breast cancer. The 5-year survival rate can be as high as 98.1% for a stage I breast cancer and as low as 27.1% for a stage IV breast cancer (National Cancer Institute, 2008). The most common route of regional spread is to the axillary lymph nodes. Other sites of lymphatic spread include the internal mammary and supraclavicular nodes (Fig. 48-5). Distant metastasis can affect any organ, but the most common sites are bone, lung, liver, pleura, adrenals, skin, and brain.

In addition to the type of breast cancer and the stage, other factors may help determine prognosis (Chart 48-3). Excessive number of copies of certain genes (amplification) or excessive amounts of their protein product (overexpression) may represent a poorer prognosis. The HER-2/neu (also known as ERBB2) oncogene is the classic example; approximately 25% to 30% of invasive breast cancers, which typically involve the more aggressive tumors, have amplification or overexpression of the HER-2/neu gene (Dawood, Broglio, Esteva, et al., 2008). Research concerning the prognostic usefulness of the proliferative rate (S-phase fraction) and DNA content (ploidy) of a tumor is ongoing.

Surgical Management

The main goal of surgery is to gain local control of the disease. With breast cancer being diagnosed today at earlier stages, options for less invasive surgical procedures are avail-

Chart 48-3 • Pathologic Factors Associated With Favorable Prognosis for Breast Cancer

- Noninvasive tumors or invasive tumors less than 1 cm
- Negative axillary lymph nodes
- Estrogen receptor (ER) and progesterone receptor (PR) proteins
- Well-differentiated tumors
- Low expression of HER-2/neu oncogene (also known as ERBB2)
- No vascular or lymphatic invasion
- Diploid tumors with low S-phase fraction

Table 48-4 SURGICAL TREATMENT OPTIONS FOR NONINVASIVE AND INVASIVE BREAST CANCER

Noninvasive Breast Cancer	Invasive Breast Cancer
Breast conservation* alone	Breast conservation* with one of the following: Sentinel lymph node biopsy Axillary lymph node dissection
Total mastectomy alone	Total mastectomy with sentinel lymph node biopsy or Modified radical mastectomy

*Breast conservation treatment includes lumpectomy, wide excision, partial or segmental mastectomy, and quadrantectomy. These are relatively synonymous terms that describe removal of varying amounts of breast tissue.

able. Surgical treatment options for noninvasive and invasive breast cancer are summarized in Table 48-4.

Modified Radical Mastectomy

Modified radical mastectomy is performed to treat invasive breast cancer. The procedure involves removal of the entire breast tissue, including the nipple–areola complex. In addition, a portion of the axillary lymph nodes are also removed in axillary lymph node dissection (ALND). If immediate breast reconstruction is desired, the patient is referred to a plastic surgeon prior to the mastectomy so that she has the opportunity to explore all available options. In modified radical mastectomy, the pectoralis major and pectoralis minor muscles are left intact, unlike in radical mastectomy, in which the muscles are removed. Radical mastectomy is rarely performed today.

Total Mastectomy

Like modified radical mastectomy, **total mastectomy** (ie, simple mastectomy) also involves removal of the breast and nipple–areola complex but does not include ALND. Total mastectomy may be performed in patients with noninvasive breast cancer (eg, DCIS), which does not have a tendency to spread to the lymph nodes. It may also be performed prophylactically in patients who are at high risk for breast cancer (eg, LCIS, BRCA mutation). A total mastectomy may also be performed in conjunction with sentinel lymph node biopsy (SLNB) for patients with invasive breast cancer.

Breast Conservation Treatment

The goal of breast conservation treatment (ie, lumpectomy, wide excision, partial or segmental mastectomy, quadrantectomy) is to excise the tumor in the breast completely and obtain clear margins while achieving an acceptable cosmetic result. If the procedure is being performed to treat a noninvasive breast cancer, lymph node removal is not necessary. For an invasive breast cancer, lymph node removal (SLNB or ALND) is indicated. The lymph nodes are removed through a separate semicircular incision in the axilla. In 1990, the National Institutes of Health (NIH) issued a consensus statement that breast conservation along with radiation therapy in stage I and stage II breast cancer resulted in a survival rate equal to that of modified radical mastectomy.

Table 48-5 COMPARISON OF SENTINEL LYMPH NODE BIOPSY AND AXILLARY LYMPH NODE DISSECTION

Sentinel Lymph Node Biopsy (SLNB)	Axillary Lymph Node Dissection (ALND)
Shorter operating room time (approximately 15 to 30 minutes)	Longer operating room time (approximately 60 to 90 minutes)
No surgical drain	Surgical drain
Local anesthesia with IV moderate sedation as outpatient surgery (unless being performed in conjunction with total mastectomy)	General anesthesia; usually overnight admission (sometimes done as outpatient surgery)
Lymphedema incidence approximately 0% to 8%	Lymphedema incidence approximately 10% to 30%
Presence of neuropathic sensations postoperatively (prevalence lower than after axillary lymph node dissection)	Presence of neuropathic sensations postoperatively
Decreased range of motion in affected arm unlikely postoperatively but may occur	Decreased range of motion likely postoperatively
Seroma (collection of serous fluid in the axilla) may occur postoperatively	Seroma may occur postoperatively

Sentinel Lymph Node Biopsy

As previously discussed, the status of the lymph nodes is the most important prognostic factor in breast cancer. Approximately two thirds of women with early-stage breast cancer who have an ALND have negative nodes. In the mid-1990s, SLNB emerged as a less invasive alternative to ALND and is now considered a standard of care for the treatment of early-stage breast cancer. ALND is associated with potential morbidity, including lymphedema, cellulitis, decreased arm mobility, and sensory changes. Studies have shown that SLNB is highly accurate and is associated with a local recurrence rate similar to that of ALND (Bergkvist, deBoniface, Jonsson, et al., 2008; Krag, Anderson, Julian, et al., 2007). Table 48-5 compares sentinel lymph node biopsy and axillary lymph node dissection.

The **sentinel lymph node**, which is the first node (or nodes) in the lymphatic basin that receives drainage from the primary tumor in the breast, is identified by injecting a radioisotope and/or blue dye into the breast; the radioisotope or dye then travels via the lymphatic pathways to the node. In SLNB, the surgeon uses a hand-held probe to locate the sentinel lymph node, excises it, and sends it for pathologic analysis, which is often performed immediately during the surgery using frozen section analysis. If the sentinel lymph node is positive, the surgeon can proceed with an immediate ALND, thus sparing the patient a return trip to the operating room and additional anesthesia. (The patient could also opt to return for additional surgery at a later time.) If the sentinel lymph node is negative, a standard ALND is not needed, thus sparing the patient the sequelae of the procedure. After the operation is complete, all the specimens are sent to pathology for more thorough analysis.

Nursing Management

Patients who undergo SLNB in conjunction with breast conservation are generally discharged the same day. Patients who undergo SLNB with total mastectomy usually stay in the hospital overnight, possibly longer if breast reconstruction is being performed. The patient must be informed that although frozen section analysis is highly accurate, false-negative results can occur. A negative sentinel lymph node on frozen section analysis may show metastatic disease on subsequent analysis, indicating that ALND is still necessary. The patient should also be reassured that the radioisotope and blue dye are generally safe. The patient may notice a blue-green discoloration in the urine or stool for the first 24 hours as the blue dye is excreted. The incidence

of lymphedema, decreased arm mobility, and seroma formation (collection of serous fluid) in the axilla is generally low, but the patient should be prepared for this possibility. A recent study demonstrated that women who have SLNB alone have neuropathic sensations similar to those who undergo ALND, although the prevalence and severity of these sensations and the resulting distress are lower with SLNB (Baron, Fey, Borgen, et al., 2007).

The nurse must not overlook the psychosocial needs of the patient who has undergone SLNB. Although SLNB is a less invasive procedure than ALND and results in a shorter recovery period, a patient who has undergone SLNB also has many difficult issues surrounding her breast cancer diagnosis and treatment. The nurse must listen, provide emotional support, and refer the patient to appropriate specialists when indicated.

NURSING PROCESS

THE PATIENT UNDERGOING SURGERY FOR BREAST CANCER

Assessment

The health history is a valuable tool to assess the patient's reaction to the diagnosis and her ability to cope with it. Pertinent questions include the following:

- How is the patient responding to the diagnosis?
- What coping mechanisms does she find most helpful?
- What psychological or emotional supports does she have and use?
- Is there a partner, family member, or friend available to assist her in making treatment choices?
- What are her educational needs?
- Is she experiencing any discomfort?

Diagnosis

Preoperative Nursing Diagnoses

Based on the health history and other assessment data, major preoperative nursing diagnoses may include the following:

- Deficient knowledge about the planned surgical treatments
- Anxiety related to the diagnosis of cancer
- Fear related to specific treatments and body image changes

- Risk for ineffective coping (individual or family) related to the diagnosis of breast cancer and related treatment options
- Decisional conflict related to treatment options

Postoperative Nursing Diagnoses

Based on the health history and other assessment data, major postoperative nursing diagnoses may include the following:

- Pain and discomfort related to surgical procedure
- Disturbed sensory perception related to nerve irritation in affected arm, breast, or chest wall
- Disturbed body image related to loss or alteration of the breast
- Risk for impaired adjustment related to the diagnosis of cancer and surgical treatment
- Self-care deficit related to partial immobility of upper extremity on operative side
- Risk for sexual dysfunction related to loss of body part, change in self-image, and fear of partner's responses
- Deficient knowledge: drain management after breast surgery
- Deficient knowledge: arm exercises to regain mobility of affected extremity
- Deficient knowledge: hand and arm care after ALND

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include the following:

- Lymphedema
- Hematoma/seroma formation
- Infection

Planning and Goals

The major goals may include increased knowledge about the disease and its treatment; reduction of preoperative and postoperative fear, anxiety, and emotional stress; improvement of decision-making ability; pain management; improvement in coping abilities; improvement in sexual function; and the absence of complications.

Preoperative Nursing Interventions

Providing Education and Preparation about Surgical Treatments

Patients with newly diagnosed breast cancer are expected to absorb an abundance of new information during a very emotionally difficult time. The nurse plays a key role in reviewing treatment options by reinforcing information provided to the patient and answering any questions. The nurse fully prepares the patient for what to expect before, during, and after surgery. Patients undergoing breast conservation with ALND, or a total or modified radical mastectomy, generally remain in the hospital overnight (or longer if they have immediate reconstruction). Surgical drains will be inserted in the mastectomy incision and in the axilla if the patient undergoes an ALND. A surgical drain is generally not needed after a SLNB. The patient should be informed that she will go home with the drain(s) and that complete instructions about drain care will be provided prior to discharge. In addition, the patient should be

informed that she will often have decreased arm and shoulder mobility after an ALND and that she will be shown range-of-motion exercises prior to discharge. The patient should also be reassured that appropriate analgesia and comfort measures will be provided to alleviate any postoperative discomfort.

Reducing Fear and Anxiety and Improving Coping Ability

The nurse must help the patient cope with the physical as well as the emotional effects of surgery. Many fears may emerge during the preoperative phase. These can include fear of pain, mutilation (after mastectomy), and loss of sexual attractiveness; concern about inability to care for oneself and one's family; concern about taking time off from work; and coping with an uncertain future. Providing the patient with realistic expectations about the healing process and expected recovery can help alleviate fears. Maintaining open communication and assuring the patient that she can contact the nurse at any time with questions or concerns can be a source of comfort. The patient should also be made aware of available resources at the treatment facility as well as in the breast cancer community such as social workers, psychiatrists, and support groups. Some women find it helpful and reassuring to talk to a breast cancer survivor who has undergone similar treatments.

Promoting Decision-Making Ability

The patient may be eligible for more than one therapeutic approach; she may be presented with treatment options and then asked to make a choice. This can be very frightening for some patients, and they may prefer to have someone else make the decision for them (eg, surgeon, family member). The nurse can be instrumental in ensuring that the patient and family members truly understand their options. The nurse can then help the patient weigh the risks and benefits of each option. The patient may be presented with the option of having breast conservation treatment followed by radiation or a mastectomy. The nurse can explore the issues with the individual patient by asking questions such as the following:

- How would you feel about losing your breast?
- Are you considering breast reconstruction?
- If you choose to retain your breast, would you consider undergoing radiation treatments 5 days a week for 5 to 6 weeks?

Questions such as these can help the patient focus. Once the patient's decision is made, it is very important to support it.

Postoperative Nursing Interventions

Relieving Pain and Discomfort

Many patients tolerate the breast surgery quite well and have minimal pain during the postoperative period. This is particularly true of the less invasive procedures such as breast conservation treatment with SLNB. However, all patients must be carefully assessed, because individual patients can have varying degrees of pain. Patients who have had more invasive procedures such as a modified radical mastectomy with immediate reconstruction may have considerably

more pain. All patients are discharged home with analgesic medication (eg, oxycodone and acetaminophen [Percocet] or propoxyphene and acetaminophen [Darvocet]) and are encouraged to take it if needed. An over-the-counter analgesic such as acetaminophen may provide sufficient relief. Sometimes patients complain of a slight increase in pain after the first few days of surgery; this may occur as patients regain sensation around the surgical site and become more active. However, patients who report excruciating pain must be evaluated to rule out any potential complications such as infection or a hematoma. Alternative methods of pain management such as taking warm showers and using distraction methods (eg, guided imagery) may also be helpful.

Managing Postoperative Sensations

Because nerves in the skin and axilla are often cut or injured during breast surgery, patients experience a variety of sensations. Common sensations include tenderness, soreness, numbness, tightness, pulling, and twinges. These sensations may occur along the chest wall, in the axilla, and along the inside aspect of the upper arm. After mastectomy, some patients experience phantom sensations and report a feeling that the breast or nipple is still present. Overall, patients do not find these sensations severe or distressing (Baron, et al., 2007). Chart 48-4 presents specific information from this study. Sensations usually persist for several months and then begin to diminish, although some may persist for as long as 5 years and possibly longer. Patients should be reassured that this is a normal part of healing and that these sensations are not indicative of a problem.

Promoting Positive Body Image

Patients who have undergone mastectomy often find it very difficult to view the surgical site for the first time. No matter how prepared the patient may think she is, the appearance of an absent breast can be very emotionally distressing. Ideally, the patient sees the incision for the first time when she is with the nurse or another health care provider who is available for support.

The nurse first assesses the patient's readiness and provides gentle encouragement. It is important to maintain the patient's privacy while assisting her as she views the incision; this allows her to express feelings safely to the nurse. Asking the patient what she perceives, acknowledging her feelings, and allowing her to express her emotions are important nursing actions. Reassuring the patient that her feelings are a normal response to breast cancer surgery may be comforting. If the patient has not had immediate reconstruction, providing her with a temporary breast form to place in her bra on discharge can help alleviate feelings of embarrassment or self-consciousness.

Promoting Positive Adjustment and Coping

Providing ongoing assessment of how the patient is coping with her diagnosis of breast cancer and her surgical treatment is important in determining her overall adjustment. Assisting the patient in identifying and mobilizing her support systems can be beneficial to her well-being. The patient's spouse or partner may also need guidance, support, and education. The patient and partner may benefit from a wide network of available community resources, including

CHART
48-4

NURSING RESEARCH PROFILE Sensory Morbidity After Breast Cancer Surgery

Baron, R. H., Fey, J. V., Borgen, P. I., et al. (2007). Eighteen sensations after breast cancer surgery: A 5-year comparison of sentinel lymph node biopsy and axillary lymph node dissection. *Annals of Surgical Oncology*, 14(5), 1653–1661.

Purpose

Women with breast cancer often report a variety of sensations following surgery and question whether these sensations are normal. The purpose of this study was to compare the prevalence, severity, and level of distress associated with sensations after sentinel lymph node biopsy (SLNB) with axillary lymph node dissection (ALND) at 3 to 15 days (baseline) and 5 years after breast cancer surgery. Long-term differences in sensations after SLNB and ALND have rarely been addressed by researchers, making it difficult for clinicians to provide effective guidance and symptom management.

Design

This descriptive study prospectively evaluated sensations in 133 women who had SLNB and in 54 women who had more extensive ALND. Researchers used the Breast Sensation Assessment Scale, a Likert-type scale to assess the presence and severity of 18 sensations and posed an additional question about the prevalence, severity, and resulting distress of phantom sensations. Study participants completed the scale six times over a 5-year period, beginning 3 to 15 days after surgery during their initial postoperative visit and by mail at

3, 6, 12, 24, and 60 months after surgery. Although the investigators had conducted previous studies of women using a larger sample, only women described in the present study provided data at all six data collection points. These women represent 47% of the original sample; loss to follow-up from the previous studies was similar in the SLNB and ALND groups.

Findings

The prevalence and severity of sensations and the resulting level of distress were lower in women who had SLNB compared with those who had ALND. Tenderness and twinges were prevalent at baseline after SLNB and remained so over 5 years. Numbness and tightness were prevalent after ALND and continued over 5 years; however, these sensations decreased in prevalence over time. In general, the majority of sensations were reportedly neither severe nor distressing. In women who underwent mastectomy, the severity and resulting distress caused by phantom sensations were low.

Nursing Implications

Nurses can use the results of this study to provide women undergoing SLNB and ALND with accurate information about postoperative sensations. It is important to provide this information to help women anticipate these sensations and understand that they are a normal part of the healing process.

the Reach to Recovery program of the ACS, advocacy groups, or a spiritual advisor. Encouraging the patient to discuss issues and concerns with other patients who have had breast cancer may help her to understand that her feelings are normal and that other women who have had breast cancer can provide invaluable support and understanding.

The patient may also have considerable anxiety about the treatments that will follow surgery (ie, chemotherapy and radiation) and their implications. Providing her with information about the plan of care and referring her to the appropriate members of the health care team also promote coping during recovery. Some women require additional support to adjust to their diagnosis and the changes that it brings. If a woman displays ineffective coping, consultation with a mental health practitioner may be indicated.

Improving Sexual Function

Once discharged from the hospital, most patients are physically allowed to engage in sexual activity. However, any change in the patient's body image, self-esteem, or the response of her partner may increase her anxiety level and affect sexual function. Some partners may have difficulty looking at the incision, whereas others may be completely unaffected. Encouraging the patient to openly discuss how she feels about herself and about possible reasons for a decrease in libido (eg, fatigue, anxiety, self-consciousness) may help clarify issues for her. Helpful suggestions for the patient may include varying the time of day for sexual activity (when the patient is less tired), assuming positions that are more comfortable, and expressing affection using alternative measures (eg, hugging, kissing, manual stimulation).

Most patients and their partners adjust with minimal difficulty if they openly discuss their concerns. However, if issues cannot be resolved, a referral for counseling (eg, psychologist, psychiatrist, psychiatric clinical nurse specialist, social worker, sex therapist) may be helpful. The ambulatory care nurse in the outpatient clinic or hospital should inquire whether the patient is having difficulty with sexuality issues because many patients are reluctant or embarrassed to bring it up themselves.

Monitoring and Managing Potential Complications

LYMPHEDEMA. Lymphedema occurs in about 10% to 30% of patients who undergo ALND and in about 0% to 8% of patients who have SLNB (Langer, Guller, Berclaz, et al., 2007; Lucci, McCall, Beitsch, et al., 2007). Risk factors for lymphedema include increasing age, obesity, presence of

extensive axillary disease, radiation treatment, and injury or infection to the extremity (Warren, Brorson, Borud, et al., 2007). Lymphedema results if functioning lymphatic channels are inadequate to ensure a return flow of lymph fluid to the general circulation. After axillary lymph nodes are removed, collateral circulation must assume this function. Transient edema in the postoperative period occurs until collateral circulation has completely taken over this function, which generally occurs within a month. Performing prescribed exercises, elevating the arm above the heart several times a day, and gentle muscle pumping (making a fist and releasing) can help reduce the transient edema. The patient needs reassurance that this transient swelling is not lymphedema.

Once lymphedema develops, it tends to be chronic, so preventive strategies are vital. After ALND, the patient is taught hand and arm care to prevent injury or trauma to the affected extremity, thus decreasing the likelihood for lymphedema development (Chart 48-5). The patient is instructed to follow these guidelines for the rest of her life. She is also instructed to contact the physician or a nurse immediately if she suspects that she has lymphedema, because early intervention provides the best chance for control. If allowed to progress without treatment, the swelling can become more difficult to manage. Treatment may consist of a course of antibiotics if an infection is present. A referral to a rehabilitation specialist (eg, occupational or physical therapist) may be necessary for a compression sleeve or glove, exercises, manual lymph drainage, and a discussion of ways to modify daily activities to avoid worsening lymphedema.

HEMATOMA OR SEROMA FORMATION. Hematoma formation (collection of blood inside a cavity) may occur after either mastectomy or breast conservation and usually develops within the first 12 hours after surgery. The nurse assesses for signs and symptoms of a hematoma at the surgical site, which may include swelling, tightness, pain, and bruising of the skin. The surgeon should be notified immediately if there is gross swelling or increased bloody output from the drain. Depending on the surgeon's assessment, a compression wrap may be applied to the incision for approximately 12 hours, or the patient may be returned to the operating room so that the incision may be reopened to identify the source of bleeding. Some hematomas are small, and the body absorbs the blood naturally. The patient may take warm showers or apply warm compresses to

CHART
48-5

PATIENT EDUCATION

Hand and Arm Care After Axillary Lymph Node Dissection

- Avoid blood pressures, injections, and blood draws in affected extremity.
- Use sunscreen (higher than 15 SPF) for extended exposure to sun.
- Apply insect repellent to avoid insect bites.
- Wear gloves for gardening.
- Use cooking mitt for removing objects from oven.
- Avoid cutting cuticles; push them back during manicures.
- Use electric razor for shaving armpit.
- Avoid lifting objects greater than 5–10 pounds.
- If a trauma or break in the skin occurs, wash the area with soap and water, and apply an over-the-counter antibacterial ointment (Bacitracin or Neosporin).
- Observe the area and extremity for 24 hours; if redness, swelling, or a fever occurs, call the surgeon or nurse.

help increase the absorption. A hematoma usually resolves in 4 to 5 weeks.

A seroma, a collection of serous fluid, may accumulate under the breast incision after mastectomy or breast conservation or in the axilla. Signs and symptoms may include swelling, heaviness, discomfort, and a sloshing of fluid. Seromas may develop temporarily after the drain is removed or if the drain is in place and becomes obstructed. Seromas rarely pose a threat and may be treated by unclogging the drain or manually aspirating the fluid with a needle and syringe. Large, long-standing seromas that have not been aspirated could lead to infection. Small seromas that are not bothersome to the patient usually resolve on their own.

INFECTION. Although infection is rare, it is a risk after any surgical procedure. This risk may be higher in patients with conditions such as diabetes, immune disorders, and advanced age, as well as in those with poor hygiene. Patients are taught to monitor for signs and symptoms of infection (redness, warmth around incision, tenderness, foul-smelling drainage, temperature greater than 40°C [100.4°F], chills) and to contact the surgeon or nurse for evaluation. Treatment consists of oral or IV antibiotics (for more severe infections) for 1 or 2 weeks. Cultures are taken of any foul-smelling discharge.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patients who undergo breast cancer surgery receive a tremendous amount of information preoperatively and postoperatively. It is often difficult for the patient to absorb all of the information, partly because of the emotional distress that often accompanies the diagnosis and treatment. Prior to discharge, the nurse must assess the patient's readiness to assume self-care responsibilities and identify any gaps in knowledge. A review of teaching, with reinforcement, may be required to ensure that the patient and family are prepared to manage the necessary care at home. The nurse reiterates symptoms the patient should report, such as infection, seroma, hematoma, or arm swelling. All teaching should be reinforced during office visits and by telephone.

Most patients are discharged 1 or 2 days after ALND or mastectomy (possibly later if they have had immediate reconstruction) with surgical drains in place. Initially, the drainage fluid appears bloody, but it gradually changes to a

serosanguineous and then a serous fluid over the next several days. The patient is given instructions about drainage management at home (Chart 48-6). If the patient lives alone and drainage management is difficult, a referral for a home care nurse should be made. The drains are usually removed when the output is less than 30 mL in a 24-hour period (approximately 7 to 10 days). The home care nurse also reviews pain management and incision care.

Generally, the patient may shower on the second postoperative day and wash the incision and drain site with soap and water to prevent infection. If immediate reconstruction has been performed, showering may be contraindicated until the drain is removed. A dry dressing may be applied to the incision each day for 7 days. The patient should realize that sensation may be decreased in the operative area because the nerves were disrupted during surgery and should be informed that gentle care is needed to avoid injury. After the incision has completely healed (usually after 4 to 6 weeks), lotions or creams may be applied to the area to increase skin elasticity. The patient can begin to use deodorant on the affected side, although many women note that they no longer perspire as much as before the surgery.

After ALND, patients are taught arm exercises on the affected side to restore range of motion (Chart 48-7). After SLNB, patients may also benefit from these exercises, although they are less likely to have decreased range of motion than those who have undergone ALND. Range-of-motion exercises are initiated on the second postoperative day, although instruction often occurs on the first postoperative day. The goals of the exercise regimen are to increase circulation and muscle strength, prevent joint stiffness and contractures, and restore full range of motion. The patient is instructed to perform range-of-motion exercises at home three times a day for 20 minutes at a time until full range of motion is restored (generally 4 to 6 weeks). Most patients find that after the drain is removed, range of motion returns quickly if they have adhered to their exercise program.

If the patient is having any discomfort, taking an analgesic 30 minutes before beginning the exercises can be helpful. Taking a warm shower before exercising can also loosen stiff muscles and provide comfort. When exercising, the patient is encouraged to use the muscles in both arms and to maintain proper posture. Specific exercises may need to be prescribed and introduced gradually if the patient has had skin grafts; has a tense, tight surgical incision; or has

HOME CARE CHECKLIST

Surgical Breast Cancer Patient With a Drainage Device

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate how to empty and measure fluid from the drainage device.	✓	✓
• Demonstrate how to milk clots through the tubing of the drainage device.	✓	✓
• State observations that require contacting the physician or nurse (eg, sudden change in color of drainage, sudden cessation of drainage, signs or symptoms of an infection).	✓	✓
• Care for the drain site as per surgeon's recommendation.	✓	✓
• Identify when the drain is ready for removal (usually when draining less than 30 mL for a 24-hour period).	✓	✓

CHART
48-7

PATIENT EDUCATION
Exercise After Breast Surgery

1. *Wall handclimbing.* Stand facing the wall with feet apart and toes as close to the wall as possible. With elbows slightly bent, place the palms of the hand on the wall at shoulder level. By flexing the fingers, work the hands up the wall until arms are fully extended. Then reverse the process, working the hands down to the starting point.

2. *Rope turning.* Tie a light rope to a doorknob. Stand facing the door. Take the free end of the rope in the hand on the side of surgery. Place the other hand on the hip. With the rope-holding arm extended and held away from the body (nearly parallel with the floor), turn the rope, making as wide swings as possible. Begin slowly at first; speed up later.

3. *Rod or broomstick lifting.* Grasp a rod with both hands, held about 2 feet apart. Keeping the arms straight, raise the rod over the head. Bend elbows to lower the rod behind the head. Reverse maneuver, raising the rod above the head, then return to the starting position.

4. *Pulley tugging.* Toss a light rope over a shower curtain rod or doorway curtain rod. Stand as nearly under the rope as possible. Grasp an end in each hand. Extend the arms straight and away from the body. Pull the left arm up by tugging down with the right arm, then the right arm up and the left down in a see-sawing motion.

had immediate reconstruction. Self-care activities, such as brushing the teeth, washing the face, and brushing the hair, are physically and emotionally therapeutic because they aid in restoring arm function and provide a sense of normalcy for the patient.

The patient is instructed about postoperative activity limitation. Generally, heavy lifting (more than 5 to 10 lb) is avoided for about 4 to 6 weeks, although normal house-

hold and work-related activities are promoted to maintain muscle tone. Brisk walking, use of stationary bikes and stepping machines, and stretching exercises may begin as soon as the patient feels comfortable. Once the drain is removed, the patient may begin to drive if she has full arm range of motion and is no longer taking opioid analgesics. General guidelines for activity focus on the gradual introduction of previous activities (eg, bowling, weight training) once fully

healed, although checking with the physician or nurse beforehand is recommended.

CONTINUING CARE. Patients who have difficulty managing their postoperative care at home may benefit from a home health care referral. The home care nurse assesses the patient's incision and surgical drain(s), adequacy of pain management, adherence to the exercise plan, and overall physical and psychological functioning. In addition, the home care nurse reinforces previous teaching and communicates important physiologic findings and psychosocial issues to the patient's primary care provider, nurse, or surgeon.

The frequency of follow-up visits after surgery may vary but generally should occur every 3 to 6 months for the first several years. The patient may alternate visits with the surgeon, medical oncologist, or radiation oncologist, depending on the treatment regimen. The ambulatory care nurse can also be a great source of comfort and security for the patient and family and should encourage them to telephone if they have any questions or concerns. It is common for people to ignore routine health care when a major health issue arises, so women who have been treated for breast cancer should be reminded of the importance of participating in routine health screening.

Evaluation

Expected Preoperative Patient Outcomes

Expected preoperative patient outcomes may include:

1. Exhibits knowledge about diagnosis and surgical treatment options
 - a. Asks relevant questions about diagnosis and available surgical treatments
 - b. States rationale for surgery
 - c. Describes advantages and disadvantages of treatment options
2. Verbalizes willingness to deal with anxiety and fears related to the diagnosis and the effects of surgery on self-image and sexual functioning
3. Demonstrates ability to cope with diagnosis and treatment
 - a. Verbalizes feelings appropriately and recognizes normalcy of mood lability
 - b. Proceeds with treatment in timely fashion
 - c. Discusses impact of diagnosis and treatment on family and work
4. Makes decisions regarding treatment options in timely fashion

Expected Postoperative Patient Outcomes

Expected postoperative patient outcomes may include:

1. Reports that pain has decreased and states pain and discomfort management strategies are effective
2. Identifies postoperative sensations and recognizes that they are a normal part of healing
3. Exhibits clean, dry, and intact surgical incisions without signs of inflammation or infection
4. Lists the signs and symptoms of infection to be reported to the nurse or surgeon
5. Verbalizes feelings regarding change in body image

6. Discusses meaning of the diagnosis, surgical treatment, and fears appropriately
7. Participates actively in self-care measures
 - a. Performs exercises as prescribed
 - b. Participates in self-care measures as prescribed
8. Discusses issues of sexuality and resumption of sexual relations
9. Demonstrates knowledge of postdischarge recommendations and restrictions
 - a. Describes follow-up care and activities
 - b. Demonstrates appropriate care of incisions and drainage system
 - c. Demonstrates arm exercises and describes exercise regimen and activity limitations during postoperative period
 - d. Describes care of affected arm and hand and lists indications to contact the surgeon or nurse
10. Experiences no complications
 - a. Identifies signs and symptoms of reportable complications (eg, redness, heat, pain, edema)
 - b. Explains how to contact appropriate health care providers in case of complications

Radiation Therapy

Radiation therapy is used to decrease the chance of a local recurrence in the breast by eradicating residual microscopic cancer cells. Breast conservation treatment followed by radiation therapy for stages I and II breast cancer results in a survival rate equal to that of a modified radical mastectomy (NCCN, 2009). If radiation therapy, which is part of breast conservation treatment (Chart 48-8), is contraindicated, a mastectomy would then be indicated.

External-beam radiation (the most common type) typically begins about 6 weeks after breast conservation to allow the surgical site to heal. If systemic chemotherapy is indicated, radiation therapy usually begins after its completion. Before radiation begins, the patient undergoes a planning session called a simulation in which the anatomic areas to be treated are mapped out and then identified with small permanent ink markings. External-beam radiation, which delivers high-energy photons from a linear accelerator, is administered to the entire breast region (whole breast radiation). Each treatment lasts only a few minutes and is

Chart 48-8 • Contraindications to Breast-Conservation Treatment

Note: Breast-conservation treatment includes both surgery and radiation.

Absolute Contraindications

- First or second trimester of pregnancy
- Presence of multicentric disease in the breast
- Prior radiation to the breast or chest region

Relative Contraindications

- History of collagen vascular disease
- Large tumor-to-breast ratio
- Tumor beneath nipple

generally given 5 days a week for 5 to 6 weeks. After completion of radiation to the entire breast, many patients receive a “boost,” a dose of radiation to the lumpectomy site where the cancer cells were located. The boost consists of the same dose of radiation but is less penetrating and directed to a smaller area. The treatments are not painful.

Because most breast cancer recurrences appear at or near the lumpectomy site, the need for whole breast radiation is now being questioned. Partial breast radiation (radiation to the lumpectomy site alone) is now being evaluated at some institutions in carefully selected patients. One approach is **brachytherapy**, which delivers partial breast radiation by placing a radioactive source within the lumpectomy site. This technique can lead to an improved quality of life because the treatments are administered over 4 to 5 days instead of 5 to 6 weeks. Another approach is intraoperative radiation therapy (IORT), in which a single intense dose of radiation is delivered to the surgical site in the operating room immediately following the lumpectomy. Short-term results of both of these approaches are promising with regard to rates of local recurrence and overall survival (Sauer, Sautter-Bihl, Budach, et al., 2007). Many questions remain unanswered, and longer follow-up with larger studies is needed to document the long-term effectiveness and potential side effects of these techniques. In the meantime, whole breast radiation remains the standard treatment of choice.

Although not widely used today after mastectomy, postoperative radiation is indicated for women at high risk for cancer recurrence (ie, chest wall involvement, four or more positive lymph nodes, tumors larger than 5 cm, positive surgical margins).

Side Effects

Generally, radiation therapy is well tolerated. Acute side effects consist of mild to moderate erythema, breast edema, and fatigue. Occasionally, skin breakdown may occur in the inframammary fold or near the axilla toward the end of treatment. Fatigue can be depressing, as can the frequent trips to the radiation oncology unit for treatment. The patient needs to be reassured that the fatigue is normal and not a sign of recurrence. Side effects usually resolve within a few weeks to a few months after treatment is completed. Rare long-term effects of radiation therapy include pneumonitis, rib fracture, and breast fibrosis.

Nursing Management

Self-care instructions for patients receiving radiation are provided to assist in the maintenance of skin integrity during the treatments and for several weeks after completion. They pertain only to the area being treated and not to the rest of the body.

- Use mild soap with minimal rubbing.
- Avoid perfumed soaps or deodorants.
- Use hydrophilic lotions (Lubriderm, Eucerin, Aquaphor) for dryness.
- Use a nondrying, antipruritic soap (Aveeno) if pruritus occurs.
- Avoid tight clothes, underwire bras, excessive temperatures, and ultraviolet light.

Follow-up care includes teaching the patient to minimize sun exposure to the treated area (ie, using sunblock

with sun protection factor [SPF] 15 or above) and reassuring the patient that minor twinges and shooting pain in the breast are normal after radiation treatment.

Systemic Treatments

Chemotherapy

Adjuvant chemotherapy involves the use of anticancer agents in addition to other treatments (ie, surgery, radiation) to delay or prevent a recurrence of breast cancer. It is recommended for patients who have positive lymph nodes or who have invasive tumors greater than 1 cm in size, regardless of nodal status. It is considered in patients with tumors that are 0.6 cm to 1 cm, are moderately to poorly differentiated, or have unfavorable features (NCCN, 2009). Table 48-6 outlines general indications for adjuvant chemotherapy. A survival benefit has been shown in premenopausal and postmenopausal women who received chemotherapy, although data are limited in women older than 70 years of age. Chemotherapy is most commonly initiated after breast surgery and before radiation.

Chemotherapy regimens for breast cancer combine several agents (polychemotherapy), generally administered over a period of 3 to 6 months. Decisions regarding the optimal regimen are based on a variety of factors, including tumor characteristics (ie, tumor size, lymph node status, hormone receptor status, HER-2/neu status) and the patient’s age, physical status, and existing comorbid conditions. A regimen that includes cyclophosphamide (Cytosan), methotrexate (Trexall), and fluorouracil (Fluoroplex) (CMF) has been the most widely used adjuvant therapy. It is usually well tolerated and may be considered for patients with a low risk of recurrence. CMF also may be considered for use in patients who have a high risk for cardiac toxicity (a potential side effect of anthracycline-based regimens) or who have other limiting comorbidities. Anthracycline-based regimens (eg, doxorubicin [Adriamycin],

Table 48-6 GENERAL INDICATIONS FOR ADJUVANT CHEMOTHERAPY FOR BREAST CANCER

Nodal Status, Tumor Size	Adjuvant Chemotherapy
Node negative, 0.5 cm or less	None
Node negative 0.6–1 cm (well differentiated)	None
Node negative, 0.6–1 cm (moderately or poorly differentiated and/or unfavorable features)	Consider chemotherapy
Node negative, greater than 1 cm	Chemotherapy
Node positive, any tumor size	Chemotherapy

- In addition to chemotherapy, patients with HER-2/neu positive tumors will receive trastuzumab if they have node positive disease; or node negative disease with a tumor greater than 1 cm. Trastuzumab is a monoclonal antibody that targets and inactivates the HER-2/neu protein. HER-2/neu is overproduced in 25% to 30% of tumors and is associated with rapid growth and poor prognosis.
- Following chemotherapy, patients with hormone receptor positive (ER+/PR+) tumors will receive hormonal therapy (tamoxifen or aromatase inhibitor) if they have either node positive disease; node negative disease with a tumor >1cm; or node negative with a tumor 0.6cm–1cm and moderately or poorly differentiated and/or unfavorable features.

Note: These are only general guidelines. Recommendations may vary depending on factors such as prognostic variables, patient age, and comorbid conditions.

epirubicin [Ellence]) were associated with a decrease in the annual breast cancer death rate by 38% in women younger than 50 years and 20% in women ages 50 to 69 (McArthur & Hudis, 2007a). Cyclophosphamide, doxorubicin, and fluorouracil (CAF) and doxorubicin and cyclophosphamide (AC) are examples of combination regimens often administered to higher risk patients.

The taxanes (paclitaxel [Taxol], docetaxel [Taxotere]) are generally incorporated into treatment regimens for patients with larger, node-negative cancers and for those with positive axillary lymph nodes. The addition of four cycles of paclitaxel after a standard course of AC (regimen known as ACT) has been found to increase the disease-free period and improve overall survival in patients with operable breast cancer and positive lymph nodes (DeLaurentis, Cancello, D'Agostino, et al., 2008).

Much attention has been focused on **dose-dense chemotherapy**, the administration of chemotherapeutic agents at standard doses with shorter time intervals between each cycle of treatment. Patients who received ACT every 2 weeks, compared with those who received it on the conventional schedule of every 3 weeks, had an improved disease-free and overall survival (McArthur & Hudis, 2007b). Long-term follow-up of this study and other clinical trials are ongoing to determine optimal treatment regimens, doses, and timing.

Side Effects

Today, many of the side effects of adjuvant chemotherapy can be managed well, allowing patients to maintain their daily routines and work schedules. In large part, this has been a result of the meticulous educational and psychological preparation provided to patients and their families by oncology nurses, oncologists, social workers, and other members of the health care team. In addition, strides have been made in the effectiveness of antiemetic agents used to alleviate nausea and vomiting and the use of hematopoietic growth factors to treat neutropenia and anemia.

Common physical side effects of chemotherapy for breast cancer may include nausea, vomiting, bone marrow suppression, taste changes, alopecia (hair loss), mucositis, neuropathy, skin changes, and fatigue. A weight gain of more than 10 lb occurs in about half of all patients; the cause is unknown. Premenopausal women may also experience temporary or permanent amenorrhea.

Specific side effects vary with the type of chemotherapeutic agent used. In general, CMF and the taxanes are better tolerated than the anthracyclines. However, the taxanes can cause peripheral neuropathy, arthralgias, and myalgias, particularly at high doses. During taxane administration, hypersensitivity reactions may occur; therefore, the patient must be premedicated. Alopecia is also common. The side effects of the anthracyclines may be severe and include cardiotoxicity in addition to nausea and vomiting, bone marrow suppression, and alopecia. Their vesicant properties can lead to tissue necrosis if infiltration of the medication infusion occurs.

Nursing Management

Nurses play an important role in helping patients manage the physical and psychosocial sequelae of chemotherapy.

(Chapter 16 provides an in-depth discussion of side-effect management.) Instructing the patient about the use of antiemetics and reviewing the optimal dosage schedule can help minimize nausea and vomiting. The different classes of antiemetic agents include serotonin (5-HT-3) receptor antagonists (palonosetron [Aloxi], granisetron [Kytril], ondansetron [Zofran]); neurokinin-1 receptor antagonists (aprepitant [Emend]); dopamine receptor antagonists (prochlorperazine [Compazine], metoclopramide [Reglan]); benzodiazepines (lorazepam [Ativan]); and corticosteroids (dexamethasone [Decadron]). Measures to ease the symptoms of mucositis may include rinsing with normal saline or sodium bicarbonate solution, avoiding hot and spicy foods, and using a soft toothbrush.

Some patients may require hematopoietic growth factors to minimize the effects of chemotherapy-induced neutropenia and anemia. Granulocyte colony-stimulating factors (G-CSFs) boost the white blood cell count, helping reduce the incidence of neutropenic fever and infection. The short-acting form, filgrastim (Neupogen), is injected subcutaneously for 7 to 10 days after chemotherapy administration. The long-acting form, pegfilgrastim (Neulasta), is injected once, 24 hours after chemotherapy. Erythropoietin growth factor increases the production of red blood cells, thus decreasing the symptoms of anemia. The short-acting form, epoetin alfa (Epogen) is usually administered weekly. The long-acting form, darbepoetin alfa (Aranesp), can be administered every 2 to 3 weeks. The nurse instructs the patient and family on proper injection technique of hematopoietic growth factors and about symptoms that require follow-up with a physician (Chart 48-9).

To prevent some of the emotional trauma associated with alopecia, it often helps to have a patient obtain a wig before hair loss begins to occur. The nurse may provide a list of wig suppliers in the patient's geographic region. Familiarity with creative ways to use scarves and turbans may also help minimize the patient's distress. The patient needs reassurance that new hair will grow back when treatment is completed, although the color and texture may be different. The ACS offers a program called Look Good, Feel Better that provides useful tips for applying cosmetics during the period a patient is receiving chemotherapy.

Chemotherapy may negatively affect the patient's self-esteem, sexuality, and sense of well-being. This, combined with the stress of a potentially life-threatening disease, can be overwhelming. Providing support and promoting open communication are important aspects of nursing care. Referring the patient to the dietitian, social worker, psychiatrist, or spiritual advisor can provide additional support. Numerous community support and advocacy groups are available for patients and their families. Complementary therapies, such as guided imagery, meditation, and relaxation exercises, can also be used in conjunction with conventional treatments.

Hormonal Therapy

The use of **adjuvant hormonal therapy**, with or without the addition of chemotherapy, is considered in women who have hormone receptor-positive tumors. Its use can be determined by the results of an **estrogen and progesterone receptor assay**. About two thirds of breast cancers are dependent

CHART
48-9  **HOME CARE CHECKLIST**
Self-Administration of Hematopoietic Growth Factors

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State the purpose for the injections.	✓	✓
• Identify the equipment necessary for self-injection.	✓	✓
• Identify appropriate body sites for self-injection.	✓	✓
• Demonstrate how to draw up the solution in a syringe if indicated (note: darbepoetin and pegfilgrastim come in prefilled syringes).	✓	✓
• Demonstrate how to give an injection properly.	✓	✓
• State possible side effects of medication.	✓	✓
• Demonstrate correct disposal of sharps.	✓	✓
• Describe proper storage of supplies.	✓	✓
• State reasons for contacting the physician or nurse (eg, excessive pain, fever).	✓	✓

on estrogen for growth and express a nuclear receptor that binds to the estrogen; thus, they are estrogen receptor–positive (ER+). Similarly, tumors that express the progesterone receptor are progesterone receptor–positive (PR+). Hormonal therapy involves the use of medications that compete with estrogen by binding to the receptor sites (selective estrogen receptor modulators [SERMs]), or by blocking estrogen production (**aromatase inhibitors**). Generally, tumors that are ER+/PR+ have the greatest likelihood of responding to hormonal therapy and have a more favorable prognosis than those that are ER–/PR–. Premenopausal and perimenopausal women are more likely to have non–hormone-dependent lesions, whereas postmenopausal women are more likely to have hormone-dependent lesions.

Traditionally, the SERM tamoxifen has been the primary hormonal agent used in treatment of premenopausal and postmenopausal breast cancer and remains the mainstay in premenopausal women. As a SERM, tamoxifen has estrogen antagonistic (estrogen-blocking) and agonistic (estrogen-like) effects on certain tissues. Its antagonistic effects in the breast prevent estrogen from binding to the receptor sites, thus preventing tumor growth. Tamoxifen has positive agonistic effects on blood lipid profiles and bone mineral density in postmenopausal women. It also has agonistic effects on endometrial tissue and blood coagulation processes, leading to an increased incidence of endometrial

cancer and thromboembolic events (eg, deep vein thrombosis, superficial phlebitis, pulmonary embolism). Nevertheless, the benefits of tamoxifen in most women with breast cancer outweigh the risks.

The aromatase inhibitors anastrozole (Arimidex), letrozole (Femara), and exemestane (Aromasin) are important components in the hormonal management of postmenopausal women. Most of the circulating estrogens in postmenopausal women are derived from the conversion of the adrenal androgen androstenedione to estrone and the conversion of testosterone to estradiol. Aromatase inhibitors work by blocking the enzyme aromatase from performing the conversion, thereby decreasing the level of circulating estrogen in peripheral tissues. Clinical trials have demonstrated that the aromatase inhibitors are superior to tamoxifen in terms of disease-free survival. Benefits were seen in patients who received an aromatase inhibitor as their initial adjuvant therapy, as therapy given after 2 to 3 years of tamoxifen, or when given for 5 years after receiving tamoxifen for 5 years (Carpenter, 2008). These data ensure that aromatase inhibitors will play an increasingly central role in the long-term management and follow-up of early-stage breast cancer. Trials are ongoing to determine the optimal treatment regimen and the timing of the treatment. Table 48-7 outlines the adverse effects of adjuvant hormonal therapy. Chart 48-10 outlines appropriate patient education to manage the adverse effects.

Table 48-7  **ADVERSE REACTIONS ASSOCIATED WITH ADJUVANT HORMONAL THERAPY USED TO TREAT BREAST CANCER**

Therapeutic Agent	Adverse Reactions/Side Effects
Selective Estrogen Receptor Modulator Tamoxifen (Nolvadex)	Hot flashes, vaginal dryness/discharge/bleeding, irregular menses, nausea, mood disturbances; increased risk for endometrial cancer; increased risk for thromboembolic events (deep vein thrombosis, pulmonary embolism, superficial phlebitis)
Aromatase Inhibitors Anastrozole (Arimidex) Letrozole (Femara) Exemestane (Aromasin)	Musculoskeletal symptoms (arthritis, arthralgia, myalgia), increased risk of osteoporosis/fractures, nausea/vomiting, hot flashes, fatigue, mood disturbances

CHART
48-10

PATIENT EDUCATION

*Managing Side Effects of Adjuvant Hormonal Therapy in Breast Cancer***Hot Flashes**

- Wear breathable, layered clothing.
- Avoid caffeine and spicy foods.
- Perform breathing exercises (paced respirations).
- Consider medications (vitamin E, antidepressants) or acupuncture.

Vaginal Dryness

- Use vaginal moisturizers for everyday dryness (eg, Replens, Vitamin E suppository).
- Apply vaginal lubrication during intercourse (eg, Astroglide, K-Y jelly).

Nausea and Vomiting

- Consume a bland diet.
- Try to take medication in the evening.

Musculoskeletal Symptoms

- Take nonsteroidal analgesics as recommended.
- Take warm baths.

Risk of Endometrial Cancer

- Report any irregular bleeding to a gynecologist for evaluation.

Risk for Thromboembolic Events

- Report any redness, swelling, or tenderness in the lower extremities, or any unexplained shortness of breath.

Risk for Osteoporosis or Fractures

- Undergo a baseline bone density scan.
- Perform regular weight-bearing exercises.
- Take calcium supplements with vitamin D.
- Take bisphosphonates (eg, alendronate) or calcitonin as prescribed.

Targeted Therapy

One of the most exciting areas of research in the systemic treatment of breast cancer involves the use of targeted therapies. Trastuzumab (Herceptin) is a monoclonal antibody that binds specifically to the HER-2/neu protein. This protein, which regulates cell growth, is present in small amounts on the surface of normal breast cells and in most breast cancers. Approximately 25% to 30% of tumors overexpress (overproduce) the HER-2/neu protein and are associated with rapid growth and poor prognosis. Trastuzumab targets and inactivates the HER-2/neu protein, thus slowing tumor growth.

Unlike chemotherapy, trastuzumab spares the normal cells and has limited adverse reactions, which may include fever, chills, nausea, vomiting, diarrhea, and headache. However, when trastuzumab is administered to patients who have previously been treated with an anthracycline, the risk of cardiac toxicity is increased. The medication has been shown to improve survival rates in women with HER-2/neu–positive metastatic breast cancer and is now regarded as standard therapy. It may be administered as a single agent or in combination with chemotherapy. More recently, trastuzumab has been shown to be effective in treating early-stage breast cancer that is HER-2/neu positive. Adding trastuzumab to standard chemotherapy reduces the risk of recurrence by 52% and death by 33% (Romond, Perez, Bryant, et al., 2005). Patients with node-positive disease or node-negative disease with a tumor greater than 1 cm in size should receive trastuzumab for 1 year (Piccart-Gebhart, Procter, Leyland-Jones, et al., 2005). Another monoclonal antibody, bevacizumab (Avastin), is used in combination with paclitaxel to treat metastatic breast cancer (NCCN, 2007). It interferes with the vascular endothelial growth factor (VEGF), thus preventing the growth of new blood vessels that supply tumor cells with blood, oxygen, and nutrients that they need to grow. It is generally well tolerated but can cause hypertension and proteinuria.

Treatment of Recurrent and Metastatic Breast Cancer

Despite the advances made in the treatment of breast cancer, it may recur locally (on the chest wall or in the conserved breast), regionally (in the remaining lymph nodes), or systemically (in distant organs). In metastatic disease, the bone, usually the hips, spine, ribs, skull, or pelvis, is the most common site of spread. Other sites of metastasis include the lungs, liver, pleura, and brain.

The overall prognosis and optimal treatment are determined by a variety of factors such as the site and extent of recurrence, the time to recurrence from the original diagnosis, history of prior treatments, the patient's performance status, and any existing comorbid conditions. Patients with bone metastases generally have a longer overall survival compared with metastases in visceral organs.

Local recurrence in the absence of systemic disease is treated aggressively with surgery, radiation, and hormonal therapy. Chemotherapy may also be used for tumors that are not hormonally sensitive. Local recurrence may be an indicator that systemic disease will develop in the future, particularly if it occurs within 2 years of the original diagnosis.

Metastatic breast cancer involves control of the disease rather than cure. Treatment includes hormonal therapy, chemotherapy, and targeted therapy. Surgery or radiation may be indicated in select situations. Premenopausal women who have hormonally dependent tumors may eliminate the production of estrogen by the ovaries through oophorectomy (removal of the ovaries) or suppression of estrogen production by medications such as leuprolide (Lupron) or goserelin (Zoladex).

Patients with advanced breast cancer are monitored closely for signs of disease progression. Baseline studies are obtained at the time of recurrence. These may include complete blood count; comprehensive metabolic panel; tumor markers (ie, carcinoembryonic antigen, cancer antigen 15-3); bone scan; CT of the chest, abdomen, and pelvis;

and MRI of symptomatic areas. Additional x-rays may be performed to evaluate areas of pain or abnormal areas seen on bone scan (eg, long bones, pelvis). These studies are repeated at regular intervals to assess for effectiveness of treatment and to monitor progression of disease.

Nursing Management

Nurses play an important role in not only educating patients and managing their symptoms but also in providing emotional support. Many patients find that recurrence of the disease is more distressing than the initial cancer diagnosis. They not only have to contend with another round of treatments but are faced with a greater uncertainty about their future and long-term survival. The nurse can help the patient identify coping strategies and set priorities to optimize quality of life. Family members and significant others should be included in the treatment plan and follow-up care. Referrals to support groups, psychiatry or psychiatric clinical nurse specialist, social work, and complementary medicine programs (eg, guided imagery, meditation, yoga) should be made as indicated.

Nurses also play important roles in providing palliative care, if indicated. The highest priorities should include alleviating pain and providing comfort measures. A frank discussion with the patient and family regarding their preferences for end-of-life care should occur before the need arises to ensure a smooth transition without disruption of care. Referrals to hospice and home health care should be initiated as necessary. Chapter 16 provides more information on the general care of the patient with advanced cancer. Chapter 17 discusses end-of-life care.

Reconstructive Procedures After Mastectomy

Breast reconstruction can provide a significant psychological benefit for women who are already struggling with the emotional distress of losing a breast. A consultation with a plastic surgeon can help the patient understand procedures for which she is a candidate and the pros and cons of each. Factors to consider include body size and shape, comorbid conditions (eg, hypertension, diabetes mellitus, obesity), personal habits such as smoking, and patient preference. The patient must be informed that although breast reconstruction can provide a good cosmetic result, it will never precisely duplicate the natural breast. Realistic preparation can help the patient avoid unrealistic expectations. Once reconstruction

is complete, the opposite breast may require augmentation, reduction, or mastopexy to achieve symmetry on both sides. The patient must also be informed that breast reconstruction neither will interfere with breast cancer treatments nor affect the risk of cancer recurrence. Reconstruction is considered an integral component in the surgical treatment of breast cancer and is usually covered by insurance companies.

Many women elect immediate reconstruction at the time of the mastectomy operation. This can be beneficial in that it saves the woman from undergoing general anesthesia a second time and it saves the cost and stress of future hospitalizations. However, it does increase the length of the surgical procedure. Delayed reconstruction is preferable in women who are having a difficult time deciding on the type of reconstruction they desire. It may also be preferable in patients with advanced disease such as inflammatory breast cancer, where the breast cancer treatments should begin without delay. Any delays in healing after immediate reconstruction may interfere with the initiation of treatment.

Tissue Expander Followed by Permanent Implant

Breast reconstruction using a **tissue expander followed by a permanent implant** is the simplest and most common method used today (Fig. 48-6). To accommodate an implant, the skin remaining after a mastectomy and the underlying muscle must gradually be stretched by a process called tissue expansion. The surgeon places a balloonlike device called a tissue expander through the mastectomy incision underneath the pectoralis muscle. A small amount of saline is injected through a metal port intraoperatively to partially inflate the expander. Then, for about 6 to 8 weeks, at weekly intervals, the patient receives additional saline injections through the port until the expander is fully inflated. It remains fully expanded for about 6 weeks to allow the skin to loosen. The expander is then exchanged for a permanent implant. This is usually performed as an outpatient surgical procedure.

Advantages of this expansion procedure are a shorter operating time and a shorter recuperation period than for autologous reconstruction (see Tissue Transfer Procedures below). A disadvantage is a tendency for the implant to feel firm and round, with little natural ptosis (sag). Women with a small to medium opposite breast with little ptosis are good candidates for this procedure. Women who have had radiation or who have connective tissue disease are not good candidates because of the decreased elasticity of the skin.

Figure 48-6 Breast reconstruction with tissue expander. **A**, Mastectomy incision line prior to tissue expansion. **B**, The expander is placed under the pectoralis muscle and is gradually filled with saline solution through a port to stretch the skin enough to accept a permanent implant. **C**, The breast mound is restored. Although permanent, scars will fade with time. The nipple and areola are reconstructed later. (Adapted from *Breast reconstruction*. Arlington Heights, IL: American Society of Plastic and Reconstructive Surgeons.)

NURSING ALERT

The patient must be cautioned not to have an MRI while the tissue expander is in place because the port contains metal. This is not an issue once the permanent implant is in place because it does not contain any metal.

The patient should be informed that for the rest of her life she should not engage in any exercises that will develop the pectoralis muscle because this can result in distortion of the reconstructed breast.

Tissue Transfer Procedures

Autologous reconstruction is the use of the patient's own tissue to create a breast mound. A flap of skin, fat, and muscle with its attached blood supply is rotated to the mastectomy site to create a mound that simulates the breast. Donor sites may include the **transverse rectus abdominis myocutaneous (TRAM) flap** (abdominal muscle) (Fig. 48-7), gluteal flap (buttock muscle), or the latissimus dorsi flap (back muscle) (Fig. 48-8). The results more closely resemble a real breast because the skin and fat from the donor sites are similar in consistency to a natural breast. These procedures avoid the use of synthetic material. However, they are far more complex and involve longer operative time (ranging from about 5 to 10 hours total time for the mastectomy and reconstruction) and longer recuperation than a tissue expander procedure. The risk of potential complications (eg, infection, bleeding, flap necrosis) is also greater. Therefore, patients must be in relatively good health, and those with medical conditions (eg, atherosclerosis, pulmonary disease, heart failure) that affect circulation or compromise oxygen delivery are not good candidates. Other poor candidates include those with uncontrolled type 1 diabetes mellitus or morbid obesity and heavy smokers.

Figure 48-7 Breast reconstruction: transverse rectus abdominis myocutaneous (TRAM) flap. **A**, A breast mound is created by tunneling abdominal skin, fat, and muscle to the mastectomy site. **B**, Final location of scars. (Adapted from *Breast reconstruction*. Arlington Heights, IL: American Society of Plastic and Reconstructive Surgeons.)

Figure 48-8 Breast reconstruction: latissimus dorsi flap. **A**, The latissimus muscle with an ellipse of skin is rotated from the back to the mastectomy site. **B**, Because the flap is usually not bulky enough to provide an adequate breast mound, an implant is often also required. (Adapted from *Breast reconstruction*. Arlington Heights, IL: American Society of Plastic and Reconstructive Surgeons.)

The TRAM flap is the most commonly performed tissue transfer procedure. A free TRAM procedure may also be performed; in this case, the skin, fat, muscle, and blood supply are completely detached from the body and then transplanted to the mastectomy site using microvascular surgery (use of a microscope to reconnect the vessels). Postoperatively, patients who have undergone TRAM procedures often face a lengthy recovery (often 6 to 8 weeks) and have incisions both at the mastectomy site and at the donor site in the abdomen. The nurse must assess the newly constructed breast site for changes in color, circulation, and temperature because flap loss is a potential complication. Mottling or an obvious decrease in skin temperature is reported to the surgeon immediately. Breathing and leg exercises are essential because the patient is more limited in her activity and is at greater risk for respiratory complications and deep vein thrombosis. Measures to help the patient reduce tension on the abdominal incision during the first postoperative week include elevating the head of the bed 45 degrees and flexing the patient's knees.

Once the patient is able to ambulate, she can protect the surgical incision by splinting it and will gradually achieve a more upright position. The patient is instructed to avoid high-impact activities and lifting (more than 5 to 10 lb for 6 to 8 weeks after surgery) to prevent stress on the incision.

Nipple–Areola Reconstruction

After the breast mound has been created and the site has healed, some women choose to have nipple–areola reconstruction. This is a minor surgical procedure carried out either in the physician's office or at an outpatient surgical facility. The most common method of creating a nipple is with the use of local flaps (skin and fat from the center of the new breast mound), which are wrapped around each other to create a projecting nipple. The areola is created using a skin graft. The most common donor site is the upper inner thigh because this skin has darker pigmentation than the skin on the reconstructed breast. After the nipple graft has healed, micropigmentation (tattooing) can be performed

to achieve a more natural color. The surgeon can usually match the reconstructed nipple–areola complex with that of the contralateral breast for an acceptable cosmetic result.

Prosthetics

Not all patients desire or are candidates for reconstructive surgery. A breast prosthesis, an external form that simulates the breast, is another option. Prostheses are available in different shapes, sizes, colors, and materials, although they are most often made of silicone. They can be placed inside a pocket in a bra or can adhere directly to the chest wall. The nurse can provide the patient with the names of shops where she can be fitted for a prosthesis, or the patient can call the Reach to Recovery program of the ACS for appropriate referrals. The patient should be encouraged to find a shop with a comfortable, supportive atmosphere that employs a certified prosthetics consultant. Generally, medical supply shops are not recommended because often they do not have the appropriate resources to ensure the proper fitting of a prosthesis.

Prior to discharge from the hospital, the nurse usually provides the patient with a temporary, lightweight, cotton-filled form that can be worn until the surgical incision is well healed (4 to 6 weeks). After that, the patient can be fitted for a prosthesis. Insurance companies generally cover the cost of the prosthesis and the special bras that hold it in place. A breast prosthesis can provide a psychological benefit and assist the woman in resuming proper posture because it helps balance the weight of the remaining breast.

Special Issues in Breast Cancer Management

Implications of Genetic Testing

The rapid advancement in genetics has brought new knowledge about genetically inherited breast cancer, but it has also raised potential ethical and psychosocial issues. Although the actual testing for the *BRCA1* and *BRCA2* genes involves a simple blood test, it is these issues that must be addressed. Before undergoing genetic testing, a person should meet either with a clinician who has expertise in this area or with a certified genetics counselor to discuss risk factors as well as the benefits, sequelae, and limitations of testing.

How people react when they receive their actual test results is not always easy to predict. A negative test in a person who comes from a family with a known mutation may lead to enormous relief. However, a negative test in a family with no known mutation may be a source of undue reassurance; the possibility of existing genes that cannot yet be detected remains. A negative test may also lead to feelings of guilt in a person whose family members did not receive favorable test results; this is known as survivor's guilt. A positive test could act as a motivator in a person to pursue appropriate screening or treatment, or it could cause tremendous anxiety, depression, and worry.

In addition, test results may be ambiguous, leading to feelings of confusion and uncertainty. People must be informed that not all gene carriers develop breast cancer (incomplete penetrance) and that not all noncarriers are protected.

Other issues include those of cost: Who should pay for genetics testing and the services that relate to it? Difficult ethical questions arise concerning whether the person who is tested should disclose the test results. Is it ethical to withhold results from family members who may be at risk? If they are told, what effect will it have on them? People considering testing must be informed that there is no guarantee that test results will remain confidential. Once confidentiality is breached, it could unleash potential discrimination in employment and insurability. There are laws now, however, in many states to protect the individual if this should happen. People must be well informed of all of the issues and potential implications prior to undergoing genetics testing. Nurses play a role in educating and counseling patients and their family members about the implications of genetic testing. Nurses provide support and clarification and make referrals to appropriate specialists when indicated.

Pregnancy and Breast Cancer

Breast cancer during pregnancy is defined as breast cancer diagnosed during gestation or within 1 year of childbirth and occurs in 1 in 3000 women (NCCN, 2007). Because of increased levels of hormones produced during pregnancy and subsequent lactation, the breast tissue becomes tender and swollen, making it more difficult to detect a mass. If a mass is found during pregnancy, ultrasound is the preferred diagnostic method because it involves no exposure to radiation. If indicated, mammography with appropriate shielding, FNA, and biopsy can be performed. Modified radical mastectomy remains the most common form of surgical treatment. SLNB is typically not performed because of the unknown effects of the radioisotope and the blue dye on the fetus. Breast conservation treatment may be considered if the breast cancer is diagnosed during the third trimester. Radiation can then be delayed until after delivery because it is contraindicated during pregnancy. Chemotherapy should be avoided during the first trimester; the fetal organs are still developing, and it poses a great risk for fetal malformations. However, chemotherapy has been administered during the second and third trimesters with few reported abnormalities. Long-term effects on the fetus are still being studied. If a woman is close to term, a cesarean section may be performed as soon as maturation of the fetus allows, and then treatment is initiated. If aggressive disease is detected early in pregnancy and chemotherapy is advised, termination of the pregnancy may be considered. If a mass is found while a woman is breastfeeding, she is urged to stop to allow the breast to involute (return to its baseline state) before any type of surgery is performed.

Fertility issues and the future desire for children are major concerns of young breast cancer survivors. Certain chemotherapeutic agents, particularly cyclophosphamide, can lead to amenorrhea. Even if the woman is still fertile, many physicians recommend postponing pregnancy for 2 to 3 years after primary treatment because recurrence rates are the highest during this time. Women taking tamoxifen for 5 years are cautioned to avoid pregnancy because of potential effects on the fetus. This waiting period may make it more difficult for the woman to later become pregnant as she advances in age. These issues should be discussed with the patient prior to initiating treatment. There are options

today that may help preserve a woman's fertility, and prior to the onset of chemotherapy she should seek the opinion of a reproductive specialist (Partridge & Ruddy, 2007). Fertile Hope, a national nonprofit organization, can also provide updated information on reproduction (see Resources at the end of the chapter).

Quality of Life and Survivorship

With increased early detection and improved treatment modalities, women with breast cancer have become the largest group of cancer survivors. However, the treatment or simply the diagnosis of breast cancer may have long-term effects that negatively affect the patient and her family. The patient should be prepared early on for the potential long-term effects of the disease so she has realistic expectations and can make informed decisions.

Breast cancer survivors may experience a variety of issues as a result of their diagnosis and treatment. Estrogen withdrawal from chemotherapy-induced menopause and hormonal treatments can lead to a variety of symptoms, including hot flashes, vaginal dryness, urinary tract infections, weight gain, decreased sex drive, and increased risk of osteoporosis. HT to alleviate symptoms is contraindicated in women with breast cancer. Certain chemotherapeutic agents can cause long-term cardiac effects and neuropathy. In addition, patients may experience impaired cognitive functioning such as difficulty concentrating (often referred to as chemobrain). Rare long-term effects of radiation can include pneumonitis and rib fractures. Long-term sequelae after breast surgery may include lymphedema (mainly after ALND), pain, and sensory disturbances. Once lymphedema develops, it tends to be a chronic problem, so prevention strategies (discussed earlier) are vital. Patients have also reported sensations such as tenderness and soreness 5 years after their surgical procedure (Baron, et al., 2007).

Some of these symptoms can also lead to fatigue and sleep disturbances. Long-term psychosocial sequelae may include anxiety, depression, uncertainty about the future, and fear of recurrence. In the workplace, the patient may suffer from fear of discrimination, concern over coworkers' reactions, fear of losing insurance benefits, and lack of physical stamina. Studies have found, however, that many of these issues are not recognized or addressed (Khatcherssian & Swainey, 2008).

Gerontologic Considerations

When deciding on the optimal treatment modality for an elderly patient, age alone should not be the single determining factor. Many older women, regardless of their advancing chronological age, remain in excellent health. Therefore, the woman's treatment preferences should play a strong role in the decision-making process. It should not be assumed that elderly women are less concerned about their appearance than their younger counterparts. One study surveyed 75 women who were 60 years of age or older about their thoughts on breast reconstruction (Bowman, Lennox, Clugston, et al., 2006). More than 90% of the women believed that age should not be taken into consideration before being offered the option of breast reconstruction. Of the women who were not told about immediate reconstruc-

tion at the time of their diagnosis, 100% believed that it should have been discussed. Research studies on women older than 70 years of age are lacking. Nurses can play an important role in conducting research on this older population, thus adding to the knowledge base.

A thorough assessment must be performed before any treatment is initiated, and careful monitoring must occur throughout the course of treatment to avoid complications. The physical and psychosocial assessment of the older woman should include general health, currently existing comorbidities, performance status, cognitive status, current medications, available resources, and support systems.

Breast Health of Women With Disabilities

Women with a variety of disabilities may be unable to detect changes in their own breasts. Those with decreased sensation in their fingers may be unable to palpate even large breast masses, and those with vision loss may be unable to detect changes in the appearance of their breasts. Women with disabilities tend to undergo mammography less often than recommended (Poulos, Balandin, Llewellyn, et al., 2006). They may lack transportation to the imaging facility, and they may be unable to undress without assistance, stand, or maintain positioning for a mammogram. Many imaging facilities do not have accessible mammography equipment, and staff members may be unfamiliar with modifications in positioning needed to obtain acceptable scans (Smeltzer & Sharts-Hopko, 2005). Furthermore, health care providers often neglect to recommend health screening for women with disabilities, despite the fact that they have the same risks for breast cancer as other women and generally have a normal or near-normal life expectancy (U.S. Department of Human Services, 2005). The more severe the disability, the less likely that a woman will undergo mammography. For those women who cannot be adequately positioned for a mammogram, ultrasound may be used as an alternative; however, these women may need more frequent clinical breast examinations.

Women with disabilities who are diagnosed with breast cancer tend to be offered breast conservation surgery less often than other women. However, they have the same concerns about body image as other women.

An essential role of the nurse is to assist women with disabilities to identify accessible health screening and to advocate for greater accessibility of imaging centers and other health care facilities. Reminding women of the need for recommended clinical breast examinations and mammograms is an important part of nursing care.

RECONSTRUCTIVE BREAST SURGERY

Breast reconstruction is elective surgery that can enhance a woman's self-image and sense of well-being. Women desire reconstruction for a variety of physical and psychological reasons. Therefore, it is important that the health care team conduct a thorough assessment prior to reconstructive surgery to evaluate the woman's underlying desire, motivation, and expectations. Preparing a woman realistically could help her to avoid potential disappointment. A variety of

reconstructive options are available today for women who desire a correction in the size or the shape of the breast, including reduction **mammoplasty** (breast reduction), augmentation mammoplasty (breast enlargement), and mastopexy (breast lift). Several options are also available to reconstruct the breast after a mastectomy.

Reduction Mammoplasty

Reduction mammoplasty is usually performed on women who have breast hypertrophy (excessively large breasts). The weight of the enlarged breasts can cause discomfort, fatigue, embarrassment, and poor posture.

Reduction mammoplasty is an outpatient procedure that is performed under general anesthesia. Most commonly, an anchor-shaped incision that circles the areola is made, extending downward and following the natural curve of the crease beneath the breast (inframammary fold). Depending on the size of the breast, the nipple may be moved up to a higher position while still attached to the breast tissue or it may be separated and transplanted to a new location. Drains are placed in the incision and remain for 2 to 5 days.

During the preoperative consultation, the patient should be informed that there is a possibility that sensory changes of the nipple (such as numbness) may occur. These sensations are normal and usually resolve after several months but can sometimes persist. The procedure may also make breastfeeding impossible, although some women have breastfed successfully. The patient must also be aware that if she gains weight (usually more than 10 lb), her breasts may also enlarge.

After reduction mammoplasty, many women verbalize feelings of extreme satisfaction, possibly because of the relief they experience. The patient is instructed to wear a supportive bra 24 hours a day for 2 weeks to prevent tension on the swollen breast and incision line. Vigorous exercise (eg, jumping, jogging) should be avoided for about 6 weeks after surgery.

Augmentation Mammoplasty

Augmentation mammoplasty is requested by women who desire larger or fuller breasts. The procedure is performed by placing a breast implant either under the pectoralis muscle (subpectoral) or under the breast tissue (subglandular). The subpectoral approach is preferred because it interferes less with clinical breast examinations and mammograms. The incision line can be placed in the inframammary fold, in the axilla, or around the areola. The procedure is performed as an outpatient procedure under general anesthesia. A drain is not necessary. Postoperative instructions are the same as for reduction mammoplasty.

Saline implants are typically used for augmentation mammoplasty. Because of concerns that silicone implants could cause autoimmune diseases, they were removed from the market in 1992. In November 2006 the FDA approved the use of silicone implants as long as they were manufactured by two specific companies. This approval covered women of all ages for breast reconstruction and women 22 years of age and older for breast augmentation (U.S. FDA, 2007). Women with breast implants should be aware that mammograms may be more difficult to read, and they should seek experienced breast radiologists.

Mastopexy

Mastopexy is performed when the patient is happy with the size of her breasts but wishes to have the shape improved and a lift performed. This is also an outpatient surgical procedure, and postoperative instructions are the same as for reduction mammoplasty.

DISEASES OF THE MALE BREAST

Gynecomastia

Gynecomastia, or overdeveloped breast tissue, is the most common breast condition in the male. Adolescent boys can be affected by this condition because of hormones secreted by the testes. This type of gynecomastia is virtually always benign and resolves spontaneously in 1 to 2 years. Gynecomastia can also occur in older men and usually presents as a firm, tender mass underneath the areola. In these patients, gynecomastia may be diffuse and related to use of certain medications (eg, digitalis, ranitidine [Zantac]). It may also be associated with certain conditions, including feminizing testicular tumors, infection in the testes, and liver disease resulting from factors such as alcohol abuse or a parasitic infection.

Patients in their late teens to late 40s presenting with idiopathic (unknown cause) gynecomastia should have a testicular examination and possibly a testicular ultrasound. Treatment of the enlarged breast tissue is based on patient preference and is usually reserved for those men who cannot tolerate the cosmetic appearance of the breast or who have severe pain associated with the condition. Observation is acceptable in most cases because gynecomastia may resolve on its own. Surgical removal of the tissue through a small incision around the areola is the best treatment option. Liposuction performed by a plastic surgeon is another possibility, although this does not allow for pathologic examination of the tissue.

Male Breast Cancer

Cancer of the male breast accounts for less than 1% of all cases of breast cancer. The average age at the time of diagnosis is 67 years, but the disease may occur in younger men, especially if there is a genetic link (Nahleh & Girnius, 2006). There is a well-documented link to mutations in the *BRCA2* gene in men with breast cancer; men 70 years of age with a *BRCA2* mutation have an estimated cumulative risk of breast cancer of 6.8% (Tai, Domchek, Parmigiani, et al., 2007). In sporadic cases of male breast cancer (no known family history), risk factors may include a history of mumps orchitis, radiation exposure, and Klinefelter's syndrome (a chromosomal condition reflecting decreased testosterone levels). Liver disease due to factors such as alcohol abuse or a parasitic infection, which compromises estrogen metabolism, may also lead to an increase in rates of male breast cancer. Symptoms include a painless lump beneath the areola, nipple retraction, bloody nipple discharge, or skin ulceration. Diagnostic tests and treatment modalities are similar to those used for women.

Early detection is uncommon in male breast cancer because of the rare nature of the disease. Neither patient nor physician suspects male breast cancer early in its development. Treatment generally consists of a total mastectomy with either SLNB or ALND. As in women with breast cancer, prognosis depends on the stage of disease at presentation. Involvement of the axillary lymph nodes is the most important prognostic indicator. Male breast cancers are very likely to be ER+, and tamoxifen, although it has several side effects, is a mainstay of treatment.

Because breast cancer is primarily a disease of women, men may feel that a certain stigma is attached to their diagnosis. Health care professionals must be sensitive to their needs and provide information and support.

CRITICAL THINKING EXERCISES

EBP 1 You are reviewing early detection guidelines with a 65-year-old woman who has a *BRCA1* mutation. She had an MRI 1 week ago that was normal. Because of this, she asks you if she can skip having her mammogram. What would you advise? What screening modalities would you recommend to her on a yearly basis? What is the evidence base for your recommendations? How would you determine the strength of that evidence?

EBP 2 A 45-year-old woman tells you that nobody in her family has breast cancer. She is relieved, she says, because now she does not have to worry about getting it either. How would you respond to this woman? What is the evidence related to the risk of breast cancer with and without a family history? What is the strength of that evidence?

3 A 50-year-old woman had a right lumpectomy and an axillary lymph node dissection for breast cancer 12 years ago. She calls you in a panic because she accidentally burned her right hand while cooking. What advice would you give her?

4 A 28-year-old woman was just diagnosed with breast cancer. She will need surgery and most likely chemotherapy. She desperately wants to have children. How would you address this issue? What resources would be appropriate to provide to the patient?

EBP 5 A 54-year-old woman with breast cancer has completed surgery, chemotherapy, and radiation treatment. She tolerated the treatments very well both physically and emotionally. She is now taking tamoxifen, which she started 6 months ago, and she feels very depressed and anxious. What would you recommend for this woman? What is the evidence base for the recommendations you would provide? How would you determine the strength of that evidence?

chapter 49

Assessment and Management of Problems Related to Male Reproductive Processes

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe structures and function of the male reproductive system.
- 2 Discuss nursing assessment of the male reproductive system and identify diagnostic tests that complement assessment.
- 3 Discuss the causes and management of male sexual dysfunction.
- 4 Compare the types of prostatectomy with regard to advantages and disadvantages.
- 5 Use the nursing process as a framework for care of the patient undergoing prostatectomy.
- 6 Describe the nursing management of patients with testicular cancer.
- 7 Describe the various conditions affecting the penis, including pathophysiology, clinical manifestations, and management.

GLOSSARY

androgen deprivation therapy (ADT): surgical (orchietomy) or medical castration (eg, with luteinizing hormone–releasing hormone agonists)

benign prostatic hyperplasia (BPH): noncancerous enlargement or hypertrophy of the prostate; the most common pathologic condition in older men

brachytherapy: delivery of radiation therapy through internal implants called seeds to a localized area of tissue

circumcision: excision of the foreskin, or prepuce, of the glans penis

cryosurgery of the prostate: localized treatment of the prostate by application of freezing temperatures

cystostomy: surgical creation of an opening into the urinary bladder

cryptorchidism: most common congenital defect in males; characterized by failure of one or both of the testes to descend into the scrotum

epididymitis: infection of the epididymis that usually descends from an infected prostate or urinary tract; also may develop as a complication of gonorrhea

erectile dysfunction: also called impotence; the inability to either achieve or maintain an erection sufficient to accomplish sexual intercourse

hydrocele: a collection of fluid, generally in the tunica vaginalis of the testis, although it also may collect within the spermatic cord

GLOSSARY (Continued)

minimally invasive therapy: treatments such as laparoscopic and robotic prostatectomy, cryotherapy, and high-intensity focused ultrasound (HIFU); are less invasive than other procedures with less morbidity, lower blood loss, and more rapid recovery

orchietomy: surgical removal of one or both of the testes

orchitis: inflammation of the testes (testicular congestion) caused by pyogenic, viral, spirochetal, parasitic, traumatic, chemical, or unknown factors

penile cancer: malignancy that can involve the glans, the body of the penis, the urethra, and regional or distant lymph nodes

Peyronie's disease: buildup of fibrous plaques in the sheath of the corpus cavernosum, causing curvature of the penis when it is erect

phimosis: condition in which the foreskin is constricted so that it cannot be retracted over the glans; can occur congenitally or from inflammation and edema

priapism: an uncontrolled, persistent erection of the penis from either neural or vascular causes, including medications, sickle cell thrombosis, leukemic cell infiltration, spinal cord tumors, and tumor invasion of the penis or its vessels

prostate cancer: A common type of cancer in men; involves the prostate gland

prostatectomy: open or laparoscopic surgical removal of the entire prostate, the prostate urethra, the attached seminal vesicles plus the ampulla of the vas deferens

prostate-specific antigen (PSA): substance that is produced by the prostate gland; is used in combination with digital rectal examination to screen for prostate cancer

prostatism: obstructive and irritative symptom complex that includes increased frequency and hesitancy in starting urination, a decrease in the volume and force of the urinary stream, acute urinary retention, and recurrent urinary tract infections

prostatitis: inflammation of the prostate gland caused by infectious agents (bacteria, fungi, mycoplasma) or various other problems (eg, urethral stricture, prostatic hyperplasia)

spermatogenesis: production of sperm in the testes

testicular cancer: cancer of one or both testes

testosterone: male sex hormone secreted by the testes; induces and preserves the male sex characteristics

transurethral resection of the prostate (TURP): resection of the prostate through endoscopy; the surgical and optical instrument is introduced directly through the urethra to the prostate, and the gland is then removed in small chips with an electrical cutting loop

varicocele: an abnormal dilation of the veins of the pampiniform venous plexus in the scrotum (the network of veins from the testis and the epididymis, which constitute part of the spermatic cord)

vasectomy: also called male sterilization; ligation and transection of part of the vas deferens, with or without removal of a segment of the vas, to prevent the passage of the sperm from the testes

Disorders of the male reproductive system include a wide variety of conditions that usually affect both urinary and reproductive systems. Because these disorders involve the genitalia and often affect sexuality, the patient may experience anxiety and embarrassment. The nurse must be aware of the patient's need for privacy as well as his need for education and support. This requires an openness to discuss critical and sensitive issues with the patient, including his partner when appropriate, as well as effective assessment, management, and communication. Nurses must be comfortable when examining male genitalia and must recognize their own attitudes and perceptions about male reproductive problems. Education of the patient and partner about treatment and self-care strategies is essential (Zang, Chung & Wong, 2008).

ASSESSMENT OF THE MALE REPRODUCTIVE SYSTEM

Anatomic and Physiologic Overview

In the male, several organs serve as parts of both the urinary tract and the reproductive system. Disorders in the male reproductive organs may interfere with the functions of one or both of these systems. As a result, diseases of the male reproductive system are usually treated by a urologist. The structures in the male reproductive system include the (1) external male genitalia, consisting of the testes, epididymides, scrotum, and penis, and the (2) internal male genitalia, consisting of the vas deferens (ductus deferens), ejaculatory duct, and prostatic and membranous sections of the urethra, seminal vesicles, and certain accessory glands, such as the prostate gland and Cowper glands (bulbourethral glands) (Fig. 49-1).

The testes have a dual function: **spermatogenesis** (production of sperm) and secretion of the male sex hormone **testosterone**, which induces and preserves the male sex characteristics. The testes are formed in the embryo, within

the abdominal cavity, near the kidney. During the last month of fetal life, they descend posterior to the peritoneum and pierce the abdominal wall in the groin. Later, they progress along the inguinal canal into the scrotal sac. In this descent, they are accompanied by blood vessels, lymphatics, nerves, and ducts, which support the tissue and make up the spermatic cord. This cord extends from the internal inguinal ring through the abdominal wall and the inguinal canal to the scrotum. As the testes descend into the scrotum, a tubular extension of peritoneum accompanies them. Normally, this tissue is obliterated during fetal development; only the tunica vaginalis, which covers the testes, remains. If the peritoneal process remains open into the abdominal cavity, a potential sac remains into which abdominal contents may enter to form an indirect inguinal hernia.

The testes, or ovoid sex glands, are encased in the scrotum, which keeps them at a slightly lower temperature than the rest of the body to facilitate spermatogenesis. The testes consist of numerous seminiferous tubules in which the spermatozoa form. Collecting tubules transmit the spermatozoa into the epididymis, a hoodlike structure lying on the testes and containing winding ducts that lead into the vas deferens. This firm, tubular structure passes upward through the inguinal canal to enter the abdominal cavity behind the peritoneum. It then extends downward toward the base of the bladder. An outpouching from this structure is the seminal vesicle, which acts as a reservoir for testicular secretions. The tract is continued as the ejaculatory duct, which passes through the prostate gland to enter the urethra. Testicular secretions take this pathway when they exit the penis during ejaculation.

The penis is the organ for both copulation and urination. It consists of the glans penis, the body, and the root. The glans penis is the soft, rounded portion at the distal end of the penis. The urethra, the tube that carries urine, opens at the tip of the glans. The glans is naturally covered by elongated penile skin—the foreskin—which may be retracted to expose the glans. However, many men as newborns have had the foreskin removed (**circumcision**). The body of the

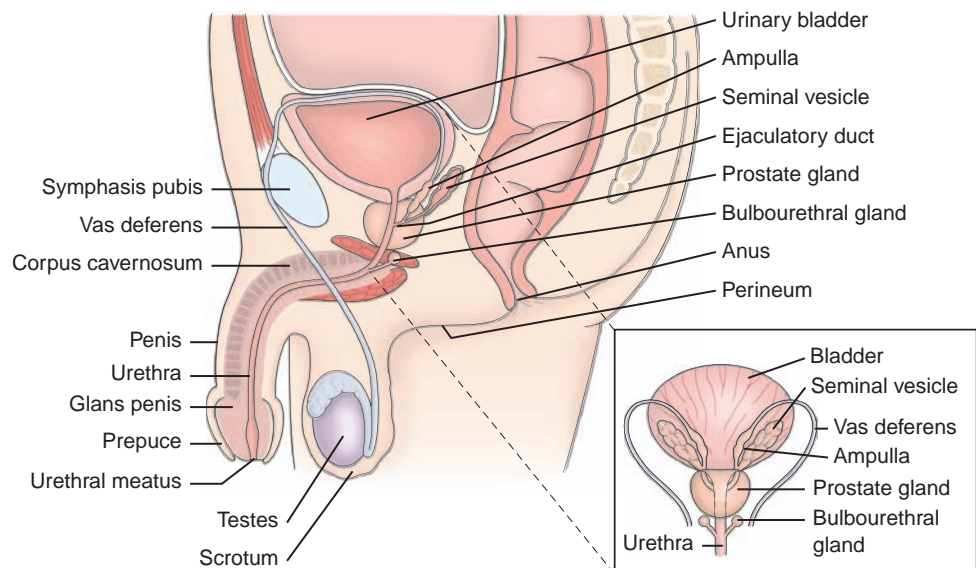

Figure 49-1 Structures of the male reproductive system.

penis is composed of erectile tissues containing numerous blood vessels that become dilated, leading to an erection during sexual excitement. The urethra, which passes through the penis, extends from the bladder through the prostate to the distal end of the penis.

The prostate gland, lying just below the neck of the bladder, is composed of four zones and four lobes. It surrounds the urethra and is traversed by the ejaculatory duct, a continuation of the vas deferens. This gland produces a secretion that is chemically and physiologically suitable to the needs of the spermatozoa in their passage from the testes. Cowper glands lie below the prostate, within the posterior aspect of the urethra. This gland empties its secretions into the urethra during ejaculation, providing lubrication.

Gerontologic Considerations

As men age, the prostate gland enlarges, prostate secretion decreases; the scrotum hangs lower; the testes decrease in weight, atrophy, and become softer; and pubic hair becomes sparser and stiffer. Changes in gonadal function include a decline in plasma testosterone levels and reduced production of progesterone (Table 49-1). Other changes include decreasing sexual function, decreased libido (sexual desire), slower sexual response, longer time before sexual arousal can occur again, increased incidence of genitourinary tract cancer, and urinary incontinence. Libido and potency often decrease in as many as two thirds of men older than 70 years of age (Tabloski, 2006). Vascular problems cause about half of the cases of impotence in men older than 50 years of age.

However, male reproductive capability is maintained with advancing age. Although degenerative changes occur in the seminiferous tubules and sperm production decreases, spermatogenesis continues, allowing men to produce viable sperm throughout their lives (McCance & Huether, 2005).

Male hypogonadism (decreased function of the testes) starts gradually at approximately 50 years of age, resulting in decreased testosterone production. The older man notices that the sexual response slows, erection takes longer, full erections may not be attained, and ejaculation takes longer to occur and control or resolution may occur without orgasm. Sexual function can be affected by psychological problems, illnesses, and medications. In general, the entire sexual act takes longer. Sexual activity is closely correlated with the man's sexual activity in his earlier years; if he was more active than average as a young man, he will most

likely continue to be more active than average in his later years.

Men older than 50 years of age are at risk for cancer of the kidney, bladder, prostate, and penis. The digital rectal examination (DRE), prostate-specific antigen (PSA) test, and urinalysis, which screens for hematuria, may uncover a higher percentage of malignancies at earlier stages and lead to lower treatment-associated morbidity as well as a lower mortality.

Urinary incontinence occurs in one fifth of community-dwelling older men and rises to nearly 50% in men in long-term care settings (Tabloski, 2006). Therefore, older adults admitted to acute care settings should be screened for this problem. Urinary incontinence may have many causes, including medications, neurologic disease, or benign prostatic hyperplasia (BPH). Diagnostic tests are performed to exclude reversible causes. New-onset urinary incontinence is a nursing priority that requires evaluation.

Assessment

Health History

Male sexuality is a complex phenomenon that is strongly influenced by personal, cultural, religious, and social factors. Sexuality and male reproductive function become concerns in the presence of illness and disability (Bruner & Calvano, 2007). Throughout the assessment process, the nurse must recognize the importance of sexuality to the patient. Assessment of male reproductive function begins with an evaluation of urinary function and symptoms. The patient is asked about his usual state of health and any recent change in general physical and sexual activity. Any symptoms or changes in function are explored fully and described in detail. Symptoms related to bladder function and urination, collectively referred to as **prostatism**, are explored further. They may occur with an obstruction caused by an enlarged prostate gland: increased urinary frequency, decreased force of urine stream, and “double” or “triple” voiding (the patient needs to urinate two or three times over a period of several minutes to completely empty his bladder). The patient is also assessed for dysuria (painful urination), hematuria (blood in the urine), nocturia (urination during the night), and hematospermia (blood in the ejaculate).

Assessment also involves addressing sexual function, including manifestations of sexual dysfunction. The extent of

Table 49-1 AGE-RELATED CHANGES IN THE MALE REPRODUCTIVE SYSTEM

Age-Related Changes	Physiologic Changes	Manifestations
Decrease in sex hormone secretion, especially testosterone	Decreased muscle strength and sexual energy	Changes in sexual response: prolonged time to reach full erection, rapid penile detumescence and prolonged refractory period
	Shrinkage and loss of firmness of testes; thickening of seminiferous tubules	Decrease in number of viable sperm
	Fibrotic changes of corpora cavernosa	Smaller testes
	Enlargement of prostate gland	Erectile dysfunction
		Weakening of prostatic contractions
		Hyperplasia of prostate gland
		Signs and symptoms of obstruction of lower urinary tract (urgency, frequency, nocturia)

the history depends on the patient's presenting symptoms and the presence of factors that may affect sexual function such as chronic illnesses or disability (eg, diabetes, multiple sclerosis, stroke, cardiac disease), use of medications that affect sexual function (eg, antihypertensive and anticholesterol medications, psychotropic agents), stress, use of alcohol, and patient's willingness to discuss sexual issues.

By initiating an assessment about sexual concerns, the nurse conveys the message that changes in sexual functioning are valid topics and provides a safe environment for discussing these sensitive topics. A number of models are available to assist in assessing patient's problems and concerns. The PLISSIT (*permission, limited information, specific suggestions, intensive therapy*) model of sexual assessment and intervention may be used to provide a framework for nursing interventions (Annon, 1976). It provides a graded counseling approach that allows health care professionals to deal with sexual issues with a level of comfort and expertise. The model begins by asking the patient's permission (P) to discuss sexual functioning. Limited information (LI) about sexual function may then be provided to the patient. As the discussion progresses, the nurse may offer specific suggestions (SS) for interventions. A professional who specializes in sex therapy may provide more intensive therapy (IT) as needed. The BETTER (*bringing up the topic, explaining, telling, timing, educate about treatment-related sexual side effects, recording*) model was developed more recently to assist health care professionals to include sexuality in the assessment of patients with cancer (Katz, 2005, 2007).

Patients may find it difficult to express their feelings and concerns regarding their sexuality, especially after a body image change. Discussing sexuality with patients who have an illness or disability can be uncomfortable for nurses and other health care providers; this, in turn, makes discussion of these issues more difficult and uncomfortable for patients. Health care professionals may unconsciously have stereotypes about the sexuality of people who are ill or have a disability (eg, the belief that people with disabilities are asexual or should be sexually inactive). In addition, patients are often embarrassed to initiate a discussion about sexual issues with their health care providers (Zang, et al., 2008).

Physical Assessment

In addition to the usual aspects of the physical examination, two essential components address disorders of the male genital or reproductive system: the DRE and the testicular examination.

Digital Rectal Examination

The DRE is used to screen for prostate cancer and is recommended annually for every man older than 50 years of age (45 years of age for men at high risk [African American men and men with a strong family history of prostate cancer]) annually (American Cancer Society [ACS], 2009). The DRE enables the skilled examiner, using a lubricated, gloved finger placed in the rectum, to assess the size, symmetry, shape, and consistency of the posterior surface of the prostate gland (Fig. 49-2). The clinician assesses for tenderness of the prostate gland on palpation and for the presence and consistency of any nodules. The DRE may be performed with the patient leaning over an examination table or positioning the man in a

Figure 49-2 A, Palpation of the prostate gland during digital rectal examination (DRE) enables the examiner to assess the size, shape, and texture of the gland. B, The prostate is round, with a palpable median sulcus or groove separating the lateral lobes. It should feel rubbery and free of nodules and masses.

side-lying position with legs flexed toward the abdomen or supine with legs resting in stirrups. To minimize discomfort and relax the anal sphincter during the rectal examination, the patient is instructed to take a deep breath and exhale slowly as the practitioner inserts a finger. If possible, he should turn his feet inward so his toes are touching. Although this examination may be uncomfortable and embarrassing for the patient, it is an important screening tool.

Testicular Examination

The male genitalia are inspected for abnormalities and palpated for masses. The scrotum is palpated carefully for nodules, masses, or inflammation. Examination of the scrotum can reveal such disorders as hydrocele, inguinal hernia, testicular torsion, orchitis, epididymitis, or a tumor of the testis. The penis is inspected and palpated for ulcerations, nodules, inflammation, discharge, and curvature. If the patient is uncircumcised, the foreskin should be retracted for visualization of the glans penis. The testicular examination provides an excellent opportunity to instruct the patient on how to perform a testicular self-examination (TSE) and its importance in early detection of testicular cancer. TSE should begin during adolescence.

Diagnostic Evaluation

Prostate-Specific Antigen Test

The cells within the prostate gland produce a protein that can be measured in the blood called the **prostate-specific antigen (PSA)**. It is a sensitive but not specific test for prostate cancer. In the absence of prostate cancer, serum PSA levels vary with age, race, and prostate volume. Increased levels may indicate prostate cancer. However, a number of other conditions such as BPH, acute urinary retention, and acute prostatitis may cause high PSA levels. Values of PSA may also increase after ejaculation. PSA levels

are measured in nanograms per milliliter (ng/mL). In most laboratories, values less than 4.0 ng/mL are generally considered normal, and values greater than 4.0 ng/mL are considered elevated. The use of age-specific reference ranges for populations with a low incidence of prostate cancers (eg, Chinese) helps minimize unnecessary biopsies.

A serum PSA level and a DRE, which are recommended by the American Cancer Society (2009), are used to screen for prostate cancer for men with at least a 10-year life expectancy and for men at high risk, including those with a strong family history of prostate cancer and of African American ethnicity. The PSA test is also used to monitor patients for recurrence after treatment for cancer of the prostate, based on evidence-based guidelines (National Comprehensive Cancer Network [NCCN], 2009). Neither the DRE nor PSA is 100% accurate, but when used together, their accuracy increases.

Ultrasonography

Transrectal ultrasound (TRUS) may be performed in patients with abnormalities detected by DRE and in those with elevated PSA levels. After DRE has been completed, a lubricated, condom-covered, rectal probe transducer is inserted into the rectum, along the anterior wall. Water may be introduced into the condom to help transmit sound waves to the prostate. TRUS may be used in detecting nonpalpable prostate cancers and in staging localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS.

Prostate Fluid or Tissue Analysis

Specimens of prostate fluid or tissue may be obtained for culture if disease or inflammation of the prostate gland is suspected. A biopsy of the prostate gland may be necessary to obtain tissue for histologic examination. This may be performed at the time of prostatectomy or by means of a perineal or transrectal needle biopsy. Six to 12 biopsies from all four prostate zones may be obtained during a TRUS-guided biopsy.

Tests of Male Sexual Function

If the patient cannot engage in sexual intercourse to his satisfaction, a detailed history is obtained. Nocturnal erections occur in healthy males of all ages. Nocturnal penile tumescence tests may be conducted in a sleep laboratory to monitor

changes in penile circumference during sleep using various methods to determine number, duration, rigidity, and circumference of penile erections; the results help identify whether the erectile dysfunction is caused by physiologic or psychologic factors. Additional tests, including psychological evaluations, are also part of the diagnostic workup and are usually conducted by a specialized team of health care providers.

DISORDERS OF MALE SEXUAL FUNCTION

Erectile Dysfunction

Erectile dysfunction, also called impotence, is the inability to achieve or maintain an erect penis (Seftel, Miner, Kloner, et al., 2007). The man may report decreased frequency of erections, inability to achieve a firm erection, or rapid detumescence (subsiding of erection). In the United States, 30 million men experience erectile dysfunction; more than half of men 40 to 70 years of age are unable to attain or maintain an erection sufficient for satisfactory sexual performance (Tanagho & McAninch, 2008). The physiology of erection and ejaculation is complex and involves parasympathetic and sympathetic components. Erection involves the release of nitric oxide into the corpus cavernosum during sexual stimulation. Its release activates cyclic guanosine monophosphate (cGMP), causing smooth muscle relaxation. This allows flow of blood into the corpus cavernosum, resulting in erection (Beckman, Abu-Lebdeh & Mynderse, 2006; Porth & Matfin, 2009).

Erectile dysfunction has both psychogenic and organic causes. Psychogenic causes include anxiety, fatigue, depression, pressure to perform sexually, negative body image, absence of desire, privacy, and trust and relationship issues. Organic causes include cardiovascular disease, endocrine disease (diabetes, pituitary tumors, testosterone deficiency, hyperthyroidism, and hypothyroidism), cirrhosis, chronic renal failure, genitourinary conditions (radical pelvic surgery), hematologic conditions (Hodgkin lymphoma, leukemia), neurologic disorders (neuropathies, parkinsonism, spinal cord injury, multiple sclerosis), trauma to the pelvic or genital area, alcohol, smoking, medications (Chart 49-1), and drug abuse.

CHART
49-1

PHARMACOLOGY

Classes of Medications Associated With Erectile Dysfunction

- Antiadrenergics and antihypertensives: guanethidine (Ismelin), clonidine (Catapres), hydralazine (Apresoline), metoprolol (Lopressor)
- Anticholinergics and phenothiazines: prochlorperazine (Compazine), trihexyphenidyl (Artane)
- Antiseizure agents: carbamazepine (Tegretol)
- Antifungals: ketoconazole (Nizoral)
- Antihormone (prostate cancer treatment): flutamide (Eulexin), leuprolide (Lupron)
- Antipsychotics: haloperidol (Haldol), chlorpromazine (Thorazine)
- Antispasmodics: oxybutynin (Ditropan)
- Anxiolytics, sedative-hypnotics, tranquilizers: lorazepam (Ativan), triazolam (Halcion)
- Beta-blockers: nadolol (Corgard)
- Calcium channel blockers: nifedipine (Adalat, Procardia)
- Carbonic anhydrase inhibitors: acetazolamide (Diamox)
- H₂ antagonists: nizatidine (Axid)
- Nonsteroidal anti-inflammatory drugs: naproxen (Naprosyn)
- Diuretics: hydrochlorothiazide (HydroDIURIL), furosemide (Lasix), spironolactone (Aldactone)
- Antidepressants: tricyclic antidepressants: amitriptyline (Elavil), desipramine (Norpramin); selective serotonin reuptake inhibitors: fluoxetine (Prozac), sertraline (Zoloft)
- Parkinson's disease medications: levodopa (Sinemet)
- Antihistamines: diphenhydramine (Benadryl)

Assessment and Diagnostic Findings

The diagnosis of erectile dysfunction requires a sexual and medical history; an analysis of presenting symptoms; a physical examination, including a neurologic examination; a detailed assessment of all medications, alcohol, and drugs used; and various laboratory studies. Nocturnal penile tumescence tests are conducted to monitor changes in penile circumference. This test can help to determine if erectile impotence has an organic or a psychological cause. In healthy men, nocturnal penile erections closely parallel rapid eye movement (REM) sleep in occurrence and duration. Organically impotent men show inadequate sleep-related erections that correspond to their waking performance. Arterial blood flow to the penis is measured using a Doppler probe. In addition, nerve conduction tests and extensive psychological evaluations may be carried out. Figure 49-3 describes the evaluation and treatment of erectile dysfunction.

Medical Management

Treatment can be medical, surgical, or both, depending on the cause. The American Urological Association (AUA) guidelines on treatment of erectile dysfunction suggest that therapy for associated disorders (eg, alcoholism, diabetes) or adjustment of medications may be necessary (AUA, 2005). Endocrine therapy instituted to treat erectile dysfunction secondary to hypothalamic-pituitary-gonadal dysfunction may reverse the condition. Insufficient penile blood flow may be treated with vascular surgery. Patients with erectile dysfunction from psychogenic causes are referred to a health care provider or therapist who specializes in sexual dysfunction. Patients with erectile dysfunction secondary to organic causes may be candidates for penile implants.

Currently available therapies for the treatment of erectile dysfunction include pharmacologic therapy (including urethral suppositories), penile implants, and vacuum constriction devices (Table 49-2). These options should be considered in a stepwise fashion, with increasing invasiveness and risk balanced against the likelihood of efficacy. The patient and, if possible, his partner, should be informed of the relevant treatment options and their associated risks and benefits. The choice of treatment is made jointly by the physician, patient, and partner, taking into consideration patient preferences and expectations.

Pharmacologic Therapy

Phosphodiesterase-5 (PDE-5) inhibitors, oral medications that are used to treat erectile dysfunction, are first-line therapy (AUA, 2005). Currently available PDE-5 inhibitors include sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis). Each of these agents has a similar mechanism of action but a different pharmacologic action and clinical use. Erection involves the release of nitrous oxide in the vasculature of the corpus cavernosum as a result of sexual stimulation. This subsequently leads to smooth muscle relaxation in blood vessels supplying the corpus cavernosum, resulting in increased blood flow and an erection. During sexual stimulation, PDE-5 inhibitors increase blood flow to the penis (Carson, 2007; Porth & Matfin, 2009).

When PDE-5 inhibitors are taken about 1 hour before sexual activity, they are effective in producing an erection with

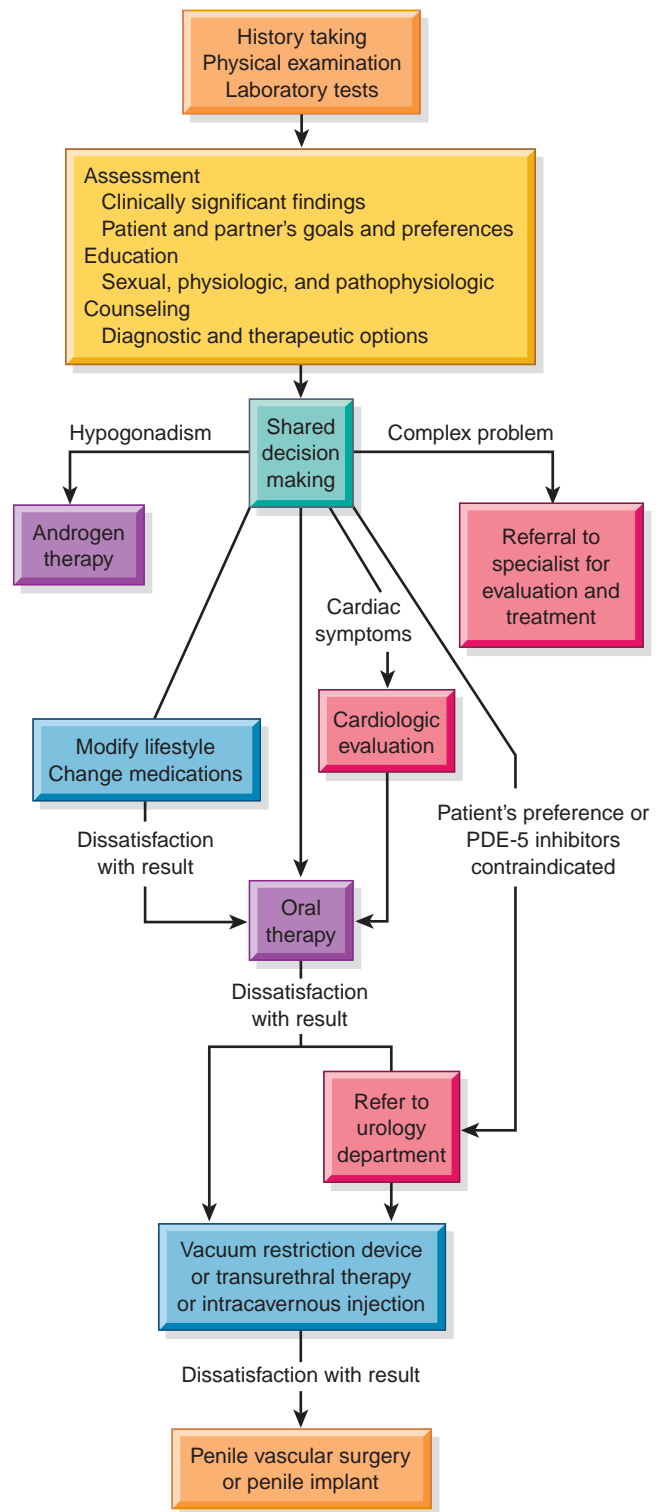

Figure 49-3 Evaluation and treatment of men with erectile dysfunction. (Redrawn from Lue, T. F. (2000). Erectile dysfunction. *New England Journal of Medicine*, 342(24), 1807. © 2000 Massachusetts Medical Society. All rights reserved. Used with permission.)

sexual stimulation; the erection can last about 1 to 2 hours. The most common side effects of these medications include headache, flushing, dyspepsia, diarrhea, nasal congestion, and lightheadedness. These agents are contraindicated in men

Table 49-2 TREATMENTS FOR ERECTILE DYSFUNCTION

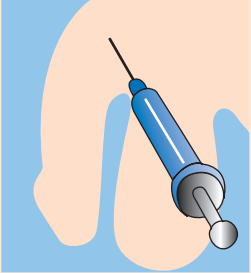

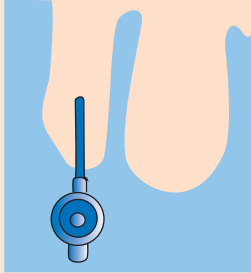

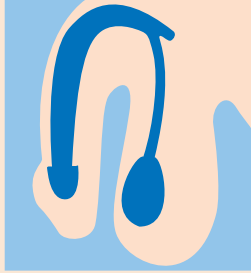

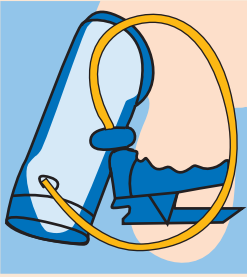

Method	Description	Advantages and Disadvantages	Duration
Pharmacologic therapy <ul style="list-style-type: none"> • Oral medication (sildenafil [Viagra]; vardenafil [Levitra]; tadalafil [Cialis]) 	Smooth muscle relaxant causing blood to flow into penis	Can cause headache and diarrhea Contraindicated for men taking nitrate medications Used with caution in patients with retinopathy, especially diabetic retinopathy	Taken orally 1 hour before intercourse Stimulation is required to achieve erection Erection can last 1 hour
Oral medication <ul style="list-style-type: none"> • Injection (alprostadil, papaverine, phentolamine) 	Smooth muscle relaxant causing blood to flow into penis	Firm erections are achievable in more than 50% of cases Pain at injection site; plaque formation, risk of priapism	Injection 20 minutes before intercourse Erection can last up to 1 hour
<ul style="list-style-type: none"> • Urethral suppository (alprostadil) 	Smooth muscle relaxant causing blood to flow into penis	May be used twice a day Urethral and genital pain; risk of hypertension and syncope Not recommended with pregnant partners	Inserted 10 minutes before intercourse Erection can last up to 1 hour
Penile implants <ul style="list-style-type: none"> • Semi-rigid rod • Inflatable • Soft silicone 	Surgically implanted into corpus cavernosum	Reliable Requires surgery Healing takes up to 3 weeks Subsequent cystoscopic surgery is difficult Semirigid rod results in permanent semierrection	Indefinite Inflatable prosthesis: saline returns from penile receptacle to reservoir

Table 49-2 TREATMENTS FOR ERECTILE DYSFUNCTION (Continued)

Method	Description	Advantages and Disadvantages	Duration
Negative-pressure (vacuum) devices 	Induction of erection with vacuum; maintained with constriction band around base of penis	Few side effects Cumbersome to use before intercourse Vasocongestion of penis can cause pain or numbness	To prevent penile injury, constriction band must not be left in place for longer than 1 hour

Penile vacuum pump

who take organic nitrates (eg, isosorbide [Isordil, Nitro-Dur], nitroglycerin), because taken together, these medications can cause side effects such as severe hypotension (Beckman, et al., 2006; Carson, 2007; Porth & Matfin, 2009). In addition, PDE-5 inhibitors must be used with caution in patients with retinopathy, especially in those with diabetic retinopathy. Patient teaching about the use of these medications and their side effects is summarized in Table 49-3.

For patients in whom PDE-5 inhibitors are contraindicated or ineffective, other pharmacologic measures to induce erections include injecting vasoactive agents, such as alprostadil, papaverine, and phentolamine, directly into the penis. Complications include priapism (a persistent abnormal erection) and development of fibrotic plaques at the injection sites. Alprostadil is also formulated in a gel pellet that can be inserted into the tip of the urethra using an applicator to create an erection.

Penile Implants

Two general types of penile implants are available: the malleable, noninflatable, nonhydraulic prosthesis (also called the semirigid rod); and the inflatable, hydraulic prostheses (AUA, 2006; Henry & Wilson, 2007). The semirigid rod (eg, the Small-Carrion prosthesis) results in a permanent semierection but can be bent into an unnoticeable position when appropriate. The inflatable prosthesis simulates natural erections and natural flaccidity. Complications after implantation include infection, erosion of the prosthesis through the skin (more common with the semirigid rod than with the inflatable prosthesis), and persistent pain, which may require removal of the implant. Subsequent cystoscopic surgery, such as transurethral resection of the prostate (TURP), is more difficult with a semirigid rod than with the inflatable prosthesis.

Factors to consider in choosing a penile prosthesis are the patient’s activities of daily living, social activities, and the expectations of the patient and his partner. Ongoing counseling for the patient and his partner is usually necessary to help them adapt to the prosthesis.

Negative-Pressure Devices

Negative-pressure (vacuum) devices may also be used to induce an erection. A plastic cylinder is placed over the flaccid penis, and negative pressure is applied. When an erection is

attained, a constriction band is placed around the base of the penis to maintain the erection. The patient is instructed not to leave the constricting band in place for longer than 1 hour to avoid penile injury. Only devices with a vacuum limiter are recommended for use (AUA, 2005). Although many men find this method satisfactory, others experience premature loss of penile rigidity or pain when applying suction or during intercourse.

Nursing Management

Personal satisfaction and the ability to sexually satisfy a partner are common concerns of patients. Men with illnesses and disabilities may need the assistance of a sex therapist to identify, implement, and integrate their sexual beliefs and behaviors into a healthy and satisfying lifestyle. The nurse can inform patients about support groups for men with erectile dysfunction and their partners. Information about Impotence Anonymous for patients and I-Anon for their partners can be found at the end of this chapter.

Disorders of Ejaculation

Premature ejaculation (PE) is defined as the occurrence of ejaculation sooner than desired, either before or shortly after penetration, causing distress to either one or both partners (AUA, 2004). It is one of the most common complaints of men or couples, affecting 20% to 30% of men (Schuster, 2006; Waldinger, 2007). The spectrum of responses ranges from occasional ejaculation with intercourse or self-stimulation to complete inability to ejaculate under any circumstances. A variety of forms of PE have been identified: (1) lifelong PE caused by neurobiological or genetic conditions, (2) acquired PE (medical or psychological), (3) natural variable PE (normal variation), and (4) premature-like ejaculatory dysfunction (psychological). Other ejaculatory problems may include inhibited (delayed or retarded) ejaculation, which is the involuntary inhibition of the ejaculatory reflex. Retrograde ejaculation occurs when semen travels toward the bladder instead of exiting through the penis, resulting in infertility. This form of PE may occur after prior prostate or urethral surgery or with diabetes and use of medications such as antihypertensives.

Table 49-3 PHARMACOLOGIC TREATMENT OF ERECTILE DYSFUNCTION

	Sildenafil (Viagra)	Vardenafil (Levitra)	Tadalafil (Cialis)
Recommended dose	Initial dose is 25 mg Usual dose is 50 mg Maximal dose is 100 mg/24 hours	Usual dose is 10 mg Maximum dose is 20 mg/24 hours If you are 65 years of age or older, the starting dose is 5 mg	Dosage range is 5–20 mg, based on individual response Maximum dose is 20 mg/24 hours Maximum dose is 10 mg every 48 hours if you have decreased liver or kidney function
When to take	Take the medication 30 minutes to 4 hours before intercourse. <i>There must be sexual stimulation to produce an erection.</i>	Follow the same directions as with sildenafil; take the medication 1 hour before intercourse. The peak action occurs in 30 to 120 minutes. <i>There must be sexual stimulation to produce an erection.</i>	Take the medication before sexual activity. Effect peaks at 30 minutes to 6 hours; effect may last up to 36 hours. <i>There must be sexual stimulation to produce an erection.</i>
Frequency of use	If you take this medication more than once a day, it will not have an increased effect. You may take it 7 days per week if you wish, but only once in 24 hours. It does not build up in your bloodstream. Remember to take it only when you want to have intercourse.	The recommended frequency for this medication is 10 mg in 24 hours.	The effects of this medication may last up to 36 hours. This allows for increased spontaneity in the sexual experience.
Side effects	Side effects include headache, flushing, indigestion, nasal congestion, abnormal vision, diarrhea, dizziness, and rash. You may also have low blood sugar and abnormal liver function tests; your physician can determine this.	Side effects include headache, flushing, runny nose, indigestion, sinusitis, flulike syndrome, dizziness, nausea, back pain, and joint pain. Tell your physician if you experience any of these effects. You may also have abnormally elevated liver enzymes; your physician can determine this.	Side effects are similar to those of sildenafil and vardenafil. Tadalafil may also cause back pain and muscle aches. Tell your physician if you experience any of these side effects.
Contraindications	Do not take if you are taking nitrate medications such as nitroglycerine (eg, Nitro-Bid) or isosorbide mononitrate (eg, Imdur). Do not take if you have high uncontrolled blood pressure, coronary artery disease, or have had a heart attack within the past 6 months. Do not take if you have been diagnosed with a cardiac dysrhythmia or kidney or liver dysfunction.		
Drug interactions	This medication can react with other medications that you may be taking. Provide your physician and pharmacist with a complete list of all prescribed as well as over-the-counter medications that you are using.		
Use of PDE-5 inhibitors with penile injections or urethral suppositories	The use of PDE-5 inhibitors with other forms of therapy for erectile dysfunction has not been tested and should be avoided.		

Evaluation of PE involves a thorough sexual history focusing on the duration of symptoms, time to ejaculation, degree of voluntary control over ejaculation, frequency of occurrence, and course of the problem since the first sexual encounter (Schuster, 2006; Waldinger, 2007). Treatment, which depends on the nature and severity of PE and perceived distress it causes, includes behavioral and psychological approaches, as well as pharmacologic therapy that attempts to alter the sensory input or retard the ejaculatory response. Behavioral therapy (eg, counseling, sex therapy, psychoeducation, and couples therapy) often involves both the man and his sexual partner. The couple is encouraged to identify their sexual needs and to communicate those needs to each other. Pharmacologic management involves selective serotonin reuptake inhibitors, α_1 adrenoceptor antagonists, the tricyclic antidepressant clomipramine (Anafranil), and topical anesthetics. In some cases, a combination of pharmacologic and behavioral therapy may be effective.

Inhibited ejaculation is most often caused by psychological factors, neurologic disorders (eg, spinal cord injury [SCI], multiple sclerosis, neuropathy secondary to diabetes), surgery (prostatectomy), and medications. Chemical, vibratory, and electrical methods of stimulation have been used with some success. Treatment usually addresses the physical and psychological factors involved in inhibited ejaculation (Schuster, 2006). Although outpatient therapy may involve numerous sessions (12 to 18), it often results in a success rate of 70% to 80%. The outcome depends on a previous satisfying sexual experience history, a short duration of the ejaculatory problem, feelings of sexual desire, feelings of attraction to one's sexual partner, motivation for treatment, and absence of serious psychological problems.

For men with retrograde ejaculation, the urine may be collected shortly after ejaculation, revealing a large amount of sperm in the urine. This urine may also be collected to obtain adequate viable sperm for use in artificial insemination. In men with SCI, techniques that may be used to

obtain sperm for artificial insemination include self-stimulation, vibratory stimulation, or electroejaculation. Electroejaculation involves the use of a specially designed probe that is inserted into the rectum next to the prostate. The probe delivers a current that stimulates the nerves and produces contraction of the pelvic muscles and ejaculation. However, spontaneous or stimulated ejaculation may cause autonomic dysreflexia (AD) (overstimulation of the autonomic nervous system) in patients with SCI at T6 or above, creating a life-threatening situation. If this disorder is not treated promptly, it may lead to seizures, stroke, and even death.

INFECTIONS OF THE MALE GENITOURINARY TRACT

Acute uncomplicated cystitis in adult men is uncommon but occasionally occurs in men whose sexual partners have vaginal infections with *Escherichia coli*. Asymptomatic bacteriuria may also result from genitourinary manipulation, catheterization, or instrumentation. Urinary tract infections (UTIs) are discussed in Chapter 45.

According to the Centers for Disease Control and Prevention (CDC, 2008), more than 19 million people develop sexually transmitted diseases (STDs) or sexually transmitted infections (STIs) annually in the United States; almost half of all STDs occur in people 18 to 24 years of age. The incidence of STDs has declined over the past several years, except in specific populations, including men who have sex with men. STDs affect people from all walks of life—from all social, educational, economic, and racial backgrounds. The single greatest risk factor for contracting an STD is the number of sexual partners. As the number of partners increases, so does the risk of exposure to a person infected with an STD. For men who have sex with men, the CDC recommends annual testing for human immunodeficiency virus (HIV), syphilis, *Chlamydia*, and gonorrhea (CDC, 2006).

Several diseases are classified as STDs: urethritis (gonococcal and nongonococcal), genital ulcers (genital herpes infections, primary syphilis, chancroid, granuloma inguinale, and lymphogranuloma venereum), genital warts (human papillomavirus [HPV]), scabies, pediculosis pubis, molluscum contagiosum, hepatitis and enteric infections, proctitis, and acquired immunodeficiency syndrome (AIDS). Trichomoniasis and STDs characterized by genital ulcers are thought to increase susceptibility to HIV infection. Trichomoniasis is associated with nonchlamydial, nongonococcal urethritis.

Current treatment guidelines for STDs are available from the CDC (2006, 2007). Treatment must target the patient as well as his sexual partners and sometimes an unborn child. A thorough history, including a sexual history, is crucial to identify patients at risk and to direct care and teaching. Partners of men with STDs must also be examined, treated, and counseled to prevent reinfection and complications in both partners and to limit the spread of the disease. Sexual abstinence during treatment and recovery is advised to prevent the transmission of STDs. Use of synthetic condoms for at least 6 months after completion of

treatment is recommended to decrease transmission of HPV infection as well as other STDs. It is important to assess and test for other STDs because patients who have one STD may also have another. Use of spermicides with nonoxynol 9 (known as N-9) is discouraged; these agents do not protect against HIV infection and may increase the risk of transmission of the virus. See Chapters 52 and 70 for more detailed discussions of HIV infection and AIDS and other STDs.

CONDITIONS OF THE PROSTATE

Prostatitis

Prostatitis is an inflammation of the prostate gland that is often associated with lower urinary tract symptoms and symptoms of sexual discomfort and dysfunction. The condition affects 5% to 10% of men. It is the most common urologic diagnosis in men younger than 50 years of age and the third most common such diagnosis in men older than 50 years (Potts & Payne, 2007; Wein, Kavoussi, Novick, et al., 2007). Prostatitis may be caused by infectious agents (bacteria, fungi, mycoplasma) or other conditions (eg, urethral stricture, benign prostatic hyperplasia). *E. coli* is the most commonly isolated organism, although *Klebsiella* and *Proteus* species are also found (Potts & Payne, 2007). The micro-organisms colonize the urinary tract and ascend to the prostate, ultimately causing infection. The causal pathogen is usually the same in recurrent infections.

There are four types of prostatitis: acute bacterial prostatitis (type I); chronic bacterial prostatitis (type II); chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) (type III), and asymptomatic inflammatory prostatitis (type IV). Type III, which occurs in more than 90% of cases, is further classified as type IIIA or type IIIB, depending on the presence (type IIIA) or absence (type IIIB) of white blood cells in semen after prostate massage.

Clinical Manifestations

Acute prostatitis is characterized by the sudden onset of fever, dysuria, perineal prostatic pain and severe lower urinary tract symptoms: dysuria, frequency, urgency, hesitancy, and nocturia. Approximately 5% of cases of type I prostatitis (acute prostatitis) progress to type II prostatitis (chronic bacterial prostatitis) (Wein, et al., 2007). Patients with type II disease are typically asymptomatic between episodes. Patients with type III prostatitis often have no bacteria in the urine in the presence of genitourinary pain. Patients with type IV prostatitis are usually diagnosed incidentally during a workup for infertility, an elevated PSA test, or other disorders.

Medical Management

The goal of treatment is to eradicate the causal organisms. Hospital admission may be necessary for patients with unstable vital signs, sepsis, or intractable pelvic pain; those who are frail or immunosuppressed; or those who have diabetes or renal insufficiency. Specific treatment is based on the type of prostatitis and on the results of culture and sensitivity testing of the urine (Potts & Payne, 2007). If

bacteria are cultured from the urine, antibiotics, including trimethoprim-sulfamethoxazole (TMP-SMZ) or a fluoroquinolone (eg, ciprofloxacin [Cipro]), may be prescribed, and continuous therapy with low-dose antibiotics may be used to suppress the infection. If the patient is afebrile and has a normal urinalysis, anti-inflammatory agents may be used. Alpha-adrenergic blocker therapy (eg, tamsulosin [Flomax]), may be prescribed to promote bladder and prostate relaxation.

Factors contributing to prostatitis, including stress, neuromuscular factors, and myofascial pain, are also addressed. Supportive, nonpharmacologic therapies may be prescribed. These include biofeedback, pelvic floor training, physical therapy, reduction of prostatic fluid retention by ejaculation through sexual intercourse or masturbation, sitz baths, stool softeners, and evaluation of sexual partners to reduce the possibility of cross-infection.

Nursing Management

If the patient experiences symptoms of acute prostatitis (fever, severe pain and discomfort, inability to urinate, malaise), he may be hospitalized for intravenous (IV) antibiotic therapy. Nursing management includes administration of prescribed antibiotics and provision of comfort measures, including prescribed analgesic agents and sitz baths.

The patient with chronic prostatitis is usually treated on an outpatient basis and needs to be instructed about the importance of continuing antibiotic therapy and recognizing recurrent signs and symptoms of prostatitis.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The nurse instructs the patient to complete the prescribed course of antibiotics. If IV antibiotics are to be administered at home, the nurse instructs the patient and family about correct and safe administration. Arrangements for a home care nurse to oversee administration may be needed. Hot sitz baths (10 to 20 minutes) may be taken several times daily. Fluids are encouraged to satisfy thirst but are not “forced,” because an effective medication level must be maintained in the urine. Foods and liquids with diuretic action or that increase prostatic secretions, such as alcohol, coffee, tea, chocolate, cola, and spices, should be avoided. A suprapubic catheter may be necessary for severe urinary retention. During periods of acute inflammation, sexual arousal and intercourse should be avoided. To minimize discomfort, the patient should avoid sitting for long periods. Medical follow-up is necessary for at least 6 months to 1 year because prostatitis caused by the same or different organisms can recur. The patient is advised that the UTI may recur and is taught to recognize its symptoms.

Benign Prostatic Hyperplasia (Enlarged Prostate)

Benign prostatic hyperplasia (BPH) is one of the most common diseases in aging men. It can cause bothersome lower urinary tract symptoms that affect quality of life by in-

terfering with normal daily activities and sleep patterns (AUA, 2006; Kaplan, 2006). BPH typically occurs in men older than 40 years of age. By the time they reach 60 years of age, 50% of men have BPH. It affects as many as 90% of men by 85 years of age. BPH is the second most common cause of surgical intervention in men older than 60 years of age.

Pathophysiology

The cause of BPH is not well understood, but testicular androgens have been implicated. Dihydrotestosterone (DHT), a metabolite of testosterone, is a critical mediator of prostatic growth. Estrogens may also play a role in the cause of BPH; BPH generally occurs when men have elevated estrogen levels and when prostate tissue becomes more sensitive to estrogens and less responsive to DHT. Smoking, heavy alcohol consumption, obesity, reduced activity level, hypertension, heart disease, diabetes, and a Western diet (high in animal fat and protein and refined carbohydrates, low in fiber) are risk factors for BPH (Parsons, 2007).

BPH develops over a prolonged period; changes in the urinary tract are slow and insidious. BPH is a result of complex interactions involving resistance in the prostatic urethra to mechanical and spastic effects, bladder pressure during voiding, detrusor muscle strength, neurologic functioning, and general physical health (McCance & Huether, 2005). The hypertrophied lobes of the prostate may obstruct the bladder neck or urethra, causing incomplete emptying of the bladder and urinary retention. As a result, a gradual dilation of the ureters (hydronephrosis) and kidneys (hydronephrosis) can occur. Urinary retention may result in UTIs because urine that remains in the urinary tract serves as a medium for infective organisms.

Clinical Manifestations

BPH may or may not lead to lower urinary tract symptoms; if symptoms occur, they may range from mild to severe. Severity of symptoms increases with age, and half of men with BPH report having moderate to severe symptoms. Obstructive and irritative symptoms may include urinary frequency, urgency, nocturia, hesitancy in starting urination, decreased and intermittent force of stream and the sensation of incomplete bladder emptying, abdominal straining with urination, a decrease in the volume and force of the urinary stream, dribbling (urine dribbles out after urination), and complications of acute urinary retention (more than 60 mL of urine remaining in the bladder after urination), and recurrent UTIs. Ultimately, chronic urinary retention and large residual volumes can lead to azotemia (accumulation of nitrogenous waste products) and renal failure.

Generalized symptoms may also be noted, including fatigue, anorexia, nausea, vomiting, and pelvic discomfort. Other disorders that produce similar symptoms include urethral stricture, prostate cancer, neurogenic bladder, and urinary bladder stones.

Assessment and Diagnostic Findings

The health history focuses on the urinary tract, previous surgical procedures, general health issues, family history of prostate disease, and fitness for possible surgery (AUA, 2006).

A patient voiding diary is used to record voiding frequency and urine volume. A DRE often reveals a large, rubbery, and nontender prostate gland. A urinalysis to screen for hematuria and UTI is recommended. A PSA level is obtained if the patient has at least a 10-year life expectancy and for whom knowledge of the presence of prostate cancer would change management. The AUA Symptom Index or International Prostate Symptom Score (IPSS) can be used to assess the severity of symptoms (AUA, 2006).

Other diagnostic tests may include urinary flow-rate recording and the measurement of postvoid residual (PVR) urine. If invasive therapy is considered, urodynamic studies, urethroscopy, and ultrasound may be performed. Complete blood studies are performed. Cardiac status and respiratory function are assessed because a high percentage of patients with BPH have cardiac or respiratory disorders because of their age.

Medical Management

The goals of medical management of BPH are to improve quality of life, improve urine flow, relieve obstruction, prevent disease progression, and minimize complications. Treatment depends on the severity of symptoms, the cause of disease, the severity of the obstruction, and the patient's condition.

If a patient is admitted on an emergency basis because he is unable to void, he is immediately catheterized. The ordinary catheter may be too soft and pliable to advance through the urethra into the bladder. In such cases, a thin wire (stylet) is introduced (by a urologist) into the catheter to prevent the catheter from collapsing when it encounters resistance. A metal catheter with a pronounced prostatic curve may be used if obstruction is severe. An incision into the bladder (a suprapubic **cystostomy**) may be needed to provide urinary drainage.

Discussion of all treatment options by the physician enables the patient to make an informed decision based on symptom severity, the effect of BPH on his quality of life, and preference. Patients with mild symptoms and patients with moderate or severe symptoms who are not bothered by them and have not developed complications may be managed with watchful waiting. With this approach, the patient is monitored and reexamined annually but receives no active intervention (Kaplan, 2006). Other therapeutic choices include pharmacologic treatment, minimally invasive procedures, and surgery.

Pharmacologic Therapy

Pharmacologic treatment for BPH includes use of alpha-adrenergic blockers and 5-alpha-reductase inhibitors (AUA, 2006). Alpha-adrenergic blockers, which include alfuzosin (Uroxatral), terazosin (Hytrin), doxazosin (Cardura), and tamsulosin, relax the smooth muscle of the bladder neck and prostate. This improves urine flow and relieves symptoms of BPH. Side effects include dizziness, headache, asthenia/fatigue, postural hypotension, rhinitis, and sexual dysfunction (Kaplan, 2006; Lepor, 2007).

Another method of treatment involves hormonal manipulation with antiandrogen agents. The 5-alpha-reductase inhibitors, finasteride (Proscar) and dutasteride (Avodart), are used to prevent the conversion of testosterone to DHT

and decrease prostate size. Side effects include decreased libido, ejaculatory dysfunction, erectile dysfunction, gynecomastia (breast enlargement), and flushing. Combination therapy (doxazosin and finasteride) has decreased symptoms and reduced clinical progression of BPH (AUA, 2006; Kaplan, 2006).

Use of phytotherapeutic agents and other dietary supplements (*Serenoa repens* [saw palmetto berry] and *Pygeum africanum* [African plum]) are not recommended, although they are commonly used. They may function by interfering with the conversion of testosterone to DHT. In addition, *S. repens* may directly block the ability of DHT to stimulate prostate cell growth. These agents should not be used with finasteride, dutasteride, or estrogen-containing medications.

Surgical Treatment

Other treatment options include minimally invasive procedures and resection of the prostate gland.

Minimally Invasive Therapy

Several forms of **minimally invasive therapy** may be used to treat BPH. Transurethral microwave heat treatment (TUMT) involves the application of heat to prostatic tissue. High-energy TUMT devices (CoreTherm, Prostatron, Targis) and low-energy devices (TherMatrx) are available (AUA, 2006). A transurethral probe is inserted into the urethra, and microwaves are directed to the prostate tissue. The targeted tissue becomes necrotic and sloughs. To minimize damage to the urethra and decrease the discomfort from the procedure, some systems have a water-cooling apparatus.

Other minimally invasive treatment options include (transurethral needle ablation [TUNA]) by radiofrequency energy and the UroLume stent. TUNA uses low-level radiofrequencies delivered by thin needles placed in the prostate gland to produce localized heat that destroys prostate tissue while sparing other tissues. The body then resorbs the dead tissue. Prostatic stents are associated with significant complications (eg, eucrustation, infection, chronic pain); therefore, they are used only for patients with urinary retention and in patients who are poor surgical risks (AUA, 2006).

Surgical Resection

Surgical resection of the prostate gland is another option for patients with moderate to severe lower urinary tract symptoms of BPH and for those with acute urinary retention or other complications. The specific surgical approach (open or endoscopic) and the energy source (electrocautery versus laser) are based on the surgeon's experience, the size of the prostate gland, the presence of other medical disorders, and the patient's preference. If surgery is to be performed, all clotting defects must be corrected and medications for anticoagulation withheld because bleeding is a complication of prostate surgery.

Transurethral resection of the prostate (TURP) remains the benchmark for surgical treatment of BPH. It involves the surgical removal of the inner portion of the prostate through an endoscope inserted through the urethra; no external skin incision is made. It can be performed with

ultrasound guidance. The treated tissue either vaporizes or becomes necrotic and sloughs. The procedure is performed in the outpatient setting and usually results in less postoperative bleeding than a traditional surgical prostatectomy.

Other surgical options for BPH include transurethral incision of the prostate (TUIP), transurethral electrovaporization, laser therapy, and open prostatectomy (AUA, 2006; Kaplan, 2006). TUIP is an outpatient procedure used to treat smaller prostates. One or two cuts are made in the prostate and prostate capsule to reduce constriction of the urethra and decrease resistance to flow of urine out of the bladder, and no tissue is removed. Open prostatectomy involves the surgical removal of the inner portion of the prostate via a suprapubic, retropubic, or perineal (rare) approach for large prostate glands. Prostatectomy may also be performed laparoscopically or by a robot-assisted laparoscopy.

Nursing management of patients undergoing these procedures is described later in this chapter.

Cancer of the Prostate

Prostate cancer is the most common cancer in men other than nonmelanoma skin cancer. It is the second most common cause of cancer death in American men, exceeded only by lung cancer, and is responsible for 10% of cancer-related deaths in men. Among men diagnosed with prostate

cancer, 98% survive at least 5 years, 84% survive at least 10 years, and 56% survive 15 years (ACS, 2009).

Prostate cancer is common in the United States and northwestern Europe but is rare in Africa, Central America, South America, China, and other parts of Asia. African American men have a high risk of prostate cancer; furthermore, they are twice as likely to die of prostate cancer than men of any other racial or ethnic group. The findings of the African-American Hereditary Prostate Cancer Study suggest that a strong genetic link increases the risk of early-onset disease (Jones, Underwood & Rivers, 2007). Other risk factors in African American men include their lower level of engagement in the health care system, disparities in health care, and cultural and structural barriers. These findings support the need for education about prostate cancer and screening in African American men (Weinrich, Vijayakumar, Powell, et al., 2007). Culturally sensitive promotional campaigns, teaching and counseling about prostate cancer, screening, and treatment are important in increasing awareness of the high incidence of prostate cancer and mortality rates in African American men (Chart 49-2).

Other risk factors for prostate cancer include increasing age; the incidence of prostate cancer increases rapidly after the age of 50 years. More than 70% of cases occur in men older than 65 years of age. A familial predisposition may occur in men who have a father or brother previously diagnosed with prostate cancer, especially if their relatives were

NURSING RESEARCH PROFILE

Knowledge About Hereditary Prostate Cancer in African American Men

Weinrich, S., Vijayakumar, S., Powell, I. J., et al. (2007). Knowledge of hereditary prostate cancer among high-risk African American men. *Oncology Nursing Forum*, 34(4), 854–860.

Purpose

Because African American men develop prostate cancer 50% to 60% more often than Caucasians and die from it at twice the rate of any other ethnic group, it is critical for this group to be aware of their increased risk and the need for screening for early detection of prostate cancer. The purpose of this study was to measure the level of knowledge about hereditary prostate cancer in a group of high-risk African American men.

Design

For this cross-sectional, correlational pilot study, investigators recruited a sample of 79 high-risk African American men (defined as those with four or more men in their families with prostate cancer) from four geographic areas. These men, who were also participants in the African American Hereditary Prostate Cancer Study, came from all educational levels, and their average age was 54 years. Almost half ($n = 38$, 48%) of them had received a diagnosis of prostate cancer. Researchers conducted telephone interviews using a scripted telephone protocol and a true-false, nine-item questionnaire, called the "Knowledge of Hereditary Prostate Cancer Scale," developed by the first author. Each man's individual answers were scored as correct or incorrect, with a range of possible total scores ranging from 0 to 9. To reach each participant, an average of 2.5 calls was needed; each call lasted an average of 15 minutes.

Findings

Data analysis revealed a range of scores from 3.5 to 9, with a mean score of 6.34 (standard deviation = 1.11). The authors interpreted this as a low level of knowledge about hereditary prostate cancer; answering six of nine questions correctly would produce a score of 67%.

Nursing Implications

The authors interpreted the high percentage of incorrect responses to questions about genetic testing, prevention, and risk based on a positive family history as indicating a need for education. They proposed that cancer fatalism (eg, the belief that death is inevitable when cancer is present) may account for a high percentage of incorrect or unanswered responses to a question measuring risk probability based on a positive prostate cancer test. In the current genomic health care system, a critical need exists for nurses to have a sound understanding of genetics and to educate high-risk African American men and their families about hereditary prostate cancer. The lack of knowledge exhibited by the participants in this study suggests a decreased likelihood of prostate cancer screening. The American Cancer Society recommends prostate cancer screening at 45 years of age for African American men and men with a positive family history (5 years earlier than the recommended age for men in the general population). Nurses can encourage early prostate screening. They have a valuable role in promoting healthy behaviors among high-risk African American men through education and other innovative strategies.

diagnosed at a young age. Genes that may be associated with increased risk of prostate cancer include hereditary prostate cancer 1 (*HPC1*) and *BRCA1* and *BRCA2* mutations (Jones, et al., 2007; Lessick & Katz, 2006). The risk of prostate cancer is also greater in men whose diet contains excessive amounts of red meat or dairy products that are high in fat (ACS, 2009). Endogenous hormones, such as androgens and estrogens, also may be associated with the development of prostate cancer.

Several large-scale studies have examined the ability of 5-alpha reductase inhibitors (finasteride and dutasteride) to delay or prevent prostate cancer (Tindall & Rittmaster, 2008).

Clinical Manifestations

Cancer of the prostate in its early stages rarely produces symptoms. Usually symptoms that develop from urinary obstruction occur in advanced disease. Prostate cancer tends to vary in its course. If the cancer is large enough to encroach on the bladder neck, signs and symptoms of urinary obstruction occur (difficulty and frequency of urination, urinary retention, and decreased size and force of the urinary stream). Other symptoms may include blood in the urine or semen and painful ejaculation. Hematuria may occur if the cancer invades the urethra or bladder. Sexual dysfunction is common before the diagnosis is made.

Prostate cancer can spread to lymph nodes and bone. Symptoms of metastases include backache, hip pain, perineal and rectal discomfort, anemia, weight loss, weakness, nausea, oliguria (decreased urine output), and spontaneous pathologic fractures. These symptoms may be the first indications of prostate cancer.

Assessment and Diagnostic Findings

If prostate cancer is detected early, the likelihood of cure is high. It can be diagnosed through an abnormal finding with the DRE, serum PSA, and ultrasound-guided TRUS with biopsy. Detection is more likely with use of combined diagnostic procedures. Routine repeated DRE (preferably by the same examiner) is important because early cancer may be detected as a nodule within the gland or as an extensive hardening in the posterior lobe. The more advanced lesion is “stony hard” and fixed. DRE also provides useful clinical information about the rectum, anal sphincter, and quality of stool.

The diagnosis of prostate cancer is confirmed by a histologic examination of tissue removed surgically by TURP, open prostatectomy, or ultrasound-guided transrectal needle biopsy. Fine-needle aspiration is a quick, painless method of obtaining prostate cells for cytologic examination and determining the stage of disease.

Most prostate cancers are detected when a man seeks medical attention for symptoms of urinary obstruction or are found by routine DRE and PSA testing. Cancer detected incidentally when TURP is performed for clinically benign disease and lower urinary tract symptoms occurs in about 1 of 10 cases. Abnormal DRE and elevated levels of PSA may raise suspicion of prostate cancer, but detection requires confirmation with a prostate biopsy.

TRUS helps detect nonpalpable prostate cancers and assists with staging of localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS. The biopsies are examined by a pathologist to both determine if

cancer is present and to grade the tumor. The most commonly used tumor grading system is the Gleason score. This system assigns a grade of 1 to 5 for the most predominant architectural pattern of the glands of the prostate and a secondary grade of 1 to 5 to the second most predominant pattern. The Gleason score is then reported as, for example, 2 + 4; the combined value can range from 2 to 10. With each increase in Gleason score, there is an increase in tumor aggressiveness. Lower Gleason scores indicate well-differentiated and less aggressive tumor cells; higher Gleason scores indicate undifferentiated cells and more aggressive cancer. A total score of 8 to 10 indicates a high-grade cancer (AUA, 2007).

Categorization of low-risk, intermediate-risk, and high-risk prostate cancer is determined by the extent of cancer in the prostate gland, whether or not the cancer is localized to the prostate, the aggressiveness of the cells, and the spread to the lymph nodes and beyond. Level of risk, in turn, is used to determine treatment options.

Bone scans, skeletal x-rays, and magnetic resonance imaging (MRI) may be used to identify metastatic bone disease. Pelvic computed tomography (CT) may be performed to determine if the cancer has spread to the lymph nodes. The radiolabeled monoclonal antibody capromab pendetide with indium 111 (ProstaScint) is an antibody that can be used to detect either recurrent prostate cancer at low PSA levels or metastatic disease (NCCN, 2008).

Medical Management

Treatment is based on the patient's life expectancy, symptoms, risk of recurrence after definitive treatment, size of the tumor, Gleason score, PSA level, likelihood of complications, and patient preference. Therapy is often guided by the use of a nomogram or risk stratification scheme suggested by the NCCN (2008) and AUA (2007) clinical practice guidelines. A multidisciplinary team approach is essential for the development of appropriate treatment. Management may be nonsurgical and involve watchful waiting or be surgical and entail **prostatectomy**. Nursing care of the patient with cancer of the prostate is summarized in the plan of nursing care in Chart 49-3.

Patients with prostate cancer may also choose nonsurgical watchful waiting. This approach involves actively monitoring the course of disease and intervening only if the cancer progresses or if symptoms warrant other intervention. It is an option for patients with life expectancy of less than 5 years and low-risk cancers. Advantages include absence of side effects of more aggressive treatment, improved quality of life, avoidance of unnecessary treatment, and decreased initial costs. Disadvantages include missed chance at cure, risk of metastasis, subsequent need for more aggressive treatment, anxiety about living with untreated cancer, and need for frequent monitoring (Bailey, Wallace & Mishel, 2007; NCCN, 2008).

Surgical Management

Radical prostatectomy is considered the standard first-line treatment for prostate cancer and is used with patients whose tumor is confined to the prostate. It is the complete surgical removal of the prostate, seminal vesicles, tips of the vas deferens, and often the surrounding fat, nerves, and

 CHART
49-3

PLAN OF NURSING CARE
The Patient With Prostate Cancer

NURSING DIAGNOSIS: Anxiety related to concern and lack of knowledge about the diagnosis, treatment plan, and prognosis
GOAL: Reduced stress and improved ability to cope

Nursing Interventions

1. Obtain health history to determine the following:
 - a. Patient's concerns
 - b. His level of understanding of his health problem
 - c. His past experience with cancer
 - d. Whether he knows his diagnosis of malignancy and its prognosis
 - e. His support systems and coping methods
2. Provide education about diagnosis and treatment plan:
 - a. Explain in simple terms what diagnostic tests to expect, how long they will take, and what will be experienced during each test.
 - b. Review treatment plan and allow patient to ask questions.
3. Assess his psychological reaction to his diagnosis/prognosis and how he has coped with past stresses.
4. Provide information about institutional and community resources for coping with prostate cancer: social services, support groups, community agencies.

Rationale

1. Nurse clarifies information and facilitates patient's understanding and coping.
2. Helping the patient to understand the diagnostic tests and treatment plan will help decrease his anxiety and promote cooperation.
3. This information provides clues in determining appropriate measures to facilitate coping.
4. Institutional and community resources can help the patient and family cope with the illness and treatment on an ongoing basis.

Expected Outcomes

- Appears relaxed
- States that anxiety has been reduced or relieved
- Demonstrates understanding of illness, diagnostic tests, and treatment when questioned
- Engages in open communication with others

NURSING DIAGNOSIS: Urinary retention related to urethral obstruction secondary to prostatic enlargement or tumor and loss of bladder tone due to prolonged distention/retention
GOAL: Improved pattern of urinary elimination

Nursing Interventions

1. Determine patient's usual pattern of urinary function.
2. Assess for signs and symptoms of urinary retention: amount and frequency of urination, suprapubic distention, complaints of urgency and discomfort.
3. Catheterize patient to determine amount of residual urine.
4. Initiate measures to treat retention:
 - a. Encourage assuming normal position for voiding.
 - b. Recommend using Valsalva maneuver preoperatively, if not contraindicated.
 - c. Administer prescribed cholinergic agent.
 - d. Monitor effects of medication.
5. Consult with physician regarding intermittent or indwelling catheterization; assist with procedure as required.
6. Monitor catheter function; maintain sterility of closed system; irrigate as required.
7. Prepare patient for surgery if indicated.

Rationale

1. Provides a baseline for comparison and goal to work toward
2. Voiding 20 to 30 mL frequently and output less than intake suggest retention.
3. Determines amount of urine remaining in bladder after voiding.
4. Promotes voiding:
 - a. Usual position provides relaxed conditions conducive to voiding.
 - b. Valsalva maneuver exerts pressure to force urine out of bladder.
 - c. Stimulates bladder contraction.
 - d. If unsuccessful, another measure may be required.
5. Catheterization will relieve urinary retention until the specific cause is determined; it may be an obstruction that can be corrected only surgically.
6. Adequate functioning of catheter is to be ensured to empty bladder and to prevent infection.
7. Surgical removal of obstruction may be necessary.

Expected Outcomes

- Voids at normal intervals
- Reports absence of frequency, urgency, or bladder fullness
- Displays no palpable suprapubic distention after voiding
- Maintains balanced intake and output

CHART
49-3

PLAN OF NURSING CARE
The Patient With Prostate Cancer (Continued)

NURSING DIAGNOSIS: Deficient knowledge related to the diagnosis of: cancer, urinary difficulties, and treatment modalities
GOAL: Understanding of the diagnosis and ability to care for self

Nursing Interventions

1. Encourage communication with the patient.
2. Review the anatomy of the involved area.
3. Be specific in selecting information that is relevant to the patient's particular treatment plan.
4. Identify ways to reduce pressure on the operative area after prostatectomy:
 - a. Avoid prolonged sitting (in a chair, long automobile rides), standing, walking.
 - b. Avoid straining, such as during exercises, bowel movement, lifting, and sexual intercourse.
5. Familiarize patient with ways of attaining/maintaining bladder control.
 - a. Encourage urination every 2 to 3 hours; discourage voiding when supine.
 - b. Avoid drinking cola and caffeine beverages; urge a cutoff time in the evening for drinking fluids to minimize frequent voiding during the night.
 - c. Describe perineal exercises to be performed every hour.
 - d. Develop a schedule with patient that will fit into his routine.
6. Demonstrate catheter care; encourage his questions; stress the importance of position of urinary receptacle.

Rationale

1. This is designed to establish rapport and trust.
2. Orientation to one's anatomy is basic to understanding its function.
3. This is based on the treatment plan; as it varies with each patient, individualization is desirable.
4. This is to prevent bleeding; such precautions are in order for 6 to 8 weeks postoperatively.
5. These measures will help control frequency and dribbling and aid in preventing retention.
 - a. By sitting or standing, patient is more likely to empty his bladder.
 - b. Spacing the kind and amount of liquid intake will help to prevent frequency.
 - c. Exercises will assist him in starting and stopping the urinary stream.
 - d. A schedule will assist in developing a workable pattern of normal activities.
6. By requiring a return demonstration of care, collection, and emptying of the device, he will become more independent and also can prevent backflow of urine, which can lead to infection.

Expected Outcomes

- Discusses his concerns and problems freely
- Asks questions and shows interest in his disorder
- Describes activities that help or hinder recovery
- Identifies ways of attaining/maintaining bladder control
- Demonstrates satisfactory technique and understanding of catheter care
- Lists signs and symptoms that must be reported should they occur

NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements related to decreased oral intake because of anorexia, nausea, and vomiting caused by cancer or its treatment
GOAL: Maintain optimal nutritional status

Nursing Interventions

1. Assess the amount of food eaten.
2. Routinely weigh patient.
3. Elicit patient's explanation of why he is unable to eat more.
4. Cater to his individual food preferences (eg, avoiding foods that are too spicy or too cold).
5. Recognize effect of medication or radiation therapy on appetite.

Rationale

1. This assessment will help determine nutrient intake.
2. Weighing the patient on the same scale under similar conditions can help monitor changes in weight.
3. His explanation may present easily corrected practices.
4. He will be more likely to consume larger servings if food is palatable and appealing.
5. Many chemotherapeutic agents and radiation therapy promote anorexia.

Expected Outcomes

- Responds positively to his favorite foods
- Assumes responsibility for his oral hygiene
- Reports absence of nausea and vomiting
- Notes increase in weight after improved appetite

 CHART
49-3

PLAN OF NURSING CARE
The Patient With Prostate Cancer (Continued)

Nursing Interventions	Rationale	Expected Outcomes
6. Inform patient that alterations in taste can occur. 7. Use measures to control nausea and vomiting: a. Administer prescribed antiemetics, around the clock if necessary. b. Provide oral hygiene after vomiting episodes. c. Provide rest periods after meals. 8. Provide frequent small meals and a comfortable and pleasant environment. 9. Assess patient's ability to obtain and prepare foods.	6. Aging and the disease process can reduce taste sensitivity. In addition, smell and taste can be altered as a result of the body's absorption of byproducts of cellular destruction (brought on by malignancy and its treatment). 7. Prevention of nausea and vomiting can stimulate appetite. 8. Smaller portions of food are less overwhelming to the patient. 9. Disability or lack of social support can hinder the patient's ability to obtain and prepare foods.	
NURSING DIAGNOSIS: Sexual dysfunction related to effects of therapy: chemotherapy, hormonal therapy, radiation therapy, surgery GOAL: Ability to resume/enjoy modified sexual functioning		
Nursing Interventions	Rationale	Expected Outcomes
